Abstract

Wearable digital health technologies (DHTs) have become increasingly popular in recent years, enabling more capabilities to assess behaviors and physiology in free-living conditions. The *All of Us* Research Program (AoURP), a National Institutes of Health initiative that collects health-related information from participants in the United States, has expanded its data collection to include DHT data from Fitbit devices. This offers researchers an unprecedented opportunity to examine a large cohort of DHT data alongside biospecimens and electronic health records. However, there are existing challenges and sources of error that need to be considered before using Fitbit device data from the AoURP. In this viewpoint, we examine the reliability of and potential error sources associated with the Fitbit device data available through the AoURP Researcher Workbench and outline actionable strategies to mitigate data missingness and noise. We begin by discussing sources of noise, including (1) inherent measurement inaccuracies, (2) skin tone–related challenges, and (3) movement and motion artifacts, and proceed to discuss potential sources of data missingness in Fitbit device data. We then outline methods to mitigate such missingness and noise in the data. We end by considering how future enhancements to the AoURP's Fitbit device data collection methods and the inclusion of new Fitbit data types would impact the usability of the data. Although the reliability considerations and suggested literature are tailored toward Fitbit device data in the AoURP, the considerations and recommendations are broadly applicable to data from wearable DHTs in free-living conditions.

Introduction

Wearable digital health technologies (DHTs) have become increasingly popular in recent years, especially as DHTs offer better user experiences, more capabilities, and greater functionality to assess behaviors and physiology in free-living conditions. The *All of Us* Research Program (AoURP) is an initiative that is seeking to collect health-related information, including DHT data, from a diverse cohort of over 1 million participants in the United States. In the AoURP, DHT data are collected alongside electronic health records, biospecimens, surveys, and standardized physical measurements. The goal is to make these data accessible to both researchers and participants to advance precision diagnosis, prevention, and treatment [1].

In 2019, the AoURP expanded its data collection with the Fitbit Bring-Your-Own-Device (BYOD) project. This expansion has allowed participants to share their historical and ongoing Fitbit account data through the *All of Us* participant portal [2]. The AoURP's efforts to include Fitbit device data have continued to expand with the WEAR study, which gives eligible participants a no-cost Fitbit Charge 4 or Fitbit Versa 3 device [3]. Data from the BYOD project are available through the AoURP Researcher Workbench, which offers data access and analysis tools for DHT data, electronic health record data, biospecimens, surveys, and physical measurements [4].

As of 2023, over 15,000 *All of Us* participants have shared Fitbit device data [5]. The Researcher Workbench provides access to these data, including Fitbit-defined heart rate by zones that are based on percentages of estimated maximum heart rate, minute-level heart rate, daily activity summaries, minute-level intraday steps, daily sleep summaries, and sleep levels [6].

Digital biomarkers derived from DHTs can potentially be used to improve clinical diagnostics, predict disease status, and support personalized clinical decision-making [7]. With the increasing use of DHTs like Fitbit devices in the AoURP and other research and clinical settings, it is important that those working with these data consider the inherent limitations of Fitbit devices, given their underlying technology. This will enable improved data processing and fit-for-purpose implementations of Fitbit devices in research and clinical settings. Researchers might ask the following: "How reliable is the data from these devices? What are the sources of noise, error, and bias that should be accounted for when using this data? How can these be accounted for?"

In this viewpoint paper, we examine the reliability of Fitbit device data in the context of the AoURP's BYOD program. We focus on Fitbit devices, given their wide market share [8,9], the ongoing collection of data from Fitbit users in the AoURP (eg, BYOD program) [2,10], and these data's availability to registered Researcher Workbench users [5]. Data are currently not available from the AoURP regarding the Fitbit device models included in their data set. For this reason, the data cleaning strategies we present are device model agnostic. This paper focuses specifically on data considerations around physical activity (steps and movement intensities) and heart rate measurements generated by Fitbit devices on a daily and per-minute basis. Given that Fitbit device sleep data are derived from the same underlying sensors that determine heart rate and motion intensity metrics, the same fundamental considerations surrounding inherent measurement reliability should be considered when working with Fitbit device sleep metrics.

Sources of Noise

Measurement error can affect the reliability of Fitbit device data in both laboratory conditions and free-living conditions. In this section, we discuss the most commonly recognized sources of error that may be observed in Fitbit device data collected through the AoURP.

Inherent Measurement Inaccuracies

Fitbit devices include a 3-axis accelerometer and photoplethysmography (PPG) sensor, with more recent device models including additional sensors, such as an altimeter, a gyroscope, a skin temperature sensor, and multipurpose electrical sensors [11]. It may be helpful for researchers to consider the data supply chain as they work with DHT data [12]; the data that researchers generally have access to are processed, and the firmware that performs such data processing is regularly updated [13]. Aside from the data supply chain, there are also inherent limitations of the accelerometer and PPG sensors themselves that should be accounted for in data analysis.

All Fitbit models with Fitbit LLC's patented PurePulse technology (eg, Fitbit Charge, Fitbit Charge 2, Fitbit Charge 3, Fitbit Alta, Fitbit Versa, Fitbit Blaze, and Fitbit Ionic) use the same PPG hardware and software for heart rate estimation [14]. PPG sensors, which optically measure light absorption under the skin, may be affected by user motion and activity intensity, skin tone, and the wavelength of light used by the sensor [15,16]. When compared to gold-standard electrocardiography, Fitbit devices tend to underestimate heart rate [14,15,17]. Further, Fitbit device heart rate measurements have higher reliability under stationary conditions [14,18].

Fitbit devices use the 3-axis accelerometer to determine step count and categorize physical activity intensity (sedentary, light, moderate, vigorous, or moderate to vigorous) [19-21]. Comparisons between Fitbit device step counts using direct observation and gold-standard accelerometers, such as the ActiGraph GT3X+, demonstrate mixed reliability, depending on the type and speed of movement and the on-body placement of the Fitbit. During normal walking for example, the torso placement of the Fitbit device has resulted in the greatest accuracy, while ankle and wrist placement have been the most accurate in slow-walking and jogging, respectively [20]. Similar findings from other studies demonstrate that step count and physical activity intensity accuracy are affected by device placement and movement type [22-26].

Skin Tone

Skin tone may be another inherent source of error for DHTs that rely on optical measurements (eg, PPG or pulse oximetry) [27,28]. Both melanin and skin with tattoos absorb more green light, that is, wavelengths of around 530 nm, which are the LED wavelengths commonly used in PPG sensors [29]. There have been mixed findings in this area; a study by Shcherbina et al [30] on older generations (2014-2016) of consumer smartwatches found that darker skin tones positively correlated with increased heart rate error, whereas our study, in which we used more recent devices (2014-2018), did not find a relationship between heart rate measurement accuracy and skin tone across a subset of consumer smartwatches [18]. Clinical-grade pulse oximeters that rely on red and infrared optical measurement technology may also be affected by skin tone [31].

Fitbit devices may use a combination of both green and red wavelengths to estimate heart rate [15,32]. Although green wavelengths can enable more accurate heart rate measurements during movement when compared to red wavelengths, green wavelengths are more readily absorbed by melanin before reaching the photodetector [29]. Additional research is needed on whether and how the accuracy of optical-based DHT measurements, such as heart rate and saturation of peripheral oxygen (SpO_2), is affected by skin tone.

The data collected by the AoURP currently do not include data on skin color or the presence of tattoos under Fitbit devices; therefore, it is not possible to directly account for skin tone or wrist tattoos as a potential source of error in AoURP heart rate data. As a result, researchers working with *All of Us* data may need to take extra care when interpreting or translating results that may be influenced by skin tone or the presence of wrist tattoos, particularly when working with heart rate data.

Movement and Motion Artifacts

Motion artifacts can also be a source of error for heart rate, step count, and physical activity intensity data. Unexpected noise with random amplitudes and frequencies can be seen in raw sensor data and can cause the algorithms of Fitbit devices to falsely detect movement or a heart beat [33]. For example, the reliability of Fitbit Flex's step count and moderate to vigorous physical activity data was found to be dependent on the activity type (walking, stair stepping, jogging, and incline walking) [24], and step count error was shown to be higher during activity than during rest [20]. Therefore, it is likely that step count reliability varies, particularly during normal household activities, which may be logged by Fitbit devices as exercise movements.

Wearable device heart rate measurements are the most accurate under circumstances of rest, followed by physical activity and then rhythmic activity, such as walking or jogging. Our previous work demonstrated decreased reliability during rhythmic activities, such walking or typing. This was likely due to Fitbit devices mistaking the periodic signal, which was being produced by the repetitive movements, for the cardiovascular cycle. Although walking resulted in heart rate measurements that were higher than the true heart rate, typing resulted in heart rate measurements that were lower than the true heart rate [18]. A study by Benedetto et al [15] assessed Fitbit Charge 2 heart rate accuracy during stationary biking and found that the device underestimated heart rate when compared to electrocardiography.

Some possible reasons for heart rate measurement error during motion include the device's sampling and interpolation methods, unstable device positioning, and variation in the pressure applied to the skin by the sensor [15,18,34]. Researchers should be aware of the impact of physical activity type (ie, motion intensity and periodicity) on Fitbit device heart rate measurement error.

The body positioning and fit of DHTs can also be sources of motion artifacts. For example, wrist-based Fitbit devices can misclassify nonambulatory arm movements as total body motion, which may result in the overestimation of physical activity and motion intensity [35]. This misclassification of physical activity may be worse if the device is not worn correctly. To address this challenge, the Fitbit device user manuals provide instructions for specific placement on the wrist to enable the acquisition of more reliable data [36].

Sources of Data Missingness in Fitbit Device Data

It can often be challenging to determine the minimum amount of data necessary to achieve a particular analysis goal when using DHT data. A systematic review by Chan et al [37] pointed to a common definition for a "valid day" of wearable data—at least 10 intermittent hours of data present within 1 day—and a "valid week" of data—at least 3 valid days during the week. It is important for researchers to note that most Fitbit devices need to be charged at least once per week for 1 to 2 hours at the time of writing, and the need to remove the device from the wrist to charge it results in at least some data missingness. More than the minimal necessary data missingness can occur in the event that the wearer forgets to put the device back on their wrist after charging it [35]. Such nonwear is an example of structured missingness, where a contiguous block of missing observations occurs when the device is not being worn. At scale, there may be observable nonwear patterns, such as times when people commonly remove their devices (eg, during sleep) [38].

In addition to nonwear, improper device wear can also result in data missingness. Improper wear, such as insufficient tightening of the wrist strap, can lead to the sensor orientation being askew or a loss of sensor-to-skin contact, which is required for high-fidelity optical measurements, such as PPG-based heart rate measurements [39]. Moreover, observations can be impacted by large motion artifacts, and such observations (eg, high accelerometry values) may be removed by the device firmware. This leads to missing values in the final data set. To explore the extent of such data removal, our team recently compared data missingness in optical heart rate and SpO_2 observations across multiple wearables [18,40]. We found that, for heart rate measurements, the Fitbit Charge 2 had the highest amount of missing data during both rest (18.7%) and physical activity (10.4%) when compared to other consumer-grade wearables [18]. Data missingness due to improper wear or firmware attempts to account for motion artifacts may be seen in the data set as random missingness, lacking structure and predictability. However, some wearers may be more prone to improper wear or high-intensity activity, which can lead to higher amounts of missing data in individual data sets. Other factors that can affect the presence or absence of Fitbit device data include the frequency of syncing the device with the smartphone app and poor device connectivity [41,42].

There is a taxonomy of mechanisms for missing data, including (1) data missing completely at random (MCAR), where missingness is unrelated to observed characteristics; (2) data missing at random (MAR), where missingness is related to observed characteristics; and (3) data missing not at random (MNAR), where missingness is related to unobserved characteristics. Different methods are required to best account for these three missingness mechanisms during data preprocessing; thus, identifying the type of missingness is an important step in DHT data analysis. In the case of Fitbit device data, observations that are MCAR may be due to nonsystematic device malfunctions, nonsystematic errors in data transfer, or sporadic improper device wear. Observations that are MAR may be the result of a particular device model missing a type of measurement capability (eg, a device that is known to not report heart rate measurements under high-intensity activity). An example of MNAR missingness might be nonwear during a bout of illness or due to a user having a poorly fitting device. In a free-living study, such as the AoURP, all three missingness mechanisms are likely to be present in the Fitbit device data and should be identified and appropriately addressed when possible by, for example, making assumptions about the reasons for the data missingness upon analyzing missingness patterns [43].

Mitigating Missingness and Noise in DHT Data

Accounting for Data Missingness

Avoiding data missingness is best done at the data collection stage. Prospective bring-your-own-device studies may increase wear time and improve device fit by incorporating reminders for users to wear the device, adding nonwear alerts for users or the study team, and educating users on fit and charging [44]. It should be noted that AoURP Fitbit device data collection is purely observational and, at this time, does not involve providing any alerts or interventions to improve Fitbit device wear habits.

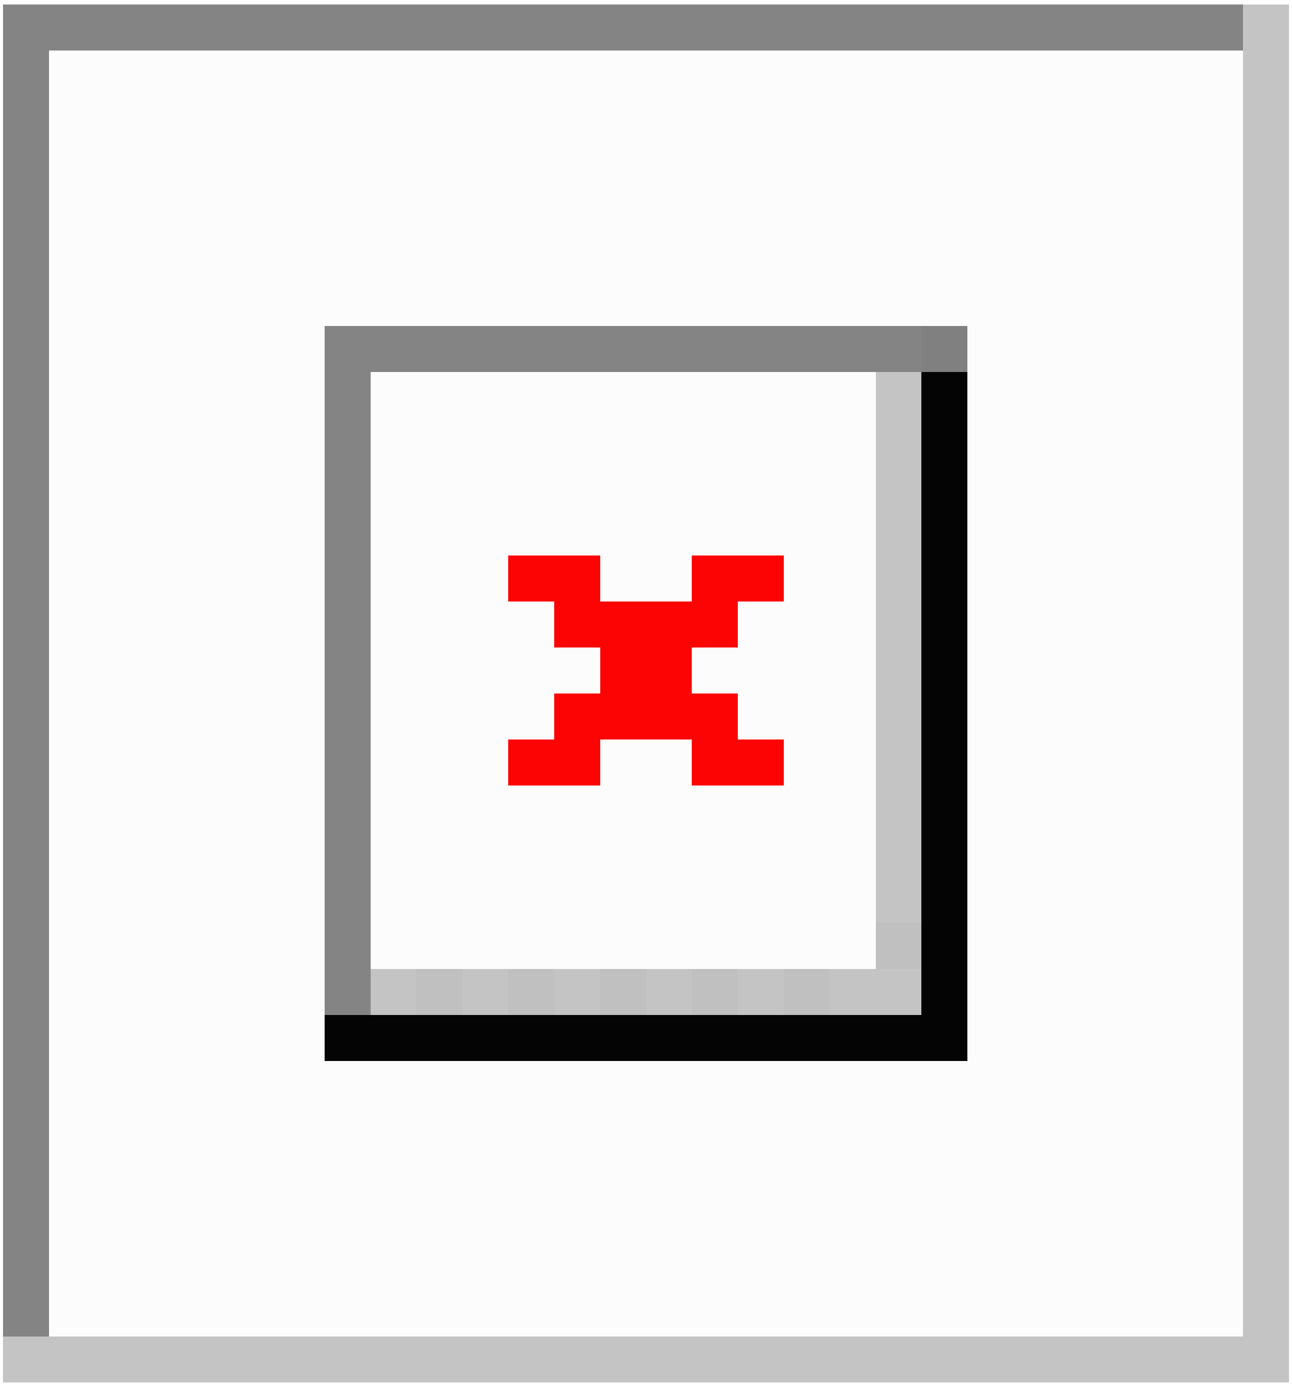
Some missingness in the data is inevitable. Accounting for data missingness begins by thoroughly identifying the reason for missingness and deciding upon the most appropriate strategy for mitigation. For AoURP researchers using Fitbit device data collected in free-living conditions, it is not always possible to distinguish MAR, MCAR, and MNAR missingness; therefore, they may need to make assumptions to decide how to proceed with mitigation [43]. In the context of Fitbit device data, we can distill a few practical solutions for addressing wear-related structured missingness [38].

The first step is to decide upon a definition for “wear” in the context of the data and the question at hand. Depending on what analysis or question is of interest, the definition of “wear” can drastically change. For example, an analysis involving sleep quality and staging may require the definition of “wear” to include common sleep hours (eg, 8 PM to 8 AM) or a minimum monitored sleep duration time, such as that reported by Fitbit devices, but other analyses may only require a daily wear level, which gives an idea of a participant’s activity and physiological state without requirements regarding wear during specific activities, such as sleep and exercise, as described in the *Sources of Data Missingness in Fitbit Device Data* section [37].

One way to calculate a daily wear level is to leverage minute-level heart rate data, as most consumer devices only collect these data when they are worn on the wrist. This would, for example, help to avoid including step count data that may have been collected when a device is in a purse. By dividing the total count of minute-level heart rate observations collected within a single day by the total number of minutes when such data were possible to collect (1440 min in 1 d), we can derive a reasonable estimate of the proportion of the day when the device was on the wrist.

Once established, the daily wear level threshold can be used for filtering out nonwear data and participants; the optimal threshold for filtering should be selected carefully to avoid unnecessary data loss (Figure 1A, Figure 1B). The optimal threshold is where data loss is minimized and there is adequate statistical power to draw conclusions from the analysis (Figure 1C).

Figure 1. Graphs A and B show the total counts of participants and days, respectively, that meet each wear threshold, with an optimal threshold of <0.4. Graph C shows the mean and median total days (per participant) with a wear level greater than or equal to each wear threshold, demonstrating an optimal threshold of between 0.3 and 0.4. The 95% CI (indicated in blue) was calculated as follows: $\mu \pm \sigma/\sqrt{n}$. The IQR (indicated in orange dashed lines) indicates the first and third quartile values. The controlled tier AoURP version 7 data set (C2022Q4R9) was used to generate Figure 1. AoURP: *All of Us* Research Program.



After removing nonwear data (ie, contiguous blocks of missing observations), it is important to identify other sources of data missingness and determine whether mitigation is best done by using imputation or by using the complete case method [43]. Sometimes, the decision can be made based on the extent of the missingness relative to the overall data volume needed for analysis, and at times, it may be deemed that the original analysis cannot be performed as planned due to insufficient data. As an example, a recent study on COVID-19 detection via Fitbit device data calculated the mean over 5-minute intervals of heart rate data; subsequently, any missing data over full 5-minute intervals were imputed by using the median heart rate value from a previously defined 14-day window [45]. Although it is common in wearable data analysis to use the mean and median values of heart rate data for imputation, new imputation methods for biomedical wearable data have also been developed to incorporate machine learning for improved imputation accuracy [46,47]. Although imputation can be beneficial because it preserves data, it should be noted that imputation is not always a good idea, particularly in cases with substantial missingness for which typical values cannot be established.

Accounting for Noise

Many methods exist to reduce noise in raw signal data (ie, sample-level or high-frequency signal data), particularly when the source of the noise is well characterized. Unfortunately, consumer devices typically do not give access to such high-frequency data, but their firmware and adaptive data collection methods are thought to include steps that account for skin tone–related errors and motion artifacts. Unfortunately, the public has no way of assessing how well these methods perform. Based on this, it is difficult for researchers to directly address errors resulting from skin tone or motion artifact errors. However, some general data cleaning strategies exist that may help to mitigate noise in the data, regardless of the source of the noise (Table 1). In this section, we discuss how to leverage changes from an individual's baseline, filtering during repeated activities, and *z* score normalization to improve the signal to noise ratio (SNR). We recommend using these techniques in combination with one another to best mitigate noise.

Table . Examples of noise mitigation methods for wearable data.

	Baseline comparisons	Sampling during periods of similar activity	*z* score normalization
Description	• Calculate the median value during a defined baseline period. • Calculate the Δ from the baseline for all other data.	• Establish specific wear times and use the "Activity Type" metric to filter an individual's Fitbit device data during similar time periods each day for comparable activity types. • Conduct analysis using these segmented data sets.	• Subtract the mean from each observation and divide by the SD.
Applicability	• Mitigate consistent measurement error (bias).	• Mitigate noise that is exacerbated under specific conditions.	• Mitigate short periods of noise.
Benefits	• Provides a "usual" picture of an individual [48].	• Assists in isolating confounding effects that may arise in different activity types and heart rate zones. • Standardizes the comparison of data across different individuals.	• Allows direct comparison of 2 observations originating from different segments of temporal data [49].
Limitations	• Need ample data to establish a baseline [48]. • Baselines can change over time.	• Recommended for large sets of longitudinal data to make accurate comparisons.	• Abstraction of units and range may make it difficult to interpret data.

On an individual level, the comparison of observations to a reliable baseline can be helpful for determining changes in biosignals over time while reducing the influence of both skin tone and motion artifacts. Reliable baselines can be established by first summarizing an individual's measurements during periods of sleep or inactivity or before a perturbation. The determination of which time period to use to establish a baseline is study dependent. Depending on the timescale of the analysis, it is also useful to consider a sliding window approach, wherein new baselines are established during predefined time periods to account for baseline changes over time. The median value of the biosignal serves as a useful baseline value because it is less susceptible to noise and outliers compared to other statistical summary metrics and provides a way to amplify the SNR during the next steps of the analysis. The establishment of and comparisons to reliable baselines have been performed in multiple studies [50-53]. One limitation of this approach is that substantial monitoring time may be needed to establish a reliable baseline for an individual due to inherent biological and behavioral variability and the effects of external factors that may be difficult to control for (eg, seasonality, circadian rhythms, weekdays vs weekends, etc) [48]. It should also be noted that comparisons to a reliable baseline would not improve the SNR in scenarios where there is a compound effect of the source of noise and the conditions of measurement [54]. For example, skin tone may only increase measurement error for certain heart rate zones (eg, high heart rate) or under circumstances of high motion. In such cases, removing data collected under certain conditions that exacerbate measurement error may be the most appropriate approach.

Another way to handle the challenge of confounding sources of measurement error is to only compare segments of data that are measured under the same conditions (eg, similar movement types and heart rate zones) [15,18,20,24,55]. This technique allows researchers to further isolate confounding sources of measurement error that may be exacerbated during different activities. First, one must define specific wear times of interest, such as wear during specific times of the day, which helps account for circadian variability. Second, when available, researchers should use the "Activity Type" provided by Fitbit devices to segment heart rate data into comparable sections. Researchers can also leverage this activity information to anticipate activities for which heart rate data may be less accurate.

In circumstances where there are short periods of incorrectly reported heart rates or step counts (eg, during high-intensity motion), simple normalization methods, such as *z* score normalization and minimum-maximum normalization, are the most useful [56,57]. Minimum-maximum normalization is useful when extreme outliers are not present in the data, especially when the data have a fixed possible range. *z* score normalization is particularly useful because it centers and scales the Fitbit device data to a mean of 0 and an SD of 1. *z* score normalization helps to reduce the comparatively higher impact of outliers within shorter data segments because it leverages information from longer segments (ie, the mean and SD) for normalization. Once normalized, the data can be compared across wearable data types and participants.

Future Directions

As the AoURP continues efforts to provide wearable data to researchers and expand the scope of the Fitbit device data made available on the Researcher Workbench, there are several future directions to be considered. Although the ideas presented herein are tailored to Fitbit device data originating from the bring-your-own-device facet of AoURP, Fitbit device data are now actively being collected from other studies, and these data may one day be integrated into the Researcher Workbench [3]. Each additional study may have unique characteristics, including the target population, which may play a role in the overall quality of the data. For example, whether a Fitbit device was provided to participants or whether they were using an existing device they purchased may be a factor in a participant's comfort level with using the device properly and regularly. Understanding the nuances and potential variations in data quality arising from different study protocols and data sources within the AoURP ecosystem necessitates further research. Investigating how specific study designs, participant demographics, and data collection protocols within the AoURP may influence the overall quality of the collected data will be crucial for researchers seeking to derive meaningful insights and improve the designs of future studies that implement DHTs.

Although Fitbit device model data are not currently available on the Researcher Workbench, it is worth considering how differing device models, software, and firmware may affect the data collected. At the time of writing, the underlying PurePulse PPG technology is the same across all Fitbit LLC heart rate tracking devices [14]. The largest differences in accelerometer-derived data have been observed between Fitbit LLC's early torso clip-on trackers and the newer wrist-based devices [20]. Additional research is needed to investigate whether there are any substantial differences in accelerometry performance across Fitbit LLC wrist-based models. With regard to data derived from heart rate and accelerometry, such as sleep tracking data, prior to Fitbit LLC's release of heart rate tracking devices in 2014 [58], Fitbit LLC's early accelerometry-only devices estimated sleep metrics based on movement alone. Only Fitbit devices with heart rate tracking will include sleep staging, wake heart rate, and sleep-time heart rate [59]. Identifying whether sleep staging metrics are available for a particular individual may be a convenient way to identify the broad type of Fitbit device that was worn. The future incorporation of other contextual information, such as environmental factors, user behaviors, and device models, will enhance the ability to detect and mitigate noise, improve overall data quality, and provide a more comprehensive understanding of an individual's health.

Conclusion

The development and validation of Fitbit device–derived digital biomarkers offer the potential for remote and continuous measurement of physiological data. Such digital biomarkers can help inform medical decisions and predict disease states [7]. The wide adoption of DHTs by both consumers and programs like the AoURP make DHTs a great source of data for researchers. Researchers can use various analytical, statistical, and machine learning approaches to further develop DHT data into digital biomarkers [60-63]. Like with any technology, there are inherent limitations and sources of error that stakeholders (eg, researchers using DHT data in their analyses) should be aware of. We encourage the *All of Us* community to use data processing techniques that address noise and missingness to reduce problems downstream in the data analysis. Although we focused on heart rate and motion data in this work, the error mitigation methods described are applicable to other forms of wearable data, including sleep data. For example, changes in total sleep time and sleep stages can be compared against baselines over time. Researchers should consider their study goals and expected outcomes when determining which data cleaning strategies are the most salient to their goals.

Abstract

Living in urban environments affects individuals' mental health through different pathways. For instance, physical activity and social participation are seen as mediators. However, aiming to understand underlying mechanisms, it is necessary to consider that the individual is interacting with its environment. In this regard, this viewpoint discusses how urban health research benefits from integration of socioecological and interdisciplinary perspectives, combined with innovative ambulatory data assessments that enable researchers to integrate different data sources. It is stated that neither focusing on the objective and accurate assessment of the environment (from the perspective of spatial sciences) nor focusing on subjectively measured individual variables (from the public health as well as a psychosocial perspective) alone is suitable to further develop the field. Addressing person-place interactions requires an interdisciplinary view on the level of theory (eg, which variables should be focused on?), assessment methods (eg, combination of time-varying objective and subjective measures), as well as data analysis and interpretation. Firstly, this viewpoint gives an overview on previous findings addressing the relationship of environmental characteristics to physical activity and mental health outcomes. We emphasize the need for approaches that allow us to appropriately assess the real-time interaction between a person and a specific environment and examine within-subject associations. This requires the assessment of environmental features, the spatial-temporal behavior of the individual, and the subjective experiences of the situation together with other individual factors, such as momentary affective states. Therefore, we finally focused on triggered study designs as an innovative ambulatory data assessment approach that allows us to capture real-time data in predefined situations (eg, while walking through a specific urban area).

KEYWORDS

physical activity; urban health; ambulatory assessment; environment; mental health; real-time data; within-subject association

Introduction

Globally, 76% of people live in cities, and a growing number of people are expected to move into urban surroundings within the next two decades [1]. Although urban settings are frequently associated with locational advantages (eg, proximity to job and educational opportunities, cultural diversity, as well as service and infrastructure provision), they are also shown by empirical evidence to increase risks for psychological stress and mental disorders among their residents [2]. Even though mental health has complex determinants, theoretical assumptions about urban health and empirical evidence suggest that increasing physical activity levels and social interactions improve mental health (eg, well-being, quality of life, and satisfaction with life) in urban residents [3,4]. Recommendations for creating health-promoting urban environments include the vision of active lifestyles and opportunities for urban residents to participate in social life supported by suitable infrastructure (ie, walkable neighborhoods and people-oriented urban designs). For instance, there is extensive research in the field of walkability in urban areas and its association with health. However, we still have only preliminary insights into people's reactions to specific environmental features (eg, greenness and noise); we also have limited insight as to for whom and under which conditions such experiences result in more physical activity (eg, active mobility), social interactions, and improved mental health. For these reciprocal associations between the person and its environment, we use the term "person-place interactions," which former studies were not able to address adequately due to methodological constraints. This shortcoming can be overcome with innovative study designs that allow us to address within-subject relations, and therefore, allow for studying the underlying mechanisms of people's health behavior and mental health after they have been exposed to different environmental features [5]. In addition, such study designs provide the opportunity to draw from existing and newly emerging data sources and data fusion techniques of different disciplines (eg, spatial science, sport and movement science, and psychology) to get a deeper understanding of person-place interactions.

Why Do We Need Information About Person-Place Interactions to Create Health-Promoting Urban Environments?

According to socioecological approaches, individuals interact with their physical and natural environment as well as the social neighborhood setting, which affects health-related behaviors such as physical activity [6]. According to Stokols [7], this interaction can be described as "cycles of mutual influences"—the environmental features of a local neighborhood are associated with urban residents' behavior and health. Reciprocally, individuals live and act within these settings and engage with environmental features in a "more or less" health-enhancing way. For instance, on the one hand, design features of the built environment as well as opportunities to get active in social settings can stimulate physical activity (eg, creating attractive stairs in urban environments). On the other hand, a person who is highly motivated to improve activity levels, experiences and perceives the environment differently than a person who is less motivated, and therefore, acts differently based on these subjective experiences and perceptions (eg, using such stairs not only for stair climbing but also for a workout or to do parkour). Furthermore, according to socioecological approaches, individuals' behavior is affected by more than just the individual level (eg, motivation, self-efficacy, habits, and personal physiological constitution) and the perceived environment (eg, attractive stairs, perceptions of urban green or blue, and noise) but also by the sociocultural factors, factors arising from the built and the social environment, as well as policy factors [8]. Therefore, learning more about person-place interactions from an interdisciplinary perspective—integrating knowledge from spatial science, psychology, sport science, transport systems, politics, and sociology—is a precondition for creating health-promoting environments. For example, an urban health policy to add cycling lanes to promote physical activity levels may be less effective, if the fit between these environmental features (eg, cycling lanes) and the target groups' needs, preferences, social-cognitive constructs (eg, attitudes), and sociodemographic backgrounds (eg, age and proportion of bike owners) are not considered. As Stokols [9] emphasized, this fit serves as an important predictor of health and well-being.

Evidence About the Associations Between the Environment, Physical Activity, and Mental Health

Considering current studies, key findings confirm that environmental features are associated with physical activity and health. An analysis of previous systematic reviews and meta-studies [10] summarizes associations between built environmental features, dietary intake, physical activity, and obesity. More than half of the included reviews focused on physical activity (n=46) and reported consistent evidence about the positive associations between walkability and physical activity (supported by 83% of the reviews), followed by positive associations between access to recreational facilities, shops and services, and parks or trails and physical activity (supported by 63% to 70% of the reviews). Another systematic review of longitudinal studies (N=36) about the effects of the built environment on adults' physical activity came to similar conclusions: new infrastructures for walking, cycling, and using public transport increase overall physical activity [11]. Further reviews, especially in the past few years, support such results for older adults [12] and children [13].

In terms of mental health impacts, an overview of systematic reviews assessed the association between the built environment and different mental health indicators (eg, well-being, depression, and stress) [14]. The authors included 11 reviews and reported insufficient and heterogeneous evidence for health-enhancing effects of the environment, with a critically low methodological study quality of 80% of the included reviews. Another meta-narrative review synthesizes the impacts of urban green space on different indicators of mental health from 38 intervention studies [15]. The results were discussed in an international World Health Organization expert panel workshop, concluding that urban green space interventions are often multifaceted but can generally be categorized in 4 groups: park-based, greenways and trails, urban greening (eg, street trees), and green built interventions (eg, green roofs). Most studies in that meta-narrative review were designed as natural experiments, and the findings showed strong evidence for park-based as well as greenway and trail interventions to promote health and well-being through increased park use and physical activity [15].

Limitations of the Empirical Evidence When Analyzing Person-Place Interactions

The aforementioned reviews provide evidence about the relationships between specific environmental features and mental health or physical activity. However, they fall short of increasing our knowledge of the time-varying associations within subjects regarding how urban residents react to specific environmental features and under which conditions such experiences result in more physical activity and improved mental health. One reason for this is that these reviews focused mainly on environmental characteristics, such as accessibility or the amount or quality of greenness, and how these characteristics moderate the relationship between the environment and physical activity or mental health. They do not provide evidence about individuals' momentary perception, experience, and subsequent behavioral, cognitive, or affective states; nor do they show how these states are related to mental health.

Kwan [16] already criticized in 2009 that spatial research about associations between environmental features and physical activity or health mainly used a "place-based" instead of a "person-based" approach and operationalized environment exposure mostly by focusing on spatial units, such as census tracts, buffer zones, or postal codes. Such a "place-based" design neglects that individuals move around and do not stay in their "home spatial unit" during their daily activities (eg, workplace, school, and leisure activities) [17].

More than 10 years later, Zhang and colleagues [18] stated that there are still only a few studies investigating the association between environment and health from the perspective of the spatial-temporal behavior of the individual. According to the results of their survey with 1003 Chinese adults, there are significant differences between environmental exposures of individuals based on home buffer zones (ie, place-based) compared to time-weighted activity travel buffers (ie, person-based) [18].

A currently published scoping review [19] also stated that person-based approaches still are in their infancy. The review is about methodological approaches to measure the spatial contexts used in socioecological physical activity research, and the included studies have been mostly published within the last 7 years. In sum, person-based spatial methods have been used rarely; only 2% (10/412) of the included studies used activity spaces, and similarly, only 2% (8/412) of the studies buffered multiple points to capture the environment. Almost a third of the studies (118/412) used place-based approaches (eg, with administrative units) as an objective approach.

Furthermore, place-based approaches do not take into consideration that individuals have different lifestyles, psychosocial characteristics, and daily routines and may react differently to influences of similar environmental features. For instance, even persons living within the same building would perceive environmental exposure of their neighborhood differently [20]. That refers to the "uncertain geographic context problem" [21], and it also highlights the importance of interdisciplinary efforts by psychologists, sport scientists, geographers, and computer scientists [7,22]. Nevertheless, empirical evidence of interdisciplinary studies integrating assessment methods of spatial science and urban planning as well as social and health sciences is still lacking [23]. Further, these approaches do not allow detailed analysis; for example, to what extent social interaction could moderate the associations between the environment and mental health or for whom the quality of greenness may be relevant. They also neglect that the environmental exposure is not only directly associated with mental health but also via affecting health-related behaviors, such as physical activity. Thus, mediators or moderators of the associations between the environment and physical activity and health have hardly been examined so far [10]; a framework to explore relationships between place and mental health by combining GPS, Geographic Information System (GIS), and accelerometer data is available in a previous study [24].

Ambulatory Assessment Approaches Are Suitable to Analyze Person-Place Interactions

To advance our understanding of person-place interactions of urban residents in everyday life, we need more studies that collect intensive longitudinal data, which facilitates the estimation of time-varying associations between environmental features, individuals' behavior, as well as their momentary experiences. Ambulatory assessments are suitable approaches for addressing such within-subject relations because they allow us to monitor physical activity (eg, via accelerometry), physiological function (eg, heart rate or electrodermal activity), and environmental parameters (eg, via geolocation tracking) in real time.

In 2018, Chaix [23] published an overview of different wearable sensors and devices to capture the environment (eg, air pollution and the number of mobile phones nearby), the behavior (eg, physical activity and GPS receivers), and individuals' physiology (eg, heart rate and electrodermal activity). He recommended integrating different sensors to generate knowledge of healthy places and situations. Such an approach allows us to assess the duration, sequences, and accumulation of different environmental exposures; it also provides rich research possibilities to assess in situ changes in mental health according to different environments or environmental features [25].

A current example of combining different sensors is the study by Marquet and colleagues [26], which combined accelerometers to assess physical activity and GPS data that was linked to spatial data sets on walkability and greenness. They found that persons with high walkability and greenness in their activity spaces had higher levels of moderate-to-vigorous physical activity. In addition, a recent study [27] combined sensors that measure black carbon concentration with a sensor that assessed galvanic skin response (as a proxy measure of stress) and a GPS device and found that increases in black carbon are related to higher skin responses (indicating higher stress levels) during active travel. Green space and a good active travel infrastructure are associated with lower skin responses while walking or cycling.

To deepen our understanding of how different individuals react to specific environmental features, it is crucial to assess the above-mentioned environmental parameters and physiological functions using sensors in an objective way; however, it is also relevant to assess subjective experiences, preferably at that moment when an association between a person and a place is assumed. It is possible to schedule e-diaries throughout the day (eg, ecological momentary assessment) to assess different psychosocial constructs (eg, momentary affective states, momentary experiences of social interactions, and momentary motivation) via self-reported measures [28,29].

Ambulatory assessment approaches have already been applied in spatial research. Perchoux et al [30,31] introduce activity spaces as an individualized measure for environmental exposure. It considers individuals' daily mobility patterns, including major spatial-temporal cluster movements between home and different daily locations, and characterizes its temporal structure (ie, frequency, regularity, and duration). Further, to match person- and place-based data, some research groups combined the assessment of activity spaces with multiple self-reports per day via e-diaries (eg, feelings, emotions, and evaluations of their environment) resulting in geographically explicit ecological momentary assessments (GEMAs) [5,20]. GEMA studies implement innovative study designs that use mobile geographic location technologies to capture participants' activity space, which can then be used to assess the dynamic environmental exposure via GIS. e-Diaries allow us to capture subjective experiences in situ, and these data can be linked to participants' current position in time and space. However, GEMA struggles with the disadvantages of "time-based" assessments because prompts to answer the web-based questionnaires were usually triggered at random time intervals. With such a sampling scheme, self-reports during rare events (eg, being physically active in the neighborhood) are likely to be missed and could therefore hardly be used for analyzing time-varying associations. For instance, a GEMA study [32] assessed how urban green space is associated with stress in adolescents living in urban surroundings. Outdoor behaviors were assessed via GPS-enabled mobile phones. To capture momentary experiences of stress, participants received randomly 3-6 text messages throughout the day, including a link to a web-based questionnaire. However, 72% of the web-based questionnaires have been filled in at home and not during outdoor behaviors. To ask participants to report retrospectively about their feelings, experiences, and thoughts in response to specific situations is likely to increase recall bias, for instance [29]. Furthermore, spatial accuracy of GEMA is an issue and should be taken into account when analyzing and interpreting the data in urban settings when the GPS device signals are likely to be interrupted, such as in streets with dense tree covers [33].

Methodological Improvements and Future Directions of Research

Answers to research questions, such as the following, are crucial to inform initiatives aiming to create health-promoting urban environments: "How does mental health and physical activity vary due to the momentary exposure to specific physical (eg, streetscape greenery and noise) or social environmental features (eg, crime or places enabling social interactions)?" and "How are these time-varying associations moderated by personal factors, which could be time-invariant, such as lifestyle, attitudes, socioeconomic status, obesity, and gender, as well as dynamic such as momentary feelings, experiences, motivations, and thoughts?"

To address these questions, we need data of within-subject relations during predefined situations in everyday life in which a contextual effect is assumed (eg, being physically active within a neighborhood). The above-mentioned GEMA approach is an appropriate design to provide first answers. However, to capture data during the "right" situations, it could be extended by (1) assessing physical activity directly via accelerometers and (2) using triggered assessments. Triggered assessments allow capturing data in predefined situations and have already been applied in other fields, such as examining time-sensitive associations between physical activity and affective states [34] or the time-sensitive assessment of contextual factors during episodes of prolonged sedentary bouts [35]. A recent example of a triggered e-diary regarding outdoor activities was presented in a study protocol with older residents of Paris [36]. The study combined GEMA with a GPS receiver and used this novel methodology to initiate e-diaries when participants were outdoors. Another study used momentary physical activity levels (assessed via accelerometry) and locations by mobile phone positioning services (eg, GPS and transmission tower) to identify outdoor activities. A trigger algorithm was used to start an e-diary whenever movement acceleration exceeds a certain threshold and participant's locations were identified as outside the home [37]. The study included 46 middle-aged adults and showed that momentary affective states varied significantly due to different social (intensity of social interaction) and physical (amount of greenness) environments. The accuracy of the walking trigger has been examined in a previous study [38].

Furthermore, activity data could be integrated into a GIS to combine information of the physical environment of the activity spaces with movement data. Advanced GISs work with time-enabled spatial analysis functions to track movements with so-called "event-based feature classes." The challenge is to provide data on the actual exposure for the time of measurement. In this context, live sensor networks are preferable over archived data but only starting to become available, for example, in Smart City Sensor Observation Networks [39,40]. Through combining different data (eg, subjective experiences via self-reports and physical activity levels and physiological functions via specific sensors) in outdoor situations with exposures to different environmental features, we would be able to investigate the associations between specific uses of the environment (eg, walking, social interactions, and doing sports) and momentary experiences (eg, reduced stress and better feelings) and how the characteristics of the environment, the living conditions, or psychological factors moderate these associations.

Despite its promising future perspectives, these kinds of person-based spatial approaches lead to several methodological challenges concerning data processing, the linking of spatial and contextual exposures to individuals, special analytical and statistical methods, and ethical aspects of participants' privacy and security [41,42]. The solution to these challenges calls for the assembly of an interdisciplinary research team, which itself might also be challenging. However, this approach would enable us to take a broader perspective on this phenomenon and get closer to draw a "bigger picture" of person-place interactions during the everyday life of urban residents.

Conclusions

Urbanization with its advantages and disadvantages concerning health is on the rise. This viewpoint paper highlights the importance of gaining knowledge regarding the effect of urban environments on people's mental health by considering socioecological and interdisciplinary perspectives in combination with triggered ambulatory data assessments. It is crucial to assess time-varying associations to investigate person-place interactions between the individual and physical, social, and contextual features. Progress in technology and methodological advances enables researchers to study in more detail how people react to specific environmental features and which situational or personal factors may moderate these associations. Lastly, combining data and knowledge of different disciplines would deepen our understanding about the person-place interactions, which is crucial to create health-promoting urban environments.

Abstract

Background: Digital health technologies are widely used for disease management, with their computing platforms, software, and sensors being used for health care. These technologies are developed to manage chronic diseases and infectious bacterial diseases, including tuberculosis (TB).

Objective: This study aims to comprehensively review the literature on the use of digital health interventions (DHIs) for enhancing TB treatment adherence and identify major strategies for their adoption.

Methods: We conducted a literature search in the PubMed, Cochrane Library, Ovid Embase, and Scopus databases for relevant studies published between January 2012 and March 2022. Studies that focused on web-based or mobile phone–based interventions, medication adherence, digital health, randomized controlled trials, digital interventions, or mobile health and ubiquitous health technology for TB treatment and related health outcomes were included.

Results: We identified 27 relevant studies and classified them according to the intervention method, a significant difference in treatment success, and health outcomes. The following interventions were emphasized: SMS text messaging interventions (8/27, 30%), medicine reminders (6/27, 22%), and web-based direct observation therapy (9/27, 33%). Digital health technology significantly promoted disease management among individuals and health care professionals. However, only a few studies addressed 2-way communication therapies, such as interactive SMS text messaging and feedback systems.

Conclusions: This scoping review classified studies on DHIs for patients with TB and demonstrated their potential for the self-management of TB. DHIs are still being developed, and evidence on the impact of digital technologies on enhancing TB treatment adherence remains limited. However, it is necessary to encourage patients' participation in TB treatment and self-management through bidirectional communication. We emphasize the importance of developing a communication system.

Introduction

Until the COVID-19 pandemic, tuberculosis (TB) was the leading cause of death from a single infectious disease, affecting approximately 10.6 million people in 2021 [1]. TB can be cured with appropriate medications; however, treatment adherence is affected by the complexity, tolerability, and long duration of the available regimens. Since low adherence increases the risk of poor treatment outcomes, several interventions have been attempted to enhance TB medication adherence [2].

Digital health interventions (DHIs) are promising for patient-centered care, as they allow for the remote monitoring of patients and can be used to conveniently remind patients to take their medications. Numerous studies have addressed how to enhance medication adherence during treatment by using mobile technologies, such as SMS text messaging [3], directly observed therapy (DOT) [3-5], video calls, phone call reminders [5,6], and web-based reports [3-7]. Studies have reported satisfaction [6-8], accuracy [6-8], acceptable uptake [5,7,8], improved drug adherence [3-5,7,9], higher rates of treatment success [5,7,8], and user acceptance [7-10] with regard to DHIs in TB management.

This review aims to summarize the existing literature on DHIs for TB treatment adherence, classify DHI techniques, identify the different types of interventions and their effects on treatment effectiveness, and evaluate adherence and health outcomes in TB treatment. This study reports on treatment outcomes, self-care management, follow-up, and the value of mobile-based communication activities that aim to improve TB treatment adherence.

Methods

We followed Arksey and O'Malley's [11] 5-stage scoping review framework, the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [12], and the Joanna Briggs Institute protocol [13].

Identifying the Relevant Studies

We conducted a literature search in the PubMed, Cochrane Library, Ovid Embase, and Scopus databases for relevant studies published between January 2012 and March 2022. A comprehensive search strategy was developed to identify relevant studies, which included but was not confined to the following search string: *("Tuberculosis" OR "TB" OR "Tuberculosis infection") AND ("RCT" OR "Randomized controlled trial" OR "Experimental study") AND ("Behavior therapy" OR "Cognitive behavioral treatment" OR "Digital intervention" OR "Digital therapeutics" OR "App-based" OR "Web-based" OR "mHealth" OR "uHealth") AND ("treatment adherence" OR "medication adherence" OR "selfcare" OR "Management" OR "Persistence" OR "Compliance")*. The search terms and strategies are presented in Multimedia Appendix 1.

Eligibility and Exclusion Criteria

We included articles that met the following criteria: (1) published in peer-reviewed journals, (2) included TB treatment adherence and health outcomes as part of the study design, (3) written in English, (4) had full text available, and (5) published between January 2012 and March 2022. Studies were excluded if they were published before 2011 or did not focus on DHIs for TB. Reviews, case studies, reports, letters, conference proceedings, and abstract-only articles were also excluded.

Study Selection and Data Synthesis

Duplicates were eliminated from each database and recorded in the first stage. The second stage involved reviewing study titles and abstracts to ensure that articles were research studies that focused on digital health technology as a main intervention tool to improve the treatment adherence of patients with TB. The full texts of the articles were scrutinized in the last stage to verify whether they satisfied the key requirements.

Data were extracted by 1 reviewer (SL), and 2 independent reviewers (VR and YP) charted the data on different characteristics, including authors, publication year, country, study design, target population, number of participants, type of DHI, duration, follow-up, outcome measures, and major findings.

The retrieved data suggested that the core attributes of digital intervention strategies fell under the following three domains, which were based on the DHIs found in the selected articles: sending reminders via SMS text messages, monitoring progress, and tracking follow-ups for the self-management of TB treatment outcomes.

Quality Assessment and Risk of Bias

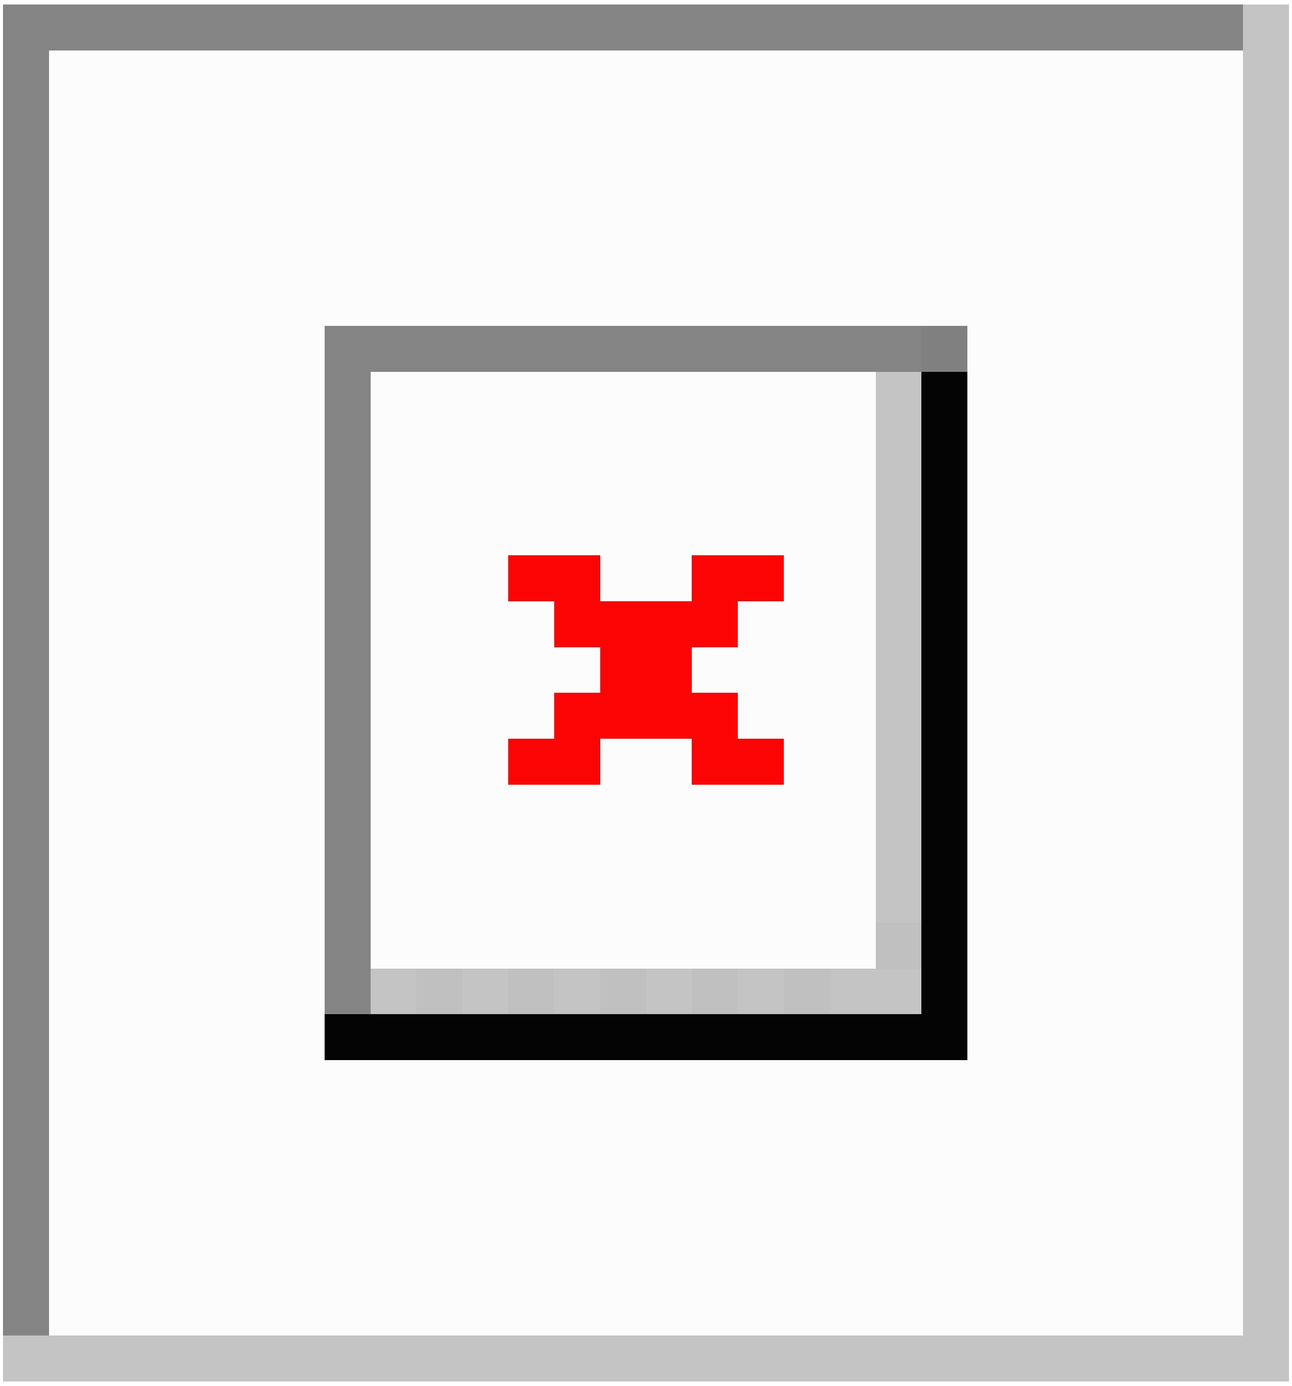
Two independent reviewers (SL and YP) evaluated the risk of bias as part of the quality assessment, using the Cochrane Collaboration's tool for assessing the risk of bias (RoB 2 [Risk of Bias 2]; version: August 9, 2019) [14]. The risk of bias was assessed based on 5 domains, and bias scores were assigned ("low risk," "some concern," or "high risk").

Results

Search Results

The literature search retrieved 305 articles; 72 duplicates were excluded, and 172 did not meet the inclusion criteria, based on the title and abstract review. As a result, 61 articles were screened for the full-text review, and 34 were excluded owing to implications regarding the exclusion criteria and unavailability of full texts. Ultimately, 27 studies were finalized for the data synthesis (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for selection of articles. RCT: randomized controlled trial.



Characteristics of the Selected Articles

Given the novelty of digital health technology in TB treatment, the number of publications was observed to have increased since 2018. A total of 27 articles [15-41] were selected; their characteristics are described in Multimedia Appendix 2. Most of the studies (19/27, 70%) were published in or after 2019 [21,22,24-31,33-41].

With regard to the study designs, 17 studies were randomized controlled trials (RCTs) [15-17,19-21,24-31,34,37,38], 8 were RCT protocols [22,23,32,33,35,36,39,40], and 2 were quasi-experimental studies [18,41]. Further, 13 studies were published in low- and middle-income countries (LMICs), including countries in Africa [18,20,22,23,28,33,35,36,40] and Asia [17,19,25,41]. Digital health technology for TB is actively used in LMICs due to the high prevalence of TB (Multimedia Appendix 3). The combined study population was aged >18 years and included participants who were diagnosed with TB or were taking TB medication. The average number of participants was 400.

Types of DHIs

Table 1 and Figure 2 present the most common technologies used in DHIs, including the duration, frequency, and outcomes of interventions. The commonest DHIs were SMS text messages and reminder messages (8/27, 30%) [15-22], DOT (9/27, 33%) [23-31], medication event reminder monitors (MERMs; 6/27, 22%) [32-37], and mobile apps (4/27, 15%) [38-41]. DOT-based DHIs included video observation therapy (VOT) [25], electronic DOT (e-DOT) [31], and wearable bracelet self-DOT [23]. Some studies evaluated a mix of interventions, including mobile app–based video observations [26,29,30,39], a web intervention [24], WhatsApp (Meta Platforms Inc) [38], and WeChat (Tencent Holdings Ltd) [39]. MERMs [32-37] were also used to determine the feasibility of a web-based follow-up [36] and a mobile-based (ie, evriMED1000 [Wisepill Technologies]) follow-up with phone call [34] reminders to enhance treatment adherence.

Table . Description of digital health technology tuberculosis (TB) interventions and related outcomes.

Study	Intervention	Main outcome	Secondary outcomes	Duration	Frequency
Bediang et al [15]	SMS text messaging	Treatment success	Treatment adherence, multidrug resistance, and satisfaction	6 mo	Daily
van der Kop et al [16]	SMS text messaging	Treatment success	Treatment adherence and treatment completion	9 mo	Weekly
Mohammed et al [17]	SMS text messaging	Treatment success	Treatment adherence and physical health measures	6 mo	Daily
Hermans et al [18]	SMS text messaging	Risk of LFU[a] in the first 2 mo of treatment	Treatment success, completion, adherence, satisfaction, and knowledge	2 mo	Other[b]
Farooqi et al [19]	SMS text messaging	Treatment default	TB treatment results according to the WHO[c,d]	2 mo	Daily
Bediang et al [20]	SMS text messaging	Treatment success	Self-reported adherence regarding attending appointments and satisfaction	6 mo	Daily
Moriarty et al [21]	SMS text messaging	TB treatment results according to the WHO[c]	Smoking cessation, reduction in alcohol use, and treatment adherence	6 mo	Twice weekly
Sahile et al [22]	SMS text messaging	Treatment adherence	ACTG[e], VAS[f], and clinic appointment attendance	2 mo	Daily
Huang et al [23]	e-DOT[g]	TB treatment results according to the WHO[c]	Treatment adherence, MGLS[h], knowledge, and quality of life	6 mo	Daily
Browne et al [24]	e-DOT	Positive detection accuracy	Treatment adherence	Other[i]	Daily
Holzman et al [25]	e-DOT	Treatment adherence	Proportion of all prescribed treatment	Other[i]	Daily
Story et al [26]	e-DOT	Treatment adherence	Treatment outcomes and health-related quality of life	6 mo	Daily
Khachadourian et al [27]	e-DOT	Treatment success	Treatment adherence, depressive symptoms, quality of life, and social support as nonclinical outcomes	4-5 mo	Daily
Crowder et al [28]	e-DOT	Treatment adherence	Reduced risk of LFU and cost-effectiveness	14 mo	Daily
Ravenscroft et al [29]	e-DOT	Treatment adherence	Treatment success at 12 mo	4 mo	Daily
Doltu et al [30]	e-DOT	Treatment adherence	Living conditions, health insurance before TB, previous treatment history, and mode of intensive phase	3 mo	Daily
Burzynski et al [31]	e-DOT	Completed doses and percentage differences between electronic vs in-person DOT[j]	Proportion of medication doses, patient adherence, and quality of care	Other[k]	Daily

Study	Intervention	Main outcome	Secondary outcomes	Duration	Frequency
Lewis et al [32]	MERM[l]	TB treatment results according to the WHO[c]	Adherence outcomes and cost-effectiveness outcomes	6 mo	Daily
Manyazewal et al [33]	MERM	Treatment adherence and sputum conversion	Adverse treatment outcomes, cost-effectiveness, and usability	15 d	Daily
Ratchakit-Nedsuwan et al [34]	MERM	Treatment success	Treatment adherence and patients' experiences	6 mo	Daily
Maraba et al [35]	MERM	Treatment adherence	Treatment success, acceptability of the intervention, and cost-effectiveness	18 mo	Daily
Tadesse et al [36]	MERM	Composite unfavorable outcome: treatment failure or death	Longitudinal technology engagement and fidelity to the intervention	6 mo	Daily
Acosta et al [37]	MERM	Treatment success	Treatment adherence, clinical failure, and LFU	4 mo	Daily
NoorHaslinda and Juni [38]	mHealth[m,n]	Treatment success and treatment adherence	N/A[o]	6 mo	Daily
Wei et al [39]	mHealth[n]	Rate of poor adherence	TB treatment results according to the WHO	6 mo	Daily
Byonanebye et al [40]	mHealth[n]	Treatment success	Treatment success, acceptability of the intervention, and cost-effectiveness	6 mo	Daily
Santra et al [41]	mHealth[n]	Treatment adherence and MGLS	N/A	Other[p]	Daily

[a]LFU: loss to follow-up.

[b]Compliance notifications (2, 7, and 11 d after the most recent appointment), appointment notifications (every 2 wk), and educational quizzes (3, 6, 9, and 12 d after the most recent appointment).

[c]Cured, treatment completed, treatment failed, died, lost to follow-up, not evaluated, or treatment success.

[d]WHO: World Health Organization.

[e]ACTG: AIDS Clinical Trial Group adherence questionnaire.

[f]VAS: visual analog scale.

[g]e-DOT: electronic directly observed therapy.

[h]MGLS: Morisky, Green, and Levine Adherence Scale.

[i]Until TB treatment completion.

[j]DOT: directly observed therapy.

[k]Completed 20 medication doses using 1 DOT method, then switched methods for another 20 doses.

[l]MERM: medication event reminder monitor.

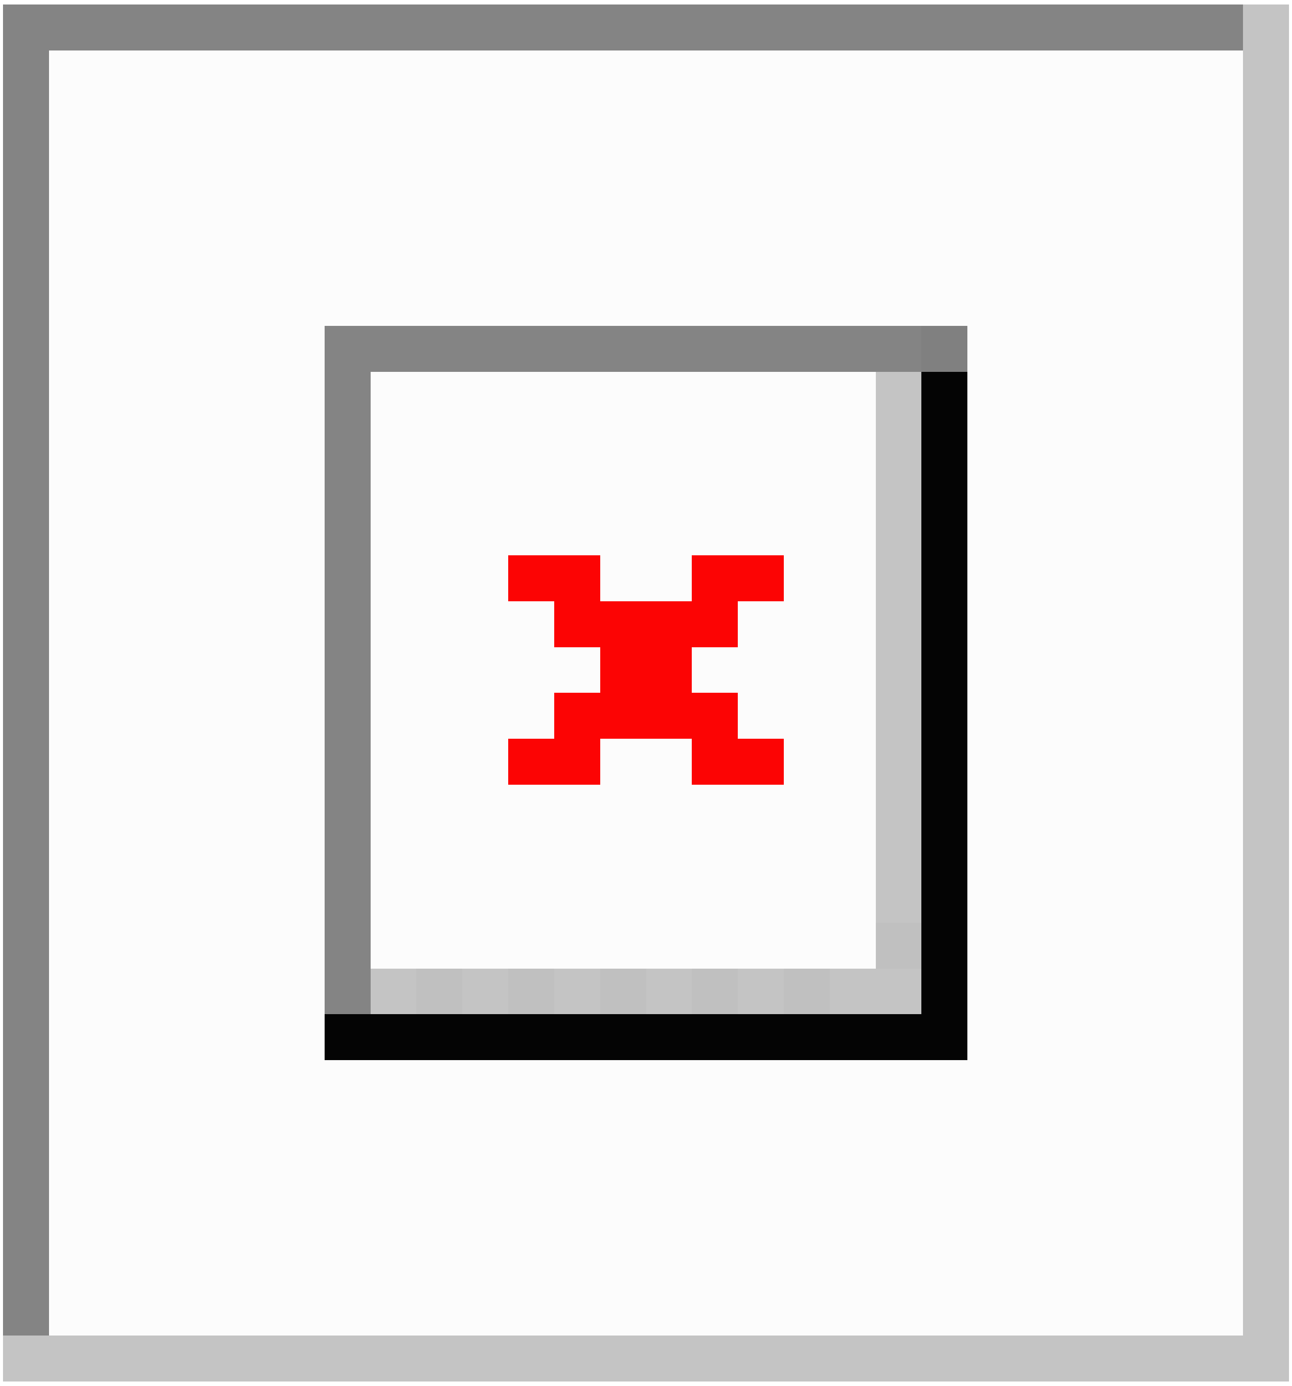
[m]mHealth: mobile health.

[n]Smartphone mobile app.

[o]N/A: not applicable.

[p]DOT for a minimum period of 30 d and a maximum of 90 d.

Figure 2. Types of digital health interventions and the number of articles published by year. e-DOT: electronic directly observed therapy; MERM: medication event reminder monitor; mHealth: mobile health.



Components of the DHIs and Outcomes

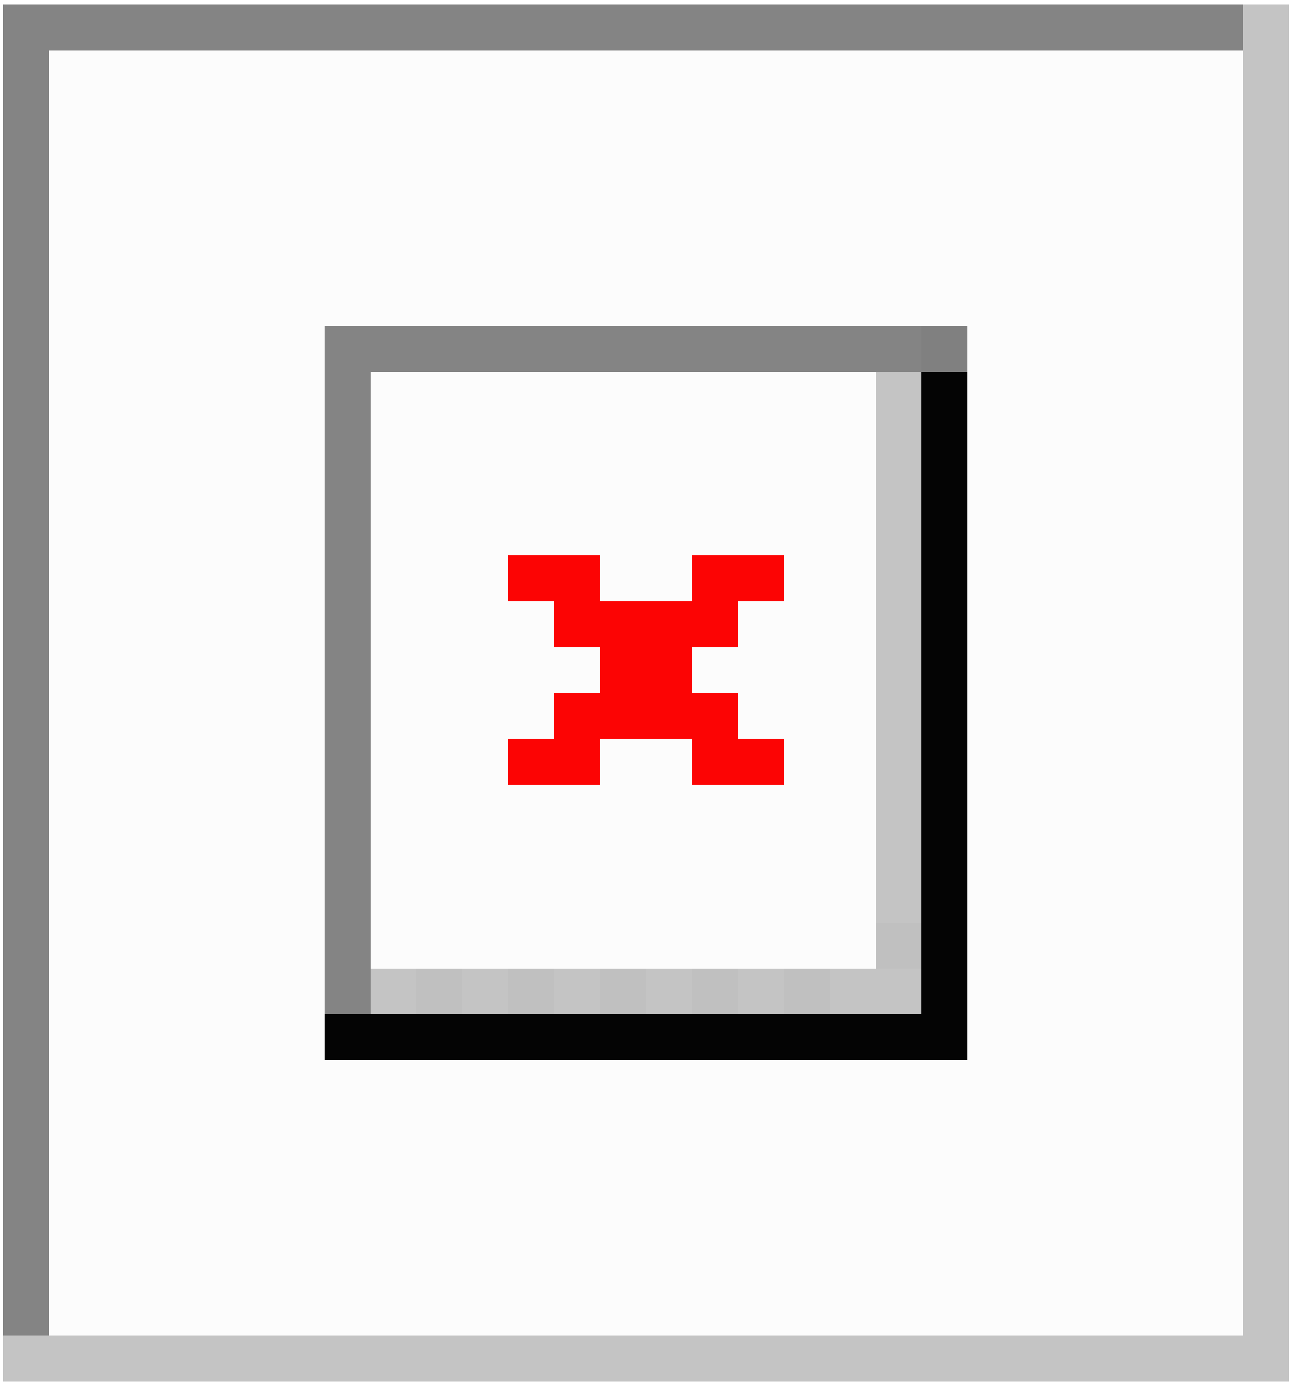
Table 2 presents the components of DHIs that were derived from the primary and secondary outcomes of the selected articles, including (1) sending reminders for treatment adherence via reinforcement SMS text messages [15-22], (2) monitoring treatment adherence by using digital technology [23-31], and (3) tracking treatment adherence through the use of mobile apps and mobile health (mHealth) technology [38-41] via treatment adherence [42] and modified behavior adherence [43] models. Figure 3 presents a modified adherence model.

Table . Distribution of digital health interventions (DHIs) and related interventions (N=27).

Components and DHIs		Articles, n (%)	References
Reminding			
	SMS text messaging	8 (30)	[15-22]
Monitoring			
	DOT[a] (e-DOT[b], VOT[c], and WOT[d])	9 (33)	[23-31]
	MERM[e]	6 (22)	[32-37]
Tracking			
	Mobile app and mHealth[f]	4 (15)	[38-41]

[a]DOT: directly observed therapy.
[b]e-DOT: electronic directly observed therapy.
[c]VOT: video observation therapy.
[d]WOT: wireless observation therapy.
[e]MERM: medication event reminder monitor.
[f]mHealth: mobile health.

Figure 3. Adherence to tuberculosis treatment is a repeated and ongoing self-management behavior. In this figure, *reminding* refers to reminding patients to take medications as prescribed (ie, correct dose, frequency, and time), *monitoring* refers to using digital health technology (eg, an app) to check whether patients are taking their medication at the prescribed frequency over the initial period, and *tracking* refers to following patients over time to determine whether they taking medications as prescribed [43].



Quality Assessment of the Selected Articles

A risk of bias assessment was performed to assess the quality of the selected articles. Only 8 of the 27 articles used an RCT design [17,20,24,26,27,29,31,37]. The risk of bias results are shown in Multimedia Appendix 4 [17,20,24,26,27,29,31,37] and Multimedia Appendix 5.

Discussion

Principal Results

This review aimed to identify DHIs related to TB treatment and management. We retrieved the relevant articles from electronic databases by using standard search terms and identified 27 articles published between 2012 and 2022. DHIs for improving treatment adherence were categorized as DHIs for sending reminders [15-22], DHIs for monitoring [23-31], and DHIs for tracking [38-41]. We identified various types of DHIs, including SMS text messaging [15-22], DOT [23-31], MERMs [32-37], and mobile apps [38-41], which improved the effectiveness of self-management, treatment adherence, and the prevention of TB in clinical and community settings.

A total of 19 studies focused on different types of interventions for reminding patients about treatment adherence and included outcomes such as medication adherence [16,21-23,29,33,35,37,41], self-reported survey satisfaction [17,20,22], and appointment attendance [20]. Treatment adherence was primarily accomplished through daily reminder SMS text messages [15-22] and phone calls [22,27,28,41] that requested confirmation of adherence. Furthermore, additional reminders were sent to patients for encouragement or motivation [15,20] if they did not respond within a given time period [16,17,23,28]. Studies also reported sending compliance reminders through daily quizzes [18]; sending reinforcement SMS text messages twice weekly for 12 weeks [21]; and sending system reminders or additional messages to remind patients about the time of medication use [17], confirm daily doses [28], notify patients about a consultation service for their upcoming monthly visits [32], encourage the use of an app [21], and promote self-satisfaction [17,20,22,27]. Rather than demonstrate treatment efficacy, SMS text messaging–based reminder interventions increased patient satisfaction [17,19]. SMS text messaging–based digital technology supports and helps patients and health care professionals to enhance health practices and clinical outcomes. An interactive reminder, such as an SMS text message or video conversation, should be developed according to the required medical monitoring process and incorporated into clinical practice.

Numerous studies have examined the use of DOT to monitor treatment adherence, including 99DOTS [28], VOT [4,29,39], asynchronous VOT [30], wireless observation therapy [24], and e-DOT [40]. DOT also includes treatment regimen monitoring interventions that are based on technology, such as wearable devices [23], mHealth apps [29], and wireless devices [24]. We identified 8 articles that reported e-DOT interventions for TB treatment adherence. Prior studies reported that participants preferred e-DOT over traditional therapy for supporting daily TB medication use during the long-term phase of TB treatment [24,27,29,30]. e-DOT should be tested in areas with a high risk of TB contraction, as e-DOT could greatly enhance the development of programs for treating the disease in LMICs. In addition, VOT interventions for new TB cases were used in combination with a mobile app [26], WeChat (for education and knowledge) [39], and treatment follow-up (with a maximum follow-up interval of 6 months). Story et al [26] reported that VOT resulted in an 80% medication adherence rate in 2 months when compared to DOT, and Ravenscroft et al [29] reported that VOT resulted in about a 45% decrease in nonadherence, which was statistically significant. Further, smartphone-enabled video surveillance of TB therapy has been proven successful and has many advantages over conventional DOT. Wade et al [44] found that VOT increased the proportion of observed treatment doses when compared to DOT; however, the effect on the treatment adherence rate was not statistically significant. Thus, audio- and video-based DHIs may be useful in reducing attrition and improving treatment adherence and health outcomes in acute care settings.

In this review, 4 RCT protocols for MERM-related monitoring interventions were also included [32,33,35,36] to obtain data on the methodological pattern of treatment adherence. Most MERMs are designed to ensure drug compliance, such as evriMED500 [32,33] or evriMED1000 [35,36]. Maraba et al [35] developed an MERM for the daily monitoring of patients and children with drug-susceptible TB during a 6- to 12-month follow-up. Additionally, Ratchakit-Nedsuwan et al [34] conducted a clinical trial of an MERM for patients with pulmonary TB for approximately 6 months; a total of 54 doses were delivered over 70 days, and the adherence rate was approximately 90%. Further, Acosta et al [37] reported that an MERM was significantly more effective than DOT. Hence, we suggest that further RCTs using MERM-based digital intervention strategies should be conducted to enhance TB treatment adherence and clinical outcomes. Since most outcomes were self-reported, additional trials are recommended to determine the accuracy of MERM system–based adherence rates.

Tracking and guiding patients remain important for the follow-up of treatment adherence in a therapeutic context. We found that 4 smartphone-, mHealth-, and mobile app–based digital devices were used to evaluate TB treatment adherence [34,40,41] and acceptability [38]. Patients with pulmonary TB who received intervention through the WhatsApp TB@Clicks module (an mHealth-based DHI) were approximately 4.1 times more likely to have favorable treatment results than a control group [38]. Another DHI for daily drug tracking resulted in drug adherence rates increasing from 85.5% to 96.4% over time [41], and a health-related VOT resulted in decreased nonadherence rates within 4 days [29]. Some apps were combined with a mobile-based pillbox system for a second consultation, resulting in satisfaction and confidence among patients [34]. These outcomes must be incorporated into future clinical trial designs that adopt trustworthy quantitative methods to determine the relative contribution of each digital health technology component.

This review's findings revealed that DHIs encouraged self-management among patients with TB and empowered them to participate in collaborative discussions during consultations. However, we found that studies on real-time, conversation-based digital technology are lacking; such technology could improve treatment adherence and foster positive health outcomes in various clinical settings. Due to the rapid development of artificial intelligence technologies, including digital tool kits and generative artificial intelligence, 2-way communication–based chatbots in TB treatment may lead to improved self-management in patients with TB.

Limitations

This review had some limitations. First, our review included studies that focused on treatment outcome–based interventions rather than health care delivery. Therefore, we did not focus on other details, such as TB prevalence, costs, or health insurance. Second, this study focused on the effects of commonly used DHIs on TB treatment outcomes in clinical and community settings. Further studies should determine how DHIs vary between the two contexts and how they interact with multidomain therapies. Third, this study did not specifically describe treatment adherence and self-management. There are no clear differences between the accurate meaning and measurement of treatment adherence in a clinical trial setting and those of self-management in a clinical or community context, and few studies have attempted to provide answers [45-47]. Fourth, many of the included studies (13/27, 48%) were conducted in LMICs because of the high prevalence of TB cases, even though high-income nations have a considerable number of studies. This could be attributed to our study's selection criteria, such as our criterion for language. Therefore, additional studies are required to identify DHIs across the entire TB care continuum.

Conclusions

This study examined 27 studies published between 2012 and 2022 and selected the most recent articles. The following three domains were identified from the selected studies: reminding, monitoring, and tracking. The preponderance of treatment adherence was reinforced by mHealth strategies, such as the use of SMS text messaging, mobile apps, mHealth technology, and MERMs. Our findings have implications for TB-related digital health research, which frequently fails to adequately address patients with TB. To preserve treatment adherence and self-care management, patients should have access to real-time, conversation-based interventions (dialogue or communication between patients and health care professionals), such as mobile- or app-based chats, regardless of the restrictions imposed by the COVID-19 pandemic. This scoping review study was conducted before our ongoing chatbot project, which focuses on a mixed methods study on chatbot communication for the treatment adherence of patients with TB. Thus, we emphasize the importance of developing a communication system. DHIs provide several advantages, including improved patient engagement, availability, and accessibility, in addition to lower workloads for practitioners. These results should be considered in the context of national TB control programs and policies to establish a strategy for sustaining TB control and health outcomes. We propose that these developments can significantly improve TB treatment adherence through global collaboration and investment.

Abstract

Background: In an aging population, it is important to activate older adults in taking care of their own health. Increasing physical activity is one way to avoid or lessen age-related physical and mental impairments. Interest in the use of information and communication technology (ICT) tools to promote physical activity among older adults is growing considerably. Such tools are suitable for communicating activation factors—skills, knowledge, and motivation—by integrating a variety of behavior change techniques (BCTs) to enhance physical activity. Although activation factors have been incorporated into physical activity interventions using ICT, little is known about the actual integration methods used in such interventions or about the effects of activation factors on influencing behavior change.

Objective: The first aim of this study was to identify which of the activation factors were covered in physical activity–promoting ICT interventions for older adults and which BCTs were used to address them. The second objective was to classify the user interaction interfaces and delivery modes that were used to promote these activation factors.

Methods: The search engines of PubMed, Web of Science, and ScienceDirect were used to search for and identify articles examining the effectiveness of ICT interventions for promoting physical activity in older adults. References and related data were selected, extracted, and reviewed independently by 2 reviewers. The risk of bias was assessed, and any conflict was addressed by a third separate reviewer. Selected articles included older adults aged ≥55 years without pre-existing medical diseases and other physical or mental conditions that could hinder movement.

Results: In total, 368 records were retrieved, and 13 studies met all inclusion criteria. Articles differed in terms of themes, timescales, user interaction interfaces, and outcome measures; therefore, a quantitative data synthesis was not feasible. Motivation was the most promoted activation factor among all trials (33 times). An app and a smartwatch were used in the majority of intervention groups (7/20, 35%) for tracking physical activity and receiving personalized feedback based on the individual goals. Skills (25 times) and knowledge (17 times) were the next most commonly addressed activation factors. Face-to-face interaction was the most used approach to targeting users' skills, including providing instructions on how to perform a behavior and exchanging knowledge via education on the health consequences of insufficient physical activity. Overall, integrating all 3 activation factors and using multiple user interaction interfaces with a variety of delivery modes proved the most effective in improving physical activity.

Conclusions: This study highlights commonly used BCTs and preferred modes of their delivery. So far, only a limited number of available BCTs (21/102, 21%) have been integrated. Considering their effectiveness, a larger variety of BCTs that address skills, knowledge, and motivation should be exploited in future ICT interventions.

KEYWORDS

older adults; information and communication technology; healthy aging; activation factors; skills; knowledge; motivation; behavior change techniques; physical activity

Introduction

Consequences of Aging

The World Health Organization projects a 34% increase in the global population of 1 billion older adults by 2030, showing a demographic trend toward an older population [1]. Several pathologies, such as pulmonary disease, neurodegenerative disorders, and cardiovascular disease, share aging as their dominant pathogenesis risk factor, though these pathologies can be positively influenced by physical activity [2-4]. Hence, managing the health of the older population is important [5].

Activation in Health Care Management

Individuals themselves can successfully be activated in their health management if they are equipped with activating factors. Activation of the individual leads to behavioral changes and consequently enhances, for example, physical activity levels [6]. Activating people involves making the individuals believe in their participatory role and fostering their confidence through improving their skills and abilities regarding their well-being. It also involves creating awareness by communicating knowledge on the necessity to act. Furthermore, it includes motivating individuals to take action to maintain and improve their health outcomes [7,8]. Evidence proves that activated individuals are independently able to better control their health and have better health outcomes [9]. As a result, activated individuals develop confidence in self–health care management [10].

Activation Using Information and Communication Technology

First, information and communication technology (ICT) interfaces communicate activation factors effectively to the user. Such activation factors can be described by using the behavior change technique (BCT) taxonomy from Michie et al [11]. This taxonomy includes 16 categories for promoting skills, knowledge, or motivation; these categories include shaping knowledge, comparing behavior, natural consequences, comparison of outcomes, goals and planning, and feedback and monitoring. Further, considering the possibilities of ICT tools, Dugas and colleagues [12] added 2 more categories (ie, personalization and gamification), including 9 BCTs in total. A review by Aldawood et al [13] also pointed out that ICT interfaces in health interventions offer various BCTs that indeed raise awareness of health and promote more self-awareness among people. Second, ICT interventions that include activation factors are effective for improving health. Such interventions include, among others, remote coaching or monitoring, automated feedback, and increased accessibility to credible health information [14,15]. Providing feedback based on detected behavior patterns, when paired with reminders to be active, leads to improvements in physical activity behavior, better health-related knowledge, and increased motivation [16]. Additionally, a web-based intervention [17] and an intervention using wearable activity trackers connected with a smartphone app [18] both showed improvements in participants' health skills, knowledge, and motivation for developing and maintaining positive health-related practices. Lastly, entertainment, such as exergames, can be used to teach health-related skills, provide feedback, and constantly motivate the user [19].

Although activation factors have been incorporated into physical activity interventions using ICT, little is known about the actual integration methods used in such interventions or about the effects of activation factors on influencing behavior change. McGarrigle and Todd [20] stated that ICT interventions incorporating BCTs may be more effective in promoting physical activity than those interventions that do not focus on such techniques. Accordingly, Dugas and colleagues [12] performed a systematic review on health behavior interventions within mobile health apps and reported on the integrated BCTs and how they influenced outcomes.

Study Aims

This systematic review, as a primary objective, aimed to identify which of the activation factors—skills, knowledge, and motivation—were covered in ICT interventions that promote the physical activity of older adults and to report the incorporated BCTs. The secondary objective was to classify the user interaction interfaces and delivery modes that were used to promote the activation factors.

Methods

Information Sources, Databases, and Searching Process

The search engines of PubMed, Web of Science, and ScienceDirect were used to search the MEDLINE, Web of Science Core Collection, and ScienceDirect databases, respectively, for peer-reviewed publications that were published until February 28, 2022. The search strategy was customized for each selected database according to their filtering options (eg, for PubMed, a combination of Medical Subject Headings and other index terms was used).

The final search string included *("mhealth" OR "telemedicine" OR "mobile application") AND ("older adults") AND ("activation" OR "physical activity" OR "self-healthcare" OR "healthy ageing")*. The results that were generated by using the abovementioned search strategy in all databases were uploaded to Rayyan (Rayyan Systems Inc) [21] for the cleaning and selection process. First, the titles and abstracts of identified studies were independently screened by 2 reviewers to select relevant studies. Second, the full texts of potentially relevant studies were obtained and independently reviewed. A third assessor, who was not part of the previous screening of articles, decided on the inclusion or exclusion of the articles in cases of conflicts.

Selection of Studies and Data Extraction

Guidelines of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement were used for the reporting of this systematic review [22]. The three databases and the reference lists of the included articles were searched and evaluated based on a set of inclusion and exclusion criteria.

Articles that met the following criteria were included: (1) a target group with an average age of ≥55 years; (2) participants without pre-existing chronic medical diseases (eg, diabetes) or mental and physical impairments (eg, repetitive falling); (3) articles that reported about digital physical activity intervention(s); (4) articles that assessed physical activity effectiveness through objective methods (eg, pedometer), subjective methods (eg, questionnaires), or a combination of objective and subjective methods; and (5) methods were embedded in one of the following designs: randomized controlled trial, quasi-experimental, clinical, or feasibility study designs.

Articles that met at least one of the following exclusion criteria were excluded: (1) articles not written in English; (2) no access to the full text; (3) a target group with an average age of <55 years; (4) a focus on older adults with pre-existing chronic medical diseases or in acute rehabilitation scenarios (eg, patients in rehabilitation after stroke); (5) articles that did not include a digital physical activity intervention; (6) articles that did not report about intervention effectiveness for physical activity; and (7) nonempirical research (eg, editorials and commentary papers).

After the selection of relevant articles, the data were extracted, and quality was assessed. The data extracted from each selected study included the author, year of publication, study design, sample size, population, intervention, technology, timescales, outcome measures, and main findings. The delivery modes of the user interaction interfaces were classified (1) as a personalized exercise introduction session at the beginning of the intervention, (2) as digital (calls, text messages, apps, the web, smartwatches, and activators), (3) as traditional (face-to-face modes and printed materials), or (4) as digital and traditional (hybrid).

The supervision of the delivery modes for the intervention groups was defined by Denton et al [23], as follows: (1) supervised (ie, physical activity is undertaken in the presence of a health care professional or qualified fitness instructor, either virtually or in person, to ensure safety and or correct technique), (2) facilitated (ie, physical activity is undertaken without the presence of a health care professional or qualified fitness instructor but with scheduled meetings or check-ins between sessions to monitor progress and provide support [virtually or in person]), or (3) unsupervised (ie, physical activity is undertaken without the presence of a health care professional or qualified fitness instructor; no support or progress tracking appointments are scheduled).

We identified and classified the used activation factors and corresponding user interfaces. The definitions of the activation factors and their classification are described in Table 1. The classification items were based on the BCT taxonomy with 16 categories developed by Michie and colleagues [11]. Additionally, the two categories suggested by Dugas and colleagues [12]—personalization and gamification—were incorporated as categories 17 and 18.

Table . Activation factors and behavior change technique taxonomy.

	Activation factor		
	Skills (ability)	Knowledge (awareness)	Motivation (triggers)
Definition	• A person will be equipped with skills via instructions or tips on the correct performance of the behavior. Observing others succeeding in performing the targeted activity is another strategy [24]. With increased ability, self-confidence will be fostered [9].	• A person will be educated by providing them with knowledge on the benefits of sufficient physical activity as well as the consequences of insufficient physical activity [25]. The awareness that it is necessary to be active will become present, and intentions will be formed [9].	• A person will be triggered to have high motivation [7,8] by gaining personalized values [26] through self-monitoring [25], monitoring by another person, monitoring via a technical device, and encouraging feedback [27].
Behavior change taxonomy categories[a,b]	• Category 4: Shaping knowledge • Category 6: Comparison of behavior • Category 8: Repetition and substitution • Category 13: Identity • Category 15: Self-belief	• Category 5: Natural consequences • Category 9: Comparison of outcomes • Category 11: Regulation	• Category 1: Goals and planning • Category 2: Feedback and monitoring • Category 3: Social support • Category 7: Associations • Category 10: Reward and thread • Category 12: Antecedents • Category 14: Scheduled consequences • Category 16: Covert learning • Category 17: Personalization • Category 18: Gamification

[a]Behavior change taxonomy categories 1 to 16 by Michie et al [11].

[b]Behavior change taxonomy categories 17 and 18 by Dugas et al [12].

Quality Assessment

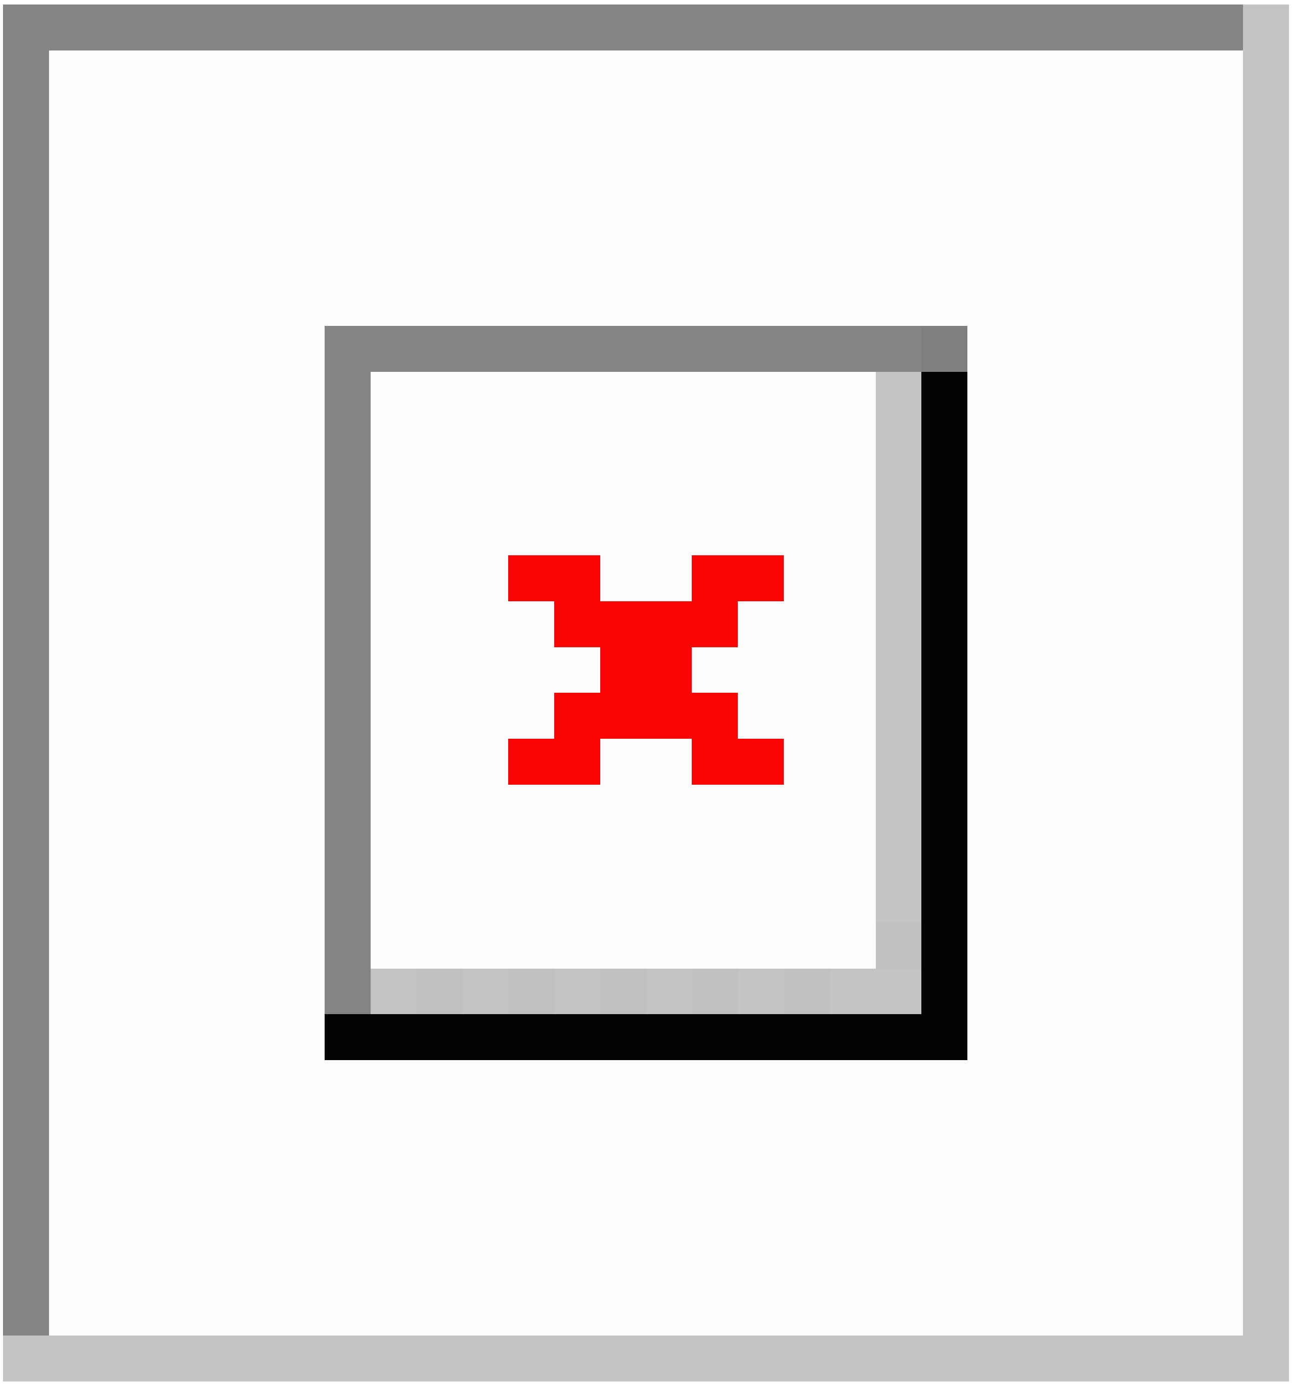
To assess the risk of bias, the Cochrane Collaboration tool Risk of Bias 2 (ROB 2), which focuses on different aspects of trial design (ie, conducting and reporting), was applied [28,29]. According to the tool, a study was classified as having a low risk of bias when it scored low on all 3 domains, a moderate risk of bias when 2 of the 3 domains were scored low, and a high risk of bias when 1 or no main domain was scored low. A meta-analysis was not feasible due to the selected studies being different with regard to the types of interventions.

Results

Studies Identified Through the Searching Process

After searching the databases, 353 abstracts were identified. Further, 15 additional abstracts were identified by searching the reference lists of the initially identified articles. After the removal of duplicates and the screening of the involved abstracts, the full texts of 46 articles were assessed for eligibility. At the end, 13 articles met the inclusion criteria and were therefore included in this systematic review. Details on the study selection process are presented in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram.



Study Characteristics

Study Design

Of the 13 included articles, 6 were randomized controlled trials, and 8 used a quasi-experimental design. The 13 articles included a total sample of 1622 participants. Male and female participants were involved in all articles; however, their exact composition was not reported in two of them [30,31]. The mean age of the study participants ranged from 63 to 80 years. The duration of the intervention ranged from 2 weeks to 24 months. The study characteristics are presented in Multimedia Appendix 1 [30-42].

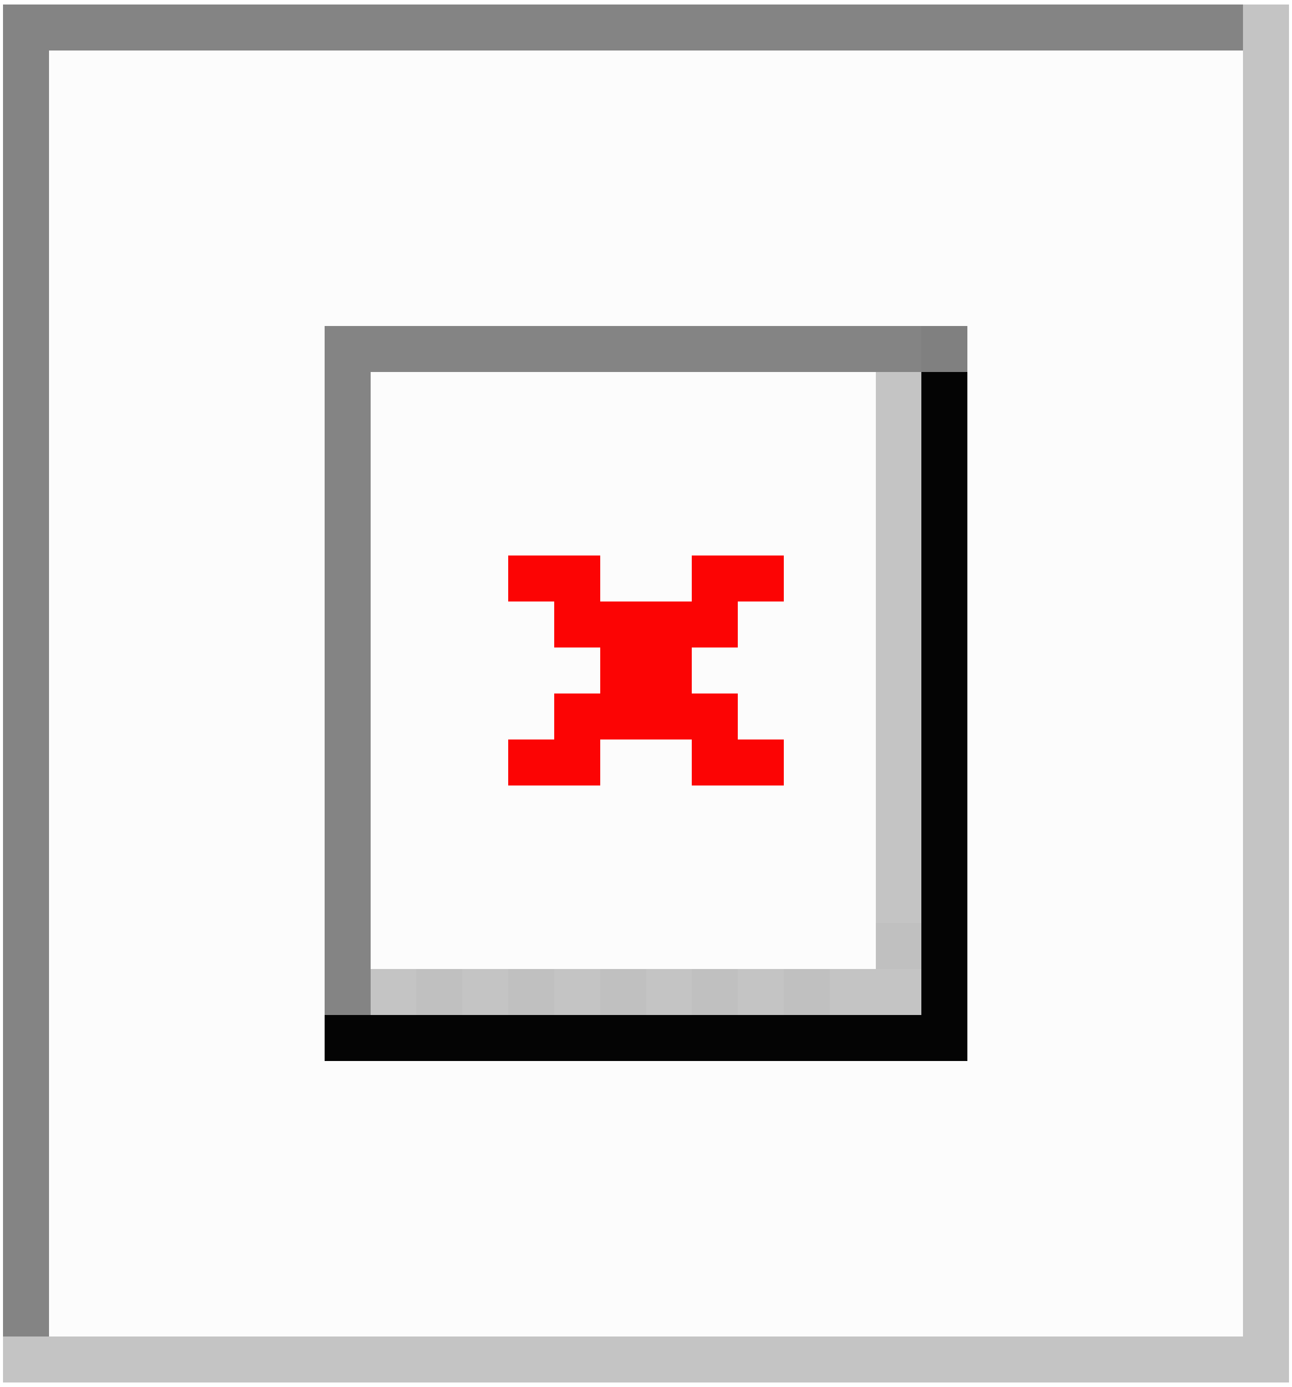
Physical Activity Assessment

To be able to analyze the effectiveness of an intervention, subjective or objective outcome measures for physical activity are necessary. In 4 articles (with 6 intervention groups), only subjective methods were used to measure physical activity (ie, questionnaires like the International Physical Activity Questionnaire). In 4 of the intervention groups, a significant beneficial effect of the digital or hybrid intervention was reported when compared to a control group [30-33]. In 8 articles (with 9 intervention groups), physical activity was measured by using only an objective assessment (ie, pedometer and accelerometer). In 3 of these intervention groups, a significant positive effect of the digital or traditional intervention on physical activity values was reported [31,34,35]. In the remaining intervention group, both objective assessments and subjective assessments were integrated, which showed significant effects on improving physical activity [36].

Activation Factors

Figure 2 presents the integrated activation factors, as well as the corresponding interfaces and delivery modes used for the user interaction in each article and intervention group. Data on the BCTs used in the intervention were extracted for each article, and the number of BCTs for each factor of activation was determined. An overview of integrated BCTs and those that were not used is presented in Multimedia Appendix 2.

Figure 2. User interaction interfaces and delivery modes for delivering activation factors [30,31,32,33,34,35,36,37,38,39,40,41,42]. Orange blocks show intervention groups with significant beneficial findings regarding physical activity. Grey blocks highlight the user interfaces used along with the integrated activation factors. A high resolution version of the figure can be found in Multimedia Appendix 3. D: digital; FA: facilitated; H: hybrid; K: knowledge; M: motivation; OB: objective; PE: personalized exercise introduction; S: skills; SU: subjective; SUP: supervised; T: traditional; U: unsupervised.



Delivering Activation Factors

For all of the interventions, motivation was the most promoted activation factor (33 times), followed by skills (25 times) and knowledge (17 times). All 3 activation factors were identified in 12 of 20 interventions. Interventions that included all 3 activation factors were shown to be more successful in increasing or maintaining physical activity levels (articles: 7/12, 58%) compared to interventions that limited themselves to 2 or fewer activation factors (articles: 3/8, 38%).

BCTs that promoted skills, knowledge, and motivation were addressed in 19, 15, and 17 of the 20 intervention groups, respectively. Effective outcomes regarding physical activity were reported while promoting skills in 47% (9/19) of trials, while promoting knowledge in 53% (8/15) of trials, and while promoting motivation in 53% (9/17) of trials.

To promote skills, instruction on how to optimally perform a behavior was most commonly delivered in the form of training prescriptions and exercise tips (eg, key movements and where the exercises should be felt) or through descriptions using pictures (16 intervention groups). The next most common BCT for promoting skills was face-to-face demonstration or demonstration through tutorial videos (8 intervention groups), followed by the provision of information on how to integrate exercise into daily activities (habit formation; 3 intervention groups) and practice (2 intervention groups). Lastly, participants were informed about antecedents of the behavior (1 intervention group). Of the 23 available BCTs [11,12] that target skills, the aforementioned 6 (23%) were used among all included articles.

The most used strategy for changing physical activity behavior by promoting knowledge was the integration of information about the health consequences that arise if physical activity is not sufficiently part of daily behaviors (13 intervention groups). Besides that, information from a credible source (7 intervention groups) and educative information, such as the salience of consequences (6 intervention groups) and the pros and cons of physical activity (1 intervention group), were also part of the interventions. Of the 13 available BCTs [11,12] that target knowledge, the aforementioned 4 (31%) were used among all included articles.

With regard to targeting motivation, the self-monitoring of physical activity (12 intervention groups) and personalized feedback (8 intervention groups), which was often combined with individual goal setting (7 intervention groups) and social support (8 intervention groups), were the most used BCTs. Others were prompts and cues (4 intervention groups), adjustment of intervention content to the performance (4 intervention groups), action planning (2 intervention groups) and problem-solving discussions for finding ways to overcome barriers (1 intervention group). Of the 66 available BCTs [11,12] that target motivation, 11 were used among all included articles.

Altogether, of the 102 potential BCTs [11,12], 21 (21%) were integrated in all articles.

User Interaction Interfaces and Delivery Modes

Various digital user interaction interfaces were used. The delivery modes of the user interaction interfaces varied, including personalized exercise introduction sessions at the beginning of the intervention, digital modes, traditional modes, and hybrids of digital and traditional modes. Further, 2 interventions were supervised, 12 were unsupervised, and 6 were facilitated.

To address skills, face-to-face interaction was commonly preferred (14 intervention groups). Other interaction interfaces included the web (5 intervention groups), smartwatches (2 intervention groups), apps (2 intervention groups), and printed materials (2 intervention groups). To cover knowledge, face-to-face interaction was often used (8 intervention groups), followed by the web (5 intervention groups), printed materials (3 intervention groups), and apps (1 intervention group). Calls, text messages, and activators were not used to target skills or knowledge. To target motivation, all user interaction interfaces, except printed materials, were used. Apps (7 intervention groups), smartwatches (7 intervention groups), and the web (6 intervention groups) were the most commonly integrated interaction interfaces, followed by face-to-face interaction (4 intervention groups), text messages (4 intervention groups), calls (3 intervention groups), and activators (2 intervention groups). The forms of feedback therefore differed, including visual, audio, and tactile feedback. The combination of digital and traditional user interaction modes resulted in significant positive physical activity outcomes.

Altogether, of 20 intervention groups, 14 used personal interactions, and the remaining 6 used solely nonpersonal interactions. The effectiveness of the physical activity of the nonpersonal interaction groups (intervention groups: 4/6, 67% effective) differed from the results of the personal interaction groups (intervention groups: 6/14, 43% effective).

Only Mouton and Cloes [30] reported on the delivered intervention dose, that is, how many attempts were made to contact each participant, how many attempts were received, and how many attempts were acted on by the participants. During their 3-month web-based interventions, the web-based intervention group visited the website, on average, 18 (SD 14) times, and the combined intervention group visited, on average, 39 (SD 21) times; these were much lower than the intended number of visits (potentially 90 visits).

Risk of Bias

Table 2 presents the results of the risk of bias assessment for the 13 included articles. The risk of bias for most of the included studies (11/13, 85%) was rated as *moderate*. Only 2 of the articles showed an overall high risk of bias [30,34]. In the article by Muntaner-Mas et al [34], a convenience sample method was used, which does not exactly randomize the sample, and the allocation of participants was not concealed, thereby introducing a selection bias. In the article by Mouton and Cloes [30], 28% of the participants dropped out of the study, thereby creating a bias and affecting the effectiveness of the study. In cases where the domains of the ROB 2 were not described in the included article, the risk of bias was rated as *unclear*. In 3 articles, the blinding of participants and personnel was not possible (performance bias) [30,34,37]. Furthermore, in 3 articles, the blinding of the outcome assessment was not possible [30,33,38] because subjective methods or a combination of subjective and objective methods was used to measure physical activity (detection bias). Additionally, 2 articles showed a high risk of attrition bias (incomplete outcome data) [30,31]. Other possible biases included small sample sizes [36,39], self-selection bias, baseline differences between study groups, and short intervention periods [35,36,39,40].

Discussion

Key Findings

This systematic review, as a primary objective, aimed to identify which of the three activation factors—skills, knowledge, and motivation—were promoted in ICT interventions for older adults and which corresponding BCTs were applied. The secondary objective was to classify the user interaction interfaces and delivery modes that promoted these activation factors. A summary of the main findings from the 13 included articles are presented in Textbox 1.

Textbox 1. Summary of the main findings.

All activation factors

- Integrating all 3 activation factors proved most effective for increasing physical activity levels

Skills

- Promoted in 19 of 20 interventions
- Six BCTs were used; main behavior change techniques (BCTs) were the instruction of optimal behavior performance and the demonstration of behavior

Knowledge

- Promoted in 15 of 20 interventions
- Four BCTs were used; main BCTs were providing information about health consequences, information from credible sources, and information about the salience of consequences

Motivation

- Promoted in 17 of 20 interventions
- Eleven BCTs were used; main BCTs were self-monitoring, feedback on behavior, social support, and goal setting

User interaction interfaces

- A mixture of interfaces raised the chances of addressing all activation factors, which resulted in effective interventions

Digital delivery modes

- Commonly used to target motivation
- Allowed for the automatic detection of activity patterns and personalized feedback

Traditional delivery modes

- Commonly used to target skills and knowledge
- Only successful if they supported digital user interaction interfaces

Subjective and Objective Outcome Measures

In this review, articles with subjective measures reported more positive outcomes than those using objective measures alone. In agreement with literature, articles that used only subjective methods to measure physical activity showed a positive outcome of the intervention, including improved physical activity levels [29]. This however could have possibly been due to self-reporting bias, whereby participants assess their own improvement over the intervention period [43,44]. Nevertheless, in the article that used a combination of subjective and objective factors, the authors also reported that their intervention was effective in improving or maintaining physical activity levels [36].

Delivering Activation Factors

Although a large variety of BCTs were integrated to promote activation factors, our findings show that for each activation factor, only a limited number of BCTs from Michie et al [11] and Dugas et al [12] were exploited. Preissner et al [45] highlighted the relevance of multiple behavioral determinants (ie, social cognitive, habitual, automatic, postintentional, and planning processes) to physical activity intention in older adults. Additionally, adult users themselves have identified a variety of BCTs to fulfill their needs and preferences for engagement with physical activity apps [46]. Our findings coincide with previous reports and indicate that BCTs that integrated a combination of all 3 activation factors indeed showed the most beneficial physical activity effects. This was also reported in a review that analyzed internet-based interventions promoting health behavioral change [47].

Improving skills results in better outcomes of interventions [48]. The most used BCTs for promoting this activation factor in the interventions of the selected studies were instructions on how to perform a behavior and demonstration of a behavior, which have proven effective in improving physical activity levels [49,50]. The integration of some other likely effective BCTs was not reported, or these BCTs were not used (eg, behavioral experiments, habit reversal, graded tasks, or the identification of self as a role model). In other studies, habit reversal [51,52] and graded tasks [50] were shown to be effective in reducing sedentary behavior and improving physical activity. These can as well be integrated into interventions using ICT tools, to increase the chance of effectiveness.

To increase knowledge, 4 BCTs that focused on information about health consequences, information from credible sources, and information about the salience of consequences were integrated. In the literature, providing information about health consequences is likewise often used to target the user's knowledge and has proved effective in reducing sedentary behavior and improving physical activity [49,53]. Other strategies (eg, providing information about social, environmental, or emotional consequences) are also available and can improve effectiveness, as seen in a systematic review with a meta-analysis [54].

To target participants' motivation, 11 BCTs, such as self-monitoring, feedback on behavior, social support, adjusting intervention content to the performance and goal setting, were used. Gamification was not used to motivate participants, even though studies show that it can also be effective as a mode of motivation [12]. Prompts and cues were used in some interventions, but considering their effectiveness in mobile health apps [12], they should be incorporated more frequently in future interventions. Other BCTs, such as self-rewards [50] and reduced rewards [55], were also not used.

User Interfaces and Delivery Modes

Of the 20 interventions, most (n=14, 70%) still used a personal interaction. Of course, personal interaction enables the addressing of users' issues and gaps in skills and knowledge (eg, raising questions and receiving a demonstration of the physical activity behavior). However, based on our findings, interventions with nonpersonal interaction can be just as effective as or even more effective than interventions with personal interactions in promoting physical activity among the population of older adults. Personal interactions are time and cost intensive, and our findings suggest that solely integrating nonpersonal interactions into physical activity interventions could be a good alternative option. However, a combination of various interfaces increases the chance of addressing all activation factors, as shown by op den Akker et al [56]. Evita—a mobile, 3D virtual fitness trainer—guides users through explanations and demonstrations of how to perform exercises. An external sensor, which is attached to a belt on the patient's hip, measures physical activity behavior. Feedback messages (eg, "you have taken more rest – take a nice walk") are also sent to the users. The advantage of digital devices is the possibility of personalized and regular feedback [57,58]. For a hybrid intervention with a mixture of traditional (face-to-face) delivery modes targeting skills and digital (web) delivery modes targeting knowledge and motivation, positive physical activity effects were detected [30]. However, for some individuals, participating with others can still be a source of inspiration to improve or maintain physical activity levels [59].

Issues With Digital Interfaces

We also reported digital interventions without significant beneficial effects on physical activity. Our results indicate that interventions involving the unsupervised usage of digital technology may be challenging for participants because of, for example, problems with log-ins, as well as access to or an abundance of information regarding physical activity (eg, recommendations, success stories, tips for exercise, goal setting, physical activity diaries, tools to measure physical activity, and local physical activity opportunities) [30]. A focus group with 46 older adults affirmed this argument; one of the main results of the focus group was that a web-based physical activity program was preferred to be simple; be not cluttered; and include personalized advice, reminders to check-in, and the ability to review goals [60]. An initial instruction and a helpline are useful for necessary technological support [61].

Limitations and Recommendations

The database search was restricted to studies published only in English. Additionally, a quantitative data synthesis (ie, meta-analysis) was not feasible because the included studies were too dissimilar in terms of the intervention content, duration, assessment of outcome measures, follow-up, and comparator groups. Future articles should consider a standard method of assessing outcome measures (possibly a combination of both subjective methods and objective methods), such as using trackers for activity levels, the Behavioral Regulation in Exercise Questionnaire for covering knowledge and motivation levels [62], and the eHealth Usability Benchmarking Instrument for measuring usability (retention and acceptability) [63]. These would make the results more homogeneous for meta-analyses. Further, using the ROB 2 tool was difficult because some of its criteria could not be accurately applied to public health interventions (eg, blinding of study personnel or participants), or the information needed to determine the categories for risk of bias was not provided or was unclear in the publication. Lastly, during our research, we noticed that some studies did not report or sufficiently describe which BCTs were included.

Conclusions

Motivation was the most promoted activation factor in the ICT interventions. However, integrating BCTs that promote all activation factors resulted in better effects in improving physical activity compared to the effects of using only 1 or 2 activation factors. Although a broad variety of BCTs were used in the articles, they were limited to about 21% (21/102) of available BCTs. Hence, many more BCTs could be exploited in future interventions. Integrating multiple interaction interfaces (eg, interfaces for delivering the intervention program and tracking one's own activity to guarantee regular and personalized feedback) was shown to be the most effective in promoting physical activity. Time-consuming and costly personal interactions are not crucial for increasing physical activity in the older population, though they are effective in supporting digital interactions. At present, study outcomes are too diverse, which hinders intervention comparisons. To make the effects of interventions comparable, future studies should report both objective measures and subjective measures.

Authors' Contributions

EB, JJN, and RD conceptualized this study. EB and JJN were responsible for screening (phase 1). RD was responsible for postscreening (phase 2: conflicts). EB and JJN wrote and prepared the original draft. RD reviewed and edited the manuscript. JJN was responsible for reference management. EB was responsible for project administration and journal submission. RD supervised this study. All authors have read and agreed to the published version of the manuscript.

Abstract

Background: Low back pain is one of the main causes of disability worldwide. Individuals with chronic conditions have been widely affected by the COVID-19 pandemic. In this context, mobile health (mHealth) has become popular, mostly due to the widespread use of smartphones. Despite the considerable number of apps for low back pain available in app stores, the effectiveness of these technologies is not established, and there is a lack of evidence regarding the effectiveness of the isolated use of mobile apps in the self-management of low back pain.

Objective: We summarized the evidence on the effectiveness of mHealth interventions on pain and disability for individuals with chronic low back pain.

Methods: We conducted a systematic review and meta-analysis comparing mHealth to usual care or no intervention. The search terms used were related to low back pain and mHealth. Only randomized controlled trials were included. The primary outcomes were pain intensity and disability, and the secondary outcome was quality of life. Searches were carried out in the following databases, without date or language restriction: PubMed, Scopus, Embase, Physiotherapy Evidence Database (PEDro), the Cochrane Library, and OpenGrey, in addition to article references. The risk of bias was analyzed using the PEDro scale. Data were summarized descriptively and through meta-analysis (pain intensity and disability). In the meta-analysis, eligible studies were combined while considering clinical and methodological homogeneity. The certainty of evidence was assessed using the GRADE (Grading of Recommendations, Assessment, Development, and Evaluations) criteria.

Results: A total of 5 randomized controlled trials were included, totaling 894 participants (447 allocated to the mHealth group and 445 to the usual care group), and they had similar methodological structure and interventions. Follow-up ranged from 6 weeks to 12 months. The studies did not demonstrate significant differences for pain intensity (mean difference −0.86, 95% CI −2.29 to 0.58; *P*=.15) and disability (standardized mean difference −0.24, 95% CI −0.69 to 0.20; *P*=.14) when comparing mHealth and usual care. All studies showed biases, with emphasis on nonconcealed allocation and nonblinding of the outcome evaluator. The certainty of evidence was rated as low for the analyzed outcomes.

Conclusions: mHealth alone was no more effective than usual care or no treatment in improving pain intensity and disability in individuals with low back pain. Due to the biases found and the low certainty of evidence, the evidence remains inconclusive, and future quality clinical trials are needed.

Introduction

Low back pain is one of the main causes of years lived with disability in all people aged ≥18 years in the world [1] and causes serious socioeconomic problems due to its high health care costs in several countries [2-4]. For example, the annual costs for this health condition have been estimated to be approximately US $200 billion in the United States, including direct health care spending and indirect costs due to productivity losses and reduced quality of life [5]. In Brazil, between 2012 and 2016, the societal costs (treatment and productivity losses) arising from low back pain were estimated to be US $2.2 billion [6].

Low back pain is recognized for its high prevalence in all age groups ≥18 years. Globally, the prevalence of this condition was estimated to be at 7.5% in 2017, representing approximately 577 million people worldwide [7]. It is worth noting that people with low back pain are frequent users of health and social care services, which causes high expenses [6,8,9]. Thus, currently, one of the great challenges is to use effective strategies to manage this condition and avoid unnecessary expenses [9]. In this context, self-management of low back pain is recommended by international clinical guidelines [10,11]. This strategy involves care programs that facilitate the management and monitoring of the health condition itself, to enable the individual to manage symptoms as well as lifestyle changes [12-14]. It is recommended that self-management includes exercise and psychotherapy to limit the use of drugs and surgical procedures in clinical practice [11,15,16].

In the past decades, there has been a growth in the use of technological resources as a means for health promotion [17,18]. One of the main resources is mobile health (mHealth), which uses mobile and wireless technologies (eg, mobile phones, patient monitoring devices, and virtual assistants) [19,20]. One of the main advantages of mHealth is easy access and usability, as well as applicability in monitoring a health condition [21]. In addition, mHealth can encourage self-management actions; provide greater speed and practicality in the delivery of information; and promote adherence to treatment and other care, including for individuals with low back pain [22-24].

Despite the considerable number of apps for low back pain available in app stores, the effectiveness of these technologies is not established, and most are of low quality [25,26]. Notwithstanding, recent systematic reviews [5,27] have demonstrated positive results using eHealth (eg, the delivery of health resources via traditional internet and interventions with computer access) in the context of self-management of low back pain while considering different outcomes, such as pain and disability. Regarding mHealth, Chen et al [28] demonstrated that this modality combined with usual care (eg, SMS text messages, telephone calls, real-time monitoring, exercises, and counseling) improved the pain intensity and disability of individuals with low back pain. However, the review had limitations, including searches being restricted to the English language and possible selection biases (eg, there was no registration of the protocol, and the authors did not present a list of excluded studies during the full-text reading). Additionally, the review did not analyze the certainty of evidence nor discussed the impacts of the risk of bias of the included studies. Thus, there is a lack of evidence regarding the effectiveness of the isolated use of mobile apps, without interaction with therapists, in the self-management of low back pain.

Accordingly, this study aimed to synthesize updated data focusing on studies that investigated the use of apps for mobile devices (ie, smartphone back pain apps) as the only form of intervention for people with low back pain, without interaction with therapists. This aspect is relevant, given the impact of the COVID-19 pandemic and the subsequent increase in the number of apps available and the use of remote treatments [18,29]. Thus, the aim of this study was to investigate the effectiveness of mHealth interventions in improving the pain intensity and disability of individuals with chronic low back pain, compared to no intervention or usual health care strategies.

Methods

Overview

This systematic review is reported according to the recommendations of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [30]. The protocol was prospectively registered in the International Prospective Register of Systematic Reviews (PROSPERO; CRD42022338759).

Eligibility Criteria

Randomized controlled trials were eligible if they met the inclusion criteria, as defined in Table 1 according to the Population, Intervention, Comparators, and Outcomes question.

The search did not restrict the year or language of publication of the studies. Studies that investigated individuals with specific low back pain and studies that used apps with interference or contact with the therapist during the intervention period were excluded.

Table . Eligibility criteria for the study according to the PICO[a] question.

PICO question item	Inclusion criteria
Population	• Economically active adult population (aged 18-59 y) with nonspecific low back pain for more than 3 mo
Intervention	• mHealth[b] technology [27]
Comparators	• No intervention or usual care (eg, maintenance of medical and pharmacological care or counseling regarding physical activity and exercise prescription) [31]
Outcomes	• Primary outcomes: pain intensity and disability • Secondary outcome: quality of life
Study design	• Randomized controlled trials

[a]PICO: Population, Intervention, Comparators, and Outcomes.

[b]mHealth: mobile health.

Information Sources

Systematic searches were performed in the following databases, with no restriction on publication date: MEDLINE (via PubMed), Scopus, Embase, Physiotherapy Evidence Database (PEDro), and the Cochrane Library, in addition to gray literature (via OpenGrey [32]). The references of the included studies were also screened, and the entire search process took place between December 13 and 26, 2022.

Search Strategy

Search strategies were composed of controlled vocabulary terms and words, according to each database. Terms referring to the investigated condition (low back pain) were combined with terms referring to the intervention of interest (mHealth). No search filters were used for study design, and the search was individually adapted for each database (Multimedia Appendix 1). The search strategy was validated by an experienced librarian.

Screening Process

The studies retrieved in the search were uploaded to Rayyan software (Rayyan Systems Inc) [33]. After confirming and deleting the duplicates, 2 reviewers independently performed the screening by title and abstract. Any disagreement between the reviewers at this stage resulted in the inclusion of the study in the full-text reading stage. Authors of registered protocols were contacted to confirm the publication of data. The second selection phase was carried out by the same reviewers independently, taking into account the eligibility criteria. Any disagreements were resolved through discussion and consensus.

Data Collection Process

The data extraction process of the included studies was performed by 2 reviewers independently; they used a previously prepared and standardized form for this review.

Data List

The information extracted included the sample size, the intervention type of the experimental and control group, the duration of the intervention, the outcomes, sources of funding, and the declaration of conflicts of interest.

Assessment of the Risk of Bias

The risk of bias in the included studies was assessed using the PEDro scale [34]. This step was performed by 2 independent assessors, with subsequent consensus. The PEDro scale contains 11 criteria to be considered from the study analysis, and each item is equivalent to 1 point in the total score of the scale. The final score ranges from 0 to 10, and the first item (eligibility) must be disregarded in the score.

Effect Measures

The following effect measures were extracted from the included studies: means and SDs for pain intensity, disability, and quality-of-life outcomes.

Synthesis Methods

For the meta-analysis, the primary outcomes were considered. To combine the results, the eligible studies were analyzed while considering the clinical and methodological homogeneity and the follow-up period of the intervention. Mean differences and 95% CIs were used as an effect measure for the pain intensity outcome. For disability, standardized mean differences and 95% CIs were calculated, grouped with Hedges correction, in view of the differences in the scales of the disability instruments adopted in the studies (eg, differences in scales and direction of effects). The values were multiplied by −1 to restore effect direction [35].

The random effects model with Knapp-Hartung adjustment [36] was used in the calculation of both outcomes. Heterogeneity was assessed by visual analysis of the similarity of point estimates and overlapping of CIs and using the χ^2 test and I^2 measure. The results were considered heterogeneous when the I^2 values were >50% and P<.10 for χ^2 values [35]. Meta-analyses were performed using the SPSS software (version 29.0; IBM Corp).

Assessment of Publication Bias

We planned to perform publication bias analysis if there were more than 10 studies included in the same comparison, by visual inspection of the funnel plot and the Egger statistical test.

Assessing the Certainty of Evidence

Certainty in the final set of evidence was assessed using the GRADE (Grading of Recommendations, Assessment, Development, and Evaluations) criteria. The 5 items of the GRADE criteria were analyzed: methodological limitations (risk of bias), inconsistency, indirectness, imprecision, and publication bias. Each of these criteria has items to be judged through a qualitative assessment of the evidence for each analyzed outcome, allowing the classification of confidence in the estimate of effects as high, moderate, low, or very low, thus making it possible to reduce or increase the level of evidence [37]. In this evaluation, pain intensity and disability were considered critical outcomes. This evaluation was performed in GRADEpro software (McMaster University and Evidence Prime Inc).

Adverse Events and Adherence

We extracted information pertaining to the number of adverse events and intervention adherence in the included studies. Adverse effects were defined as unintended responses that occur during or after an intervention but are not necessarily caused by a causal relationship to the trial intervention. An adverse event was defined as an event for which the causal relation between the intervention and the event is at least a reasonable possibility [38].

Results

Study Selection

A total of 1824 publications relevant to the review were identified. After the exclusion of duplicates and selection by title and abstract, 18 were considered eligible for full-text reading, according to the inclusion and exclusion criteria. Subsequently, 5 publications [22,39-42] were included after the full-text reading (Figure 1). The 13 excluded studies during the full-text phase are described in Multimedia Appendix 2 with the exclusion justifications.

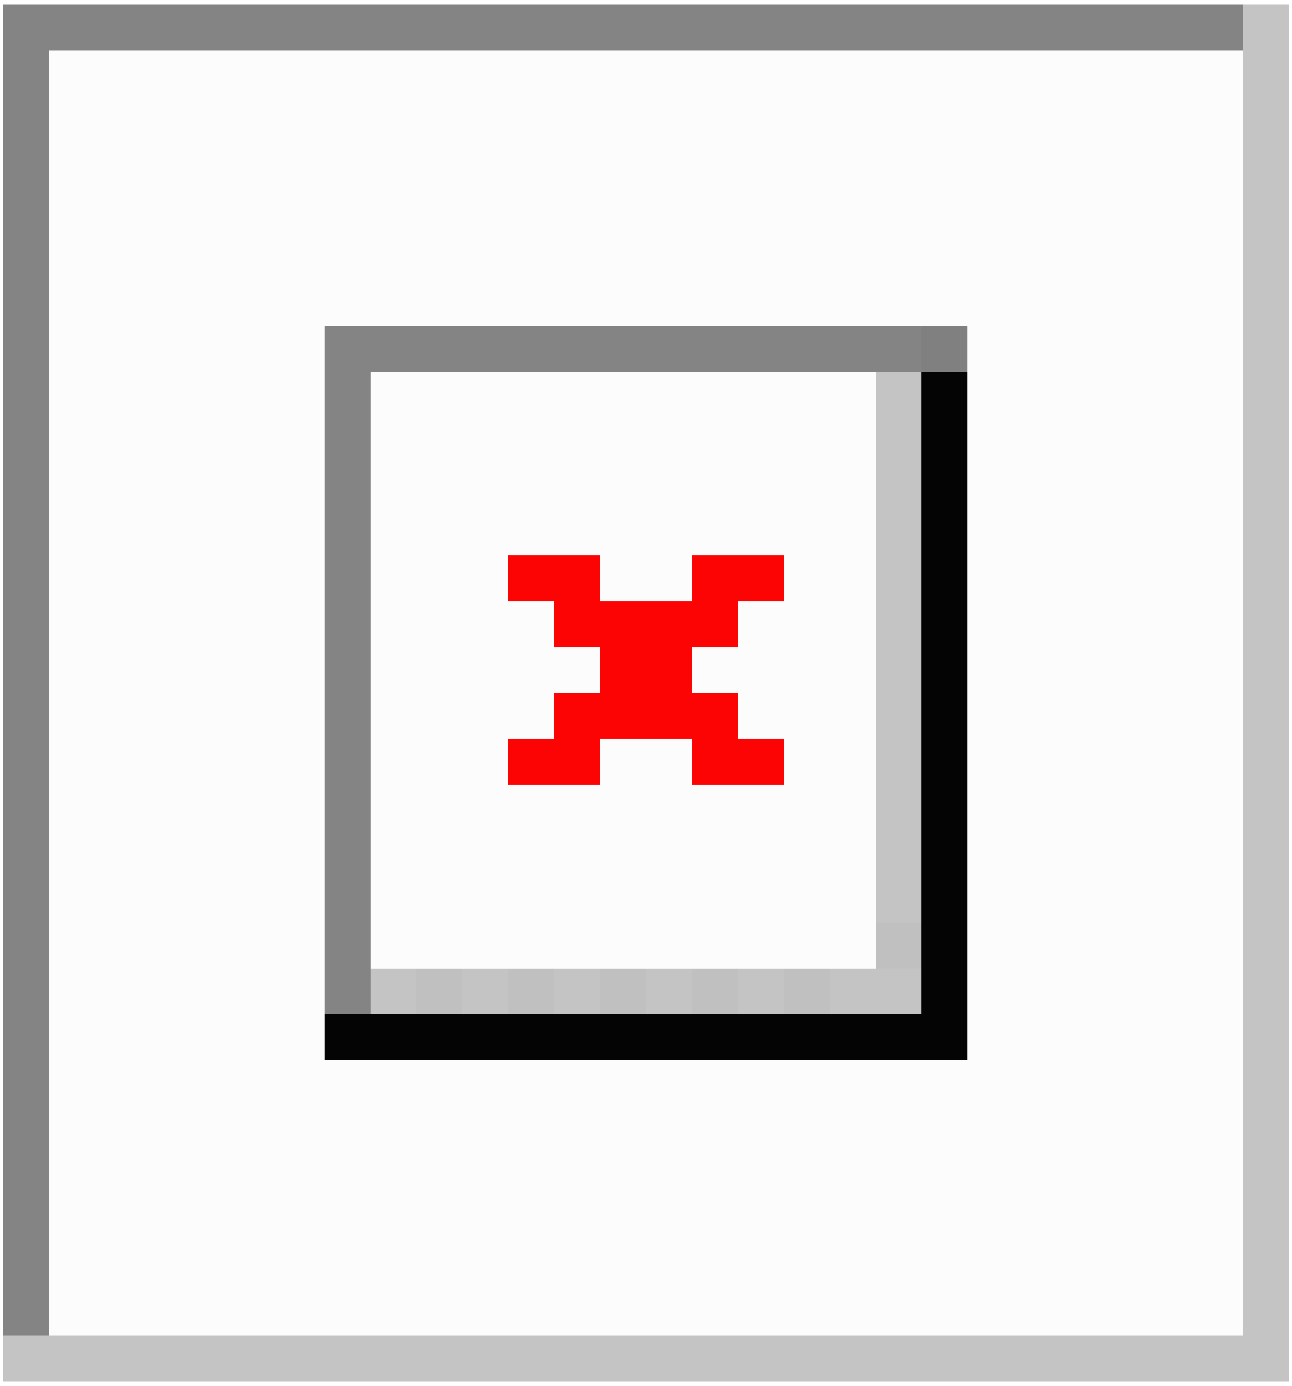

Figure 1. Flowchart of the screening and selection of studies. PEDro: Physiotherapy Evidence Database.

Characteristics and Results of Individual Studies

The included studies had a total of 894 participants (447 allocated to the mHealth group and 445 to the usual care group) and similar methodological structure and interventions. Follow-up ranged from 6 weeks to 12 months, and the studies evaluated the pain intensity and disability outcomes. The characteristics of the included studies and the findings are shown in Table 2. The studies were conducted in Jordan, India, Denmark and Norway, and Germany.

Table . Characteristics of the studies included in the review.

Characteristics	Included studies (reference and published year)				
	Almhdawi et al [39], 2020	Chhabra et al [22], 2018	Sandal et al [40], 2021	Toelle et al [41], 2019	Weise et al [42], 2022
Study design	Pilot RCT[a] with follow-up at 6 wks	RCT with follow-up at 12 wks	RCT with follow-up at 9 mo	RCT with follow-up at 12 wks	RCT with follow-up at 12 wks
Protocol number (record)	NCT03994458	Not reported	NCT03798288	DRKS00016329	DRKS00022781
Country	Jordan	India	Denmark and Norway	Germany	Germany
Study period	January to August 2019	Beginning September 2016; no information on the end date	March to December 2019	August 2017 to October 2018	August 2020 to April 2021
Population	Office workers for more than 5 y between 30 and 55 y of age, with low back pain for more than 12 wk	Individuals over 18 y of age, with persistent chronic low back pain for more than 12 wk with or without the presence of radicular symptoms	Participants aged 18 y or older, with nonspecific low back pain for more than 8 wk	Participants with nonspecific low back pain between 18 and 65 y of age[b], with continuous pain for more than 6 wk	Participants >18 y of age, with nonspecific low back pain
Participants, n	39 (20 intervention and 19 control)	93 (45 intervention and 48 control)	461 (232 intervention and 229 control)	86 (42 intervention and 44 control)	215 (108 intervention and 107 control)
Analysis	Per protocol	Intention to treat	Intention to treat	Per protocol	Intention to treat
Intervention	"Relieve my back" provides general advice, instructions, and stretching and strengthening exercises for lower back and abdominal muscles. Four phone notifications (sound and vibration with a pop-up window) were used to notify participants on taking breaks for walking, correct posture reminders, and exercise reminders.	Snapcare app+written prescription aimed to motivate, promote, and guide participants to increase their level of physical activity and adherence to exercise, including lumbar and aerobic exercises.	selfBACK app+usual care provides individualized weekly self-management recommendations for 3 key components: physical activity (number of steps), strength and flexibility exercises, and daily education messages. In addition, the app provides general information about low back pain and access to various tools (goal setting, mindfulness audios, pain relief exercises, and sleep reminders)	Kaia app involves 3 therapy modules: specific education for back pain, physical therapy or physical exercise, and mindfulness and relaxation techniques.	ViViRA provides a self-directed home exercise program using the principles of movement therapy and functional regional interdependence, plus daily reminders displayed as a notification.
Comparator	Placebo app (nutrition advice posts, along with 4 notifications: sound and vibration, along with a pop-up window with instructions) containing nutritional information unrelated to low back pain	Prescription drugs and their dosages and physical activity	Medical treatment and instruction to manage the condition according to clinician advice	Individual face-to-face sessions of standard physiotherapy once a wk (physical exercises and manual therapy). Encouragement to perform the physiotherapeutic exercises at home and to an active lifestyle. Weekly emails with a brief motivating message and links to medically oriented websites providing web-based resources for patient education about pathophysiology, diagnoses, treatment, and self-management in low back pain.	Physical exercises lasting 15 to 25 min, guided by a certified physiotherapist

Characteristics	Included studies (reference and published year)				
	Almhdawi et al [39], 2020	Chhabra et al [22], 2018	Sandal et al [40], 2021	Toelle et al [41], 2019	Weise et al [42], 2022
Duration of intervention	6 wk	12 wk	6 wk	6 wk	12 wk

Characteristics	Included studies (reference and published year)				
	Almhdawi et al [39], 2020	Chhabra et al [22], 2018	Sandal et al [40], 2021	Toelle et al [41], 2019	Weise et al [42], 2022
Outcomes	• Pain intensity: VAS[c] • Disability: ODI[d] • Quality of life: 12-item Short-Form Health Survey • Sleep quality: Pittsburgh Sleep Quality Index • Physical activity level: International Physical Activity Questionnaire	• Pain intensity: NPRS[e] • Disability: MODI[f]	• Disability: RMDQ[g] • Pain intensity: NRS[h] • Confidence in the ability to cope despite pain: Pain Self-Efficacy Questionnaire • Fear-avoidance: Fear-Avoidance Beliefs Questionnaire, physical activity subscale • Cognitive and emotional representations of disease: Brief Illness Perception Questionnaire • Quality of life: EuroQol-5 Dimension questionnaire and EuroQol VAS • Level of physical activity during leisure time: Saltin-Grimby Physical Activity Level • General improvement: Global Perceived Effect Scale	• Pain intensity: NRS • Functional measures: HFAQ[i] • Behavioral measures: GCPS[j] • Quality of life: VR-12[k]	• Pain intensity: VNRS[l]
Results	At the 6-wk assessment, pain intensity showed a significant reduction in the app group (mean 2.30, SD 2.13) compared to the control group (mean 5, SD 1.97; *P*<.001). There was also a significant reduction in disability in the app group (mean 20.25, SD 13.47) compared to the control group (mean 30.63, SD 10.63; *P*=.002). Regarding quality of life, there was a significant change in the physical component of the app group (mean 79.95, SD 16.09) compared to the control group (mean 62.26, SD 19.76; *P*=.001), a trend that was not followed by the mental component (*P*=.68).	Regarding pain intensity, no significant differences (*P*>.05) were found between the groups over time. As for disability, the scores at baseline were significantly different between the groups: mean 52.1 (SD 14.4) for the app group and mean 20.2 (SD 17.8) for the control group (*P*=.03). Nevertheless, after 12 wk of intervention, the app group (mean 41.4, SD 18.8) registered a significant improvement in disability compared to the control group (mean 29.9, SD 20.1; *P*=.001).		Both groups reported a reduction in pain intensity over time, but the app group reported a significantly lower pain intensity (mean 2.70, SD 1.51) at 12 wk compared to the control group (mean 3.40, SD 1.63; *P*=.02). Regarding disability and quality of life, no significant differences (*P*>.05) were observed between the groups, although both showed improvement over time.	Pain intensity showed a significant reduction in favor of mHealth[m] at all times (2, 6, and 12 wk; *P*<.001; Cohen *d*>0.8).

Characteristics	Included studies (reference and published year)				
	Almhdawi et al [39], 2020	Chhabra et al [22], 2018	Sandal et al [40], 2021	Toelle et al [41], 2019	Weise et al [42], 2022
			Pain intensity showed a reduction in the app group (mean 3.3, SD 2.2) compared to the control group (mean 3.9, SD 2.4; *P*=.001) at the 3-mo assessment, and this effect was maintained at the 9-mo assessment. Disability showed a significant improvement at 3 mo for the app group (mean 6.7, SD 4.7) compared to the control group (mean 7.4, SD 5.4; *P*=.03). This effect was maintained at 9 mo, but in an attenuated form: mean 6.0 (SD 5.3) for the app group and mean 6.9 (SD 5.6) for the control group. Quality of life showed no significant difference (*P*>.05) between groups at the 3- and 9-mo assessments.

[a]RCT: randomized controlled trial.

[b]Although the authors have considered participants outside the age range of our inclusion criteria (ie, participants up to 65 y of age), we decided to include it because we observed that few participants aged >59 years were included.

[c]VAS: Visual Analogue Scale.

[d]ODI: Oswestry Disability Index.

[e]NPRS: Numeric Pain Rating Scale.

[f]MODI: Modified Oswestry Disability Index.

[g]RMDQ: Roland-Morris Disability Questionnaire.

[h]NRS: Numeric Rating Scale.

[i]HFAQ: Hannover Functional Ability Questionnaire.

[j]GCPS: Graded Chronic Pain Scale.

[k]VR-12: Veterans RAND 12-Item Health Survey.

[l]VNRS: Verbal Numerical Rating Scale.

[m]mHealth: mobile health.

Based on data extraction, a summary of the results of the included studies was performed (Multimedia Appendix 3 [22,39-42]), containing the means and SDs for the pain intensity, disability, and quality-of-life outcomes. Overall, the studies reported benefits of mHealth in pain intensity, disability, and quality of life.

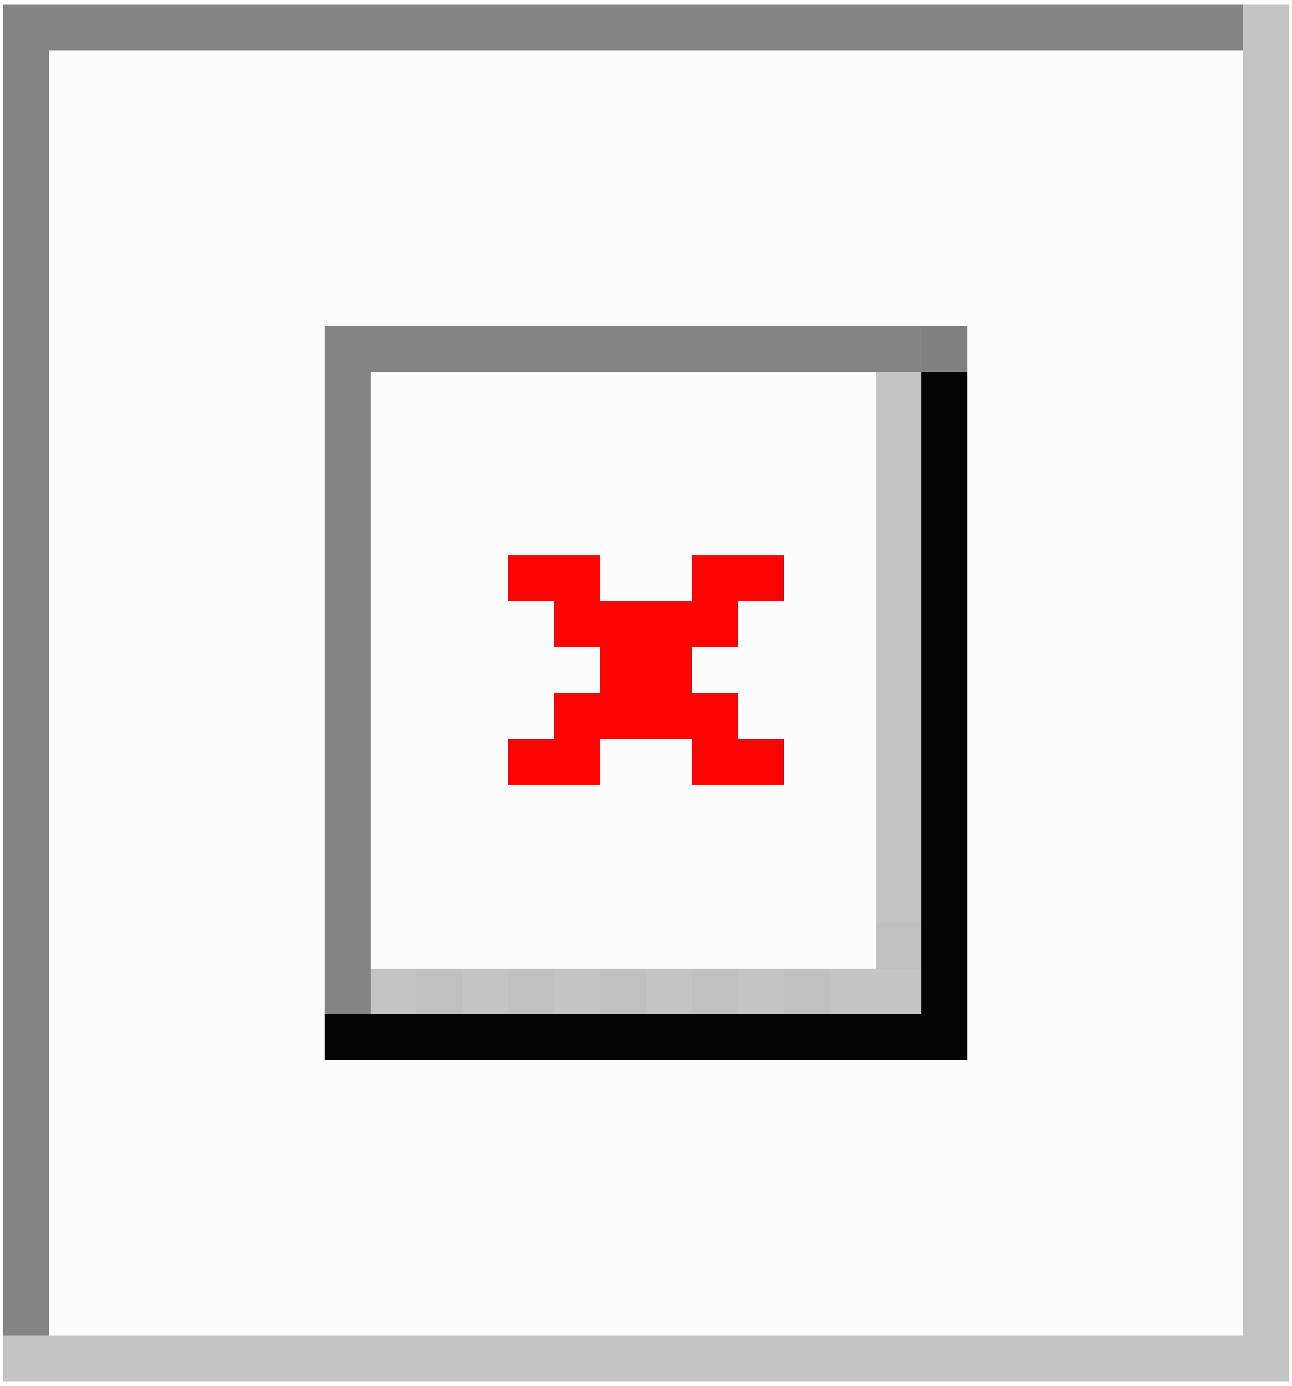
Synthesis Results

A meta-analysis was carried out for the pain intensity and disability outcomes, consisting of 4 of the 5 included studies [22,40-42] that adopted a follow-up of 12 weeks.

Pain Intensity

Of the studies included in the meta-analysis, 3 studies [22,40,41] used the Numeric Pain Rating Scale [43] and 1 study [42] used the Verbal Numerical Rating Scale to assess pain intensity. Both scales assess and rate pain from 0 to 10 points, where 0 represents the absence of pain and 10 represents intense pain [44,45]. The effects were classified as low-quality evidence (Figure 2 [22,40-42]).

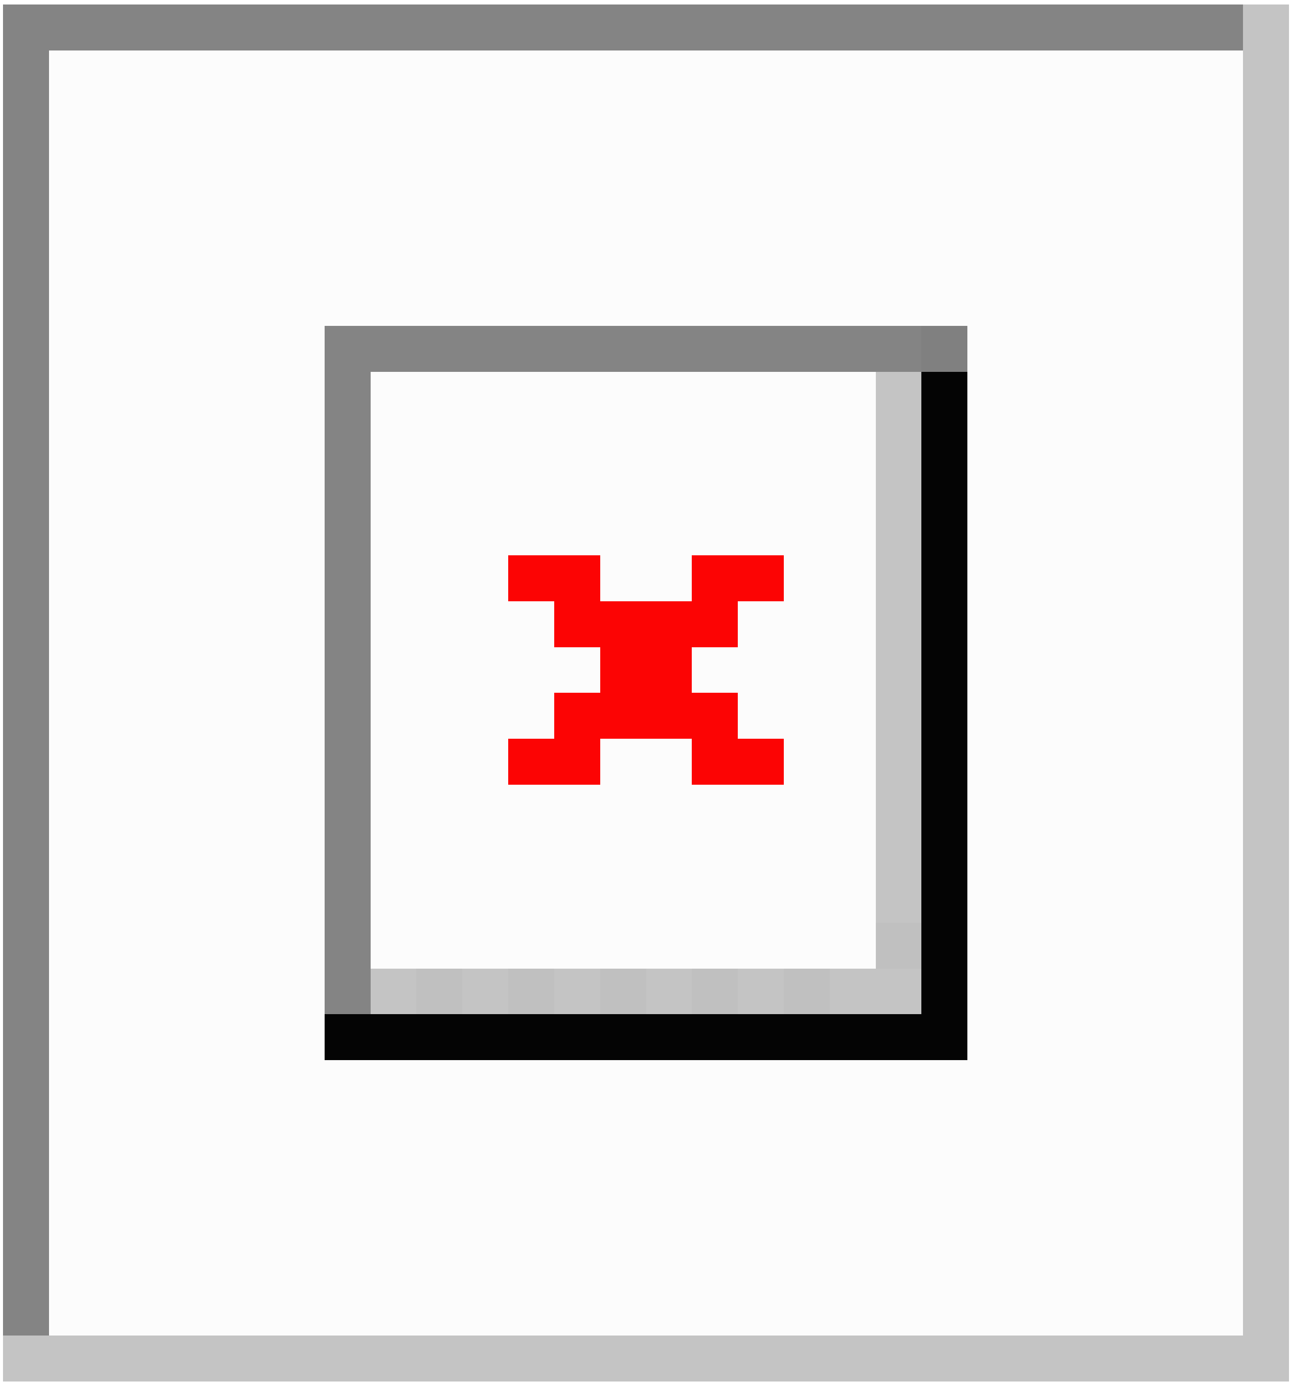
Figure 2. Forest plot of pain intensity (app: mobile health; control: usual care).



Disability

The Modified Oswestry Disability Index [22], Roland-Morris Disability Questionnaire [40] and Hanover Functional Ability Questionnaire [41] were used to assess disability. The effects were classified as low-quality evidence, and no significant differences were found between mHealth compared to usual care (*P*=.14; Figure 3 [22,40,41]).

Figure 3. Forest plot for disability (app: mobile health; control: usual care).



Risk of Bias of the Included Studies

The assessment of the risk of bias in the included studies is presented in Table 3. In all, 4 studies were classified with a final score of 7 and 1 study was classified with a score of 5. Overall, the nonblinding of participants and outcome assessors were common biases. It is worth noting that none of the included studies adopted the blinding of therapists.

Table . Risk of bias of included studies using the Physiotherapy Evidence Database (PEDro) scale.

Studies	PEDro scale items									
	1[a]	2[b]	3[c]	4[d]	5[e]	6[f]	7[g]	8[h]	9[i]	10[j]	Total score

[a]1: Participants were randomly distributed.
[b]2: Concealed allocation.
[c]3: Initially, the groups were similar.
[d]4: All participants were blinded.
[e]5: All therapists administered the therapy blindly.
[f]6: All evaluators measured the results blindly.
[g]7: Measurement of key outcomes were obtained in more than 85% of participants.
[h]8: All participants received the treatment as allocated, or the analysis was done by intention to treat.
[i]9: The results of the comparisons were described in at least 1 key result.
[j]10: The study presents both measures of accuracy and variability.
[k]Y: Yes, item met.
[l]N: No, item not met.

Publication Bias

It was not possible to perform publication bias analysis through visual inspection of the funnel plot and the Egger statistical test since only 5 studies were included. However, we consider the probability of publication bias to be low, since the searches were sensitive and gray literature was also consulted.

Certainty of Evidence

The certainty of evidence of mHealth effects was rated as low quality for both outcomes (pain intensity and disability). Details of the evidence profile are presented in Multimedia Appendices 4 and 5.

Adverse Events and Adherence

Only 2 studies [41,42] reported nonserious adverse events; however, there was no clear definition pertaining to the occurrence and severity. Weise et al [42] reported several nonserious adverse events and nonserious adverse reactions not requiring the interruption of the intervention (eg, nausea, pain increase, and transient muscle cramp). Moreover, Toelle et al [41] reported 1 participant in the mHealth group being diagnosed with a lumbar disk herniation; however, this event was deemed not related to the intervention.

Adherence to mHealth interventions was monitored by different methods and definitions. For instance, some studies defined adherence as the number of complete active days of app use [41,42], average time using the app [40], or the number of plans for self-management using the app during the first 12 weeks after randomization [39]. Participants receiving mHealth interventions had a higher adherence compared to the control group (ie, placebo app) [39]. The authors reported that participants in the mHealth group had, on average, 6 times higher daily use of the app than the control group participants. In addition, Toelle et al [41] estimated that participants used the app, on average, for 35 days within the 12 weeks of follow-up, and Sandal et al [40] demonstrated an adherence of 78% of app use. Although adherence was not associated with symptom improvements, 1 study highlighted a higher frequency of app use when pain severity was higher [42].

Discussion

Our systematic review synthesized recent evidence on the use of mHealth technology in the management of individuals with low back pain. We found 5 studies totaling 894 patients, which reported positive effects on improving pain intensity and disability. However, we found a low certainty of evidence in favor of mHealth, and our meta-analyses showed no significant differences between mHealth versus usual care or no intervention (pain intensity: P=.15 and disability: P=.14). There were no reports of serious adverse events.

Even though our review demonstrated no significant differences between mHealth versus usual care or no intervention, the adoption of mHealth provided some beneficial effects in reducing pain intensity in people with low back pain. The combined effect of the included studies was approximately 0.9 (95% CI –2.29 to 0.58) points of improvement, demonstrating that a portion of the participants benefited, specifically those who had a score above 2 points [44]. Likewise, we found no significant differences in reducing disability, which was associated with a small effect size of 0.24 (95% CI –0.69 to 0.20) in favor of mHealth. However, the study by Almhdawi et al [39] investigated the use of a mobile app in office workers with low back pain and observed an effect size of Cohen d=1.08, which was considered large. It is worth noting that, despite the use of effect size measures in meta-analyses composed of standardized means, this interpretation is still considered conflicting [46]. In this context, previous studies have shown that the minimal clinically important difference in disability for low back pain is at least a 30% reduction in the score of the scales [47,48], and the findings of our study were below this threshold. Interestingly, Zheng et al [49] demonstrated that exercise combined with self-management training delivered via mHealth presents a faster improvement in disability when compared to exercise alone via mHealth. Thus, considering the findings of these previous studies, it is possible to assume that mHealth provides, to some extent, clinically relevant effects for the management of low back pain.

We found that the quality of life of the participants improved after the use of mHealth; however, this difference was not significant compared to usual care. Among the 3 studies that investigated quality of life, Sandal et al [40] and Toelle et al [41] found no differences between mHealth and usual care. These findings corroborate those of Schlicker et al [50], which also showed no significant differences between mHealth and usual care. The study by Zheng et al [51] investigated the effects of exercise delivered via mHealth, with and without a health education process, and found significant improvements in the physiological functional aspects of quality of life in both groups. Likewise, Almhdawi et al [39] found a large effect size in favor of mHealth (Cohen d=1.18), specifically for the improvement of the physical component of quality of life, but did not find improvement in the mental component. These results indicate that the effects of mHealth on quality of life are still conflicting. The quality of life is influenced by cultural, physical, and social aspects, which makes it difficult to compare the results considering different contexts [52]. In addition, the improvement in the quality of life is more related to the improvement of disability than to pain intensity [53], and in our study, disability presented a small effect size, which may reflect the nonsignificant difference found for the quality of life.

A recent review [21] carried out a qualitative synthesis of the evidence on the perceptions and experiences of health professionals regarding the use of mHealth. The findings showed advantages arising from mHealth, such as the optimization of tasks, the speed of delivery of information, and the possibility of monitoring these patients remotely and recording data about their routine. Other studies [54,55] have shown that the satisfaction of patients who used digital interventions is similar to those who receive face-to-face care, with emphasis on the ease of use, efficiency in communication, and low cost, in addition to technology overcoming distance barriers. Another advantage is the fact that the technologies are based on active interventions, which focus on physical exercise and self-management—strategies that are considered effective to treat patients with musculoskeletal conditions [56]. Thus, mHealth can be a valuable tool for symptom control in patients with chronic low back pain. Nevertheless, factors such as adherence and the individual's ability to manage their symptoms can have a determining effect on the clinical relevance of the results. In this sense, it is suggested that strategies that favor adherence and self-efficacy should be included in the service packages delivered by mHealth. Therefore, individualized strategies are recommended, given that the use of technological resources can be a positive factor for better adherence to treatment [57].

All included studies in our review showed some methodological biases. None of the 5 included studies blinded the therapists and 4 did not blind the patients [22,40-42]. It is noteworthy that 2 studies did not adopt concealed allocation [39,41]; 4 studies did not adopt the blinding of outcome assessors [22,40-42]; and in 1 study [22], the scores at baseline were significantly different between groups. The occurrence of biases is relevant because they may overestimate or underestimate the effect of interventions [58,59]. Concealed allocation refers to how participants are allocated to groups, and an inadequate allocation increases the estimate of effect size and can generate a difference in the investigator's approach to participants, causing selection bias [60,61]. Studies that adopted an adequate blinding process showed less predisposition to findings that favored a given intervention [62]. Thus, inadequate blinding is a factor associated with biases and can alter the conduct of participants and researchers, who can change their behavior [63]. However, it is not always possible to blind therapists and participants, mainly due to the characteristics of interventions in certain areas (eg, the adoption of exercise and booklets) [64]. Two studies [39,41] did not perform the analysis of participants according to allocation; in these cases, participants who do not comply with the initial protocol are not considered, resulting in the loss of the benefits of randomization. This fact increases the risk of selection bias and the probability that changes are attributable to external factors or confounding variables [65].

Our review has the following strengths. Initially, we highlight the fact that we investigated the isolated effect of mHealth compared to usual care or no intervention in people with low back pain. This aspect reduced the risk of heterogeneity regarding the intervention and divergences in interpretations [66], which is contrary to previous studies [5,27,28]. Moreover, we took steps to minimize bias, such as including a minimum of 2 reviewers to independently assess the studies for inclusion and carry out the data extraction. In addition, 2 other independent reviewers carried out the risk-of-bias and certainty-of-evidence assessments. Furthermore, a comprehensive search strategy was adopted, comprising the major databases without language or date restrictions.

As a limitation, our review included a small number of studies due to the eligibility criteria, which favored the inclusion of a clinically homogeneous intervention. A second limitation was differences in the target audience of the included studies. The most heterogeneous study [39] carried out the research in a specific environment (ie, office), whereas the other studies included individuals from the general population. A third limitation concerns the biases present in the included studies, mainly the absence of concealed allocation and nonblinding of outcome assessors, which limited our conclusions. We also observed high heterogeneity in the pain intensity meta-analysis, which might be influenced by aspects related to the design and intervention characteristics of the included studies. For instance, the study of Weise et al [42] adopted a pragmatic trial, and the authors highlighted that the staff maintained close contact with the enrolled participants. Hence, this aspect might have influenced their intervention effects compared to the other trials [22,40,41]. Finally, owing to the small number of included studies, we have not performed sensitivity analyses.

Our review demonstrated no significant differences between mHealth interventions versus no intervention or usual care, neither on pain intensity and disability nor on quality of life. Notwithstanding, our findings suggest positive clinical effects from the use of mHealth in individuals with low back pain compared to no intervention or usual care. Owing to the biases found, the evidence remains inconclusive, and future high-quality clinical trials are warranted.

Acknowledgments

The authors thank Mr Francisco Rafael Amorim dos Santos, the librarian at the Campus UnB Ceilândia, for validating the search strategy and Mrs Renata Monique for her support as one of the independent reviewers in the title and abstract screening. All authors declared that they had insufficient funding to support open access publication of this manuscript, including from affiliated organizations or institutions, funding agencies, or other organizations. JMIR Publications provided article processing fee (APF) support for the publication of this article. Abstract

Background: Mobile phone–based cessation interventions have emerged as a promising alternative for smoking cessation, while evidence of the efficacy of mobile phone–based smoking cessation programs among young people is mixed.

Objective: This study aimed to determine the efficacy of mobile phone–based interventions compared to usual practice or assessment-only controls on smoking cessation in young people.

Methods: In this systematic review and meta-analysis, we searched Cochrane Library, Embase, PubMed, and Web of Science on March 8, 2023. We included randomized controlled trials that examined the efficacy of mobile phone–based interventions on smoking cessation in young people (age ≤30 years). The risk of bias was assessed with Cochrane Risk of Bias 2.

Results: A total of 13 eligible studies, comprising 27,240 participants, were included in this analysis. The age range of the participants was between 16 and 30 years. Nine studies were SMS text messaging interventions, and 4 studies were app-based interventions. The duration of the smoking cessation intervention varied from 5 days to 6 months. The included studies were conducted in the following countries: the United States, China, Sweden, Canada, Switzerland, and Thailand. The meta-analysis revealed that SMS text messaging interventions significantly improved continuous abstinence rates compared to inactive control conditions (risk ratio [RR] 1.51, 95% CI 1.24-1.84). The subgroup analysis showed pooled RRs of 1.90 (95% CI 1.29-2.81), 1.64 (95% CI 1.23-2.18), and 1.35 (95% CI 1.04-1.76) for continuous abstinence at the 1-, 3-, and 6- month follow-up, respectively. Pooling across 7 studies, SMS text messaging interventions showed efficacy in promoting 7-day point prevalence abstinence (PPA), with an RR of 1.83 (95% CI 1.34-2.48). The subgroup analysis demonstrated a significant impact at the 1- and 3-month follow-ups, with pooled RRs of 1.72 (95% CI 1.13-2.63) and 2.54 (95% CI 2.05-3.14), respectively, compared to inactive control conditions. However, at the 6-month follow-up, the efficacy of SMS text messaging interventions in promoting 7-day PPA was not statistically significant (RR 1.45, 95% CI 0.92-2.28). In contrast, app-based interventions did not show significant efficacy in promoting continuous abstinence or 7-day PPA. However, it is important to note that the evidence for app-based interventions was limited.

Conclusions: SMS text messaging–based smoking cessation interventions compared to inactive controls were associated with abstinence among young people and could be considered a viable option for smoking cessation in this population. More research is needed on smoking cessation apps, especially apps that target young people. Future research should focus on identifying the most effective mobile phone–based cessation approaches and on developing strategies to increase their uptake and intention.

Introduction

Background

Tobacco use is one of the leading risk factors for premature morbidity and mortality worldwide [1]. Smoking among young people is of particular concern. Despite the well-documented health risks associated with tobacco use, many young people continue to smoke or experiment with smoking. The prevalence of smoking among young people is especially troubling, as this age group is in the midst of crucial physical and psychological development. The harmful effects of smoking at this stage of life can have lifelong consequences, including increased risk of chronic disease, impaired cognitive function [2], and reduced quality of life [3]. In 2019, an estimated 155 million (95% uncertainty interval 150-160) people aged 15-24 years worldwide were tobacco smokers, with a prevalence of 20.1% in males and 4.95% in females [4]. Quitting before the age of 30 years can prevent more than 97% of the excess mortality caused by continued smoking [5]. Given the serious health risks associated with smoking, quitting is critical for young people.

While traditional cessation methods such as pharmacotherapy [6] and behavioral counseling [7] can be effective, their widespread implementation at a population level faces barriers [8]. Mobile phone–based smoking cessation interventions have emerged as a promising alternative to assist with smoking cessation [9-12]. Phone interventions are a cost-effective use of health care resources [13]. These interventions can provide personalized interactive support that is tailored to individual needs and characteristics, irrespective of location and time constraints [14,15], making them a valuable approach for smoking cessation in this demographic. Furthermore, young individuals are more open to novel and innovative approaches [16]. According to the International Telecommunications Union, approximately 66% of the global population had internet access in 2022 [17]. While previous research has suggested that SMS text message–based smoking cessation interventions were more effective than minimal smoking cessation support in the general population [18], evidence of the efficacy in young people remained inconclusive [19,20]. As countries work toward achieving the goal of reducing the prevalence of tobacco use [21], timely data on the efficacy of mobile phone–based smoking cessation programs among young people are necessary to guide effective policy and planning.

Objective

To the best of our knowledge, there are no meta-analyses supporting the efficacy of mobile phone–based smoking cessation interventions among young people. The aim of this meta-analysis was to determine the efficacy of mobile phone–based smoking cessation interventions, excluding pharmacological treatment, in helping young smokers to quit.

Methods

We adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for systematic reviews of interventions. We used a prespecified protocol registered with PROSPERO (CRD42022318845).

Search Strategy and Selection Criteria

We included randomized controlled trials (RCTs) with young smokers (30 years or younger) who wanted to quit. Included trials had to be clearly focused on smoking cessation using SMS text messaging or a smoking cessation app without pharmacotherapy, compared to a control intervention. Trials that had a focus on pregnant women were not eligible for inclusion.

Data Extraction

Studies were assessed for inclusion if they reported cigarette smoking cessation as the primary outcome. Self-reported abstinence from cigarette smoking and biochemically validated measures of abstinence were used to define smoking cessation.

Data extracted from each study included the study location, study design, population, inclusion criteria, exclusion criteria, follow-up period, details of the intervention group, details of the control group, definition of smoking cessation, number of participants, and smoking cessation rates. Wherever possible, an intention-to-treat analysis was used.

The following electronic bibliographic databases were last searched in March 2023: Cochrane Tobacco Addiction Group's Specialised Register (Source: PubMed, Embase, ClinicalTrials.gov, and the ICTRP), Embase, PubMed, and Web of Science. The search strategies used in the Cochrane Library, PubMed, Embase, and Web of Science are listed in Multimedia Appendix 1. The database literature search was restricted to the English language and studies on humans. The search terms were text messaging, phone-based, smartphone, app, mobile health, sms, txt, young, student, adolescent, and smoking cessation. Both abstracts and full manuscripts were considered.

Statistical Analysis

Authors XZ, XW, and AC independently confirmed study eligibility. Authors JL, YX, ZH, XX, YL, QS, and XZ extracted data, which were then checked by a second author (RQ, LZ, or AC). Two authors (XZ, AC, ZL, or ZS) independently assessed quality using the Cochrane Risk of Bias tool. All differences were resolved by discussion.

We used random-effects meta-analysis to analyze pooled outcome data among smokers who used SMS text messaging or an app compared with a control. Binary outcomes were estimated using risk ratios (RRs) and 95% CIs, with priority given to intention-to-treat data when available. For smoking cessation, meta-analyses were conducted for continuous abstinence and 7-day point prevalence abstinence (PPA). For 2 studies [22,23], data specifically for individuals 30 years and younger were extracted from the original data set and reanalyzed. The 7-day PPA at the 1-month follow-up for one study was derived from the third figure in Chulasai et al [24]. Heterogeneity between studies was assessed using the I^2 statistic. A subgroup analysis of the length of follow-up was also performed. Additionally, we performed a sensitivity analysis by removing the studies with a high risk of bias. All analyses were performed using R 4.2.0 (R Foundation for Statistical Computing) and Revman 5.4 (The Cochrane Collaboration).

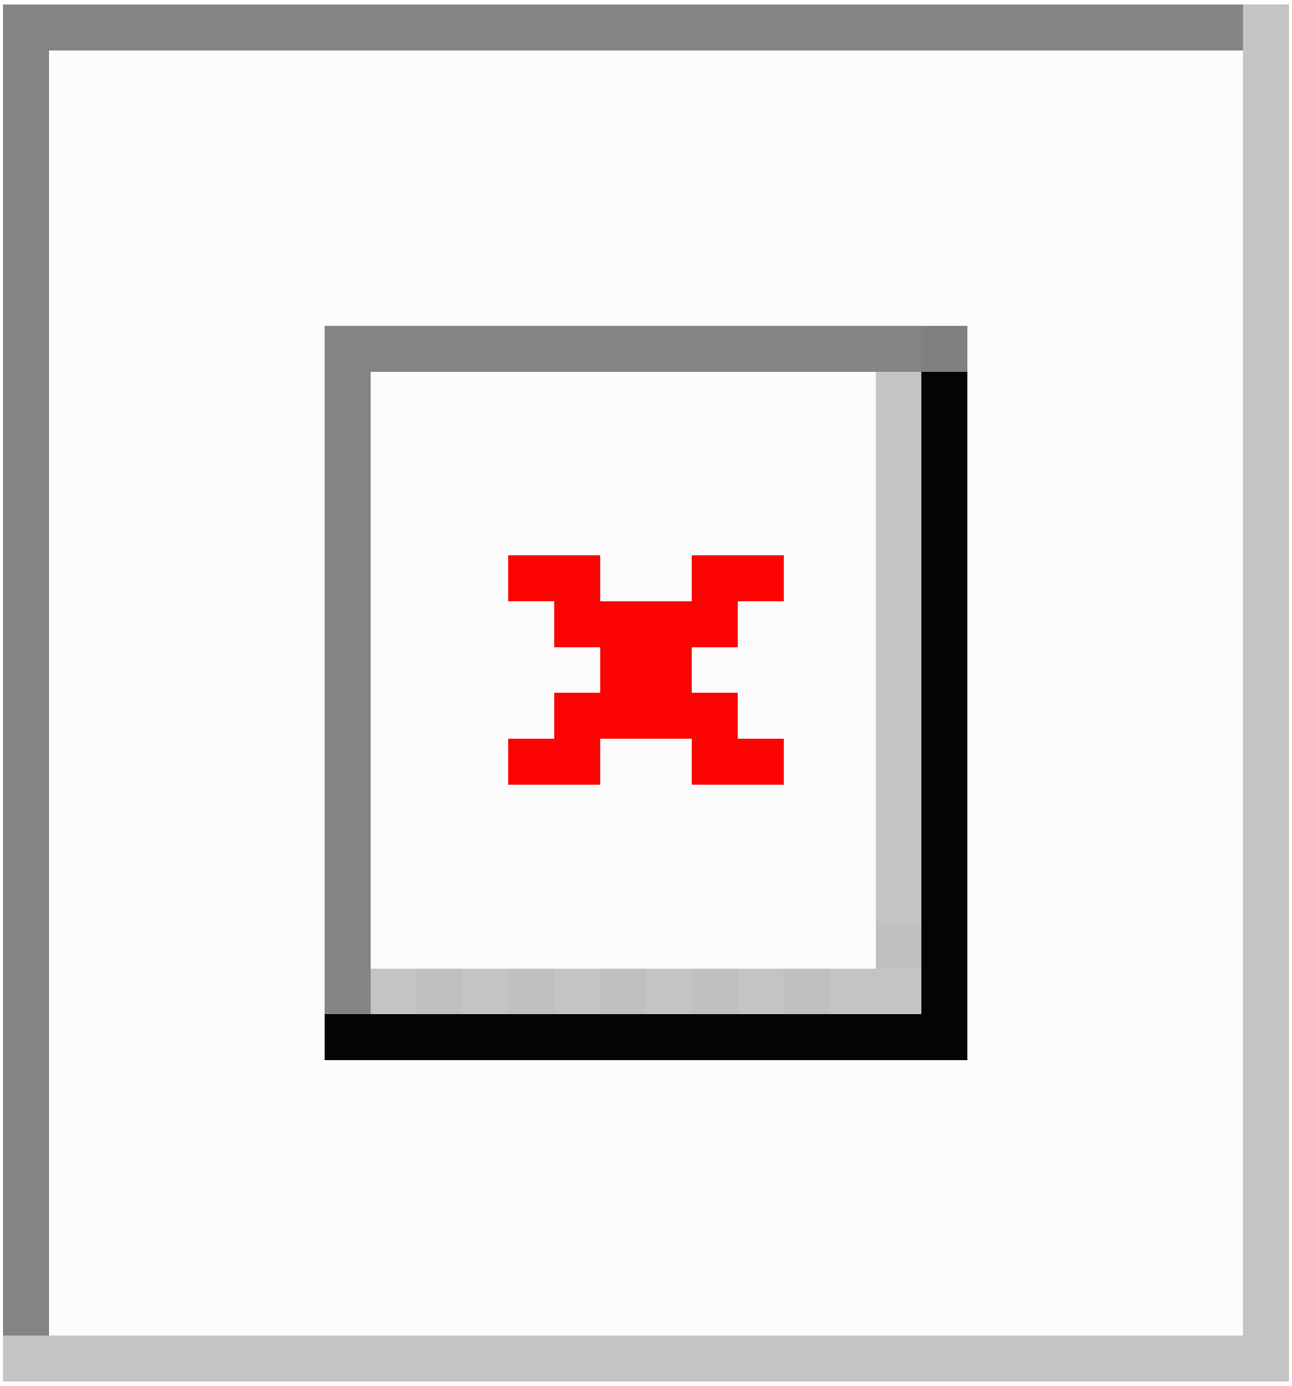
We did not perform funnel plot asymmetry because no outcome had more than 10 studies in the meta-analysis [25].

The risk of bias for studies was assessed using the Cochrane Risk of Bias 2 tool [26]. Studies were considered to be at high risk in the domain of missing outcome data if the overall loss to follow-up was more than 50% or if there was a difference in follow-up rates of more than 20% between study arms.

Results

We identified 1046 full-text trial reports or titles and abstracts (Figure 1) and identified 13 RCTs [10,15,19,20,22-27,33-33] for inclusion in the final review. The complete process is shown in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of evidence search and selection.



General Characteristics of the Selected Studies

Details of the eligible studies are presented in Table 1. A total of 13 eligible studies, comprising 27,240 participants, were included in this analysis. The age range of the participants was mainly between 16 and 30 years. Of the 13 included studies, 2 were cluster RCTs [29,32] and 11 were individual RCTs. There were 5 studies in the United States [15,28,31,33,34], 2 studies in Sweden [10,20], 2 studies in China [22,32], and 1 study each in Canada [19], Switzerland [29], and Thailand [24]. One study was conducted online [23], in which registered users of the Smoke Free app were the study participants, regardless of location. Measures of current smoking varied between studies: 4 studies [10,20,29,32] included daily smokers and weekly smokers, 2 studies [19,22] included only daily smokers, and Palmer et al [31] used a definition related to daily smoking (vaping nicotine at least 25 days/month). Three studies [15,24,28] included participants who smoked monthly or more, and Ybarra et al [34] included participants who smoked 24 cigarettes or more per week (at least 4 per day on at least 6 days in a week). One study used the definition of having smoked 100 cigarettes in life and now smoking every day or some days [33]. The remaining study [23] did not report the definition of smoker. Of the 13 studies, 5 recruited from vocational schools [29,32], high schools [20], or colleges [10,24]. The remaining studies recruited smokers from the community, health care facilities, online, or a combination of sources.

Table . Characteristics of included studies.

Study	Participants, n	Age (years)	Intervention	Control	Outcome
Baskerville et al [19], 2018, Canada, RCT[a]	1599	19-29	Crush the Crave Application	On the Road to Quitting–Self Help: The control group received an evidence-based self-help guide known as “On the Road to Quitting” that has been developed by Health Canada for young adult smokers.	Continuous self-reported abstinence at 6 months; self-reported 30-day PPA[b] from smoking at 3 and 6 months, operationalized as not having smoked any cigarettes, even a puff, or used other tobacco in the last 30 days; self-reported 7-day PPA at 3 and 6 months.
Bendtsen et al [20], 2021, Sweden, RCT	535	High school students, median 17 (IQR 16-18)	The intervention starts with a 1-week motivational phase. After 1 week the core intervention begins and runs for 12 weeks. Participants receive up to 4 texts per day during the first few weeks, and then the number of messages per day decreases.	Self-help materials: The control group could use the website of the national quit line or contact their high school’s health service for more help	Prolonged abstinence and point prevalence of smoking cessation at the 3- and 6-month follow-ups. Prolonged abstinence, following the Russel standard, was defined at the 3-month follow-up as not smoking more than 5 cigarettes in the past 8 weeks. At 6 months, the definition was altered to not smoking more than 5 cigarettes in the past 5 months. This outcome thus measures abstinence from the start of the 12-week smoking cessation program, allowing for a 4-week grace period. Point prevalence of smoking cessation, a recommended outcome by the Society for Research on Nicotine and Tobacco, was defined as not having smoked a single cigarette in the past 4 weeks. This question measures current behavior and, thus, was the same at both the 3- and 6-month follow-ups.
Chulasai et al [24], 2022, Thailand, RCT	273	18-24	The Quit with US app integrated with smoking cessation counseling from pharmacists	Smoking cessation counseling from pharmacists	The primary smoking abstinence outcome was the 7-day point prevalence at the 12-week follow-up, as recommended for smoking abstinence measures. The outcome was defined as a self-report of the previous 7 consecutive days of continuous abstinence from smoking plus an exhaled CO concentration level of ≤6 ppm.

Study	Participants, n	Age (years)	Intervention	Control	Outcome
Crane et al [23], 2018, online, RCT	18,400	18-30	Full version of the smoke-free app	Reduced version that did not include the missions	The primary outcome measure was self-reported continuous abstinence up to the 12-week follow-up.
Graham et al [28], 2021, United States, RCT	2588	18-24	This is Quitting (texting)	Assessment only control	The primary outcome was self-reported 30-day PPA at 7 months analyzed under an intention-to-treat analysis, which counted nonresponders as vaping. Secondary outcomes were 7-day PPA under the intention-to-treat analysis and retention weighted complete case analysis of 30-day and 7-day PPA.
Haug et al [29], 2013, Switzerland, cluster RCT	755	Vocational school students, mean 18.2 (SD 2.3)	Individualized texts to support smoking cessation (2 texts per week for a period of 3 months); possibility to register for a more intensive program providing strategies for smoking cessation around a self-defined quit date (2 texts per day for a period of 4 weeks)	Assessment only control group	7-day point prevalence smoking abstinence at the 6-month follow-up (ie, not having smoked a puff within the past 7 days preceding the follow-up) and 4-week point prevalence smoking abstinence were assessed
Liao et al [22], 2018, China, RCT	344	18-30	Mobile phone–based texts (3-5 messages per day); interventions (Happy Quit) for smoking cessation for the 12-week and 24-week follow-up	No cessation message intervention: Texts every week thanking them for being in the study and texts for assessment	Biochemically verified continuous smoking abstinence at 24 weeks; self-reported 7-day PPA (ie, not even a puff of smoke, for the last 7 days) at 1, 4, 8, 12, 16, 20, and 24 weeks; self-reported continuous abstinence at 4, 12, and 24 weeks.
Mays et al [15], 2021, United States, RCT	349	18-30	6-week mobile messaging intervention	Assessments only	Self-reported cessation was assessed at 6 weeks, 3 months, and 6 months.
Müssener et al [10], 2016, Sweden, RCT	1590	Mainly between 21 and 30	Texts: Those in group 1 received motivational messages (the intervention) 5 times a day for 3 days before their stated quit day and then continue to receive 3-5 motivational texts per day for week 1, 2-4 messages per day for the next 2-4 weeks, and then 10 messages per week for the remaining 8 weeks.	Texts unrelated to quitting	At the 4-month follow-up, 8 weeks of prolonged abstinence (having smoked ≤5 cigarettes during this time); self-reported 4-week PPA (not having smoked a single cigarette); self-reported 7-day PPA (defined as not smoking any cigarettes in the past 7 days)

Study	Participants, n	Age (years)	Intervention	Control	Outcome
Palmer et al [31], 2022, United States, RCT	27	17-21	Contingency management was delivered through DynamiCare Health's smartphone app for 4 weeks, in which financial incentives were delivered contingent on abstinent cotinine samples after the quit day until the end of treatment.	Assessment only: Control participants earned incentives for submitting cotinine, regardless of abstinence.	Abstinence at 1-month follow-up
Shi et al [32], 2013, China, cluster RCT	179	16-19	Tailored information via mobile phone texts for 12 weeks	A self-help pamphlet about smoking cessation	Self-reported 7- and 30-day abstinence at 12-week follow-up
Villanti et al [33], 2022, United States, RCT	437	18-30	12-week tailored text smoking-cessation program with a companion web-based intervention	Referral to online quit resources	Self-reported 30- and 7-day PPA at 12-week follow-up
Ybarra et al [34], 2013, United States, RCT	164	18-25	SMS USA, a 6-week smoking cessation intervention. Intervention participants received texts daily pre- and postquitting. Everyone receives messages 14 days prior to the quit day and through the day after the quit day. Then, participants are ”pathed“ to particular messages based upon their self-reported smoking status on day 2 and day 7 post quit. Those who are successful at quitting receive messages aimed at relapse prevention, whereas those who have slipped receive messages aimed at getting the person to recommit to quitting and trying again. Other name: Stop My Smoking USA	No intervention: Attention-matched control; messages aimed at improving one's sleep and increasing one's fitness, along with general messages about the most well-known health dangers of smoking. Messages sent on the same schedule as the intervention group.	Three-month continuous abstinence; smoking ≤5 cigarettes since the quit day 4 weeks post quit; 7-day PPA at 4 weeks

[a]RCT: randomized controlled trial.

[b]PPA: point prevalence abstinence.

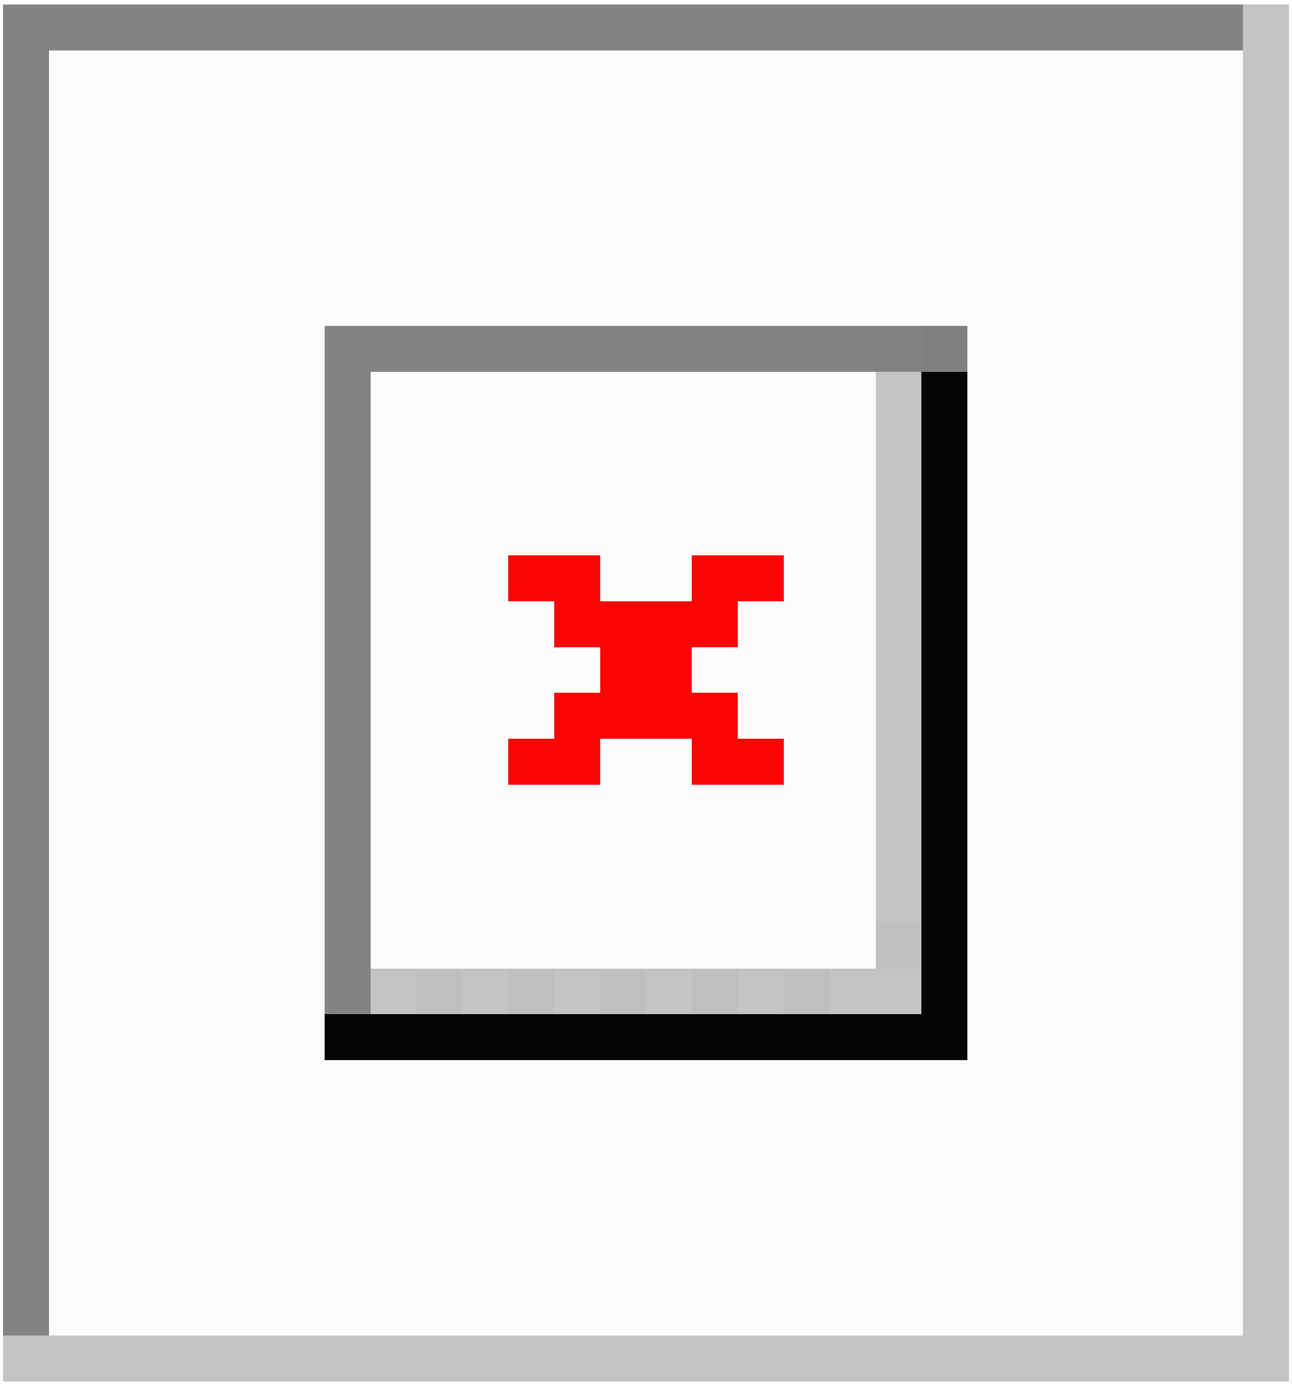
Most studies [10,15,19,22,24,31,33,34] provided incentives to participants in the form of financial rewards for follow-up, with the highest incentive being US $310 [31]. One study offered an alternative incentive in the form of a lottery draw at the end of the study instead of a monetary incentive. Nine of the selected studies provided a tailored intervention to participants [15,19,22,24,28,29,32-34]. These interventions were tailored to the user's age, stage of quitting, smoking history, stage of readiness to quit, demographics, etc.

Nine studies used SMS text messaging–based interventions [10,15,20,22,28,29,32-34], and 4 studies used app-based interventions [19,23,24,31]. The duration of the smoking cessation intervention varied from 5 days to 6 months, with 8 studies lasting ≥12 weeks [10,19,20,22,24,29,32,33], and the remaining studies lasting between 5 days and 6 weeks [15,23,28,31,34]. Most studies used an inactive control, such as an assessment-only control group [15,28,29,31], SMS text messages that were unrelated to quitting [10,22,34], or self-help cessation materials [19,20,32,33]. One study [23] provided a reduced version app that did not include the mission. One study [24] provided the control with smoking cessation counseling from a pharmacist. The majority of studies used self-reported abstinence, without biochemical verification. Four studies [22,24,31,33] used biochemically verified abstinence, such as salivary cotinine test [31,33], urine cotinine test [22], and exhaled CO concentration for verification [24].

Risk of Bias

The risk of bias assessments for individual studies is shown in Figure 2. The majority of studies reported methods of randomization and allocation concealment that were judged to be of low risk for the randomization process. The main source of some concerns was the measurement of the outcome, as these studies used self-reported smoking cessation rates without biochemical validation, and the intervention could not be blinded to participants due to its inherent characteristics. We judged 3 studies [19,23,32] to be at a high risk of bias for missing outcome data because more than 50% of participants were lost to follow-up or the difference in follow-up rates between study arms was more than 20%. The remaining studies were judged to be at a low risk in the domain of missing outcome data. Overall, 2 studies were at a low risk of bias (judged at low risk for all domains) [22,24], 3 were at high risk (judged to be at high risk in at least one domain) [19,23,32], and the remaining studies were of some concern.

Figure 2. Risk of bias summary: reviewers' judgments about each risk of bias item for each included study [10,15,19,20,22-28,29,31,34-34].



Continuous Abstinence

The result of continuous abstinence is illustrated in Figure 3. Combining data from 5 studies using a random-effects meta-analysis, a significant improvement in continuous abstinence rates was observed with SMS text messaging interventions, with an RR of 1.51 (95% CI 1.24-1.84) compared with inactive control conditions (assessment only, non–quit-related SMS text messages, or self-help materials).

For continuous abstinence, no high-risk study was identified when comparing the SMS text message intervention with the inactive control. The subgroup analysis (Figure 4) showed a pooled RR of 1.90 (95% CI 1.29-2.81) for continuous abstinence at the 1-month follow-up, with no significant heterogeneity observed among the included studies. At the 3-month follow-up, the pooled RR for SMS text messaging interventions versus an inactive control was 1.64 (95% CI 1.23-2.18), with an I^2 value of 50.4% (P=.089). At the 6-month follow-up, the SMS text messaging intervention yielded similar results as the 3-month follow-up for continuous abstinence (RR 1.35, 95% CI 1.04-1.76), with no significant heterogeneity observed (I^2=0.0%).

Figure 3. Random-effects meta-analysis for SMS text messaging compared to an inactive control on continuous abstinence [10,15,20,22,34]. MH: Mantel-Haenszel; RR: risk ratio.

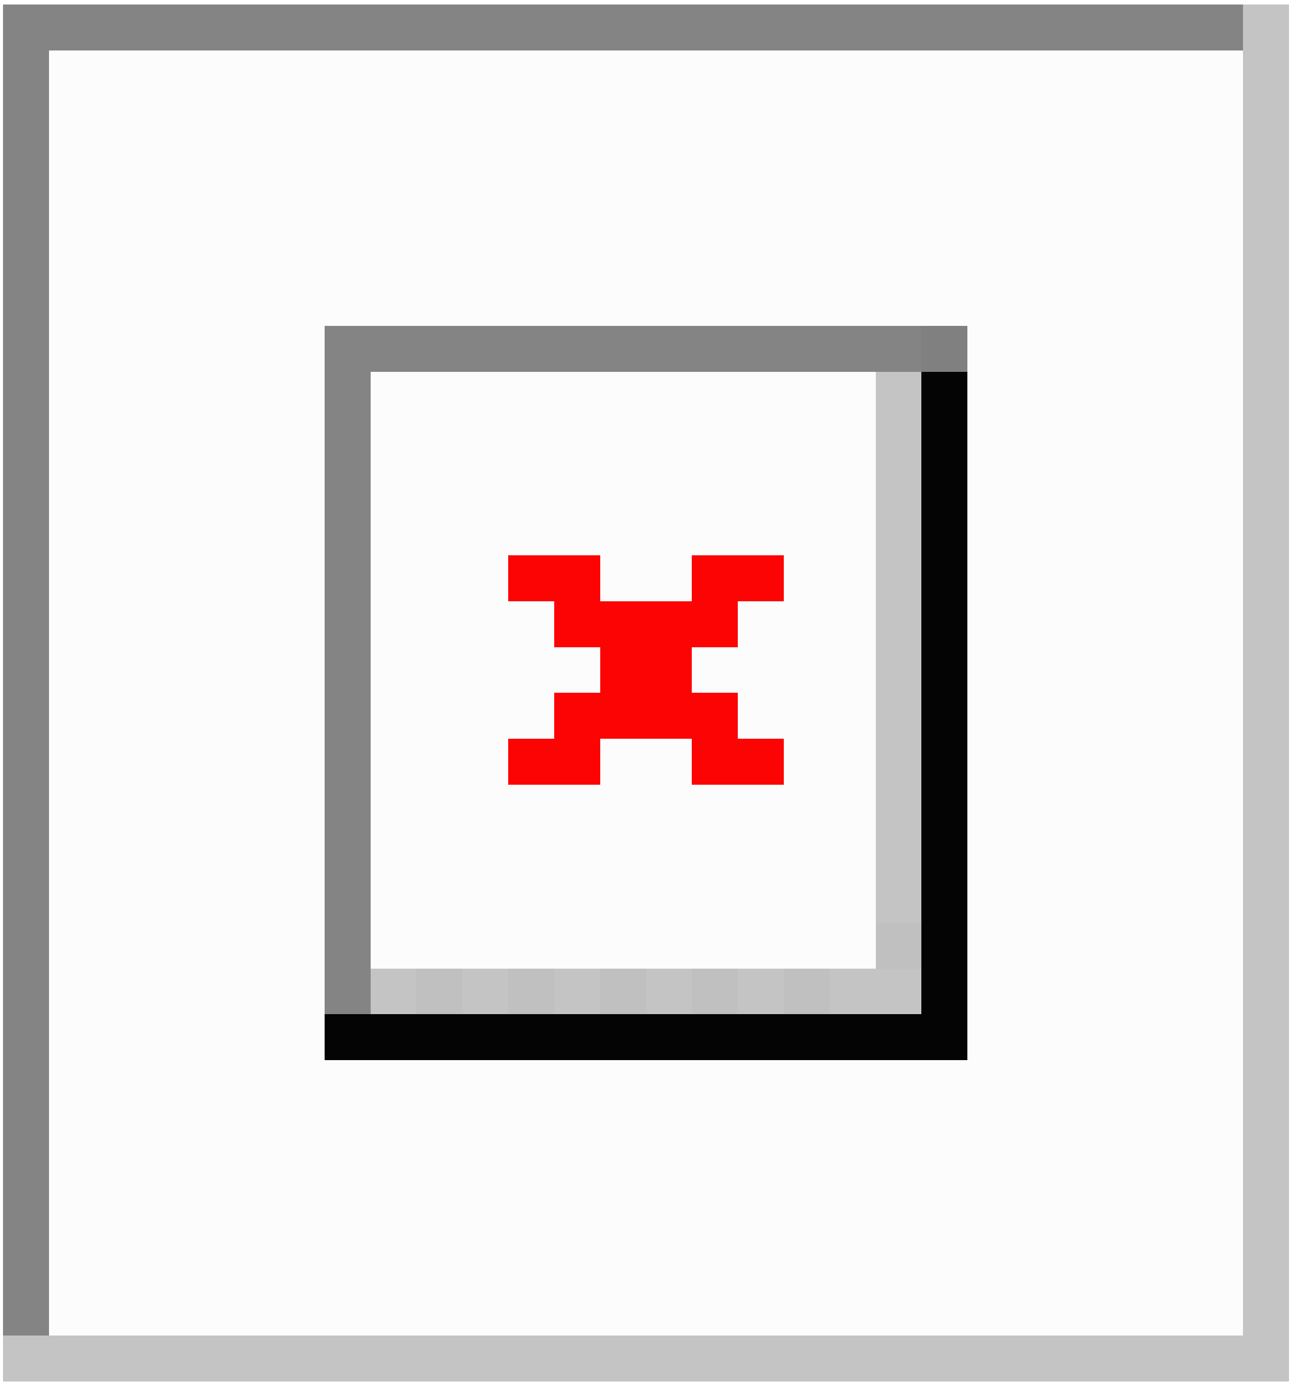


Figure 4. Subgroup analysis: random-effects meta-analysis for SMS text messaging compared to an inactive control on continuous abstinence at the 1-, 3-, and 6-month follow-ups [10,15,20,22,34]. MH: Mantel-Haenszel; RR: risk ratio.

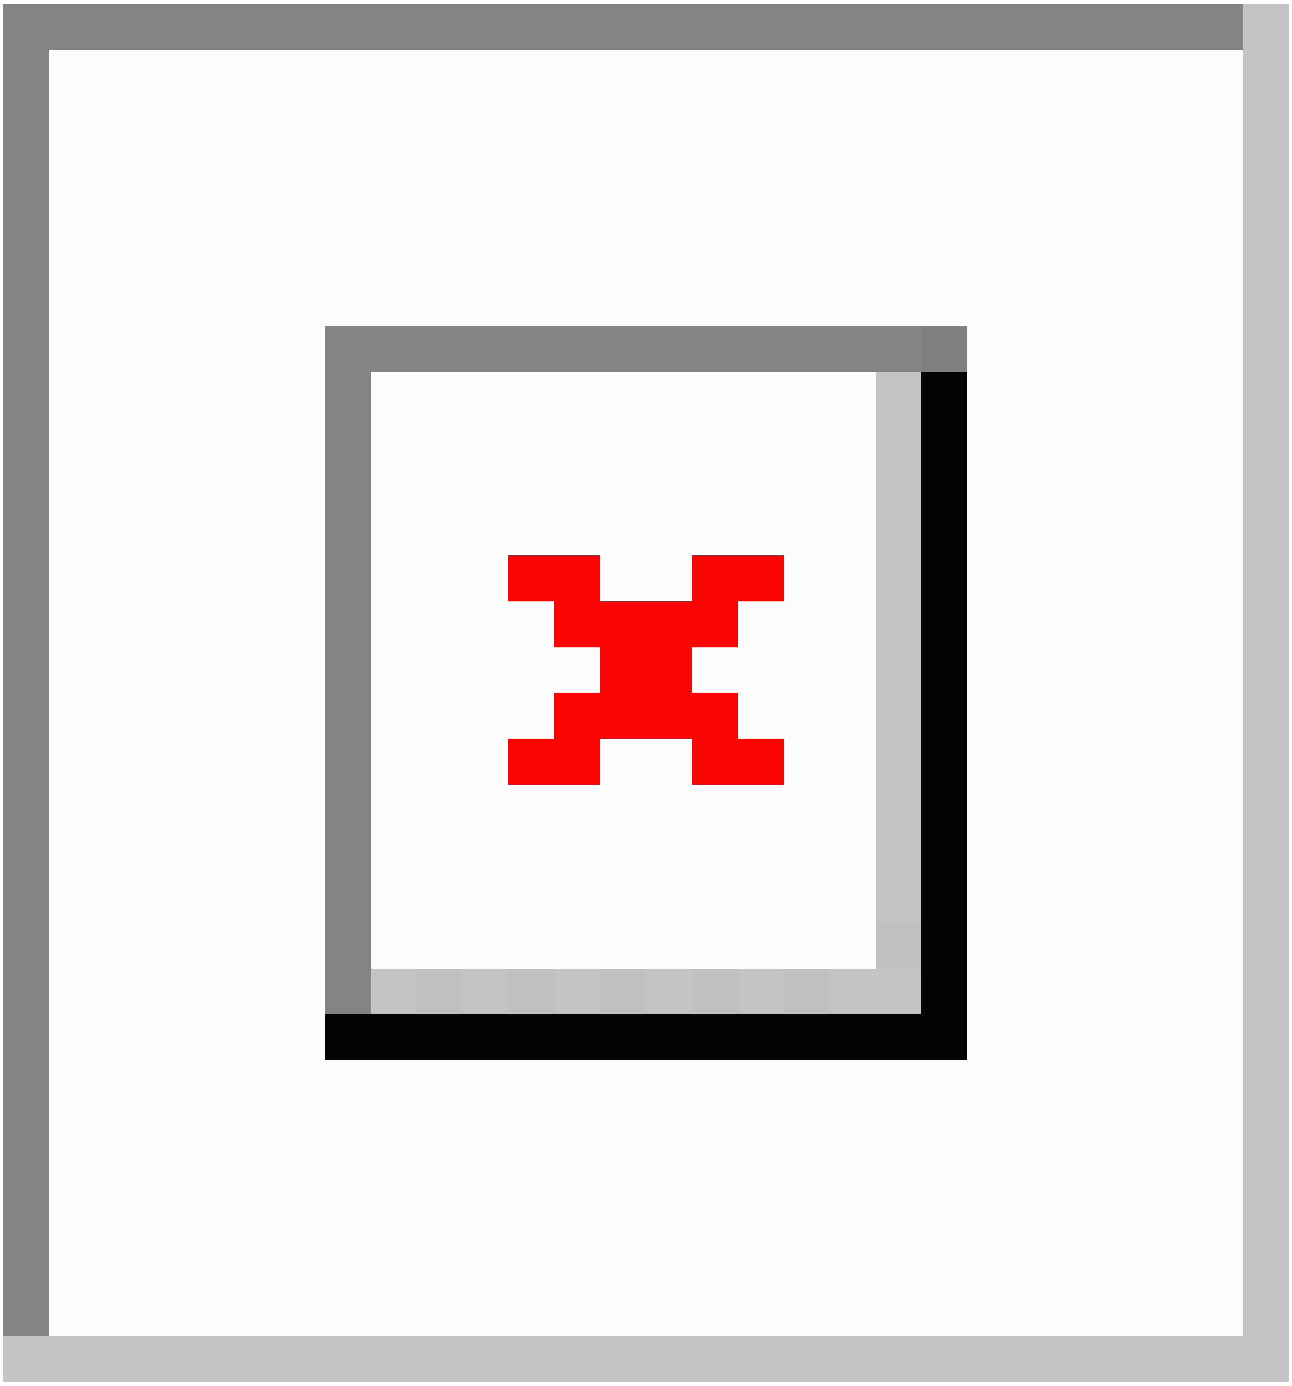
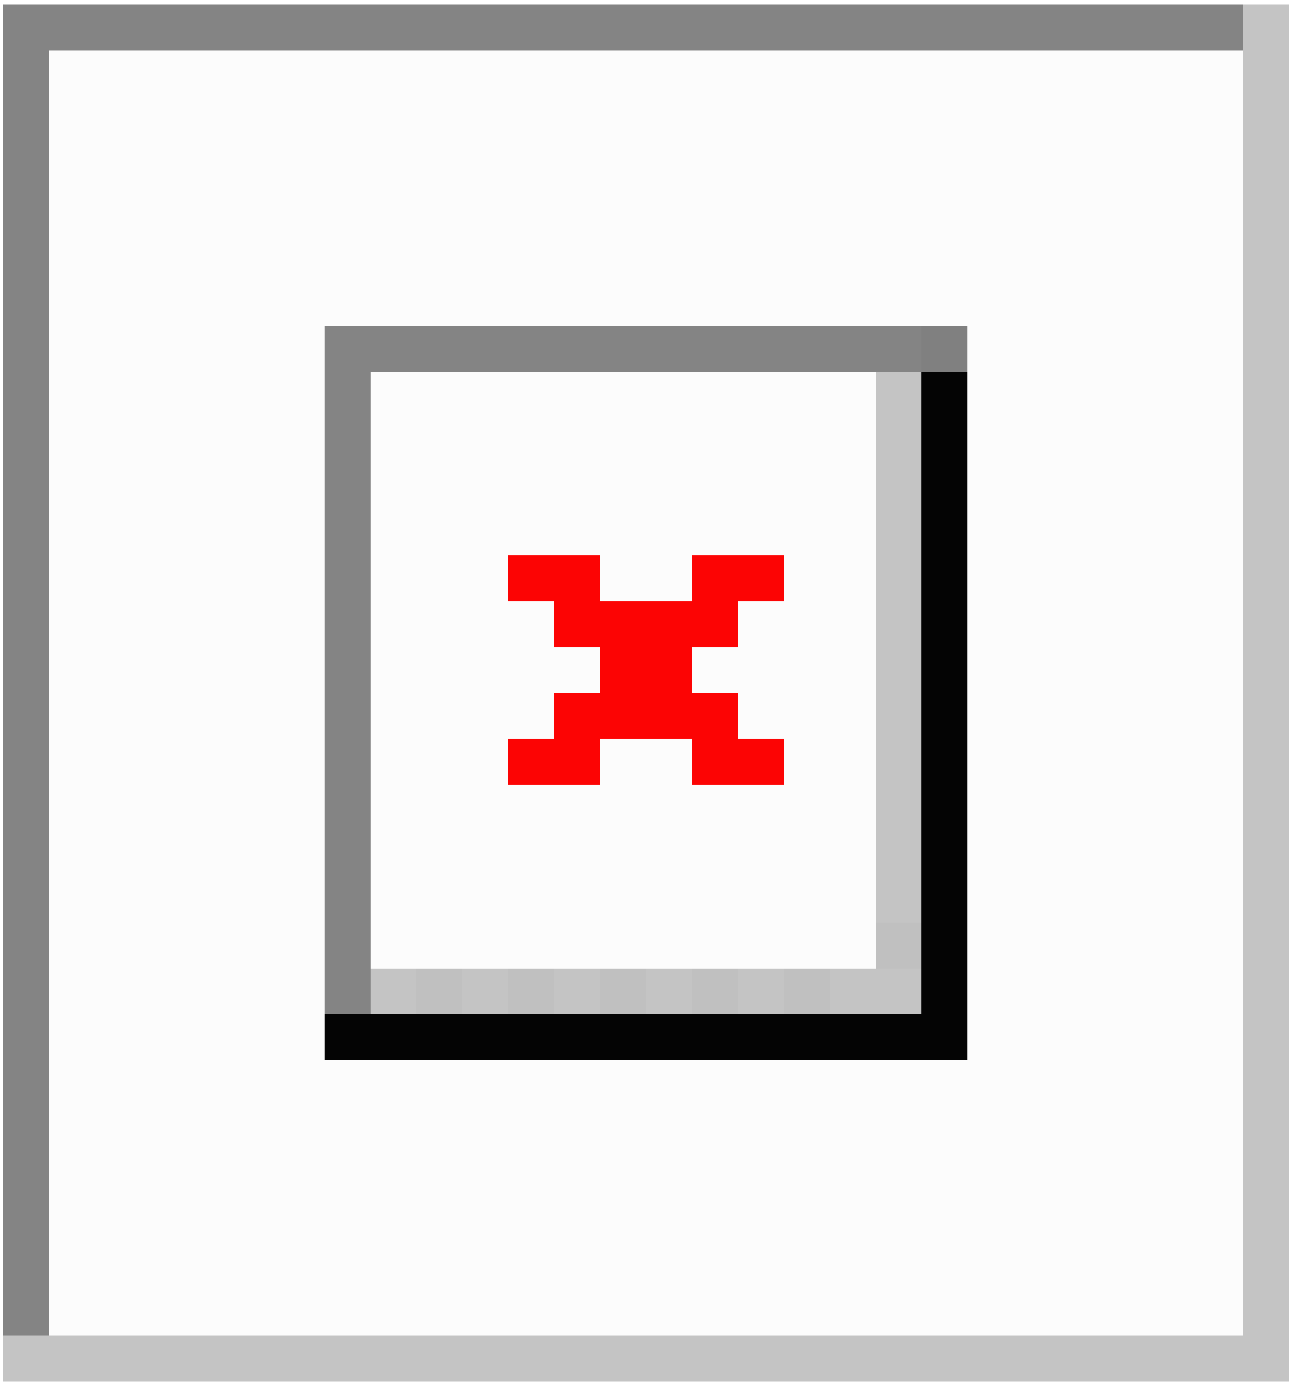


Only 2 studies provided data on the RR of continuous abstinence in the comparison between app-based interventions and controls (Figure 5). However, these studies yielded conflicting results. It is worth noting that both studies included in this analysis were subject to a high risk of bias due to missing outcome data.

Figure 5. Random-effects meta-analysis for apps compared to a control on continuous abstinence [19,23]. MH: Mantel-Haenszel; RR: risk ratio.



7-Day PPA

In terms of 7-day PPA, as illustrated in Figure 6, the meta-analysis of 7 studies showed an RR of 1.83 (95% CI 1.34-2.48), with an I^2 value of 87% (*P*<.001). A sensitivity analysis excluding high-risk studies showed consistent results (RR 1.84, 95% CI 1.32-2.57; *k*=6), indicating the stability of the results. The subgroup analysis (Figure 7) showed that SMS text messaging interventions had a significant impact at the 1- and 3-month follow-ups, with pooled RRs of 1.72 (95% CI 1.13-2.63) and 2.54 (95% CI 2.05-3.14), respectively, compared with inactive control conditions. When pooling across 3 studies, SMS text messaging interventions showed nonsignificant efficacy in promoting 7-day PPA at the 6-month follow-up (RR 1.45, 95% CI 0.92-2.28).

Figure 6. Random-effects meta-analysis for SMS text messaging compared to an inactive control on 7-day point prevalence abstinence [10,22,28,29,32-34]. MH: Mantel-Haenszel; RR: risk ratio.

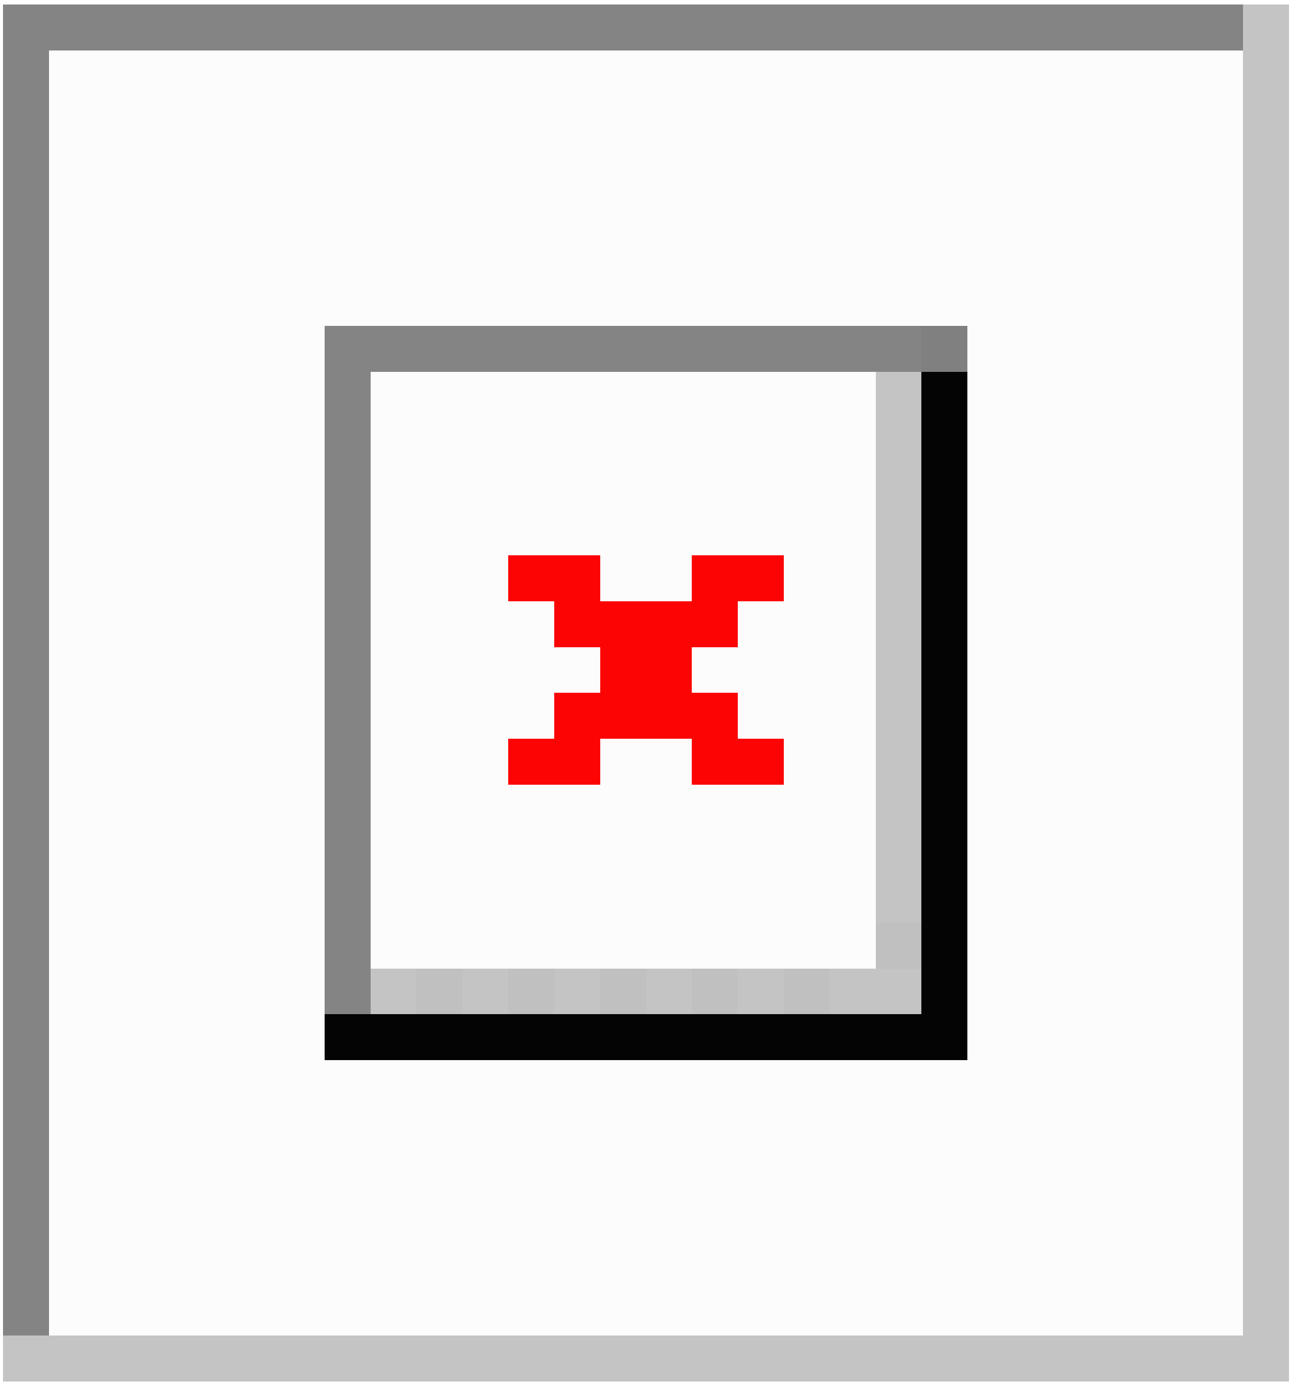


Figure 7. Subgroup analysis: random-effects meta-analysis for SMS text messaging compared to an inactive control on the 7-day point prevalence abstinence at the 1-, 3-, and 6-month follow-ups [10,22,28,29,32-34]. MH: Mantel-Haenszel; RR: risk ratio.

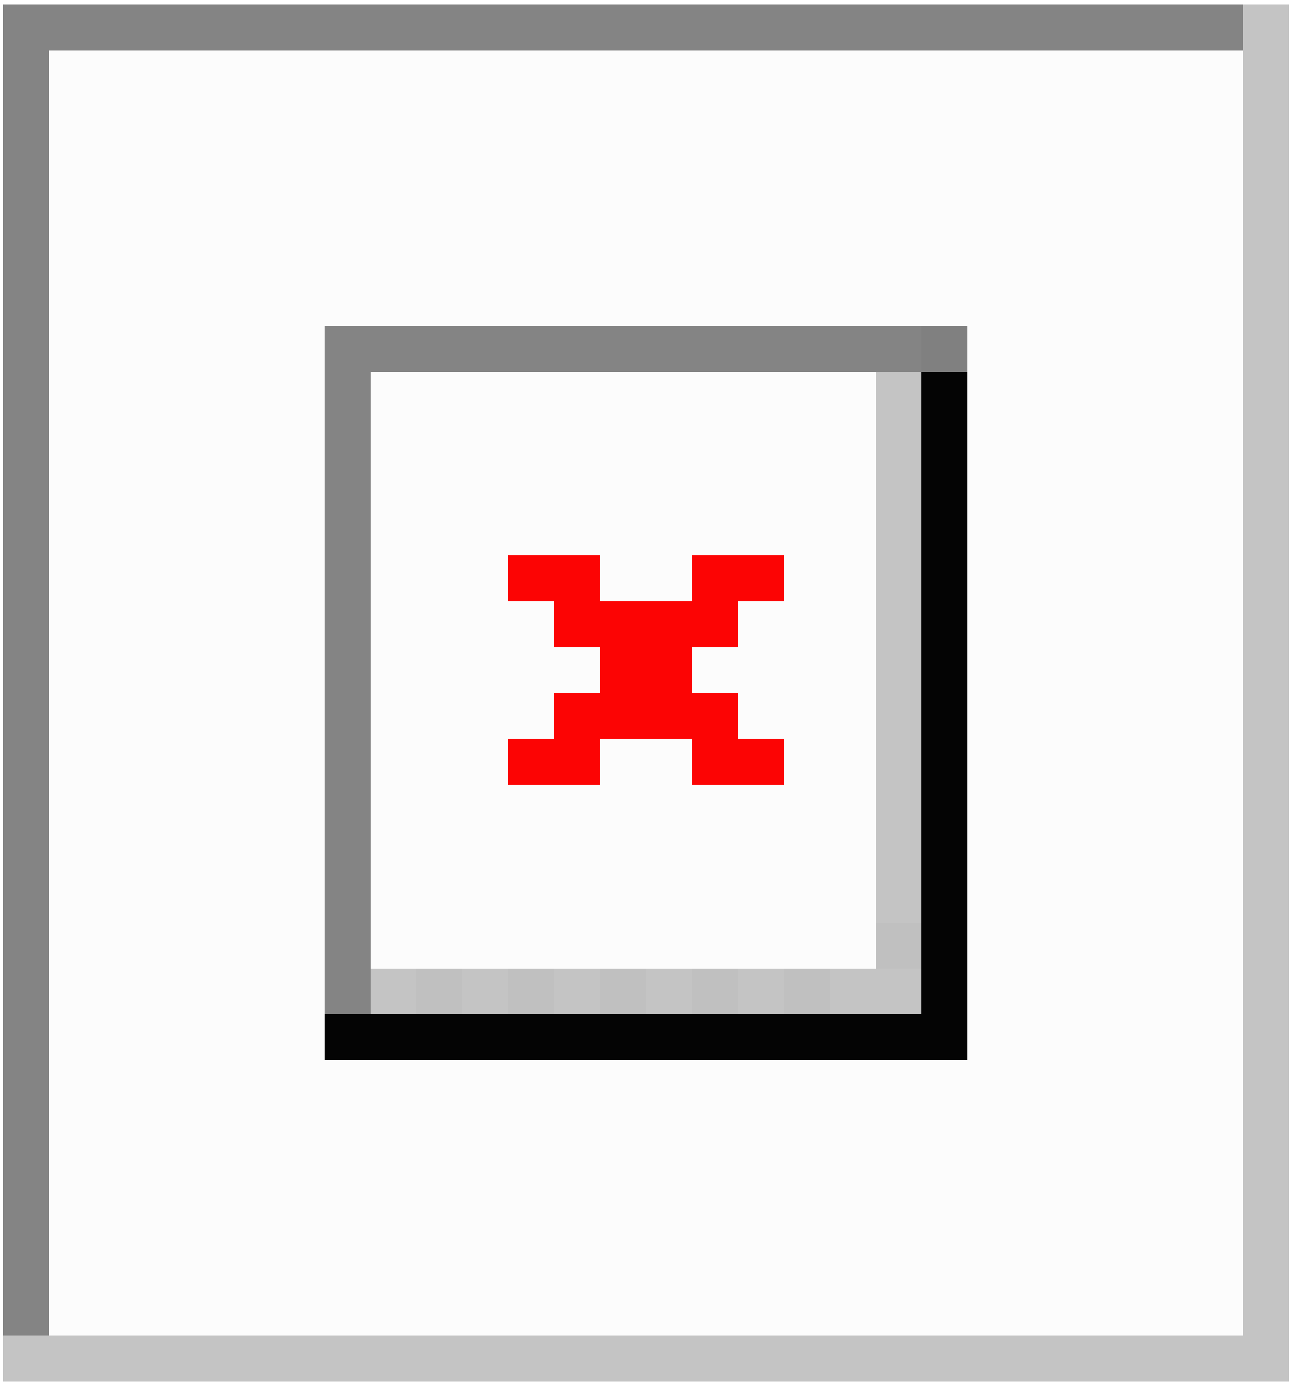
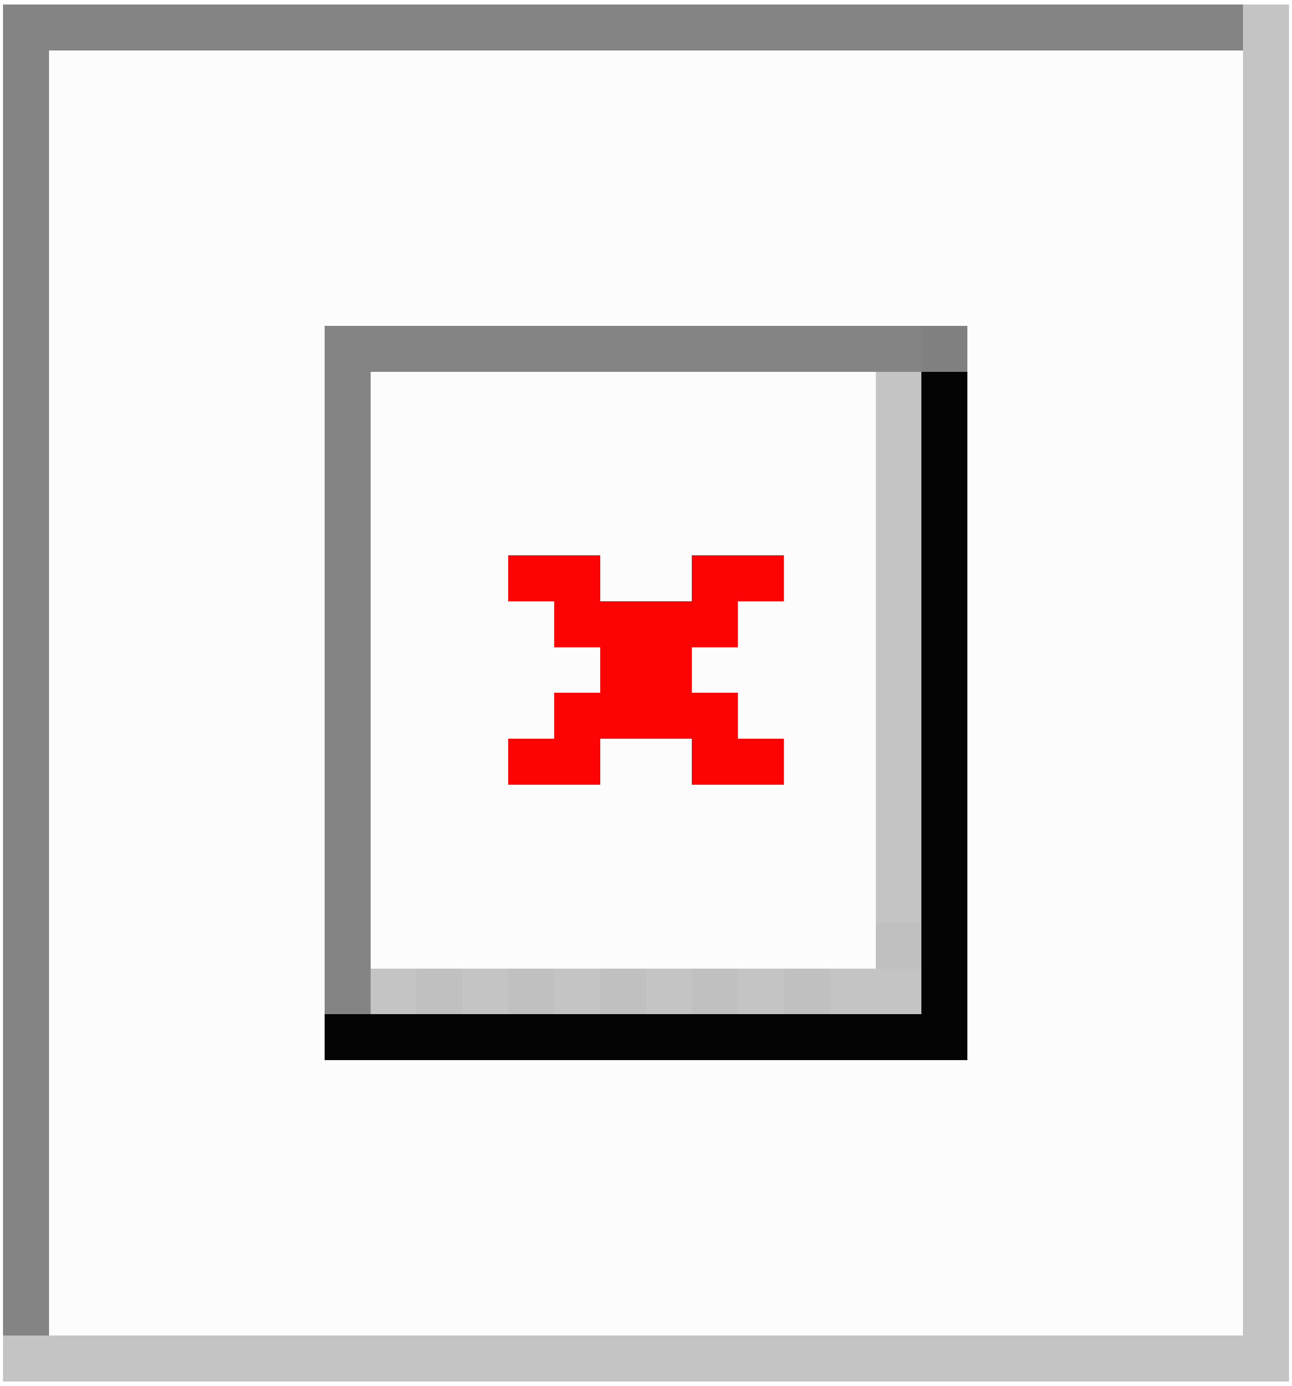


Pooling across 3 studies, app-based interventions showed no significant efficacy in promoting 7-day PPA (RR 1.27, 95% CI 0.69-2.34), indicating a lack of substantial impact (Figure 8). Notably, a high level of heterogeneity was observed among the included studies, with an I^2 value of 91% (P<.001), suggesting significant variation in the results. A sensitivity analysis was conducted by removing the study identified as having a high risk of bias. After the exclusion, the remaining studies showed a pooled RR of 1.86 (95% CI 1.41-2.46), indicating a relatively higher effect size in favor of app-based interventions. Importantly, the removal of the high-risk study resulted in a substantial decrease in heterogeneity, from 91% to 0%.

Figure 8. Random-effects meta-analysis for apps compared to a control on 7-day point prevalence abstinence [19,24,31]. MH: Mantel-Haenszel; RR: risk ratio.



Discussion

Principal Results

This study aimed to synthesize the published literature on the efficacy of mobile phone–based interventions for smoking cessation among young people. Our findings suggest that SMS text messaging interventions could be effective for smoking cessation among young individuals, whereas the evidence for app-based interventions is inconclusive. The sensitivity analysis showed stable results for SMS text messaging interventions, but conflicting results for the app-based study.

Comparison With Prior Work

Previous reviews of mobile phone–based interventions have varied considerably in terms of population characteristics [35-39] and geographical limitations [40,41]. To our knowledge, there is currently no meta-analysis supporting the efficacy of mobile phone–based interventions among young people. Our review fills this gap by providing evidence that SMS text messaging approaches to smoking cessation are robust among young people. Due to the nontemporal and nonspatial nature of mobile phone–based interventions, they can reach a wider audience and serve as a good adjunct to smoking cessation interventions for this population.

The meta-analysis showed that SMS text messaging smoking cessation interventions were effective for continuous abstinence among young people, which is in line with a previous study on general smokers [18]. The RR value at 6 months of continuous abstinence was slightly lower than that for general smokers (RR 1.54, 95% CI 1.19-2.00) [18]. This discrepancy may be attributed to the interventions lacking specific tailoring to address the unique characteristics and needs of young individuals. Smoking cessation was related to motivation to quit, which can differ across age groups [42]. A nationwide study conducted in the United States revealed the common reasons for smoking cessation in young adults aged 18-34 years; the two most popular reasons were physical fitness (64%) and the cost of tobacco (64%). More than half of current smokers also identified "encouragement from friend or relative" (55.2%) and "info about health hazards" (59.7%) as reasons for quitting smoking [43]. Despite most of the included studies in our analysis allowing for customization of the quit date, the interventions' content may not have been specifically tailored for young people. Developing more targeted cessation interventions that take into account young people's unique motivations and use patterns is crucial. This approach may help promote a positive attitude toward quitting smoking [44]. Furthermore, the efficacy of smoking cessation interventions among young people was observed to be slightly higher at 3 months compared to 1 month, as indicated by the 7-day PPA. This finding aligns with the cycle of withdrawal response, with the most intense withdrawal response occurring in the weeks when smokers first attempt to quit [45].

Less than one-third of smokers use cessation medications or behavioral counseling to support quit attempts [46]. Young smokers are more reluctant to seek treatment for smoking cessation than older smokers [47]. Pharmacotherapy and counseling often require face-to-face contact and the presence of a health care provider, which can be time-consuming and may not be covered by insurance. Additionally, adverse drug reactions to medication can be a barrier to quitting [48]. Young people are more likely to use mobile phones and novel technology in their daily lives [16]. Mobile phone–based interventions can be delivered remotely and offer a more cost-effective, discreet, convenient, and accessible alternative. Therefore, mobile phone–based smoking cessation interventions are a promising alternative for young people.

In recent years, the development of technology has led to the increasing popularity of mobile phone apps designed for health management [49,50]. The included studies were published between 2012-2022 for the SMS text messaging–based studies and between 2018-2022 for the app-based studies, indicating a relatively recent focus on app-based interventions. Mobile phone apps can provide more interactive and personalized features than SMS text messaging, such as tracking progress, setting goals, and sending notifications [23]. Apps can also offer real-time support and a wealth of resources, including educational materials, coping strategies, and social support networks [24]. However, the existing literature on app-based interventions exhibits significant heterogeneity and conflicting results. The lack of standardized protocols and guidelines for app-based smoking cessation interventions further exacerbates the challenge of generating consistent evidence. Therefore, there is a need for further research on smoking cessation apps targeted toward young people. In particular, future studies should explore the optimal features and design of smoking cessation apps.

Despite its many advantages, high dropout [51] and nonadherence [52] remain significant limitations. Incentives were offered in more than half of the included trials, and these studies generally had lower dropout rates than those without incentives. The majority of included studies with incentives had loss to follow-up rates ranging from 6% to 24%, while studies without incentives had rates between 26% and 92%. We note that the study by Crane et al [23], which was conducted in a real-world setting, reported the highest rate of missing data. This finding was in line with previous research highlighting the challenge of retaining participants in real-world studies [53]. A review showed that the personalization of content, app design, reminder form, and personal support help to improve adherence, but research on factors that influence adherence to mobile health apps remains limited [52]. Increasing people's engagement and retention is important as a key consideration for such interventions on a large scale in the real world. Future research should focus on identifying the most effective design, personalized content, features, and support mechanisms to increase their uptake and intention.

Limitations

Several limitations must be considered when interpreting the findings of this review. First, few studies examined app-based interventions, which limited the amount of available evidence for analysis and interpretation. Furthermore, considerable heterogeneity was observed among app-based studies. This scarcity of data highlights the need for further research in this area to improve the understanding of the efficacy of app-based interventions for smoking cessation. Second, the studies included in this review were largely conducted in high-income countries, limiting the generalizability of the findings to other settings. Lastly, a significant number of studies relied on self-reported abstinence without biochemical validation, raising some concerns in the domain of outcome measurement. In light of these limitations, future research should aim to address these issues and ensure the production of high-quality evidence to guide mobile phone–based smoking cessation interventions.

Conclusions

Our meta-analysis provides evidence that SMS text messaging smoking cessation interventions are effective among young people. There is a need for further research on smoking cessation apps, especially those targeted at young people. Future research should also focus on identifying the most effective mobile phone–based cessation approaches and on developing strategies to increase their uptake and intention.

Acknowledgments

This work was supported by the National High Level Hospital Clinical Research Funding (2022-NHLHCRF-LX-01-0304). The sponsor of the study had no role in the study design, collection, analysis, interpretation, or writing of this report.

Authors' Contributions

All authors were involved in the planning of the study, literature review, interpretation of the findings, and manuscript preparation. DX and XZ conceived and designed the study. DX supervised the study. DX and XZ drafted the report. XZ and ZS did the statistical analysis. All authors contributed to the data collection, analysis, and interpretation. All authors revised the report and approved the final version before submission.

Abstract

Background: Mobile health (mHealth) interventions are effective in improving chronic disease management, mainly in high-income countries. However, less is known about the efficacy of mHealth interventions for the reduction of cardiovascular risk factors, including for hypertension and diabetes, which are rapidly increasing in low- and middle-income countries.

Objective: This study aimed to assess the efficacy of mHealth interventions for diabetes and hypertension management in Africa.

Methods: We searched PubMed, Cochrane Library, Google Scholar, African Journals Online, and Web of Science for relevant studies published from inception to July 2022. The main outcomes of interest were changes in hemoglobin A_{1c} (HbA_{1c}), systolic blood pressure, and diastolic blood pressure. The random or fixed effect model was used for the meta-analysis, and the I^2 statistic was used to gauge study heterogeneity. *Z* tests and *P* values were used to evaluate the effect of mHealth interventions on HbA_{1c} and blood pressure levels.

Results: This review included 7 studies (randomized controlled trials) with a total of 2249 participants. Two studies assessed the effect of mHealth on glycemic control, and 5 studies assessed the effect of mHealth on blood pressure control. The use of mHealth interventions was not associated with significant reductions in HbA_{1c} levels (weighted mean difference [WMD] 0.20, 95% CI −0.40 to 0.80; *P*=.51) among patients with diabetes and systolic blood pressure (WMD −1.39, 95% CI −4.46 to 1.68; *P*=.37) and diastolic blood pressure (WMD 0.36, 95% CI −1.37 to 2.05; *P*=.69) among patients with hypertension. After conducting sensitivity analyses using the leave-one-out method, the Kingue et al study had an impact on the intervention, resulting in a 2 mm Hg reduction in systolic blood pressure (WMD −2.22, 95% CI −3.94 to −0.60; *P*=.01) but was nonsignificant for diastolic blood pressure and HbA_{1c} levels after omitting the study.

Conclusions: Our review provided no conclusive evidence for the effectiveness of mHealth interventions in reducing blood pressure and glycemic control in Africa among persons with diabetes and hypertension. To confirm these findings, larger randomized controlled trials are required.

Introduction

Managing chronic diseases often calls for a long-term care strategy [1]. Diabetes and hypertension remain two of the most common chronic conditions globally, resulting in the highest health care resource use and mortality [2-4]. Type 2 diabetes prevalence has become a substantial health issue, especially in African regions where type 2 diabetes is predicted to increase at the quickest rate (129%) in the world by 2045 [5-7]. Similarly, hypertension remains a major public health challenge among older adults in the African region, with an estimated pooled prevalence of 30.8% in Africa and between 30% and 31.1% in sub-Saharan Africa [8]. Poor blood pressure control among persons with hypertension is thought to involve intricate interactions between patients, health care providers, and socioeconomic variables [9]. Medication adherence has also been identified as one of the critical disease management issues, especially in enhancing life quality, health outcomes, and access to affordable health care worldwide [10,11].

Disease management programs using mobile health (mHealth) are promising emerging strategies to help patients self-manage their conditions (eg, measuring their blood pressure and sugar levels with remote professional support when needed [7,12]). mHealth is a medical and public health practice supported by portable electronic devices such as cell phones, patient monitoring devices, personal digital assistants, and other wireless gadgets [13]. This includes the use of phones and remote monitoring devices in health care and public health practice for communication, data collection, patient monitoring, and education, and to facilitate adherence to chronic disease management [14,15]. mHealth devices can improve service delivery and impact patient outcomes [15].

Previous studies in some low- and middle-income countries have assessed the application of mHealth as a tool to increase drug compliance in patients with a range of long-term illnesses, including diabetes, chronic obstructive pulmonary disease, and HIV infection [11,16]. Although several African countries are still in the pilot and development stages, an increasing number of mHealth apps have been put into use in clinical care settings [17]. The majority of small-scale pilot or feasibility mHealth intervention studies in Africa have been based on SMS text messaging systems to improve disease management [17,18].

Most individuals now possess mobile phones, and there are over 5.3 billion subscribers to mobile services worldwide, 67% of the world's population [19,20]. There will be 400 million more new mobile service customers between now and 2025, the majority of whom will come from Asia Pacific and sub-Saharan Africa, increasing the total number of subscribers to 5.7 billion (70% of the global population) [21]. There have been individual studies in Africa about mHealth interventions on disease management [22], although the data on the efficacy of mHealth in the management of diabetes and hypertension in Africa are limited and have not yet been systematically evaluated. Therefore, this systematic review assessed the effectiveness of mHealth interventions on blood pressure control among patients with hypertension and glycemic control among patients with diabetes in Africa. The findings of this paper will guide improvements to the adoption of mHealth for the management of diabetes and hypertension in African countries.

Methods

This systematic review was conducted following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [23] (Multimedia Appendix 1). The protocol was registered in PROSPERO (CRD42021230642).

Search Strategy

PubMed, Cochrane Library, Google Scholar, African Journals Online, and Web of Science were searched for relevant studies published from inception to July 2022, with assistance from a clinical librarian. The full search strategies, common Medical Subject Headings (MeSH), and search terms used across databases are available in Table S1 in Multimedia Appendix 2. The reference lists of the included studies were hand-searched to identify additional relevant studies.

Study Selection

Two independent authors (PA and KA) manually assessed and screened studies for both the titles and abstracts as well as full-text articles using an Excel sheet (Microsoft Corporation). Disagreements were resolved by consensus with a third author (CA) as necessary. This was performed in three stages as follows. First, PA screened the titles of all papers to determine their relevance. KA performed a cross-check by screening 20% of the titles excluded by the first reviewer, and it was confirmed that none of the titles screened by the second reviewer met the inclusion criteria. Second, abstracts of the papers selected after the title screening stage were again screened by PA and KA following the same procedure as described in step one. Finally, the full texts of potentially relevant papers were retrieved and evaluated by PA and KA independently to ascertain their relevance and usefulness to the review. Disagreements were settled through dialogue with CA to reach an agreement. Duplicates were also identified using EndNote reference manager (version x9; Clarivate).

Inclusion Criteria

We included studies that met the following criteria: the patients had hypertension or diabetes and were 18 years or older; the patients had received treatment at a selected health care setting; the intervention included an mHealth component; the results included target values of hemoglobin A_{1c} (HbA_{1c}), systolic blood pressure, or diastolic blood pressure; the studies were randomized controlled trials (RCTs); the articles were written in English; and the studies were conducted in hospitals and primary health centers.

Exclusion Criteria

We excluded studies in which the full text was not available after attempts to contact the author, the research participants were pregnant women or a specific patient population (eg, patients with cancer), the results did not describe primary outcomes, the primary intervention did not use mHealth devices, or the articles were unpublished manuscripts or conference abstracts.

Risk of Bias Assessment

The quality of each study was assessed using a 28-point scoring system as adopted from the Downs and Black checklist [24]. The included studies focused on the following items for assessment: items 1 through 10 evaluated whether the information provided was adequate for the reader to make an objective assessment of the study's findings; items 11 through 13 evaluated external validity, which examined the extent to which study findings could be applied to the population from which the study participants were drawn; items 14 through 20 assessed possible bias, which focused on biases in the assessment of the intervention and the result; and items 21 through 26 assessed confounding, which focused on biases in the research participant selection. To determine if neutral research results may be the result of chance or insufficient power, item 27 evaluated the study's power (Table 1).

Table . Downs and Black quality assessment.

Studies	Information based on study findings score (questions 1-10)	External validity score (questions 11-13)	Potential bias score (questions 14-20)	Confounding score (questions 21-26)	Power of study score (question 27)	Total score (maximum score of 27)	Quality as per the cutoff described
Abaza and Marschollek [25], 2017	10	3	6	5	0	24	Good
Adjei et al [26], 2015	10	3	5	5	0	23	Good
Asante et al [27], 2020	10	3	4	5	0	22	Good
Bobrow et al [28], 2016	10	3	5	6	0	24	Good
Kingue et al [29], 2013	10	3	5	6	0	24	Good
Owolabi et al [30], 2019	10	3	6	5	0	24	Good
Sarfo et al [31], 2019	10	3	6	6	0	25	Good

Data Extraction

Two authors (PA and KA) independently extracted the following study characteristics from each included article using a tested extraction form: first author, year of publication, mean age, the country where the study was conducted, the participant (patient with diabetes or hypertension), mHealth location (primary care setting, hospital, clinic, etc), condition (diabetes/hypertension), sample size, mHealth intervention, study design, and outcome of the intervention.

Data Synthesis and Analysis

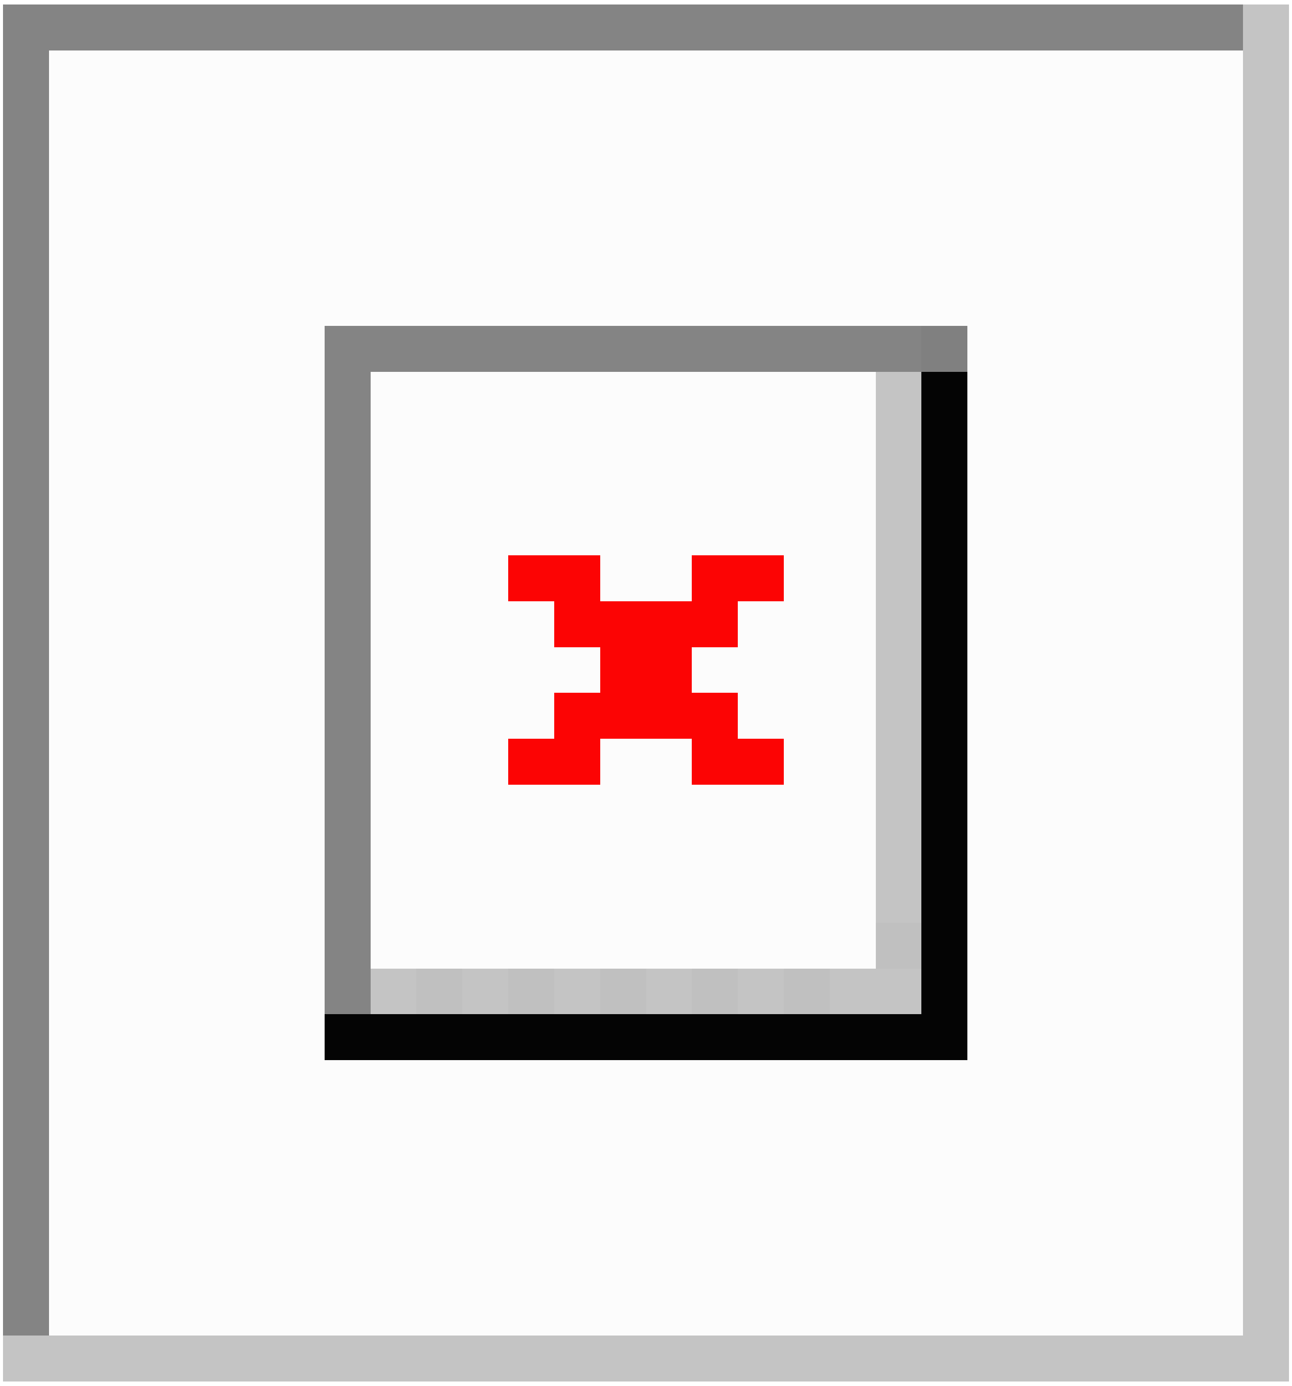
The data for the primary outcomes (HbA_{1c}, systolic blood pressure, and diastolic blood pressure) were analyzed separately using random or fixed effects models with a weighted mean difference (WMD) in ReviewManager (version 5.4; The Cochrane Collaboration) [32]. The I^2 statistic was calculated to measure the percentage of variation across trials due to heterogeneity, with values of <50% and ≥50% indicating low and high levels of heterogeneity, respectively. The WMD for blood pressure and HbA_{1c} between the intervention and control and *Z* tests were used to compare groups, and $P<.05$ was regarded as statistically significant. We checked publication bias subjectively by funnel plots and objectively by Begg and Egger tests using Stata version 16 (StataCorp). Begg and Egger tests with $P<.05$ were considered to have significant publication bias.

Results

Study Selection

We identified 2908 records from our search; authors screened 2880 titles and abstracts after duplicates were removed. In total, 7 studies (RCTs) [25-29,31] were considered eligible for inclusion. The reasons for excluding a study are provided in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of evidence search and selection.



Study Characteristics

The characteristics of the studies are shown in Tables 2 and 3. Of the 2249 participants, 1824 (54.1%) were female, the mean age ranged from 51.2 to 60.6 years, and the sample sizes ranged from 60 to 1372 participants. The studies were conducted at hospitals and primary health centers in the following countries: Ghana (n=3), South Africa (n=2), Egypt (n=1), and Cameroon (n=1). Five studies [26-29,31] reported the apps' effectiveness in controlling blood pressure among patients with hypertension (Table 4), while 2 studies [25,27] reported the effect on HbA_{1c} levels in patients with diabetes (Table 5). Of the 7 included studies, 2 articles had more than one intervention group with the same outcome measure [25,28].

Table . Study intervention and control description.

Studies	Intervention type (duration)	Intervention group	Control group
Abaza and Marschollek [25], 2017	SMS text messaging (3 mo)	Patients received daily messages and weekly reminders addressing various diabetes care categories.	The control group did not receive SMS text messages but received paper-based educational material.
Adjei et al [26], 2015	Electronic reminders (6 mo)	The intervention group was given electronic reminders for their clinical appointments, and their physicians were prompted for abnormal laboratory results [33] for 6 months.	Patients received only the usual care.
Asante et al [27], 2020	Mobile phone calls (3 mo)	The mobile phone call intervention was delivered by nurses in addition to care as usual over 12 weeks. The intervention group received up to 16 mobile phone calls (mean duration 12 min) from a diabetes specialist nurse in addition to their care as usual.	The control group received only care as usual.
Bobrow et al [28], 2016	SMS text messaging (6 and 12 mo)	SMS text messages were delivered automatically via an open source, web-based electronic medical record system. Texts were sent for 1 year from enrollment. Blood pressure measurements were collected from participants as they attended their routine clinic visits. The delivery of texts was automatically tracked, and if undelivered, a research assistant that was blinded to group allocation would contact the number of a friend or relative to obtain a new mobile phone number	The usual care group continued to receive care from the clinic and some form of written information about hypertension and healthy living, but no personalized SMS text messages were sent.
Kingue et al [29], 2013	Mobile phone calls (24 wk)	Interactive electronic communication were delivered between the patient and the provider or between multiple providers in either synchronous or asynchronous settings for the provision of health care services or consultation.	The control group only received routine treatment and care from the clinic.
Owolabi et al [30], 2019	SMS text messages (6 mo)	Participants in the intervention arm received daily educational SMS text messages on diabetes for 6 months. In addition, the intervention group received the text at an agreed time of the day, according to their needs, care plan, and goals.	The control groups proceeded with their usual care including all medical visits, tests, and diabetes support at the clinic.
Sarfo et al [31], 2019	SMS text messages (9 mo)	Patients received a Bluetooth blood pressure device and smartphone with an app for monitoring blood pressure measurements and medication intake under nurse guidance for 3 months. Participants also received motivational and support messages, advice on lifestyle behaviors like diets, physical activity, smoking cessation, and medication and appointment reminders.	The control arm received only the usual care.

Meta-Analysis of the Effects on Primary Outcomes

A total of 7 studies, 5 for blood pressure [26-29,31] and 2 for HbA_{1c} [25,27], were included in the meta-analysis.

Systolic Blood Pressure

As shown in Figure 2, one study had more than one intervention group with the same outcome measured [28]; therefore, 7 interventions are shown in the forest plot of systolic blood pressure, and the estimated WMD of systolic blood pressure between intervention and control groups was not statistically significant at −1.39 mm Hg (95% CI −4.46 to 1.68; P=.37; I^2=61%). No significant publication bias was detected visually by the funnel plot (Figure 3) or statistically by Begg (P=.30) and Egger (P=.10) tests.

Figure 2. Forest plot of the difference in systolic blood pressure between the mHealth intervention group and control group in 6 studies [26-31]. Bobrow et al [28]: (A) interactive intervention group vs control; (B) information only intervention group vs control. mHealth: mobile health.

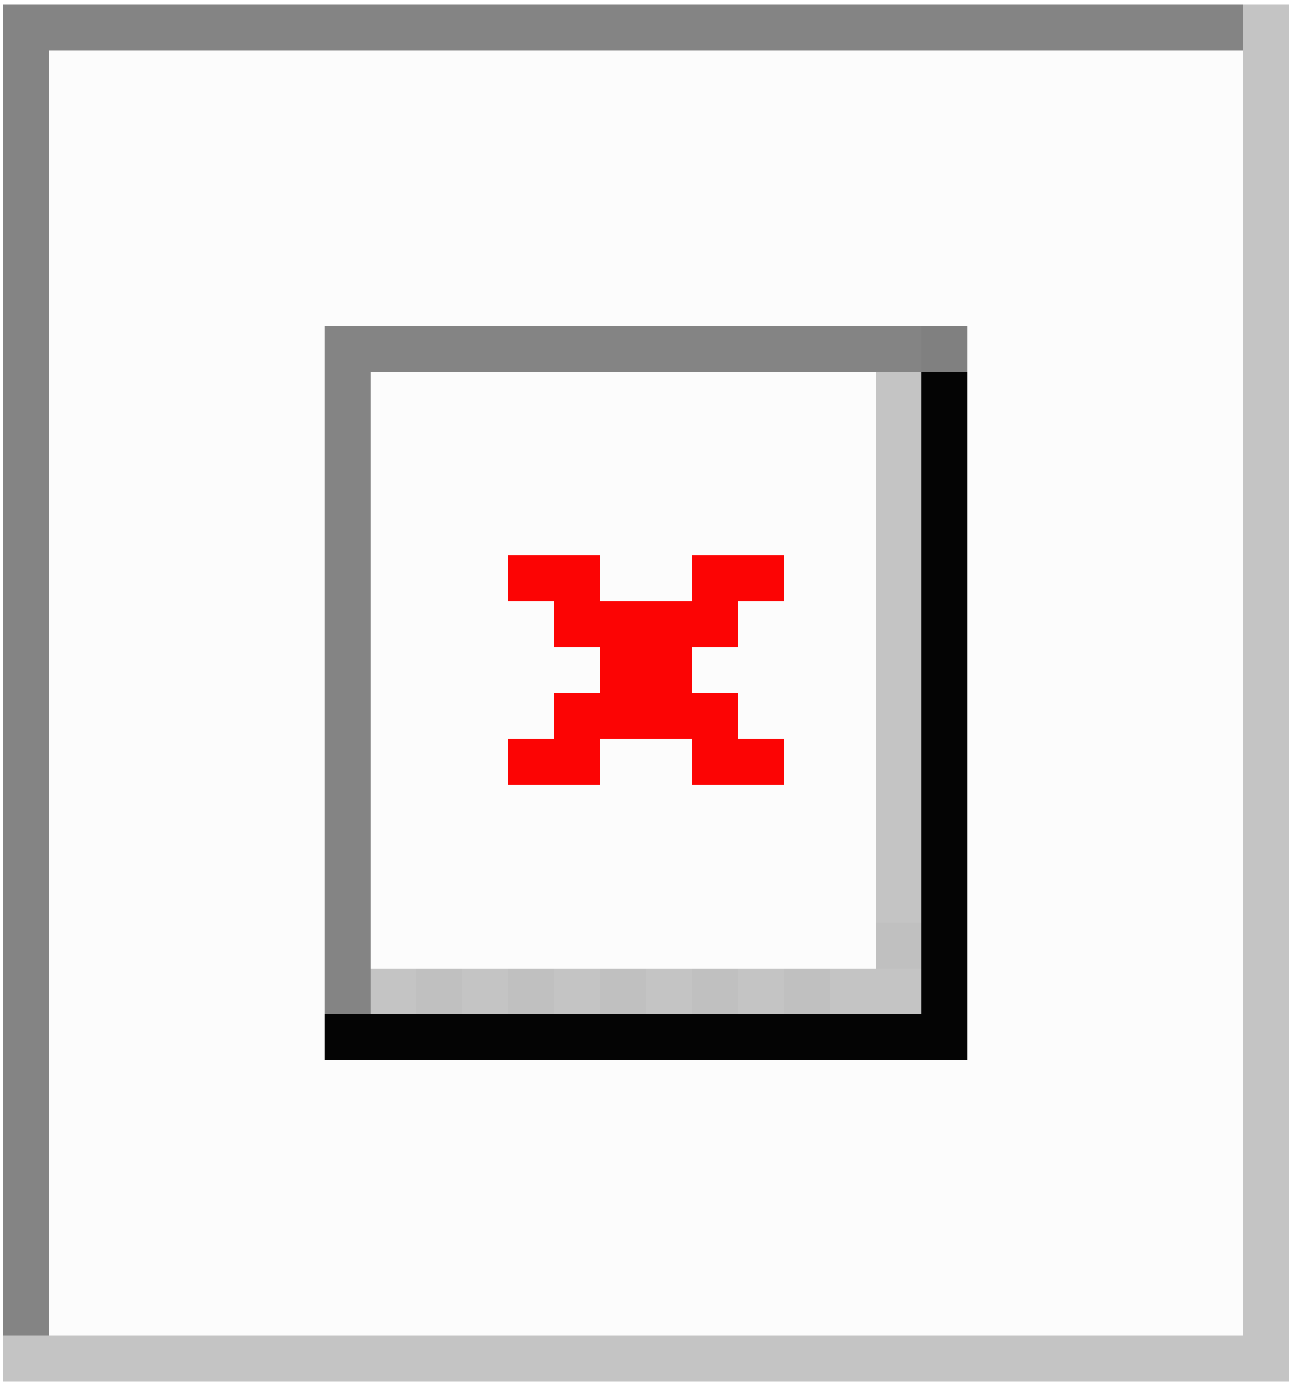

Figure 3. Funnel plot of the difference in systolic blood pressure between the mobile health intervention group and control group. diff.: difference.

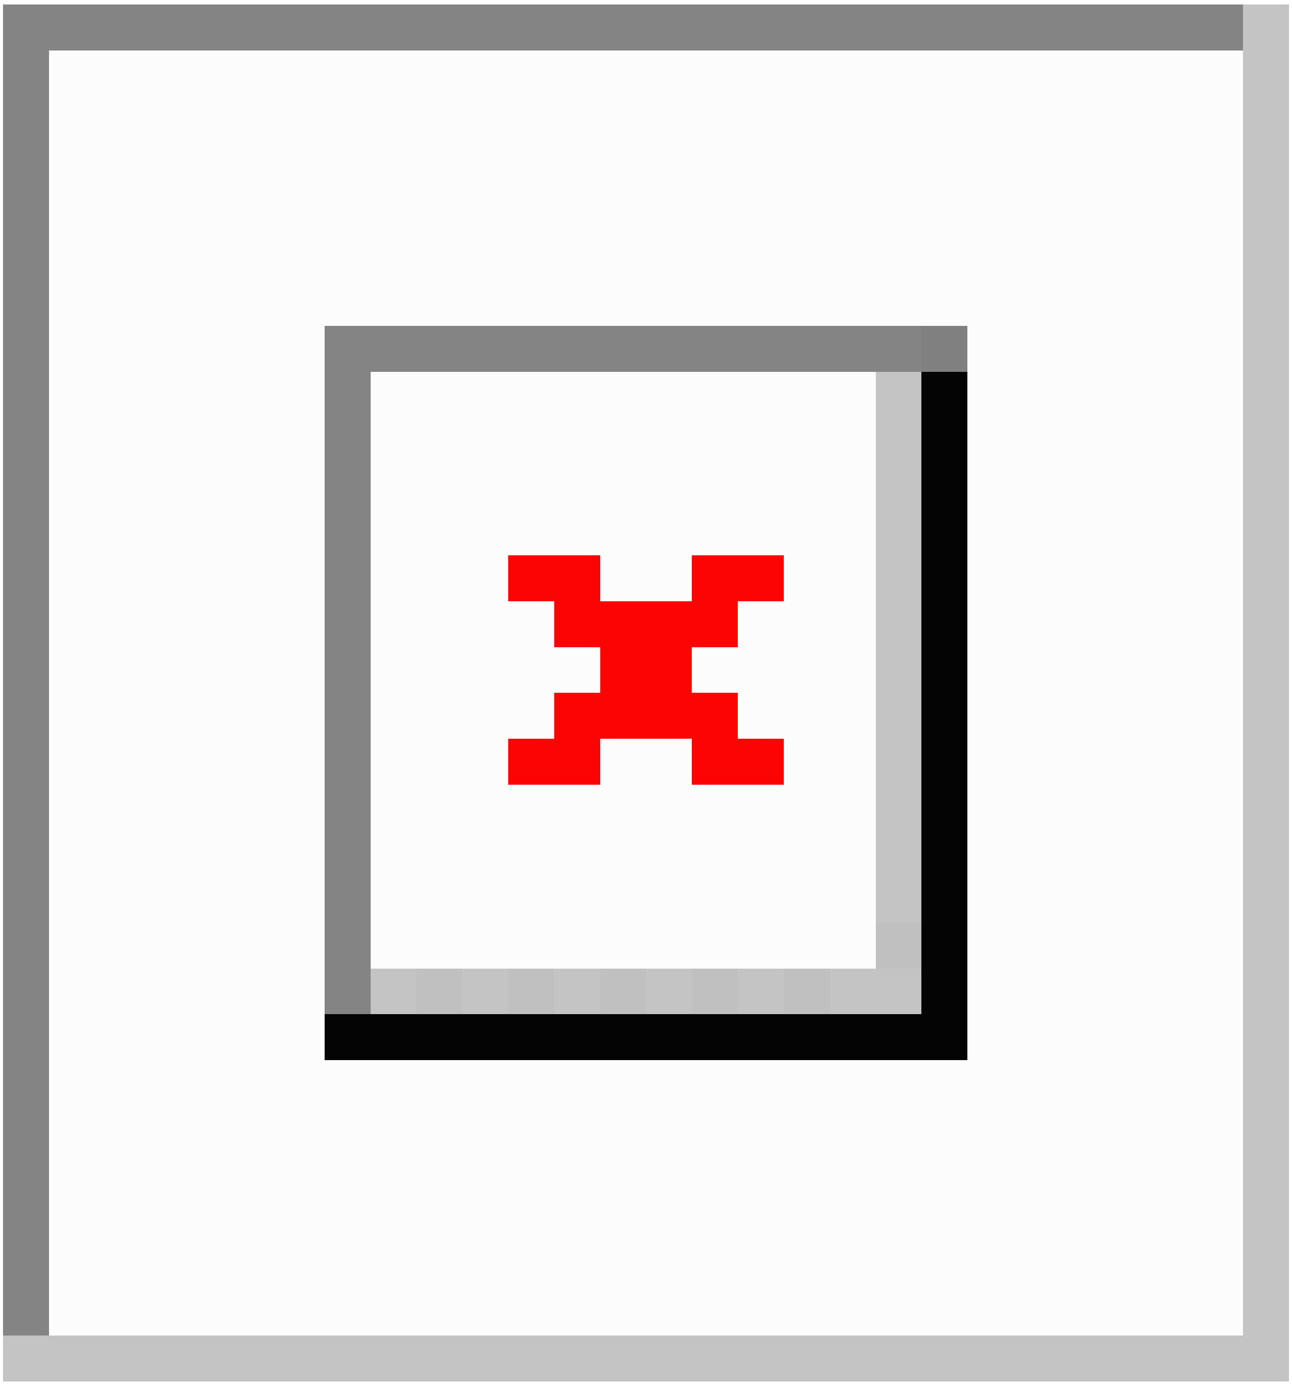

Diastolic Blood Pressure

There was no statistically significant difference in diastolic blood pressure (0.36 mm Hg, 95% CI −1.37 to 2.08; *P*=.69; I^2=47%) between the intervention and control groups (Figure 4). No significant publication bias was detected visually by the funnel plot (Figure 5) or statistically by Begg (*P*=.65) and Egger (*P*=.81) tests.

Figure 4. Forest plot of the difference in diastolic blood pressure between the mHealth intervention group and control group in 5 studies [26,27,29-31]. mHealth: mobile health.

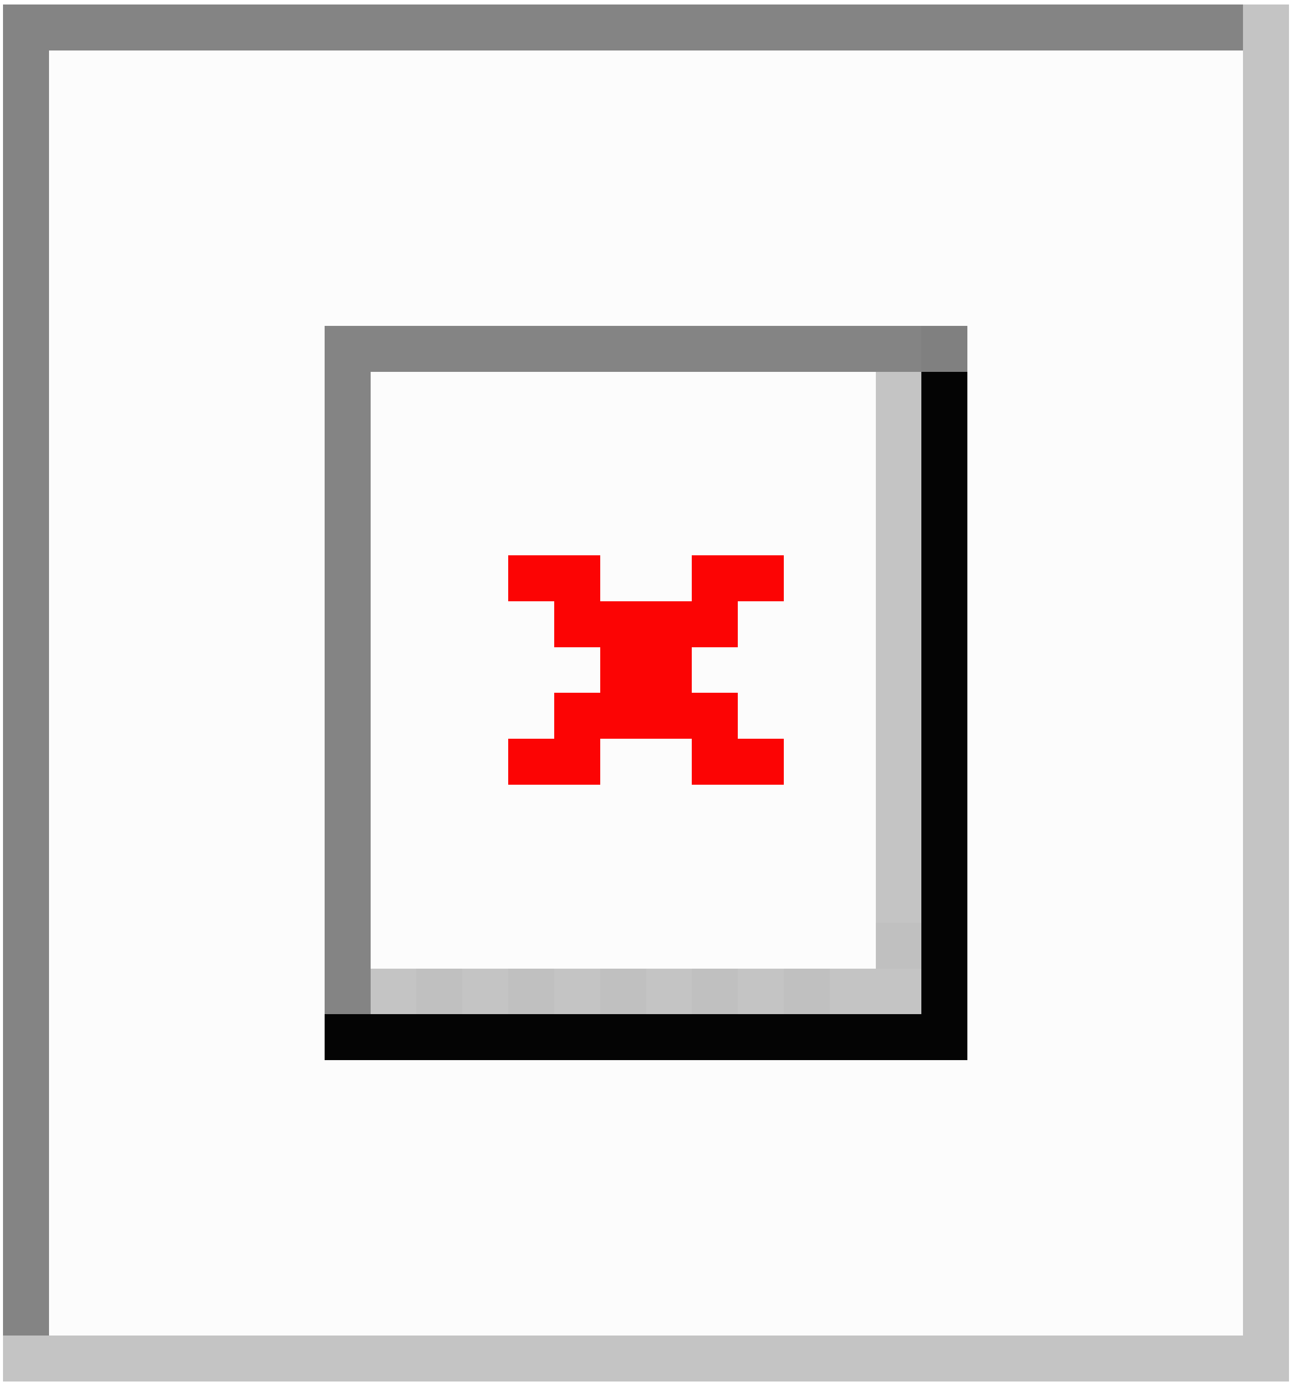

Figure 5. Funnel plot of the difference in diastolic blood pressure between the mobile health intervention group and control group. diff.: difference.

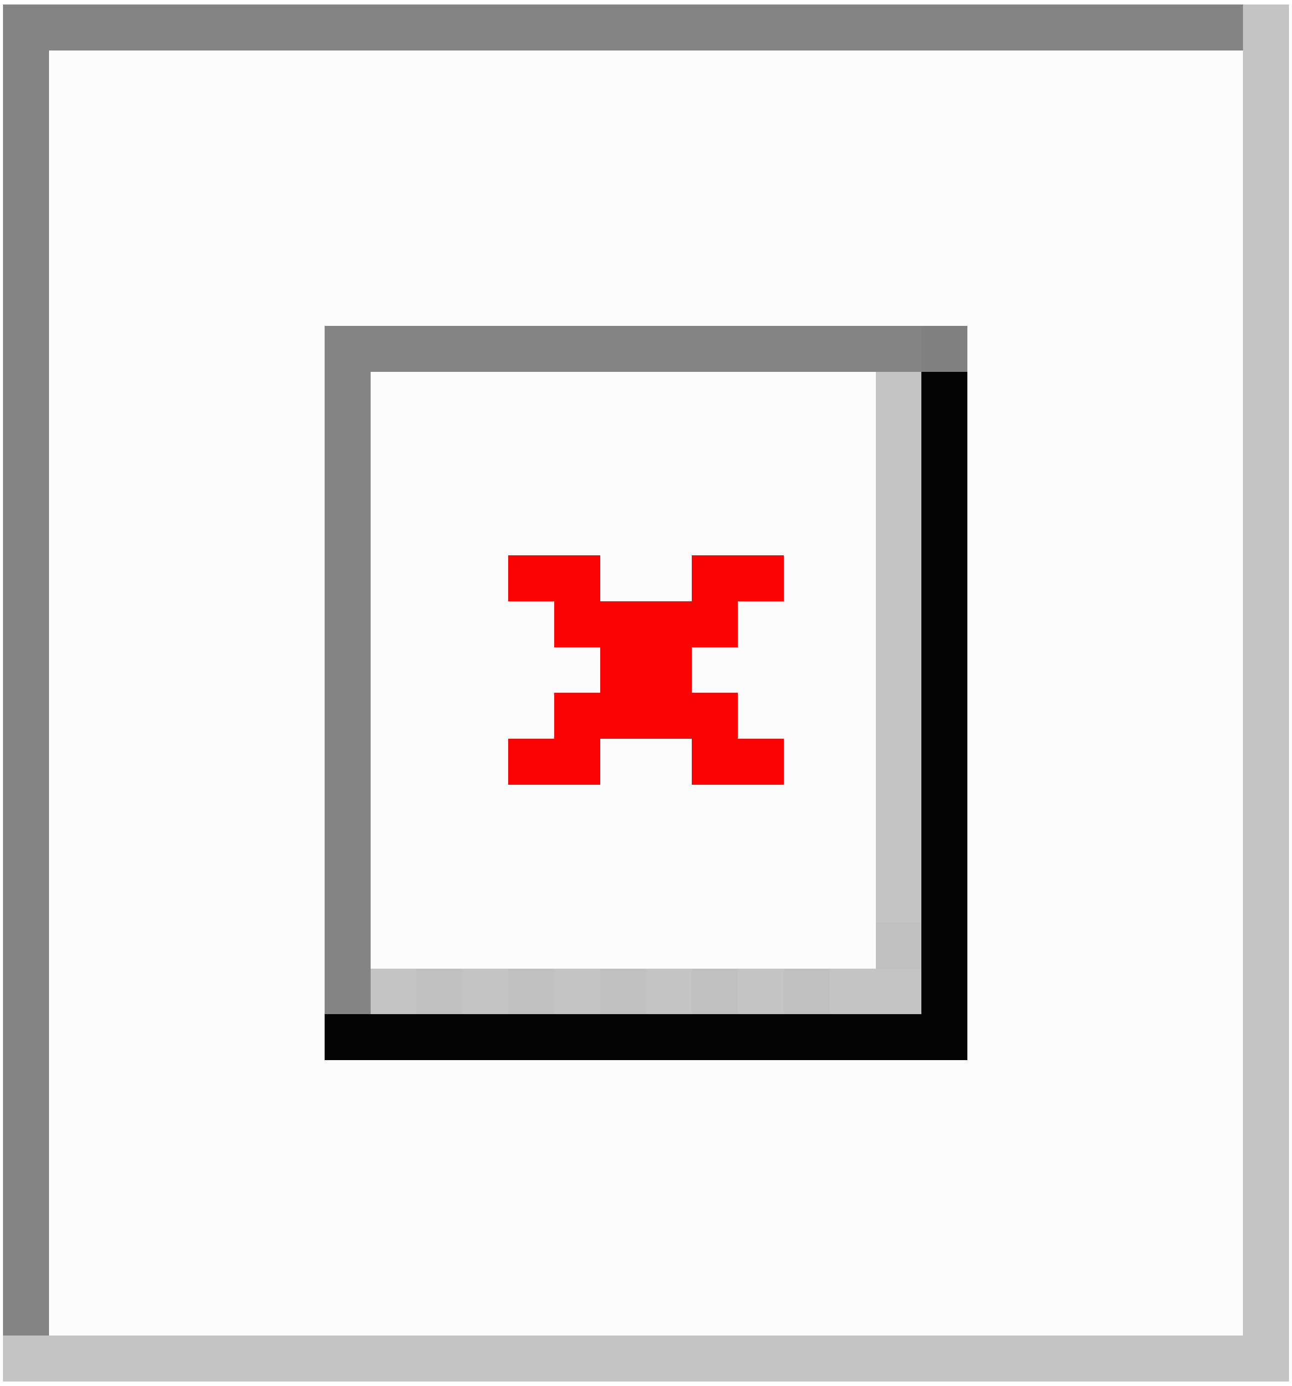

Hemoglobin A_{1c}

Additionally, as shown in Figure 6, one study had more than one intervention group with the same outcome measured [25]; hence, 3 interventions were shown in the forest plot of HbA_{1c}, and the mHealth intervention had no significant lowering effects on HbA_{1c} levels among patients with diabetes in the pooled meta-analysis at 0.20 mmol/mol (95% CI −0.40 to 0.80; *P*=.51; I^2=0%). No significant publication bias was detected visually by the funnel plot (Figure 7) or statistically by Begg (*P*=.96) and Egger (*P*=.10) tests.

Figure 6. Forest plot of the difference in hemoglobin A_{1c} between the mHealth intervention group and control group in 2 studies [25,27]. Abaza et al [25]: (A) baseline measurement; (B) end point measurement. mHealth: mobile health.

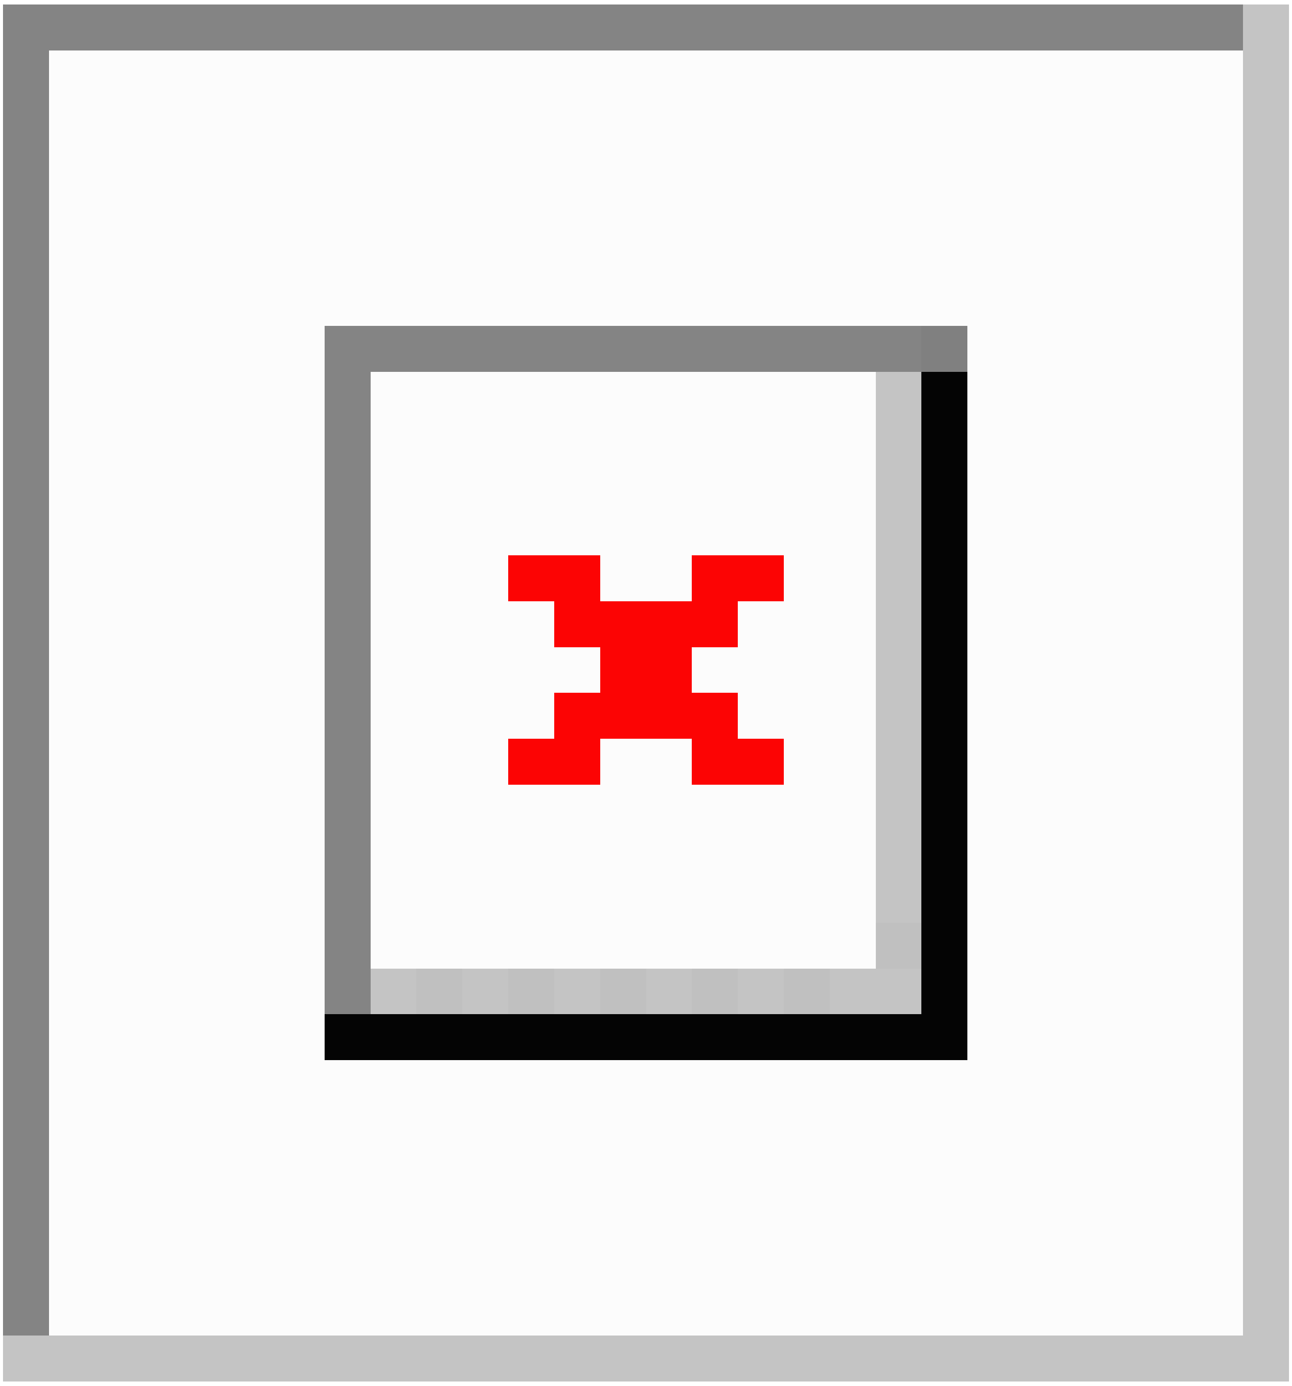

Figure 7. Forest plot of the difference in hemoglobin A_{1c} between the mobile health intervention group and control group. diff.: difference.

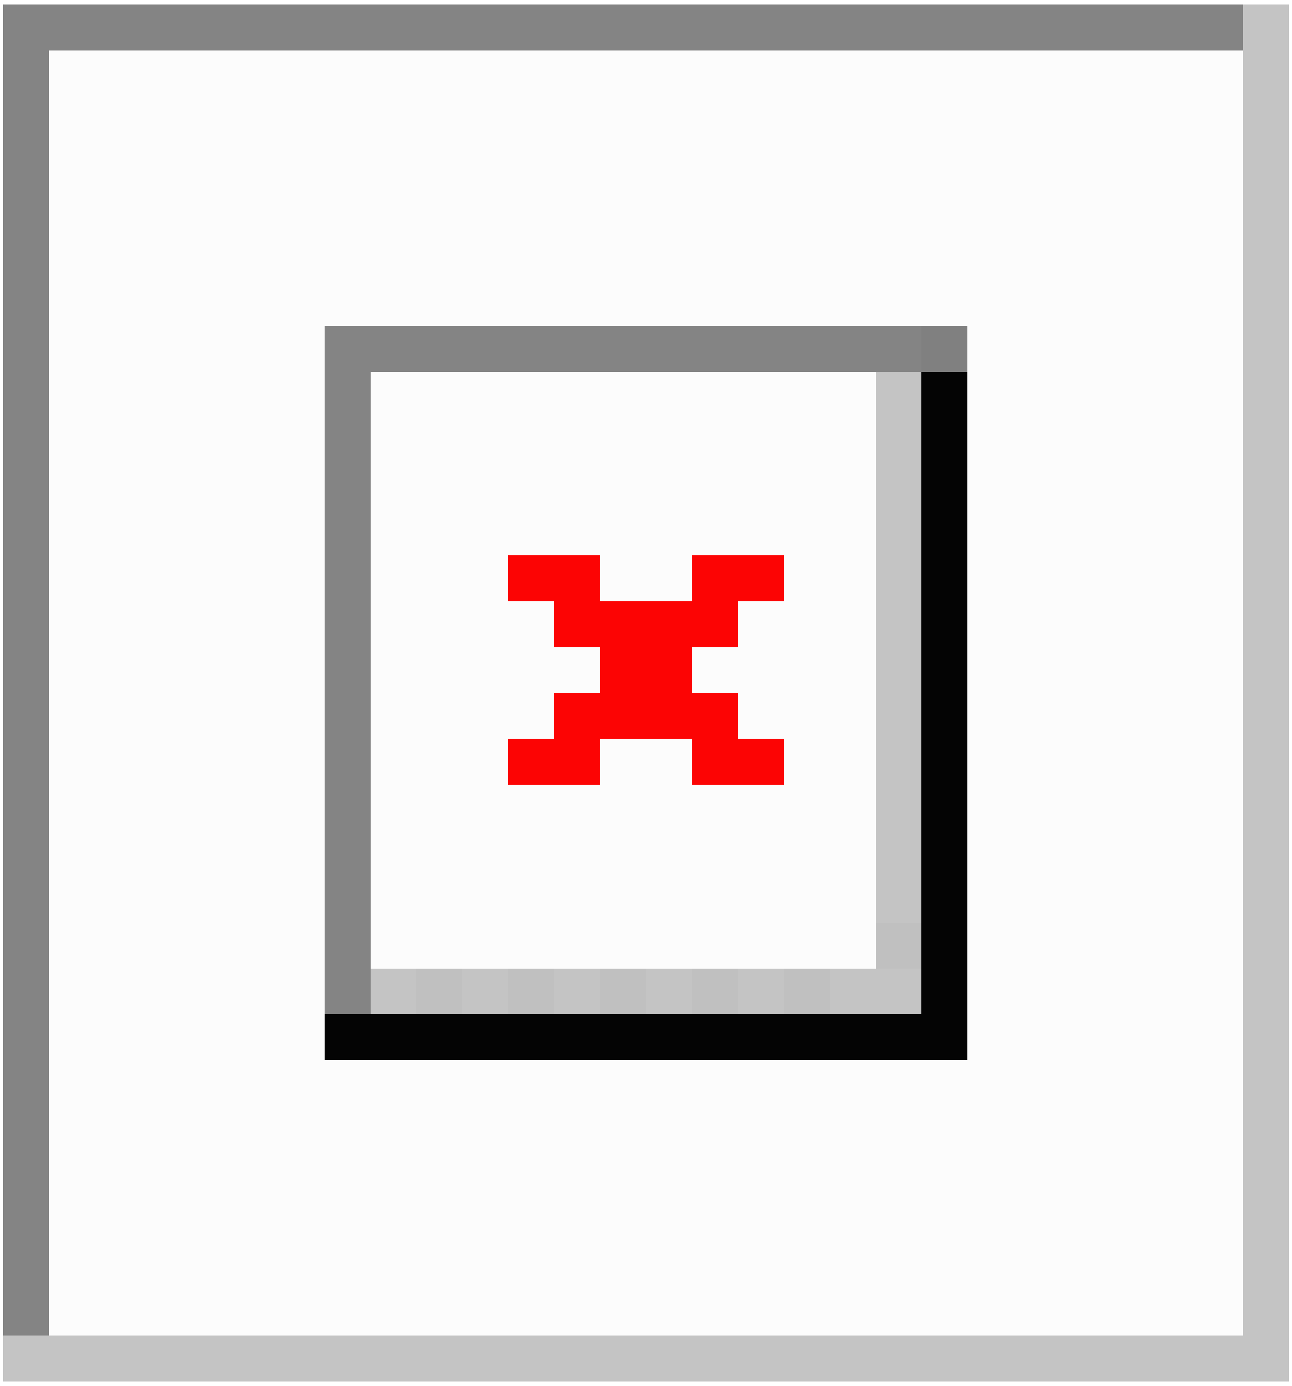

Sensitivity Analyses

Sensitivity analyses were conducted using the leave-one-out method. For systolic blood pressure, the Kingue et al [29] study had an impact on the WMD, with the pooled WMD being statistically significant after the exclusion of the Kingue et al [29] study (−2.22, 95% CI −3.94 to −0.60; *P*=.01; Figure 8). For diastolic blood pressure and HbA_{1c}, the exclusion of each of the studies rendered the WMD nonsignificant (Figures 9 and 10).

Figure 8. Leave-one-out forest plot for systolic blood pressure in 6 studies [26-31]. Bobrow et al [28]: (A) interactive intervention group vs control; (B) information only intervention group vs control.

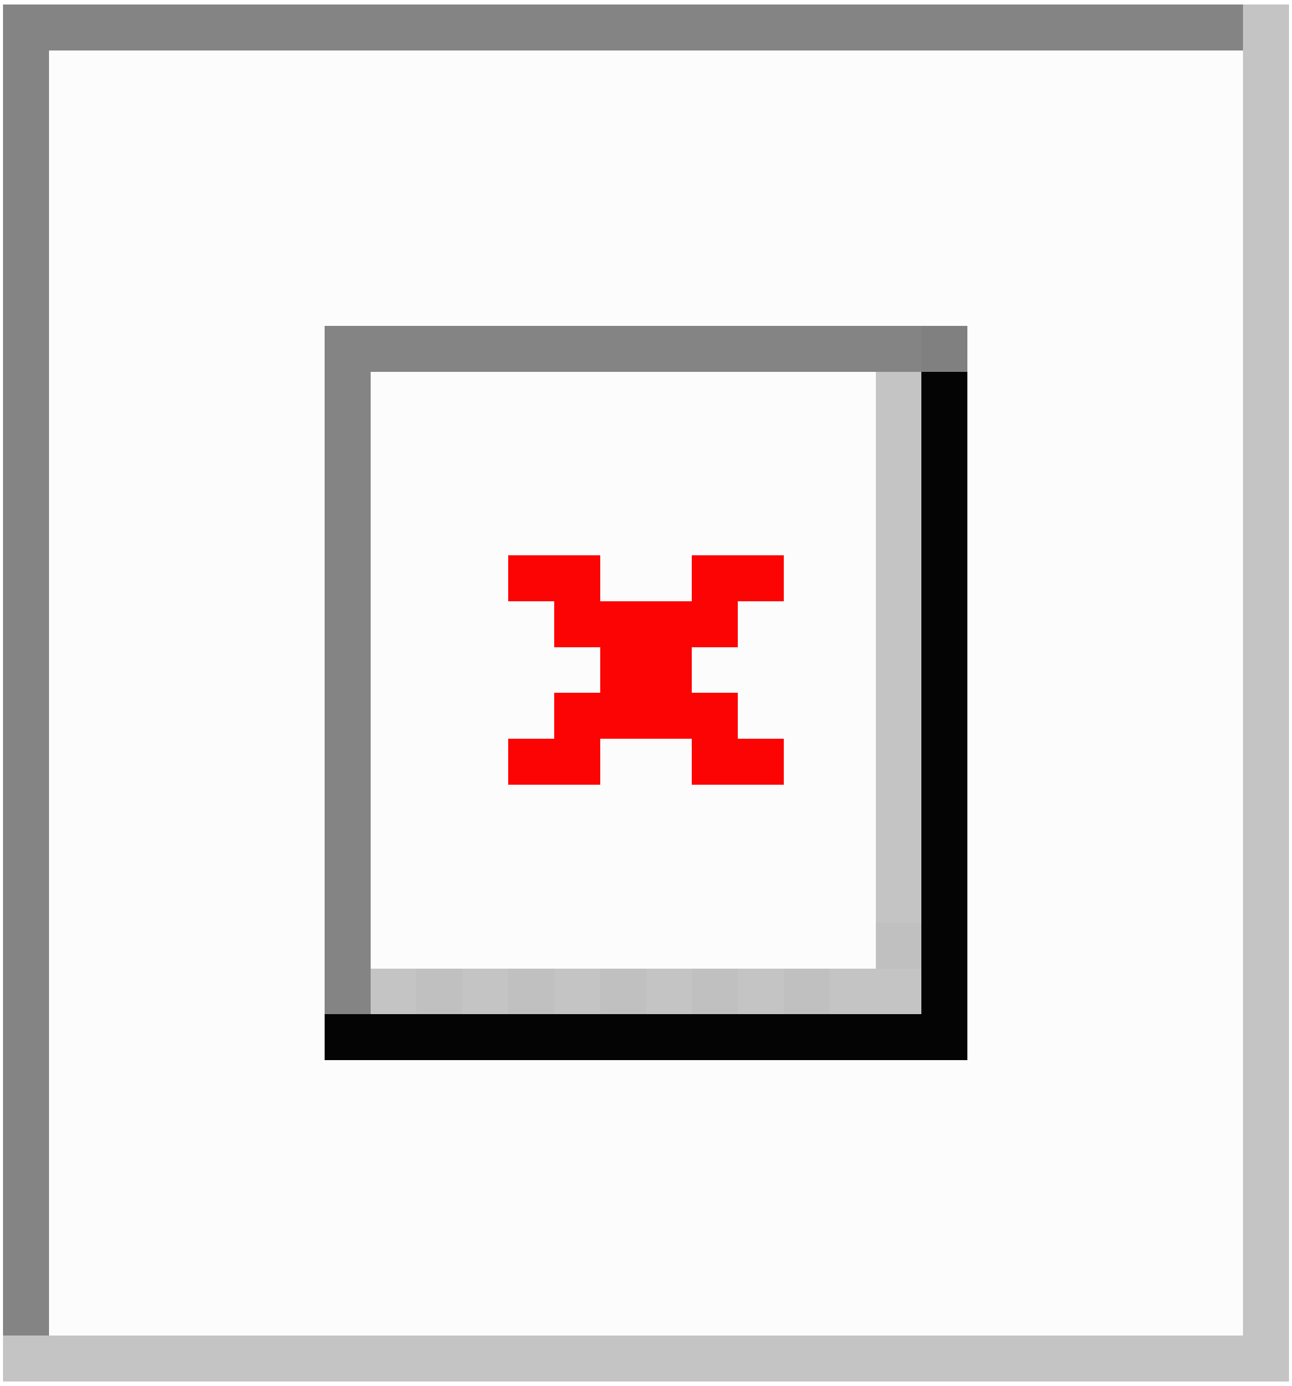

Figure 9. Leave-one-out forest plot for diastolic blood pressure in 5 studies [26,27,29-31].

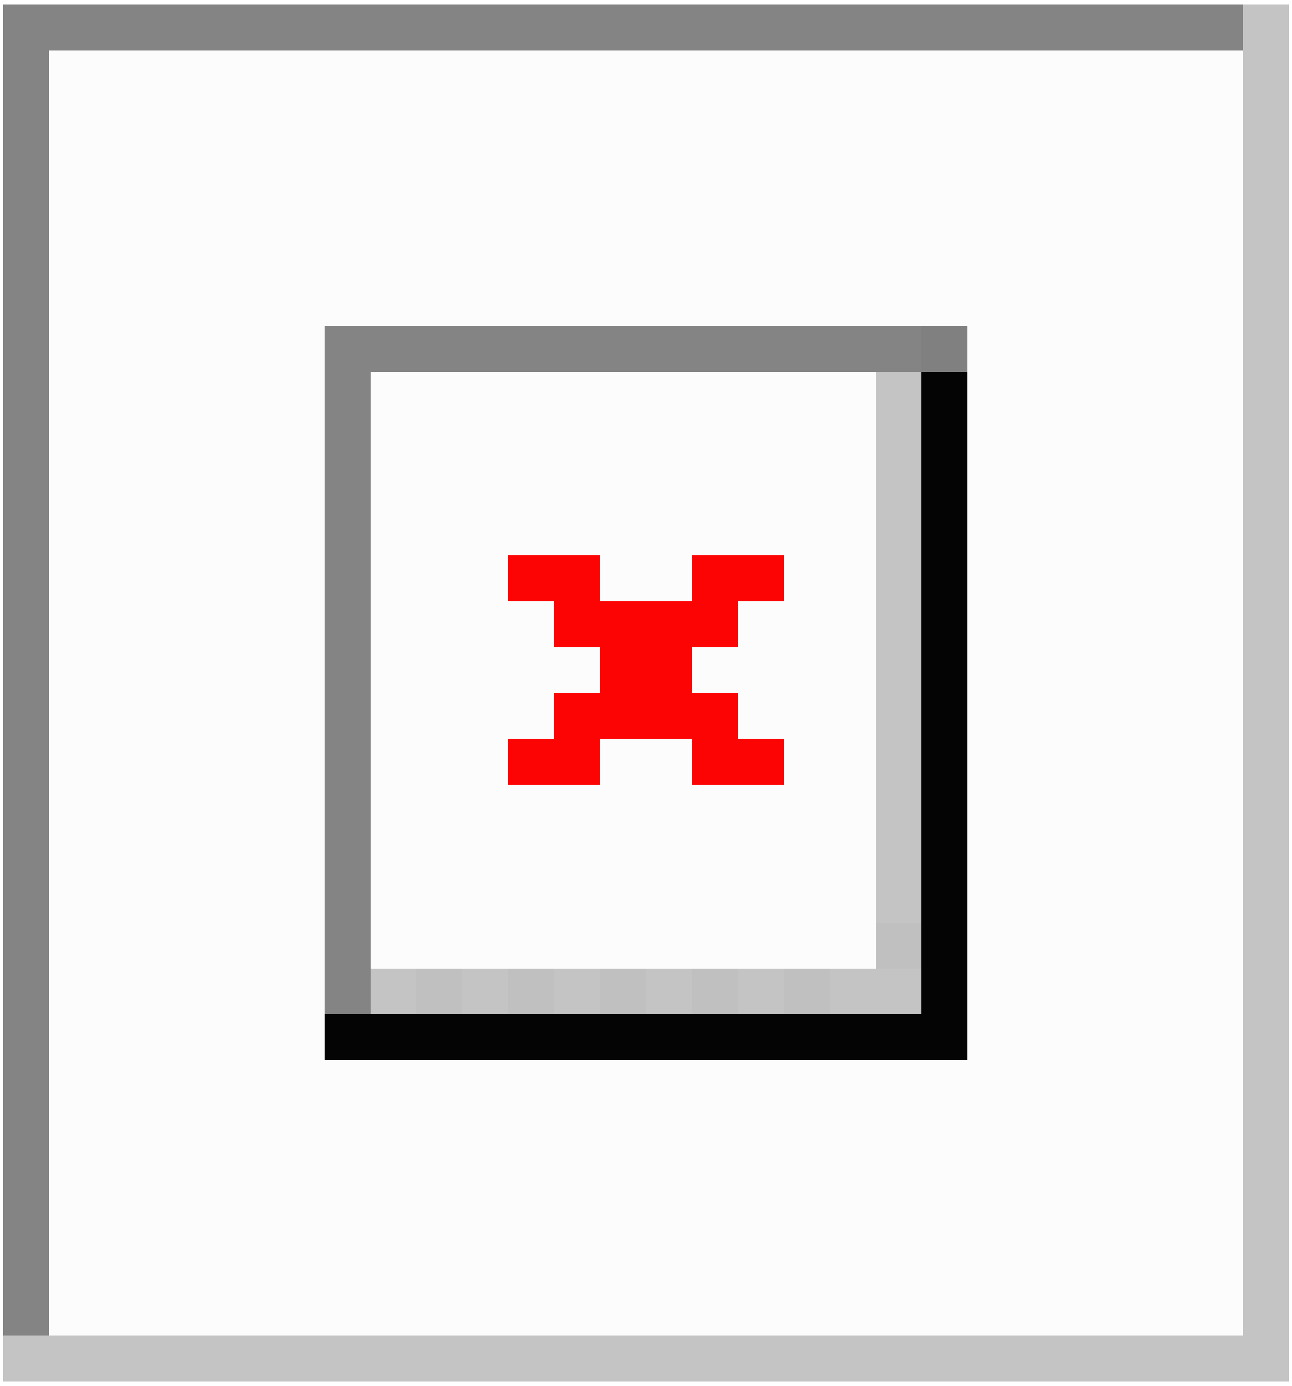

Figure 10. Leave-one-out forest plot for hemoglobin A_{1c} in 2 studies [25,27]. Abaza et al [25]: (A) baseline measurement; (B) end point measurement.

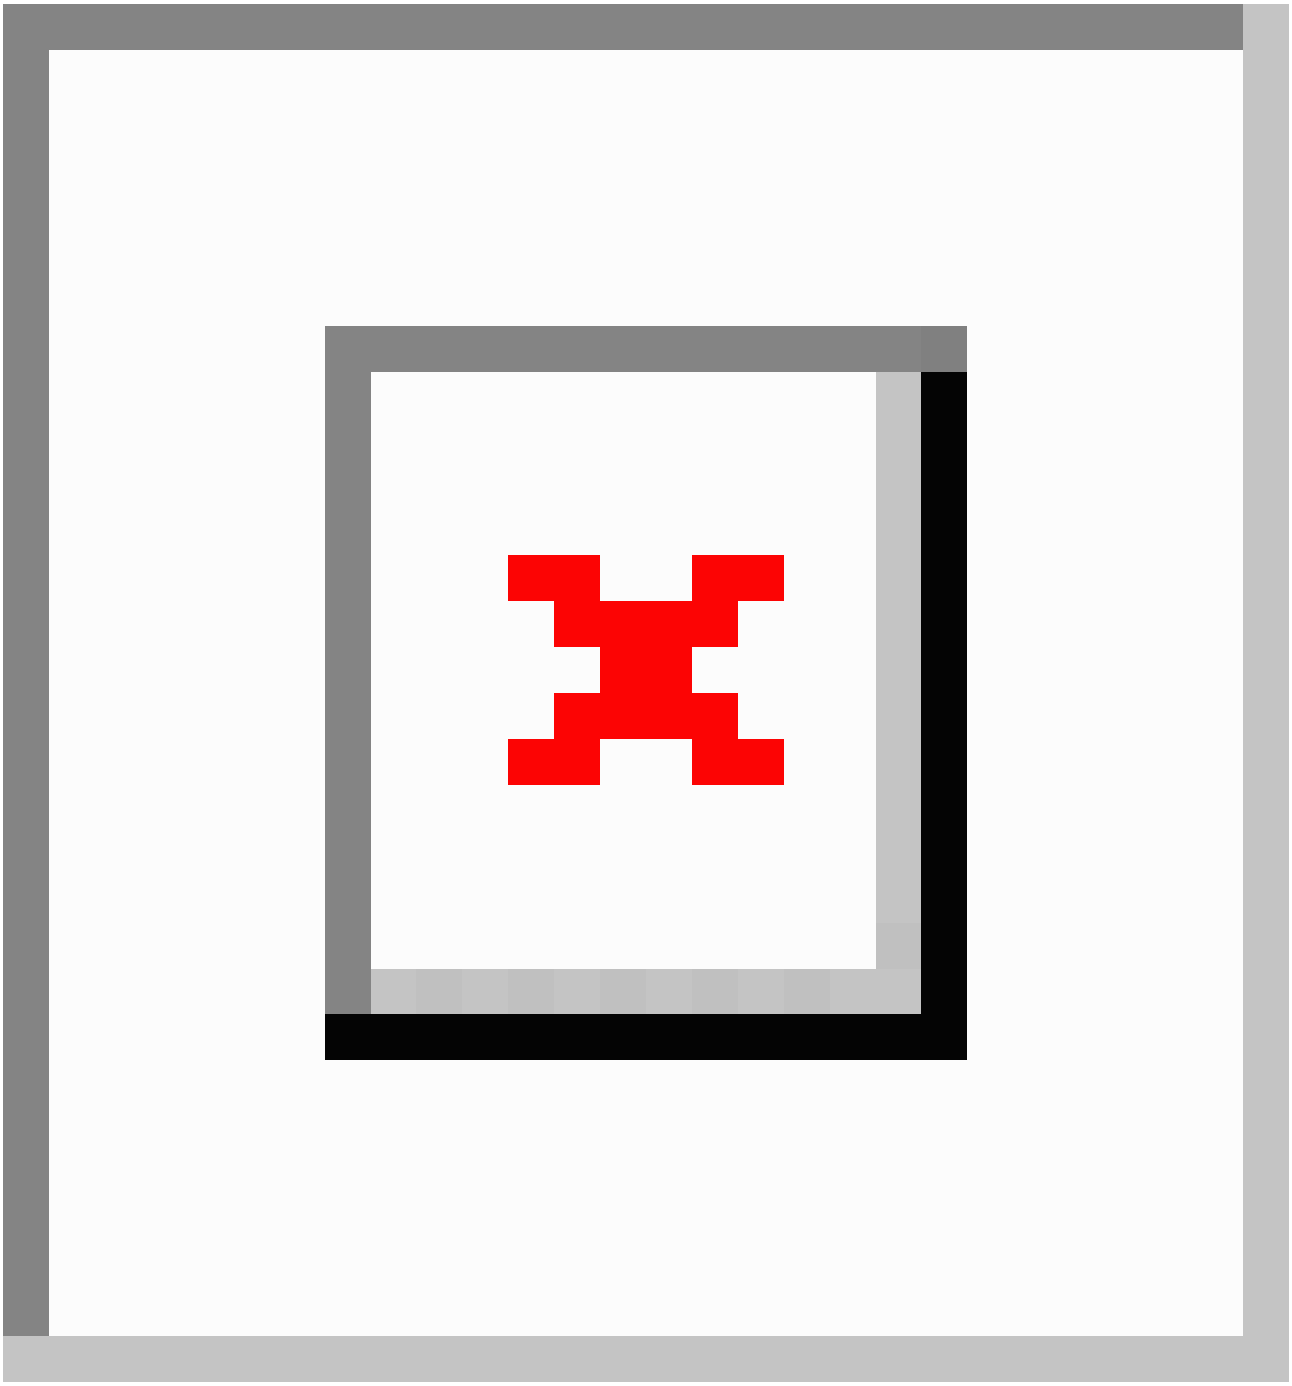

Discussion

Discussion of the Key Findings

This systematic review and meta-analysis identified 7 RCT studies that assessed the effectiveness of mHealth interventions on blood pressure and glycemic control among patients with hypertension and diabetes in Africa. In this review, the effectiveness of mHealth interventions on blood pressure and glycemic control among patients with hypertension and diabetes in Africa did not show conclusive evidence.

Systolic Blood Pressure Control

For systolic blood pressure, we observed a reduction after the mHealth intervention compared to usual care by an average of 1.39 mm Hg; however, it was not statistically significant. After conducting a leave-one-out analysis, a study by Kingue et al [29] had an impact on the WMD, and the exclusion of this study resulted in a pooled WMD reduction of 2.22 mm Hg in systolic blood pressure. This finding is consistent with previous RCT studies [20,34-36] that examined mHealth interventions on systolic blood pressure control and showed that mHealth interventions reduced systolic blood pressure by 10.4 mm Hg [20], 5.5 mm Hg [34], 3 mm Hg [35], and 3.9 mm Hg [36], respectively. In contrast, a study performed by Rubinstein et al [13] reported that the mHealth intervention did not reduce systolic blood pressure compared with usual care. This discrepancy could be explained by the relatively small sample number of studies included in this review. Another reason could be due to the different study populations, interventions, ages, and medications used.

Diastolic Blood Pressure Control

For diastolic blood pressure, our study observed no lowering effect of the mHealth intervention, which reduced by an average of 0.36 mm Hg, which is inconsistent with studies performed by Lu et al [36] and Zhang et al [20] who reported a reduction of 2.2 and 4.8 mm Hg, respectively, after the mHealth intervention compared to usual care. The disparity is that the previous studies [20,36] were conducted among patients with stroke and heart failure with a more complicated pathogenesis of hypertension, which might have resulted in the observed significant decrease in diastolic blood pressure control in this study. In patients with stroke, lower blood pressure might be achieved with strict treatment targets that also lead to a controlled condition. In previous studies, they noted a significant net reduction in body weight and intake of high-fat and high-sugar foods after the intervention [20,36]. Despite no significant findings on diastolic blood pressure control after mHealth interventions, the study by Rubinstein et al [13] reported that each 1 mm Hg decrease in diastolic blood pressure is associated with a 7% decrease in mortality from stroke and ischemic heart disease. Thus, the mHealth intervention may still be a measure worth considering for reducing blood pressure.

Glycemic Control

For glycemic control, the meta-analysis results showed no improvement after the mHealth interventions. Our study contradicts previous studies by Mao et al [35], Moattari et al [37], Kitsiou et al [4], and Huang et al [38] who found significant improvements in glycemic control following mHealth interventions among patients with diabetes. These studies have reported that patients and health care professionals who communicated by SMS text messages, telephone calls, and even electronic reminders or web servers reported greater improvement in HbA_{1c} outcomes compared with usual care [4,35,37,38]. Thus, patients with poorly controlled diabetes might benefit more from using mHealth, therefore more clinical trials are needed to confirm these findings. The Adjei and Marschollek [25] study in Ghana, despite not reporting HbA_{1c}, saw a substantial reduction in fasting plasma glucose of −1.6 mmol/L. Although evidence is scarce about the effect of mHealth interventions on the management of patients with diabetes, the difference could be attributed to the better care the system generates from the health providers. Another reason is that long-term interventions likely result in more significant changes in glycemic control than short-term mHealth interventions.

Strengths and Limitations

To the best of our knowledge, this review was the first that assessed the effectiveness of mHealth interventions in diabetes and hypertension management in Africa. Quality appraisal suggests that the quality of the included studies was good. Additionally, the included studies show no publication bias. However, there are limitations to acknowledge. Despite a thorough search, the number of included studies was relatively small, signifying that using mHealth interventions in Africa on patients with hypertension and diabetes remains an emerging area. This review may not be able to capture some significant effects due to the small samples in the included studies. Given the above limitations, future studies with larger samples are needed to validate our findings.

Conclusion

Our study showed no conclusive evidence on the effect of mHealth interventions on systolic blood pressure, diastolic blood pressure, or glycemic control. However, the sample sizes of the included studies were small; therefore, there is a need for larger RCT studies to confirm these findings.

Acknowledgments

Funding/sponsorship for the research was from the Africa eHealth Foundation.

Authors' Contributions

PA and CA designed the study. PA and KA carried out the literature search and data extraction. PA conducted the analysis and drafted the manuscript. CA and ELvdL provided critical inputs into the manuscript revision, and AL, NM, ER, and EPMvC read and approved the final manuscript. All authors had access to the data presented in this paper and accept the responsibility to submit it for publication.

Conflicts of Interest

Abstract

Background: Cardiovascular disease, cancer, diabetes mellitus, and obesity are common chronic diseases, and their prevalence is reaching an epidemic level worldwide. As the impact of chronic diseases continues to increase, finding strategies to improve care, access to care, and patient empowerment becomes increasingly essential. Health care providers use mobile health (mHealth) to access clinical information, collaborate with care teams, communicate over long distances with patients, and facilitate real-time monitoring and interventions. However, these apps focus on improving general health care concerns, with limited apps focusing on specific chronic diseases and the nutrition involved in the disease state. Hence, available evidence on the effectiveness of mHealth apps toward behavior change to improve chronic disease outcomes is limited.

Objective: The objective of this scoping review was to provide an overview of behavior change effectiveness using mHealth nutrition interventions in people with chronic diseases (ie, cardiovascular disease, diabetes mellitus, cancer, and obesity). We further evaluated the behavior change techniques and theories or models used for behavior change, if any.

Methods: A scoping review was conducted through a systematic literature search in the MEDLINE, EBSCO, PubMed, ScienceDirect, and Scopus databases. Studies were excluded from the review if they did not involve an app or nutrition intervention, were written in a language other than English, were duplicates from other database searches, or were literature reviews. Following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines, the systematic review process included 4 steps: identification of records through the database search, screening of duplicate and excluded records, eligibility assessment of full-text records, and final analysis of included records.

Results: In total, 46 studies comprising 256,430 patients were included. There was diversity in the chronic disease state, study design, number of participants, in-app features, behavior change techniques, and behavior models used in the studies. In addition, our review found that less than half (19/46, 41%) of the studies based their nutrition apps on a behavioral theory or its constructs. Of the 46 studies, 11 (24%) measured maintenance of health behavior change, of which 7 (64%) sustained behavior change for approximately 6 to 12 months and 4 (36%) showed a decline in behavior change or discontinued app use.

Conclusions: The results suggest that mHealth apps involving nutrition can significantly improve health outcomes in people with chronic diseases. Tailoring nutrition apps to specific populations is recommended for effective behavior change and improvement of health outcomes. In addition, some studies (7/46, 15%) showed sustained health behavior change, and some (4/46, 9%) showed a decline in the use of nutrition apps. These results indicate a need for further investigation on the sustainability of the health behavior change effectiveness of disease-specific nutrition apps.

Introduction

Background

Cardiovascular disease (CVD), cancer, diabetes mellitus (DM), and obesity are common chronic diseases [1], and their prevalence is reaching a substantial epidemic level internationally [2]. Chronic diseases are defined by the Centers for Disease Control and Prevention broadly as “conditions that last one year or more and require ongoing medical attention or limit activities of daily living or both” [3]. Chronic diseases affect hospitalization, mortality rates, and people’s overall health and quality of life (QOL) [1]. For example, CVD remains the most prevalent cause of morbidity and mortality in high-income countries despite significant advances in treatment over the last 5 decades. Recent epidemiological data show that CVD mortality is no longer declining and is indeed rising in some communities [4], and hospitalization rates are universally increasing [5]. Furthermore, chronic conditions such as cancer, CVD, DM, and chronic respiratory diseases caused approximately 33.2 million deaths worldwide in 2019 [6]. The prevalence of obesity has increased in all World Health Organization regions since 2000, which affects other chronic conditions as it is a risk factor for the development of CVD, DM, and several cancers [6].

As the impact of chronic diseases continues to increase, finding strategies to improve care, access to care, and patient empowerment becomes increasingly essential. Therefore, mobile health (mHealth) technology is rapidly gaining popularity among health care providers and consumers [7]. mHealth technology is defined as mobile devices (ie, mobile phones or monitoring devices) intended to be worn, carried, or accessed by patients or health care providers to monitor health status or improve health outcomes [8]. Among mobile devices, the most used are smartphones, with more than three-quarters of Americans having one, and at least one-third of smartphone owners use a health app [7,9]. Health care providers use mHealth to access clinical information, collaborate with care teams, communicate over long distances with patients, and facilitate real-time monitoring and interventions. These apps provide an opportunity to increase health care access for vulnerable populations [10]. Patients use mHealth to track their health data, access their clinical records, and communicate with their providers [11].

Furthermore, a meta-analysis [12] reported promising results for mHealth interventions in the improvement of patient outcomes such as body measurements (ie, weight and waist circumference), metabolic and physiological measurements (ie, blood pressure and glucose levels), adherence to and safe use of medication, physical activity performance, meal management, and awareness of health conditions and treatment options. Mobile apps that provide tools intended to facilitate nutrition care via smartphone technologies provide patients with more autonomy, thus empowering them and offsetting patient disengagement [13]. Moreover, mobile app–based interventions effectively improve diet and diet-related health outcomes, and effect sizes are comparable with those of traditional nondigital interventions [14]. For example, mHealth interventions can help improve lifestyle behaviors related to CVD [15,16]. A recent meta-analysis [17] found that using mHealth interventions for CVD was associated with improved blood pressure and hospitalization rates. In addition, mHealth apps have emerged as supportive tools in managing cancer as they reduce the financial burden, provide access to information, and facilitate communication [18]. Different studies and meta-analyses of patients with cancer have shown the benefits of mHealth, which include reducing fatigue or pain [19,20], providing distance physical activity programs [21,22], the use of social networks to improve QOL [23], and monitoring of symptoms [24]. mHealth offers improved and cost-effective care to people with type 2 DM (T2DM) through improved diabetes self-management [25,26]. These apps seem to increase the perception of self-care by contributing to better knowledge among people with T2DM [10]. Individuals with DM also become more confident in dealing with their illness, primarily because of decreased fear resulting from a lack of information [27,28]. For obesity, a systematic review [29] has found that technology-based interventions can provide a moderately effective way of facilitating lifestyle changes and weight loss. New technologies could help reduce economic costs, improve accessibility and adherence to treatment, and increase patient motivation and weight control [30].

The use of mobile apps for mHealth and of general health apps is increasing rapidly. However, these apps focus on improving general health care concerns, with limited apps focusing on specific chronic diseases and their nutritional intervention. The available evidence on the effectiveness of mHealth apps toward behavior change to improve chronic disease outcomes is also limited. Systematic reviews to date regarding nutrition apps have focused on healthy participants or examined the effects of dietary apps on diet improvement but not on chronic diseases [31]. Most reviews were inconclusive, with the authors recommending further research in this area to demonstrate possible benefits [32-34]. From a clinical point of view, it is essential to know if an app designed for chronic diseases produces behavior changes to improve an individual’s chronic disease outcomes. From an app creator’s point of view, it is crucial to see what needs to be done when developing an app directed toward people with chronic diseases to enhance the app’s effectiveness on behavior change and produce positive outcomes. The goal of this review was to define behavioral theories associated with mHealth use, evaluate behavior change techniques (BCTs), and describe the behavior change effectiveness using mHealth nutrition interventions in people with chronic diseases (ie, CVD, DM, cancer, and obesity).

Models and Theories of Health Behavior and Clinical Interventions

Health care and self-management of chronic conditions require effort and commitment on the part of the patient to follow treatment plans. These treatments involve many behaviors, such as dietary intake, physical activity, and prescription drug use. [35]. Theories and models are used in treatment planning to understand and explain the health behavior of individuals and can help guide clinicians to develop interventions that increase the effectiveness of health behavior change. The role of behavioral theories and models in informing digital health interventions is important to support sustainable health behavior change. A brief explanation of some of the theories and models of behavior used in these studies may help with understanding their constructs [36]: (1) the transtheoretical model shows how individuals move through 6 stages of behavior change (ie, precontemplation, contemplation, preparation, action, maintenance, and termination), which can be used to support behavior change and self-efficacy for the cessation of unhealthy behaviors and encourage a healthy lifestyle; (2) Social Cognitive Theory emphasizes self-efficacy and focuses on behavior change and outcome expectations by mastering steps to behavior change, observing others who are successful, improving mood, and ultimately increasing self-efficacy for health behavior change; (3) the Health Belief Model is based on the concept of expectancy-value and constitutes an individual's belief that their health condition is serious, their actions will reduce their risk or illness, there is a benefit to taking action for their health condition, and they have the ability to take action for health behavior change (self-efficacy); and (4) the theory of planned behavior emphasizes that motivation that is directly influenced by ability (ie, an individual's self-efficacy or perceived control over outside factors) is key to making a health behavior change [36]. There are other theories that can be used as well. For health behavior change, there is a general acceptance of the Health Belief Model along with a focus on self-efficacy found in many behavioral models such as the Social Cognitive Theory [35]. In addition, a commonly used theory to guide lifestyle interventions is the transtheoretical model [36]. There are several theories identified in this review that are important to chronic disease research on health behavior.

Methods

Information Sources and Search Strategies

In April 2022, a systematic literature search was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) strategy for each of the following diseases: obesity, DM, CVD, and cancer [37]. The PRISMA method allows for the transparent selection and analysis of literature for inclusion. The databases used in the search were MEDLINE, EBSCO, PubMed, ScienceDirect, and Scopus. These databases were chosen based on their extensive health- and technology-related literature [38]. The search strategy was similar for all diseases. It included the following keywords searched among titles, keywords, and abstracts: (1) *mobile applications* or *apps* or *mobile apps* or *mHealth* or *eHealth* AND *nutritioneducation* AND *obesity*, (2) *mobile applications* or *apps* or *mobile apps* or *mHealth* or *eHealth* AND *nutritioneducation* AND *type 2 diabetes*, (3) *mobile applications* or *apps* or *mobile apps* or *mHealth* or *eHealth* AND *nutritioneducation* AND *cardiovascular disease*, and (4) *mobile applications* or *apps* or *mobile apps* or *mHealth* or *eHealth* AND *nutritioneducation* AND *cancer.*

Eligibility Criteria

To summarize the evidence available on the topic, we included primary research studies involving an app and a nutrition intervention. Studies were excluded from the review if they did not involve an app or nutrition intervention, were written in a language other than English, were duplicates from other database searches, or were literature reviews.

Procedures

Following the PRISMA 2020 method, the systematic review process included four steps: (1) identification of records through the database search, (2) screening of duplicate and excluded records, (3) eligibility assessment of full-text records, and (4) final analysis of included records. This process can be seen in Figure 1. The results of the database searches were exported to Microsoft Excel (Microsoft Corp) for further analysis. Duplicates were removed. The remaining studies were moved to the eligibility phase, in which the authors assessed the eligibility of the articles based on the inclusion and exclusion criteria of the full text. The reason for exclusion was listed for each excluded article. The citation of the article, name of the mobile app used if available, type of intervention used, year of publication, population and sample details, study design details, purpose of the research, behavioral effectiveness, behavioral techniques, theory used, outcome measures, and results were recorded for all included studies. The authors independently reviewed the articles found in each search, and a second screening was performed by a different author. The process for screening was as follows: SG initially screened articles found in the obesity search, MA initially screened articles found in the DM search, ESG initially screened articles found in the cancer search, and AC initially screened articles found in the CVD search. SG performed a second screening of articles found in the DM search, MA performed a second screening of articles found in the obesity search, AC performed a second screening of articles found in the cancer search, and ESG performed a second screening of articles found in the CVD search.

Results

CVD Results

Demographic, Participant, and Study Design Details

There were 6 studies and mHealth app nutrition interventions comprising 451 patients included for CVD. Of the 6 studies, 4 (67%) randomized controlled trials, 1 (17%) qualitative descriptive design study, and 1 (17%) intervention evaluation were analyzed. The populations analyzed had diverse ethnicities, education levels, ages, and diagnoses. Furthermore, there were different diets or treatments among the studies, with variations in targeted behavioral domains and outcomes measured in the mHealth app nutrition interventions. App features for these studies included food tracking [8,39-41], physical activity tracking [8,41,42], nutrition and exercise knowledge and recommendations [8,40-43], scheduled reminders [39,40,42,43], clinician portals [41-43], connectivity to digital health devices [42], demonstration of the desired behavior [40,43], and challenges [41]. The aim of all studies (6/6, 100%) was to evaluate the effectiveness of mHealth in the CVD population. The included studies on nutrition apps for people with CVD can be found in Table 1.

Table 1. Included studies on cardiovascular disease (CVD; n=6).

Study	Country	Study design	Purpose	Name of mobile app and features	Behavior change theory or model	Results
Eyles et al [39]	New Zealand	Randomized controlled trial	Evaluate whether the SaltSwitch app is effective in helping people with CVD select lower-salt food purchases	SaltSwitch—all-smartphone app; features: food tracking and reminders	None	A significant reduction in mean household purchases of salt was observed during the 4-week intervention phase. A total of 87% of the participants reported using the SaltSwitch app, and 75% reported finding the SaltSwitch app very easy to use.
Indraratna et al [42]	New Zealand	Randomized controlled trial	Investigate the feasibility, efficacy, and cost-effectiveness of a smartphone app–based model of care in patients discharged after ACS[a] or HF[b] admission	TeleClinical Care TCC—all-smartphone app; features: physical activity tracking, knowledge, reminders, connectivity to digital health devices, and clinician portal	None	The intervention was associated with a significant reduction in unplanned hospital readmissions, including cardiac readmissions, and higher rates of cardiac rehabilitation completion and medication adherence. The average usability rating for the app was 4.5/5.
Agher et al [8]	France	Survey	Design an mHealth[c] app, Prevent Connect, to assess its quality for evaluating patient behavior for 4 cardiovascular risk factors (unhealthy eating, sedentary lifestyle, and alcohol and tobacco consumption) and suggest personalized recommendations and mHealth interventions for risky behaviors	Prevent Connect—all-smartphone app; features: food and physical activity tracking and knowledge	None	The app was deemed of good quality, with a mean uMARS[d] quality score of 4 on a 5-point Likert scale. The functionality and information content of the app were particularly appreciated, with a mean uMARS score of >4. The esthetics and engagement of the app were appreciated (uMARS score of 3.7). A total of 80% (42/52) of the participants declared that the app helped them become aware of the importance of addressing health behavior, and 65% (34/52) said that the app helped motivate them to change lifestyle habits.
Schmaderer et al [43]	United States	Qualitative analysis	Explore the experience of using a self-management mHealth intervention in individuals with HF to inform a future mHealth intervention study	Play-It Health—all-smartphone app; features: knowledge, reminders, clinician portal, and demonstration of behavior	None	Participants reported an overall positive experience. The education provided during the study increased self-awareness and promoted self-management of their HF. The mHealth app supported patient empowerment, resulting in better HF management and improved quality of life.
Steinberg et al [40]	United States	Randomized controlled trial	Improve adherence to the DASH[e] diet among women with HTN[f] or pre-HTN	Nutritionix—all-smartphone app; features: food tracking, knowledge, reminders, and demonstration of behavior	Behavior change principles	Intervention participants had lower systolic and diastolic BP[g] compared with active comparator participants. Most intervention participants (23/29, 79%) said that they would recommend the DASH Cloud intervention to a friend or family member. However, only 34% (10/59) indicated that the feedback SMS text messages helped them reach their diet goals.

Study	Country	Study design	Purpose	Name of mobile app and features	Behavior change theory or model	Results
Choi et al [41]	United States	Randomized controlled trial	Discover whether dietary counseling supplied through a custom smartphone app results in better adherence to a Mediterranean diet in a non-Mediterranean population than the traditional standard-of-care counseling	Unknown name—all-smartphone app; features: food and physical activity tracking, knowledge, clinician portal, and challenges	None	There were no significant differences between EXP[h] and SOC[i] regarding BP, lipid parameters, HbA_{1c}, or C-reactive protein. EXP achieved a significantly greater weight loss on average of 3.3 lbs versus 3.1 lbs for SOC. Adherence to the Mediterranean diet increased significantly over time for both groups, but there was no significant difference between the groups. Similarly, there was no significant difference in diet satisfaction between EXP and SOC, although diet satisfaction increased significantly over time for both groups. The proportion of participants with high Mediterranean diet compliance increased significantly over time—from 18.4% to 57.1% for SOC and from 27.5% to 64.7% for EXP; however, there was no significant difference between the groups.

[a]ACS: acute coronary syndrome.

[b]HF: heart failure.

[c]mHealth: mobile health.

[d]uMARS: User Version of the Mobile App Rating Scale.

[e]DASH: Dietary Approaches to Stop Hypertension.

[f]HTN: hypertension.

[g]BP: blood pressure.

[h]EXP: experimental.

[i]SOC: standard of care.

Targeted Behavior and Outcome Measures

The most commonly measured outcome in the CVD studies was usability or engagement in 83% (5/6) of the studies, followed by diet intake or quality and metabolic and physiological measurements (ie, blood pressure and urinary sodium) in 67% (4/6) of the studies. In addition, treatment adherence (ie, diet, cardiac rehabilitation, and medication) was measured in 50% (3/6) of the studies. Other measured outcomes included physical activity, weight loss, dietary knowledge, sustainability, tobacco or alcohol consumption, hospital readmissions, cost-effectiveness, food purchases, and self-management in 17% (1/6) of the studies.

BCTs Used

The most commonly used BCT was motivation or encouragement, which was used in all reviewed studies (6/6, 100%). Knowledge or education and self-monitoring were used in 83% (5/6) of the studies. Both prompts or cues and feedback were used in 50% (3/6) and 33% (2/6) of the studies, respectively. The least common BCTs included graded tasks or challenges, demonstration of behavior, self-efficacy, and goal setting in 17% (1/6) of the studies reviewed.

Behavioral Theory or Model

In total, 17% (1/6) of the analyzed studies were based on behavioral theories or models. The others (5/6, 83%) did not mention a theory. The transtheoretical model, Social Cognitive Theory, the theory of planned behavior, the Health Belief Model, the precaution adoption model, and goal-setting theories were used as the basis for 17% (1/6) of the interventions in this review section. Evidence for informing digital technology interventions reveals that the Health Belief Model has been widely used for goal setting and lifestyle changes for reducing cardiovascular risk as it focuses on confidence in one's ability to take action [36].

Behavior Change Effectiveness

CVD-specific mHealth apps significantly improved the completion of cardiac rehabilitation, were significantly cost-effective, and resulted in substantial weight loss and less salt purchases in 17% (1/6) of the studies. Furthermore, significant engagement was observed in 67% (4/6) of the studies.

In addition, some studies (1/6, 17%) showed improvement in blood pressure and self-management and rated the app quality as good. However, linking BCTs and theoretical frameworks to behavior change and CVD health measures is challenging. Therefore, this area of study should be investigated further.

Cancer Results

Demographic, Participant, and Study Design Details

In total, 9 cancer-related studies comprising 645 patients were included. Of the 9 studies, 3 (33%) focused on survivors of breast cancer, 2 (22%) focused on breast cancer, 2 (22%) focused on esophageal cancer, 1 (11%) focused on patients with either gastric or colon cancer, and 1 (11%) focused on pancreatic cancer. Various study designs were used: 22% (2/9) prospective quasi-experimental studies, 22% (2/9) prospective pilot studies, 11% (1/9) interventional observation studies, 11% (1/9) nonrandomized 2-group controlled design studies, 11% (1/9) randomized controlled trials, 11% (1/9) randomized pretest-posttest design studies, and 11% (1/9) clinical trials were analyzed. These studies can be found in Table 2. Each app had different features, including digital diaries [7,44-49], coach feedback [7,44-47,49-51], personalized physical exercise programs and nutrition plans [49,50], general nutrition and physical exercise guidelines [45,51], psychological support courses [45,51], a secure message portal to their health care teams [7,48], health knowledge education [46,48,51], and daily tasks [48,51].

Table 2. Included studies on cancer (n=9).

Study	Country	Study design	Purpose	Name of mobile app and features	Behavior change theory or model	Results
Stubbins et al [7]	United States	Prospective, single-arm, open-label clinical trial	To evaluate the feasibility and usability of MOCHA[a] to improve daily accounting of PA[b] and food intake in survivors of breast cancer and improve engagement with health practitioners and peers	MOCHA—Apple- and Android-based app; features: food and PA tracking, coach feedback, and clinician portal	None	The average number of daily uses was approximately 3.5 times per day; participants lost an average of 2 lbs. The average usability score was 77.4, which was greater than the acceptable level. More than 90% of patients found MOCHA easy to navigate, and 84% were motivated to use MOCHA daily.
Lozano-Lozano et al [49]	Spain	Prospective test-retest quasi-experimental study	To investigate the feasibility of BENECA[c] mHealth[d] in an ecological clinical setting with survivors of breast cancer by studying (1) its feasibility and (2) pretest-posttest differences regarding the lifestyles, QOL[e], and PA motivation of survivors of breast cancer	BENECA mHealth—all-smartphone app; features: food and PA tracking, coach feedback, and personalized programming	Theories of learning, Goal-Setting Theory, and Social Cognitive Theory	BENECA was considered feasible by survivors of breast cancer in terms of use (76%, 58/76), adoption (69%, 80/116), and satisfaction (positive NPS[f]). BENECA mHealth improved the QOL, EAF[g] score, and daily moderate to vigorous PA of the participants and reduced their body weight.
Lozano-Lozano et al [50]	Spain	Prospective quasi-experimental pre-post study	(1) Check whether it is feasible to find changes in inflammation biomarkers through an mHealth strategy app as a delivery mechanism of an intervention to monitor energy balance and (2) discover potential predictors of change in these markers in survivors of breast cancer	BENECA mHealth—all-smartphone app; features: food and PA tracking, coach feedback, and personalized programming	Theory of learning, Goal-Setting Theory, and Social Cognitive Theory	Differences between pre- and postassessment CRP[h] and IL-6[i] showed a significant decrease in both markers. Stepwise regression analyses revealed that changes in global QOL, as well as uMARS[j] score and hormonal therapy, were possible predictors of change in CRP concentration after using the mHealth app. Participants showed moderate satisfaction with the mHealth app; high app use (mean 47.9; maximum 56 days); and moderate to low scores in general QOL, fatigue, and pain.
Cheng et al [45]	China	Prospective, single-arm, nonrandomized pilot study	To evaluate the feasibility, safety, and efficacy of a comprehensive intervention model using an mHealth system (CIMmH[k]) in patients with esophageal cancer after esophagectomy	CIMmH—web-based program; features: food and PA tracking, knowledge, and psychological support courses	Comprehensive intervention model	At the 3-month follow-up, except for pain, eating difficulty, dry mouth, and trouble with talking, all other QOL dimensions returned to the preoperative level. There were significant reductions in weight and BMI throughout the study, and no significant changes were observed for physical fitness measured by change in the 6-minute Walk Test distance between baseline and the 1-month follow-up or between baseline and the 3-month follow-up. Depressive symptoms significantly increased 1 month after surgery, whereas other psychological measures did not show relevant changes. Although there were declines in many measures 1 month after surgery, these were much improved at the 3-month follow-up, and the recovery was more profound and faster than with traditional rehabilitation programs. Participants viewed, on average, 84% (3.38/4) of the web-based video intervention content and completed, on average, 14% (3.20/23) and 34% (9.44/28) of the web-based audio and article content, respectively. Participants completed, on average, 63% (5.01/8), 100% (1/1), and 24% (10.89/46) of the web-based nutrition, physical exercise, and psychological intervention content, respectively.

Study	Country	Study design	Purpose	Name of mobile app and features	Behavior change theory or model	Results
Soh et al [48]	Korea	Prospective study	To develop and validate a multidisciplinary mobile care system that can provide health education and self-management features to improve multiple clinical measures for patients with advanced gastrointestinal cancer	Life Manager—all-smartphone app; features: food and PA tracking, clinician portal, knowledge, and daily tasks	None	For the gastric cancer group, the "general gastric cancer education" was the most frequently viewed (322 times), and for the colon cancer group, the "warming-up exercise" was the most viewed (340 times). Of 13 measurements taken from participants, 9 were taken offline (response rate: 52%-90.1%), and 3 were taken on the web (response rate: 17.6%-57.4%). The overall satisfaction rate among participants was favorable and ranged from 3.93 to 4.01 on a 5-point Likert scale.
Cairo et al [44]	United States	Nonrandomized 2-group controlled study design with pre-post repeated measures	To evaluate if a readily available mHealth intervention (ie, Vida) can lead to healthier lifestyle habits for survivors of breast cancer	Vida—all-smartphone app; features: food and PA tracking and coach feedback	Behavior change theory	At 6 months, more patients in the app group experienced weight loss and had a significantly greater reduction in overall BMI. The app group also demonstrated statistically significant improvements in "strenuous" PA and had significant improvements in their dietary patterns as compared with the self-guided group. The app group had greater reduction in fatigue and improvement in depression, but these changes were not statistically significant. At 12 months, none of the app users were still using the app, but many were still following their wellness plan and had maintained their weight loss.
Yang et al [47]	Korea	Prospective pilot study	To evaluate the usefulness of a health care mobile app in preventing malnutrition and excessive muscle loss in patients with esophageal cancer receiving NACRT[l]	Noom—Android- and Apple-based app; features: food and PA tracking, coach feedback, and knowledge	None	The use (or activation) of the app was noted in approximately 70% (25/36) of the patients until the end of the trial. Compared with the 1:2-matched usual care group by propensity scores balanced with their age, primary tumor location, tumor stage, pre-RT[m] BMI, and pre-RT SMI[n] level, 30 operable patients showed less aggravation of the prognostic nutritional index. However, there was no significant difference in the SMI change or the number of patients with excessive muscle loss. In patients with excessive muscle loss, the walk steps significantly decreased in the last 4 weeks compared with those in the first 4 weeks. Age affected the absolute number of walk steps, whereas pre-RT sarcopenia was related to the recovery of the reduced walk steps.
Keum et al [46]	Korea	Randomized controlled study	To evaluate the efficacy of a mobile app–based program, Noom, in patients receiving chemotherapy for PDAC[o]	Noom—Android- and Apple-based app; features: food and PA tracking, coach feedback, and knowledge	None	All the study participants showed a significant improvement in nutritional status according to the PG-SGA[p] score regardless of Noom app use. Noom users showed statistically significant improvements on the global health status and QOL scales compared with non–Noom users based on the EORTC QLQ[q]. The SMI decreased in both groups during chemotherapy. The decrement was higher in the non–Noom user group than in the Noom user group, but it was not statistically significant.

Study	Country	Study design	Purpose	Name of mobile app and features	Behavior change theory or model	Results
Çınar et al [51]	Turkey	Single-blinded, single-centered, and randomized design	Mobile app–based training given to cope with the side effects of EHT[r] and how managing the symptoms and the disease process will affect the QOL of women with breast cancer	Name not provided—all-smartphone app; features: coach feedback, knowledge, psychological support courses, and daily tasks	None	QOL of the treatment group after the intervention increased, and distress level was lower compared with the control group; these results were statistically significant. Most of the patients reported that the mobile app was "informative and useful."

[a]MOCHA: Methodist Hospital Cancer Health Application.

[d]mHealth: mobile health.

[e]QOL: quality of life.

[f]NPS: Net Promoter Score.

[g]EAF: Spanish self-efficacy scale for physical activity.

[h]CRP: C-reactive protein.

[i]IL-6: interleukin-6.

[j]uMARS: User Version of the Mobile App Rating Scale.

[k]CIMmH: Comprehensive Intervention Model Using a Mobile Health System.

[l]NACRT: neoadjuvant chemoradiotherapy.

[m]RT: radiotherapy.

[n]SMI: skeletal muscle index.

[o]PDAC: pancreatic ductal adenocarcinoma.

[p]PG-SGA: Patient-Generated Subjective Global Assessment.

[q]EORTC QLQ: European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire.

[r]EHT: adjuvant endocrine hormonal therapy.

Target Behavior and Outcome Measures

The most targeted behaviors were physical activity, observed in 56% (5/9) of the included studies, and dietary behavior, observed in 78% (7/9) of the studies. The questionnaires measured both behaviors. Furthermore, QOL was measured in 67% (6/9) of the studies, followed by app use and satisfaction in 56% (5/9) of the studies. Less frequently measured outcomes included app adherence in 44% (4/9) of the studies, depression in 33% (3/9) of the studies, and fatigue in 22% (2/9) of the studies.

BCTs Used

Self-monitoring and feedback were the most frequently used in mHealth apps for cancer (8/9, 89% of the studies), followed by goal setting and motivation in 44% (4/9) of the studies each. However, only 22% (2/9) of the studies used knowledge.

Behavioral Theory or Model

Most of the analyzed studies (6/9, 67%) seemed not to be based on common theories. Only 33% (3/9) of the studies reported at least one theory. The only reported theories were Social Cognitive Theory, Goal-Setting Theory, and the comprehensive intervention model. This result is surprising given that most apps used feedback, goal setting, and motivation to conduct behavior change. Therefore, further research could use behavioral theory or models to enhance their apps for this chronic disease. However, in physical interventions (no digital technology involved), some evidence showed that the transtheoretical model combined with other models was successful in breast cancer screening behavior as it is based on the stages of behavior change and interventions can be tailored to each individual, which increases their empowerment to make change [52].

Behavior Change Effectiveness

Cancer-specific mHealth apps helped significantly improve QOL in 44% (4/9) of the studies, followed by changes in anthropometrics in 33% (3/9) of the studies. A total of 11% (1/9) of the studies reported an increase in QOL and a decrease in distress level. In contrast, physical activity and nutritional status were only significantly improved in 22% (2/9) of the studies. Similar to the CVD section, linking BCTs and theoretical frameworks to behavior change and cancer health measures is challenging. Therefore, this area of study should be investigated further.

DM Results

Demographic, Participant, and Study Design Details

In total, 13 studies comprising 1559 patients were included. Of the 13 studies, we analyzed 10 (77%) randomized controlled trials, 1 (8%) single-arm feasibility study, 1 (8%) case report, and 1 (8%) uncontrolled study. The studies included in this review involving nutrition apps for diabetes can be found in Table 3. Overall, there was a diverse population of patients diagnosed with prediabetes (glucose: 5.55-6.94 mmol/L or 100-125 mg/dL; HbA_{1c}: 39-46 mmol/mol or 5.7%-6.4%), type

1 DM, T2DM, and gestational DM (2-hour oral glucose tolerance test level of ≥9 mmol/L). The features of each app included food tracking [53-62], education, knowledge, or recommendations [54-56,59-65], physical activity tracking [54-56,59-62], weight monitoring [56,59-62], glucose monitoring [55,57,60,61,64], blood pressure monitoring [60], community support [54,59,60], feedback [54-56,59,61,62,64], health coaches [55], clinician portals [60-62], connectivity to digital health devices [56,57], scheduled reminders [56,58,59,62], gamification [59,63], and goal setting [59]. In addition, several targeted behavioral domains and outcomes were measured as a result of the mHealth app nutrition intervention. This factor revealed some interesting insights for future investigations into digital health interventions among people with DM.

Table 3. Included studies on diabetes (n=13).

Study	Country	Study design	Purpose	Name of mobile app and features	Behavior change theory or model	Results
Hong et al [53]	Korea	Case study	Examine the effect of a mobile app program ("Diabetes & Nutrition") developed between 2011 and 2012 for self-management in patients with T2DM[a] and recommend important considerations when the mobile app program is developed	Diabetes & Nutrition—all-smartphone app; features: food tracking	None	At 3 months, body weight had decreased by 4.4 kg, waist circumference had decreased by 5 cm, and HbA_{1c} level had decreased from 7.9% to 6.1%. The medication was reduced from the dose of 850 mg to 500 mg of metformin twice a day. Since then, the patient did not continue to use the "Diabetes & Nutrition" app as their level of blood glucose had stabilized and the patient felt that it was inconvenient and annoying to use the program. At 6 months, no significant change in body weight and body composition was observed in comparison with those at 3 months.
Xu et al [54]	China	2-arm RCT[b] with TTM[c]-based social media intervention	Examine the effectiveness of a 6-month mobile-based intervention (DHealthBar, a WeChat applet) combined with behavioral theory compared with a printed intervention in improving dietary behaviors, physical activity, and intention to change these behaviors among populations at high risk of T2DM	DHealthBar—all-smartphone app; features: food and physical activity tracking, knowledge, community support, and coach feedback	TTM	Participants in both groups reported a statistically significant decrease in energy intake at the 2 follow-up assessments compared with baseline. At 6 months, a significantly larger decrease was observed in the intervention group in energy, fat, and carbohydrate intake accompanied by a significantly larger increase in moderate-intensity physical activity compared with the control group. After 6 months of the intervention, participants were more likely to be at higher stages of dietary behaviors and physical activity than the control group.
Koot et al [55]	Singapore	6-month (24-week), single-arm, preintervention (baseline) and follow-up evaluation	Using the RE-AIM[d] evaluation framework, this study assessed the potential effectiveness and feasibility of GlycoLeap, a mobile lifestyle management program for people with T2DM, as an add-on to standard care.	GlycoLeap—all-smartphone app; features: food and physical activity tracking, knowledge, glucose monitoring, and coach feedback	Several theoretical frameworks, including the TTM and Health Belief Model	Program engagement (implementation) started out high but decreased with time for all evaluated components. Self-reported survey data suggest that participants monitored their blood glucose on more days in the previous week at follow-up compared with baseline and reported positive changes to their diet because of app engagement. Statistically significant improvements were observed for HbA_{1c}, with greater improvements for those who logged their weight more often. Participants had a 2.3% reduction in baseline weight. User satisfaction was high, with 74% (59/80) and 79% (63/80) of participants rating the app as good or very good and claiming that they would probably or definitely recommend it to others.
Griauzde et al [56]	United States	12-week, parallel, 3-arm, mixed methods pilot RCT	Examine the feasibility and acceptability of an mHealth[d] intervention designed to increase autonomous motivation and healthy behaviors among adults with prediabetes who had previously declined participation in a diabetes prevention program; in addition, the study aimed to examine changes in autonomous motivation among adults who were offered 2 versions of the mHealth program compared with an information-only control group	mHealth—all-smartphone app; features: food and physical activity tracking, knowledge, weight monitoring, coach feedback, connectivity to digital health devices, and reminders	Self-determination theory	No significant differences were observed in adherence rates between app-only and app-plus participants. Among all participants, mean autonomous motivation measures were relatively high at baseline (6.0 out of a 7.0 scale), with no statistically significant within- or between-group differences in follow-up scores.

Study	Country	Study design	Purpose	Name of mobile app and features	Behavior change theory or model	Results
Torbjørnsen et al [57]	Norway	3-armed RCT with 2 intervention groups and 1 control group	This study aimed to explore associations between the level of acceptability of a mobile diabetes app and the initial ability to self-manage in patients with T2DM.	Diabetes diary app (no name)—all-smartphone app; features: food tracking, glucose monitoring, and connectivity to digital health devices	None	The study found statistically significant associations between 5 of the 8 self-management domains and "perceived benefit," being one of the acceptability factors. However, when adjusting for age, gender, and frequency of use, only 1 domain, "skill and technique acquisition," remained independently associated with "perceived benefit." Frequency of use of the app was the factor that revealed the strongest association with the acceptability domain "perceived benefit." Moreover, an association was revealed between gender and frequency of use where 69% (25/36) of the high-frequency users were men.
Alfonsi et al [58]	Canada	Iterative usability testing (3 cycles)	Test the app's usability and potential impact on carbohydrate counting accuracy	iSpy—all-smartphone app; features: food tracking and reminders	None	Use of iSpy was associated with improved carbohydrate counting accuracy (total grams per meal), reduced frequency of individual counting errors of >10 g, and lower HbA_{1c} levels. Qualitative interviews and acceptability scale scores were positive. Moreover, 43% (9/21) of iSpy participants were still engaged, with use at least once every 2 weeks at the end of the study.
Block et al [59]	United States	Clinical trial	The aim was to evaluate the effectiveness of a fully automated, algorithm-driven behavioral intervention for diabetes prevention, Alive-PD, delivered via the internet, mobile phone, and automated phone calls.	Alive-PD—web-based application; features: food and physical activity tracking, knowledge, weight monitoring, community support, coach feedback, reminders, gamification, and goal setting	Learning theory, Social Cognitive Theory, and theory of planned behavior	Alive-PD participants achieved significantly greater reductions than controls in fasting glucose, HbA_{1c}, and body weight. Reductions in BMI, waist circumference, and TG[e] HDL[f] ratio were also significantly greater in Alive-PD participants than in the control group. At 6 months, the Alive-PD group reduced their Framingham 8-year diabetes risk from 16% to 11%, significantly more than the control group. Participation and retention were good; intervention participants interacted with the program a median of 17 out of 24 weeks, and 71.1% (116/163) were still interacting with the program in month 6.
Kodmaneh et al [63]	Iran	Interventional study	The aim of this study was to evaluate the effect of mobile game-based learning apps on improving dietary information in patients with T2DM.	Amoo—mobile phone game for all smartphones; features: knowledge and gamification	None	The results indicated a statistically significant difference between the pre- and posttest scores in the intervention group. However, there was no significant difference in fasting blood sugar.
Yu et al [60]	China	24-week, 4-arm, parallel group, non-blinded randomized trial	The aim of this study was to evaluate the effects of an MPA[g] combined with or without SMBG[h] on glycemic control in patients with diabetes.	Diabetes-Carer—all-smartphone app; features: food and physical activity tracking; knowledge; weight, blood pressure, and glucose monitoring; community support; and clinician portal	None	The HbA_{1c} levels in patients of all groups decreased significantly from baseline. There were significant differences in the proportions of patients that achieved HbA_{1c} <7% between groups, especially in group C and group D, compared with group A at week 24. 1,5-anhydroglucitol changes were obvious in group A and group C at week 24 from baseline. Factorial ANOVA showed that the MPA intervention was the main effective factor for HbA_{1c} change, and there was no effect on HbA_{1c} change for the SMBG intervention.

Study	Country	Study design	Purpose	Name of mobile app and features	Behavior change theory or model	Results
Garnweidner-Holme et al [64]	Norway	2-arm, multicenter, nonblinded RCT	The study analyzed secondary data from a 2-arm, multicenter, and nonblinded RCT to determine whether a smartphone app with targeted dietary information and blood glucose monitoring had an effect on the dietary behavior of women with GDM[i].	Pregnant+—all-smartphone app; features: knowledge, glucose monitoring, and coach feedback	None	All the participants showed improvements in their HDS-P+[j] from baseline. However, the Pregnant+ app did not have a significant effect on their HDS-P+. The control group reported a higher weekly frequency of choosing fish meals. No other significant differences were found between the intervention and control groups.
Agarwal et al [61]	Canada	Multicenter pragmatic RCT	The primary objective of this study was to conduct a pragmatic RCT of the Bluestar mobile app to determine if app use led to improved HbA_{1c} levels among diverse participants in real-life clinical contexts. The authors hypothesized that this mobile app would improve self-management and HbA_{1c} levels compared with controls.	BlueStar—all-smartphone app; features: food and physical activity tracking, knowledge, weight and glucose monitoring, coach feedback, and clinician portal	TTM	The results of an analysis of covariance controlling for baseline HbA_{1c} levels did not show evidence of intervention impact on HbA_{1c} levels at 3 months. Similarly, there was no intervention effect on secondary outcomes measuring diabetes self-efficacy, quality of life, and health care use behaviors. An exploratory analysis of 57 ITG[k] participants investigating the impact of app use on HbA_{1c} levels showed that each additional day of app use corresponded with a 0.016-point decrease in participants' 3-month HbA_{1c} levels. App use varied significantly by site as participants from one site logged in to the app a median of 36 days over 14 weeks; those at another site used the app significantly less.
Lim et al [62]	Singapore	Randomized clinical trial conducted at multiple primary care centers	Compare the effects of a culturally contextualized smartphone-based intervention with usual care on weight and metabolic outcomes	Nutritionist Buddy Diabetes—all-smartphone app; features: food and physical activity tracking, knowledge, weight monitoring, coach feedback, clinician portal, and reminders	Several theoretical models combined that included accountability, communication, and motivation to help adherence	Compared with the control group, intervention participants achieved significantly greater reductions in weight and HbA_{1c} levels, with a greater proportion experiencing a reduction in diabetes medications at 6 months. The intervention led to a greater HbA_{1c} reduction among participants with HbA_{1c} levels of ≥8%. Intergroup differences favoring the intervention were also noted for fasting blood glucose, diastolic blood pressure, and dietary changes.

Study	Country	Study design	Purpose	Name of mobile app and features	Behavior change theory or model	Results
Juan et al [65]	Spain	Uncontrolled study	Users would have a statistically significant increase in knowledge about the carbohydrate choices of real packaged foods after using the app.	Augmented Reality—all-smartphone app; features: knowledge	None	The results reported that their initial knowledge about carbohydrate choices was very low. This indicates that education about nutritional information in packaged foods is needed. An analysis of the pre- and postknowledge questionnaires showed that users had a statistically significant increase in knowledge of carbohydrate choices after using the app. Gender and age did not influence the knowledge acquired. The participants were highly satisfied with the app.

[a]T2DM: type 2 diabetes mellitus.

[b]RCT: randomized controlled trial.

[c]TTM: transtheoretical model.

[d]RE-AIM: Reach, Effectiveness, Adoption, Implementation, and Maintenance.

[e]TG: triglyceride.

[f]HDL: high-density lipoprotein.

[g]MPA: mobile phone app.

[h]SMBG: self-monitoring of blood glucose.

[i]GDM: gestational diabetes mellitus.

[j]HDS-P+: healthy dietary score for Pregnant+.

[k]ITG: immediate treatment group.

Targeted Behavior and Outcome Measures

The most frequently targeted behaviors were glycemic control measured using HbA_{1c} and DM self-efficacy or self-management in 46% (6/13) of the reviewed studies. In addition, dietary behavior, levels of engagement, user acceptability, or motivation, and weight or BMI were measured in 46% (6/13) of the studies, followed by waist circumference in 23% (3/13) of the studies. Less frequently measured outcomes included physical activity, stages of change, carbohydrate counting accuracy, QOL, health care use behavior, and lipids in 23% (3/13) of the studies.

BCTs Used

Numerous BCTs can be used to induce behavior change. All the DM studies reviewed (13/13, 100%) used knowledge and education, followed by self-monitoring in 77% (10/13) of the studies. Both social support or encouragement and autonomous personalized feedback were used in 54% (7/13) of the studies. Prompts or cues were used in 31% (4/13) of the studies, followed by graded tasks and gamification in 15% (2/13) of the studies. Real-time feedback and goal setting were used in 15% (2/13) of the studies reviewed. Unfortunately, no standard definition of techniques is included in the BCTs, making it challenging to identify the techniques used in the interventions [66].

Behavioral Theory or Model

Some of the analyzed studies (7/13, 54%) seemed not to be based on behavioral theories or models. In total, 46% (6/13) of the studies reported at least one theory. The transtheoretical model was most frequently used in 23% (3/13) of the studies, followed by Social Cognitive Theory, self-determination theory, models centering on cues and triggers, theory of planned behavior, behavioral economics, positive psychology, and motivational interviewing as other reported theories. Some research has shown that Social Cognitive Theory has been used in feasibility studies among populations with diabetes as it can increase confidence and promote greater sustained effort to change, making it a guide for digital technology interventions. This theory also includes skill training, which can benefit diabetes management and education programs [67,68].

Behavior Change Effectiveness

DM-specific mHealth apps improved glycemic control by significantly reducing HbA_{1c} values in 46% (6/13) of the studies. In addition, 15% (2/13) of the interventions [53,62] resulted in a decrease in the medications used for glycemic control. Some studies (6/13, 46%) showed significant engagement; however, 17% (1/6) of these studies showed a decline in engagement over time, and 17% (1/6) did not have follow-up data for engagement. Sustainability needs to be considered for the effectiveness of these types of interventions. There were also significant changes in anthropometrics in 31% (4/13) of the reviewed studies. DM self-efficacy and self-management, decrease in energy intake, and increase in physical activity were observed in 8% (1/13) of the studies. Not all studies analyzed the same outcomes for each intervention, making it difficult to link BCTs and theoretical frameworks to behavior change and health measures.

Obesity Results

Demographic, Participant, and Study Design Details

A total of 18 studies comprising 253,775 patients were included. Among these 18 studies, we analyzed 5 (28%) randomized controlled trials, 5 (28%) experimental studies, 3 (17%) feasibility studies, 2 (11%) observations, and 1 (6%) prospective cohort study. The studies involving nutrition apps among people with obesity can be found in Table 4. The studies focused on obesity prevention and treatment in many diverse populations that ranged in age, socioeconomic background, and physical status (ie, pregnancy and post partum). App features included physical activity tracking [69-78], food tracking [70,72-83], knowledge, education, or recommendations [70,72-76,78,79,82-86], push notifications or scheduled reminders [74-76,78,79,81-84,86], weight monitoring [75,76,78,81,85,86], behavior demonstration [69,75,83], motivational challenges [69,75-78,83], goal setting [69,73-75,78,81,84,85], feedback [69,70,73,75,76,81-83,86], community support [70,75,78,85], connectivity to digital health devices [70,72,81,86], clinician portals [72,73,82], and access to a health coach [76-78,81]. Furthermore, numerous behaviors were targeted, and the outcomes were analyzed to determine the effectiveness of a mobile nutrition intervention in promoting healthy weight. This information will help develop approaches and techniques for digital health behavior change interventions to prevent and treat obesity.

Table 4. Included studies on obesity (n=18).

Study	Country	Study design	Purpose	Name of mobile app and features	Behavior change theory or model	Results
Lubans et al [69]	Australia	Cluster RCT[a]	Focused on the promotion of lifetime (eg, resistance training) and lifestyle (eg, active transport) physical activities and was aligned with current physical activity guidelines, which include a recommendation to engage in muscle- and bone-strengthening physical activities at least 3 days per week	ATLAS[b]—all-smartphone app; features: physical activity tracking, behavior demonstration, challenges, goal setting, and coach feedback	Self-determination theory and Social Cognitive Theory	Focus group participants reported enjoyment of the program and felt that it had provided them with new skills, techniques, and routines for the future. However, their engagement with the smartphone app was limited. Barriers to the implementation and evaluation of the app included limited access to smartphone devices, technical problems with the push notifications, lack of access to use data, and the challenges of maintaining participants' interest in using the app.
Griffin et al [84]	United States	1-group, pre- to posttest study design	To evaluate changes in dietary and physical activity behaviors and weight after implementation of a 12-week SMS text messaging initiative (My Quest)	SMS text messaging initiative (My Quest)—all smartphones; features: knowledge, reminders, and goal setting	Social Cognitive Theory	Participants significantly improved dietary and physical activity behaviors and food environment, increased their dietary and physical activity goal setting, and reduced their body weight. A total of 56 posttest assessments were completed (84% response rate).
Van der Pligt et al [71]	Australia	Pilot intervention study nested within a cluster RCT	Effectiveness of the Mums OnLiNE[c] intervention with respect to reducing PPWR[d] and improving diet, physical activity, and sedentary behavior	Mums OnLiNE Combined and In-FANT Extend[e]—web-based application or smartphone app with telephone-based support; features: physical activity tracking	Social Cognitive Theory	Mean PPWR decreased in the intervention group and the comparison group 2 although the changes were not significant. Mean waist circumference for all groups exceeded recommendations at baseline but decreased to below recommendations for women in the intervention group and significantly for the intervention group compared with comparison groups 1 and 2. Changes in diet, physical activity, or sedentary behaviors were not significant.
Hull et al [79]	United States	Observational design based on data collected after the testing period	This paper describes the development and beta testing of the CHEW[f] smartphone app. The objective of beta testing was to test the CHEW app prototype with target users focusing on use, usability, and perceived barriers and benefits of the app.	CHEW smartphone app—Android-based app; features: food tracking and knowledge	Socioecological model	Study participants used the app on average once a week for approximately 4.5 minutes per session. Use of specific features averaged at 1-2 times per month for shopping-related activities and 2-4 times per month for the snack gallery. Mothers classified as users rated the app's WIC[g] Shopping Tools relatively high on usability and benefits. The Yummy Snack Gallery and Healthy Snacking Tips scored higher on usability than on benefits, suggesting that the nutrition education components may have been appealing.
Bughin et al [72]	France	Randomized controlled study	The aim of this study was to compare the changes in body composition, anthropometric parameters, exercise capacity, and QOL[h] within 12 weeks of patients in the TR[i] program with those of usual care patients with obesity.	TR Program—Android-based or web-based; features: food and physical activity tracking, knowledge, connectivity to digital health devices, and clinician portal	None	No significant group × time interaction was found for fat mass. Compared with the UCG[j], TRG[k] patients tended to significantly improve their waist-to-hip ratios and improved their QOL physical impact. Significant time effects were observed for body composition, 6-minute Walk Test distance, exercise metabolism, sedentary time, and QOL. Adherence (95%) and satisfaction in the TRG were good.

Study	Country	Study design	Purpose	Name of mobile app and features	Behavior change theory or model	Results
Toro-Ramos et al [78]	Korea	Intervention	This study investigated the efficacy of a smartphone intervention using a designated app with a lifestyle intervention–focused approach, including a human coaching element, toward weight loss in Korean adults who were overweight or obese.	Noom—Android- and Apple-based app; features: food and physical activity tracking, knowledge, reminders, weight monitoring, challenges, goal setting, community support, and coach feedback	None	Participants showed a clinically significant weight loss effect of −7.5% at the end of the 15-week program, and at a 52-week follow-up, a weight loss effect of −5.2% was maintained. At 15 weeks, percentage of body fat and visceral fat decreased by −6.0% to –5.4% and −3.4 kg to –2.7 kg, respectively. Fasting blood glucose level also decreased significantly by −5.7 to –14.6 mg/dL at 15 weeks. Lipid parameters showed significant improvements except for high-density lipoprotein cholesterol. The frequency of logging meals and exercise was associated with body fat loss.
Pellegrini et al [70]	United States	6-month technology-supported weight loss trial	Examine within-person variation in dietary self-monitoring during a 6-month technology-supported weight loss trial as a function of time-varying factors, including time in the study, day of the week, and month of the year	ENGAGED[l]—smartphone provided with the app; features: food and physical activity tracking, knowledge, feedback, community support, and connectivity to digital health devices	None	Participants recorded less as time in the study progressed. Fewer foods were reported on the weekends compared with on weekdays. More foods were self-monitored in January compared with in October; however, a seasonal effect was not observed.
Dodd et al [74]	Australia	Multicenter, nested randomized trial	The objective was to evaluate the impact of a smartphone app as an adjunct to face-to-face consultations in facilitating dietary and physical activity change among pregnant women.	Name not provided—smartphone was provided with the app; features: food and physical activity tracking, knowledge, reminders, and goal setting	None	Mean difference in HEI[m] score was 0.01 at 28 weeks of pregnancy and −1.16 at 36 weeks of pregnancy. There was no significant additional benefit from the provision of the smartphone app in improving HEI score. Although all women improved dietary quality throughout their pregnancy, use of the smartphone app was poor.
Stasinaki et al [77]	Switzerland	Unblinded RCT	The objective of the study was to assess novel obesity management that moved the focus from on-site consultations in a specialized childhood obesity center to an appealing, youth-friendly, low-threshold mobile intervention (PathMate2) under the supervision of pediatric obesity experts.	PathMate2—smartphone provided with the app; features: food and physical activity tracking, challenges, and coach feedback	None	At intervention start, median BMI SDS[n] of all patients was 2.61. BMI-SDS decreased significantly in the control group at time 1 but not at time 2 and did not decrease in the intervention group during the study. Muscle mass, strength, and agility improved significantly in both groups at time 2; only the intervention group significantly reduced their body fat at time 1 and time 2. Average daily PathMate2 app use rate was 71.5%. Cortisol serum levels decreased significantly after biofeedback but with no association between stress parameters and BMI-SDS.
Ali et al [73]	UAE[o]	Nonrandomized, 2-arm feasibility study	Develop and test a nutrition education intervention delivered via a website and mobile apps to university students in the UAE who were overweight and obese	Rashakaty-Basic and Rashakaty-Enhanced—web-based application and all-smartphone app; features: food and physical activity tracking, knowledge, goal setting, feedback, and clinician portal	Social Cognitive Theory	There was no significant difference in weight loss between the 2 arms. However, waist circumference decreased more in the Rashakaty-Enhanced group. Changes in knowledge related to sources of nutrients and diet-disease relationships were significantly higher among the Rashakaty-Enhanced group. Rashakaty-Enhanced participants reported increased number of days spent on moderate physical activity and minutes walked. They also reported higher scores in social support from friends to reduce fat intake and from family and friends to increase physical activity.

Study	Country	Study design	Purpose	Name of mobile app and features	Behavior change theory or model	Results
Senecal et al [86]	China	Retrospective observational analysis	To evaluate whether individuals following a weight loss program based on a mobile app, wireless scale, and nutritional program but no face-to-face care could achieve clinically significant weight loss in a large cohort	MetaWell—Android- and Apple-based app; features: knowledge, reminders, weight monitoring, feedback, and connectivity to digital health	None	251,718 individuals (79% female) were included with a mean weight loss of 4.3 kg and a mean follow-up of 120 days. Mean weight loss at 42, 60, 90, and 120 days was 4.1 kg, 4.9 kg, 5.6 kg, and 5.4 kg, respectively. At 120 days, 62.7% of participants had lost at least 5% of their initial weight. Both genders and all use frequencies showed statistically significant weight loss from baseline at each interval, and this loss was greater in men than in women. The frequency of recording was associated with greater weight loss when comparing high-, medium-, and low-use groups at all time intervals investigated.
Delisle Nyström et al [82]	Sweden	2-arm parallel RCT	Investigate the 12-month after-baseline measurements of the MINISTOP[p] intervention	MINISTOP—both web-based application and all-smartphone app; features: food tracking, knowledge, reminders, feedback, and clinician portal	Social Cognitive Theory	At the 12-month follow-up, no statistically significant difference was observed between the intervention and control groups for FMI[q], and no maintained effect for the change in composite score was observed.
Stein and Brooks [81]	United States	Longitudinal observational study	Evaluate weight loss, changes in meal quality, and app acceptability among users of the HCAI[r] with the overarching goal of increasing access to compassionate health care via mHealth[s]	Lark Weight Loss HCAI—Android- and Apple-based app; features: food tracking, reminders, weight monitoring, goal setting, coach feedback, and connectivity to digital health devices	None	Weight loss was 2.38% of baseline weight. The average duration of app use was 15 weeks, and users averaged 103 sessions each. The percentage of healthy meals increased by 31%. The in-app user trust survey had a 100% response rate and positive results, with a satisfaction score of 87 out of 100 and Net Promoter Score of 47.
Prasad et al [80]	United States	Open-label, nonrandomized, prospective 90-day TRE[t] intervention	The primary aim was to test the feasibility of a TRE intervention administered via a smartphone app aimed at reducing the eating window by 4 hours in individuals with a habitually prolonged eating window and determine the efficacy of a 90-day TRE intervention in reducing body weight and blood pressure in adults who were overweight and obese. A secondary aim was to monitor the adherence to the intervention over time.	MyCircadianClock—all-smartphone app; features: food tracking	None	The mean duration of the baseline eating window was 14 hours and 32 minutes (SD 2 hours and 36 minutes), with 56% of participants with a duration of ≥14 hours. TRE participants successfully decreased their eating window from 16 hours and 4 minutes (SD 1 hour and 24 minutes) to 11 hours and 54 minutes (SD 2 hours and 6 minutes) and reduced the number of daily eating occasions by half. Adherence to logging and to the reduced eating window was 64% (SD 22%) and 47% (SD 19%). TRE resulted in decreases in body weight, waist circumference, and systolic blood pressure.
Simpson et al [85]	Scotland	Feasibility RCT	To develop and assess the feasibility and acceptability of an app-, web-, and social support–based intervention in supporting adults with obesity to achieve weight loss goals	HelpMeDoIt!—all-smartphone app and web-based application; features: knowledge, reminders, weight monitoring, goal setting, and community support	Social Cognitive Theory and control theory	Of the 54 (74%) participants who downloaded the app, 48 (89%) used it. Objective physical activity measures perhaps showed the most potential (daily step count [1187 steps] and sedentary time [−60.8 min]). However, these outcomes were poorly completed.

Study	Country	Study design	Purpose	Name of mobile app and features	Behavior change theory or model	Results
Lin et al [75]	United States	RCT	To compare an mHealth intervention delivered via a CP[u] app with usual care controls and compare with an in-person and phone-supplemented personal coaching intervention enhanced by CP self-monitoring with usual care	CITY[v]—all-smartphone app; features: food and physical activity tracking, knowledge, reminders, weight monitoring, behavior demonstration, challenges, goal setting, feedback, and community support	Rooted in theoretical models and behavioral framework	Use of the app was highest during month 1 for both arms; thereafter, use dropped substantially and continuously until the study end. During the first 6 months, the mean percentage of days that any app component was used was higher for the CP arm (74.2%) than for the personal coaching arm (48.9%). The CP arm used the apps an average of 5.3 times per day, whereas the personal coaching participants used them 1.7 times per day. The former self-weighed more than the latter (57.1% of days vs 32.9% of days). Furthermore, the percentage of days that any app component was used, number of app uses per day, and percentage of days self-weighed all showed significant differences across the 4 weight categories for both arms. Pearson correlation showed a negative association between weight change and the percentage of days that any app component was used, number of app uses per day, and percentage of days self-weighed.
Chew et al [76]	Singapore	Prospective single-cohort study	Assess the effectiveness of adolescent engagement with a mobile app–based lifestyle intervention program as an early intervention before enrollment in a clinic-based multidisciplinary weight management program	Kurbo—all-smartphone app; features: food and physical activity tracking, knowledge, reminders, weight monitoring, challenges, and coach feedback	None	Kurbo engagement was high, with 83% (33/40) of participants completing at least 7 coaching sessions. In total, 78% (18/23) of participants rated the app as good to excellent, and 70% (16/23) stated that they would recommend it to others. There were no statistically significant changes in BMI *z* scores at 3 or 6 months. Participants showed statistically significant improvements in measured body fat percentage, self-reported QOL, and self-reported caloric intake from the 3-day food diaries at 3 and 6 months.

Study	Country	Study design	Purpose	Name of mobile app and features	Behavior change theory or model	Results
Kay et al [83]	United States	Randomized controlled feasibility trial	Comparing app-based diet tracking (active comparator) with app-based diet tracking plus feedback on DASH[w] adherence via SMS text message (intervention)	DASH Cloud—all-smartphone app; features: food tracking, knowledge, reminders, behavior demonstration, challenges, and feedback	None	DASH Cloud did not enhance DASH adherence over diet tracking alone but resulted in greater reductions in blood pressure.

Targeted Behavior and Outcome Measures

Anthropometric measurements (ie, weight, BMI, and waist-to-hip ratio) were the most targeted health outcomes, with behavior change in 78% (14/18) of the reviewed studies, followed by diet quality and physical activity in 61% (11/18) of the studies. In addition, engagement, user acceptability, or motivation levels and body composition were measured in 39% (7/18) and 28% (5/18) of the studies, respectively. QOL, behaviors (ie, goal setting and self-efficacy), and CVD measures (ie, blood pressure, heart rate, glucose, and lipids) were included as outcomes in 22% (4/18) of the studies. Less frequent measures included stress parameters (ie, chronic stress and cortisol levels), diet knowledge, reduced screen time, and behavior and health maintenance, observed in 6% (1/18) of the studies.

BCTs Used

BCTs were incorporated into each intervention. Self-monitoring was the most commonly used BCT (14/18, 78% of the reviewed studies), followed by knowledge or education (12/18, 67% of the studies). Goal setting was used in 56% (10/18) of the studies, feedback and encouragement were used in 56% (10/18) of the studies, and prompts or cues and intention formation were used in 50% (9/18) of the studies. Feedback through private messages was used in 39% (7/18) of the studies, followed by community or social support and demonstration of behavior in 33% (6/18) of the studies each. Graded tasks and gamification or incentives were used in 17% (3/18) of the studies. Finally, information about health benefits and consequences was used in 6% (1/18) of the studies in this section. Clinician portals were used in 17% (3/18) of the interventions to improve patient care. Although it is not a BCT, it is worth mentioning as a vital intervention component.

Behavioral Theory or Model

Some interventions (10/18, 56%) did not mention the basis of behavioral theories or models. A total of 6% (1/18) of the studies mentioned that they were rooted in theoretical models but did not specify which ones. Social Cognitive Theory was the most frequently used behavior model in 33% (6/18) of the studies. Self-determination theory was used in 11% (2/18) of the studies, followed by the socioecological model, control theory, and social support theory in 6% (1/18) of the studies. Furthermore, Social Cognitive Theory has been used in feasibility studies on mHealth technology lifestyle interventions for obesity, for example, by using the principle of verbal persuasion through methods such as personalized encouragement that help individuals realize that they have the capability to make the necessary healthy lifestyle changes to lose weight [87].

Behavior Change Effectiveness

Obesity-specific mHealth apps improved weight through significant reductions in 39% (7/18) of the studies. Some studies (4/18, 22%) showed a substantial decrease in body fat percentage and waist circumference. There were also significant changes in cardiovascular measurements (ie, blood pressure and lipids) and QOL in 11% (2/18) of the reviewed studies. Changes in self-efficacy, decreases in energy intake and screen time, and increases in knowledge of nutrients and physical capabilities were observed in 6% (1/18) of the studies. In total, 11% (2/18) of the studies analyzed and reported significance in the maintenance of weight loss, whereas 11% (2/18) of the studies reported a decline in changes over time. The sustainability of these interventions is an area for future research to determine the effectiveness of these types of interventions.

Discussion

Principal Findings

Overall, mHealth apps used for various chronic disease populations did improve health. These studies showed significant improvements in QOL, cardiac rehabilitation completion, glycemic control (ie, HbA_{1c}), weight reduction, and reduction in physiological measures (ie, blood pressure and lipids). In addition, some studies (3/46, 7%) showed improved self-efficacy and self-management of chronic diseases. Although many studies (35/46, 76%) did not measure long-term effectiveness, some (3/46, 7%) showed significance in maintaining weight loss, whereas others (3/46, 7%) showed a decline in changes or engagement in app use over time. A total of 24% (11/46) of the studies measured maintenance of health behavior change. Of these 11 studies, 7 (64%) sustained behavior change for approximately 6 to 12 months, and 4 (36%) showed a decline in behavior change or discontinued app use.

The main difference between the sustainability of health behavior change was the inclusion of a clinician portal or access to a health coach. Griauzde et al [56] measured postintervention qualitative data that provided reasons for app satisfaction, dissatisfaction, and ways to improve. Reasons for satisfaction included "encouraged self-reflection," reasons for app dissatisfaction included "did not consider personal circumstances," and strategies to improve the intervention included "increased interpersonal contact." Of the 46 studies, 9 (20%) included a clinician portal as a feature to enhance the app intervention, allowing for additional communication between clinicians and patients. Of the 9 studies, 7 (78%) had an effective health behavior change. Silk et al [88] reported acceptability and easy-to-use features regarding the integration of the clinician portal into their mHealth intervention. This component should be considered for health behavior change interventions and investigated further.

Of the 46 nutrition apps in this review, 37 (80%) included some type of self-monitoring feature. Of those 37 apps, 35 (95%) had at least one significant improvement or good usability rating to promote engagement with mobile apps for chronic disease self-management. This is in alignment with other research that shows that the most common self-management application for mHealth is a tracking feature [89]. In addition, when surveying clinicians working in diabetes and weight management patient care settings, the most adoptable apps included self-monitoring features [90]. However, the apps that did not include self-monitoring or tracking features showed significant improvements as well. In addition, there was variability in other features combined with tracking features (ie, knowledge, goal setting, coach feedback, and clinician portals), making it difficult to attribute behavior change to self-monitoring features alone. More research is needed to correlate specific features with health behavior change.

Except for cancer populations, a key finding in this review was that 41% (19/46) of the nutrition app interventions targeted weight management, and 58% (11/19) of those studies were effective in health behavior change. This finding is similar to that of Fakih El Khoury et al [91], who reported that dietary mobile apps positively affected measured nutritional outcomes in chronic diseases, especially weight loss. The key finding for cancer populations was that mHealth nutrition apps can significantly improve QOL. A similar result was found in a review analyzing the use of mHealth involving nutrition in a chronic kidney disease population [92]. A total of 28% (13/46) of the studies examined changes in glycemic control, HbA_{1c}, and other biometric measurements (ie, blood pressure and lipids). In total, 69% (9/13) of those studies showed a significant reduction in their measurements when using a nutrition app in their intervention. In addition, 15% (2/13) of those studies showed a decrease in medication treatment for glycemic control [53,62]. Eberle et al [93] concluded that mHealth apps with a nutrition intervention effectively enhanced diabetes management, which is comparable with our review results.

There was diversity in the chronic disease state; study design; number of participants; and variety of in-app features, BCTs, and behavior models used in the studies. However, linking these factors to a particular behavior change and health outcome posed to be difficult, which is not different from Taj et al [94] in their review of digital health behavior change technology. This review provides insight into the theories and theoretical frameworks or models used in nutrition-focused mHealth interventions to increase understanding and translate them into practice, which is essential for developing behavior change for the sustainability of health improvement. For example, this scoping review found that most apps used BCTs, such as self-monitoring in 80% (37/46) of the interventions, knowledge in 72% (33/46) of the interventions, feedback in 54% (25/46) of the interventions, and goal setting in 20% (9/46) of the interventions, for effective health behavior change, as another review [31] demonstrated.

In addition, our review found that less than half (19/46, 41%) of the studies based their nutrition apps on a behavioral theory or its constructs. Some studies (14/46, 30%) that based their interventions on theories had improved engagement, satisfaction, or app use among participants and suggested that incorporating a behavioral theory in mHealth interventions is an effective strategy, which is a comparable finding with that of another review [91]. However, other factors play a role in usability, acceptability, and overall user satisfaction. The app features, BCTs, and theory-based interventions will all affect the effectiveness of mHealth nutrition apps in health behavior change toward chronic diseases.

Another significant development in the sector of health technology is that smartphones can also be embedded with sensors or coupled with wearable sensors for health monitoring, which could enhance a nutrition app's effectiveness in health behavior change. Examples of these devices that could be coupled with nutrition apps include motion sensors such as accelerometers, gyroscopes, and magnetometers that measure motion and physical activity [95]; wearable devices such as glasses (analyzing the intake pattern with smart glasses) and rings (ring-type tactile sensors to detect food mass) for food intake measurement [96]; portable and handheld single-lead electrocardiogram devices in addition to fitness trackers to measure heart rate and heart rate variability [95]; wristwatches to measure glucose levels extracted from skin interstitial fluid through reverse ionophoresis or through saliva-, sweat-, or tear-based wearable biosensors [97]; a wrist-wearable watch with the function of a pulsimeter without a cuff to measure blood pressure [97]; and ingestible capsules that can be used for medical health monitoring [98]. These enhance personal health care and performance monitoring with the potential to complement nutrition apps and have a broad impact on our society.

Limitations

Although the results of this study showed health improvements achieved when using mHealth nutrition apps for behavior change in chronic diseases, some limitations need to be addressed. An important limitation is the lack of research on mobile apps' long-term effects (>1 year) on disease state populations. Therefore, there is no conclusive result on their long-term behavior change to determine whether the behavior continues to improve or reverses compared with the baseline. Consequently, there need to be more long-term studies conducted. Second, many studies (24/46, 52%) did not include a control group for comparison, and their sample size was small, limiting the interpretation of the results of the studies. Third, many apps are at risk of becoming rapidly obsolete owing to the fast pace at which technologies progress and, therefore, new technological innovations must be considered [8]. For example, the latest mobile technologies can connect and interact with each other, update and track personal health data in real time, and send alerts to users [8]. Similarly, most health apps have encountered serious usability problems or have not undergone usability assessment [99]. Usability affects the efficiency and efficacy of the app (ie, time to complete tasks and errors) [8]. Usability must be considered to increase the chance of the app being successfully adopted by patients [8]. Barriers to using mHealth apps include the patient's lack of integration of technology into everyday life [12] and difficulties using mobile apps [11]. In the older adult population, health problems such as cognitive changes related to aging, disability, and lack of confidence are reasons for not using digital technology [18,19]. Further research is needed to evaluate patients' experiences with apps and the benefits gained as a result. There could be a slight bias from the user perspective as there were 2% (1/46) of apps that were Android-only or web-based applications. The others (45/46, 98%) were web-based applications or all-smartphone apps. There were a few apps (4/46, 9%) that were provided through the smartphone that participants were given as part of the study, and the smartphone was not specified. A few studies (4/46, 9%) did not report the data privacy rules or the effects of users and funders on the app interventions. In addition, there are important confidentiality and funding issues that must be considered when designing interventions [100]. Finally, proficient health care providers should be involved in the app development stage to address safety during self-management and health education [101]. There is a need for comprehensive, efficient, and flexible mobile apps for the self-management of disease states with more features to increase the number of long-term users and induce better self-management and patient empowerment [101,102]. We did not conduct a systematic review or meta-analysis and, thus, did not weigh the quality of evidence or study design against the reported results. Some studies (6/46, 13%) included few participants, and the diversity of study objectives, designs, and outcomes made it difficult to compare them. We reviewed the current evidence to expand the knowledge base regarding the impact of nutrition apps on chronic disease management and assess the effectiveness of health behavior change.

Conclusions

In this scoping review, the use of mHealth nutrition apps and their effects on health behavior change were analyzed for 4 diseases (ie, cancer, CVD, DM, and obesity). The results suggest that mHealth apps involving nutrition can significantly improve health outcomes for people with chronic diseases. The study design, demographics, targeted behavior, health outcomes, BCTs, behavioral theories, and behavior change effectiveness were profoundly diverse among these studies, indicating that a *one-size-fits-all* approach for designing and implementing nutrition apps as part of chronic disease treatment is not possible. Tailoring nutrition apps to specific populations is recommended for effective behavior change and improvement of health outcomes. In addition, some studies (7/46, 15%) showed sustained health behavior change, and some (4/46, 9%) showed a decline in the use of the nutrition apps. These results indicate a need for further investigation on the sustainability of the health behavior change effectiveness of disease-specific nutrition apps.

Abstract

Background: The World Health Organization recommends that all adults with HIV adhere to antiretroviral therapy (ART). Good adherence to ART is beneficial to patients and the public. Furthermore, mHealth has shown promise in improving HIV medication adherence globally.

Objective: The aim of this meta-analysis is to analyze the effectiveness of mHealth on adherence to antiretroviral therapy in patients living with HIV.

Methods: Randomized controlled trials (RCTs) of the association between mHealth and adherence to ART published until December 2021 were searched in electronic databases. Odds ratios (ORs), weighted mean differences, and 95% CIs were calculated. This meta-analysis was performed using the Mantel-Haenszel method or the inverse variance test. We evaluated heterogeneity with the I^2 statistic. If I^2 was ≤50%, heterogeneity was absent, and a fixed effect model was used. If I^2 was >50%, heterogeneity was present, and a random effects model was used.

Results: A total of 2163 participants in 8 studies were included in this meta-analysis. All included studies were RCTs. The random effects model was used for a meta-analysis of the effects of various intervention measures compared to routine nursing; the outcome was not statistically significant (OR 1.54, 95% CI 0.99-2.38; *P*=.05). In the subgroups, only short messaging service (SMS)-based interventions significantly increased adherence to ART (OR 1.76, 95% CI 1.07-2.89; *P*=.03). Further analysis showed that only interactive or bidirectional SMS could significantly increase ART adherence (OR 1.69, 95% CI 1.22-2.34; *P*=.001). After combining the difference in CD4 cell count before and after the interventions, we concluded that there was no statistical heterogeneity among the studies (I^2=0%; tau^2=0.37; *P*=.95).

Conclusions: Interactive or bidirectional SMS can enhance intervention effects. However, whether mHealth can improve adherence to ART in patients with HIV needs further study. Owing to a lack of the required significant staff time, training, and ongoing supervision, there is still much more to do to apply mHealth to the clinical use of ART for patients living with HIV.

KEYWORDS

HIV; mHealth; antiretroviral therapy; meta-analysis

Introduction

HIV is a public health issue that every country needs to address. There were an estimated 37.7 million people living with HIV at the end of 2020 [1]. The World Health Organization (WHO) recommends that all adults with HIV should adhere to antiretroviral therapy (ART) [2]. ART does not cure HIV infection but strongly suppresses viral replication within a person's body and modifies HIV from a terminal illness to a manageable chronic disease [3]. One of the most significant factors in the effectiveness of ART is adherence [4]. Good adherence to ART is beneficial to patients and public health [5,6]. In contrast, lack of adherence increases the risk of progression to AIDS and the creation of drug-resistant strains of HIV [7]. Therefore, it is important to promote ART adherence through special techniques [8,9]. However, traditional ART adherence interventions are limited in their ability to maintain behavior modification [10]. Mobile health (mHealth) technology, which refers to the use of mobile and wireless technologies to improve health, has shown promise in improving HIV medication adherence, both globally and domestically [6,11,12]. Therefore, we performed a meta-analysis of the effectiveness of mHealth for improving adherence to ART in patients living with HIV.

Methods

Ethical Considerations

This paper contains no primary data obtained directly from research participants. Data obtained from previously published resources have been acknowledged with references. Ethical approval was not required.

Protocol Registration

The review protocol was prospectively registered with PROSPERO (International Prospective Register of Systematic Reviews; CRD42022358774).

Search Strategy

This meta-analysis was performed according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement guidelines [13]. Searching was conducted using the electronic databases PubMed, EMbase, CINAHL, ScienceDirect, the Cochrane Library, Web of Science, and ClinicalTrials.gov to identify original articles meeting the evaluation criteria for inclusion and exclusion published until December 2021. Searching was conducted and evaluated by 2 independent reviewers. The search strategy for identifying studies included the key terms *mobile health*, *human immunodeficiency virus*, *medication adherence*, *randomized controlled trial*, and other related terms. These keywords were also combined using the OR and AND operators (Multimedia Appendix 1).

Inclusion and Exclusion Criteria

The screening process was divided into 2 phases: a preliminary selection by title and abstract and a second phase that screened the full text of the remaining articles. Articles were included based on the following criteria: (1) they reported the results of a randomized controlled trial (RCT); (2) they included HIV-positive persons receiving antiretroviral treatment regardless of age, sex, or nationality; (3) the intervention measures included, but were not limited to, short message service (SMS) texts and voice calls; (4) an mHealth intervention was used in the experimental group with no limits on intervention frequency, time, content, or period and the control group received routine nursing at the same time to help patients improve their treatment compliance; and (5) the primary outcome was adherence to ART. This was measured directly (eg, by pill count) or indirectly (eg, by self-reporting). If the article reported the use of a variety of measurement methods, priority was given to measurement results obtained with the self-report method. The secondary outcome was CD4 cell count.

The exclusion criteria included the following: (1) the study was a duplicate, (2) the study was a systematic review or meta-analysis, (3) the study was missing outcome measures, (4) the experimental group used a variety of interventions, and (5) the control group did not receive routine nursing.

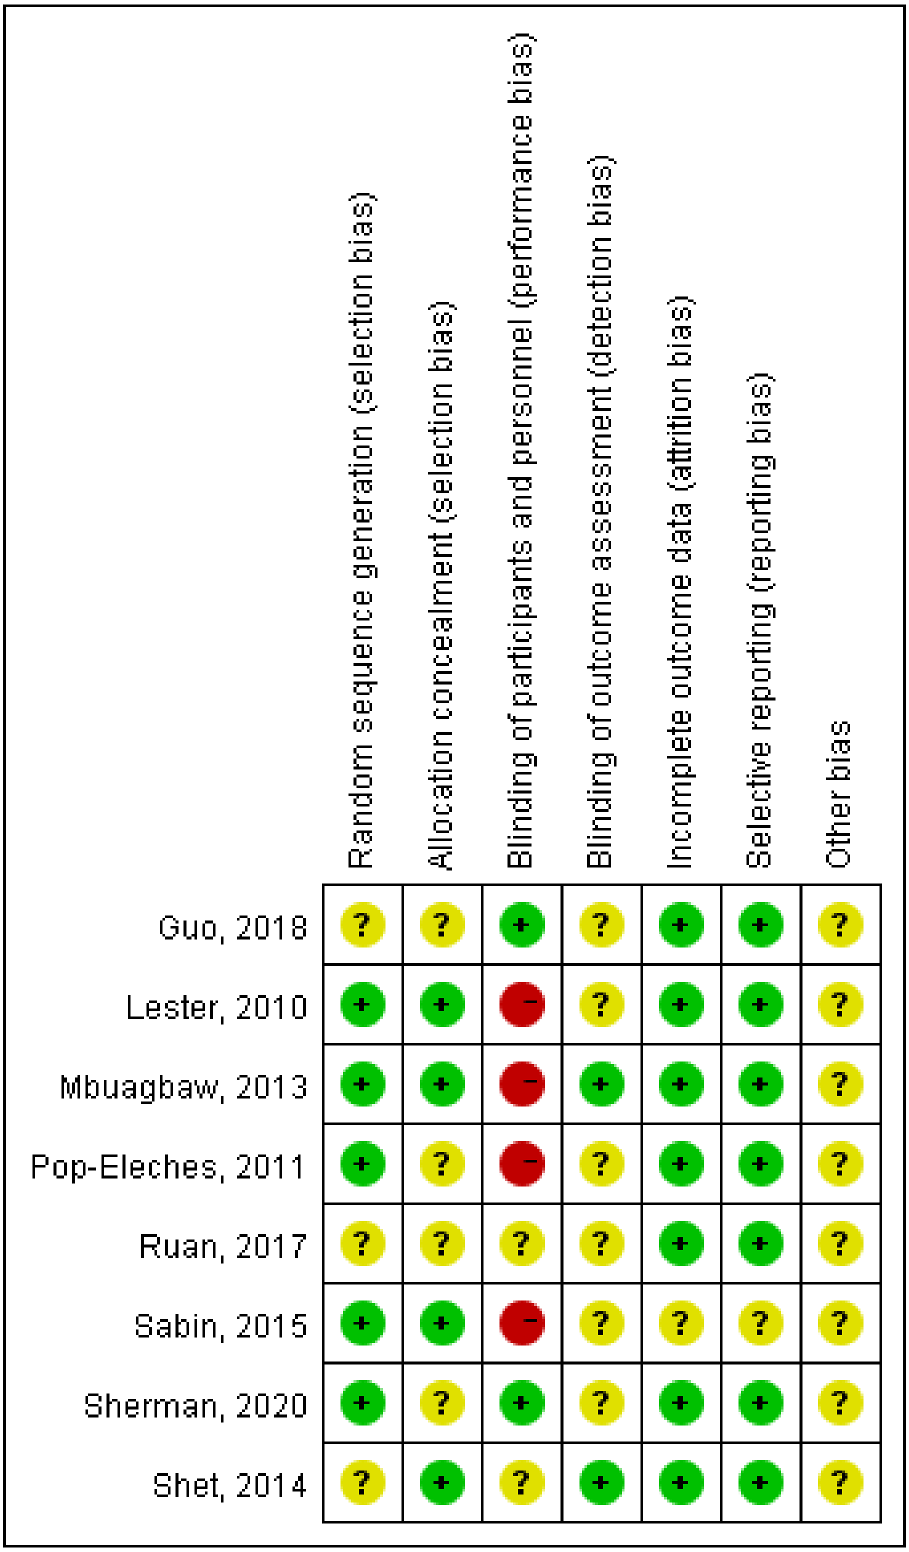
Data Extraction

A predesigned Excel sheet was used to extract and organize the data into categories by 2 independent researchers. These data included (1) authors, (2) location, (3) publication date, (4) intervention details (ie, intervention mode and duration), (5) outcome measures, including ART adherence and CD4 cell counts, and (6) risk of bias.

Risk of Bias and Quality Assessment

Two of the authors assessed the risk of bias using RevMan (version 5.4; Cochrane Collaboration); the results are summarized in Figure 1. The Cochrane Collaboration's Risk of Bias tool was also used to assess quality and risk of bias. This tool assesses bias in 7 domains: random sequence generation (for selection bias), concealment of the allocation sequence (for selection bias), blinding of participants and personnel (for performance bias), blinding of outcome assessment (for detection bias), incomplete outcome data (for attrition bias), selective outcome reporting (for reporting bias), and other biases. Studies are assigned a low risk of bias, an unclear risk of bias, or a high risk of bias.

Figure 1. Risk of bias of the studies included in the meta-analysis. Green indicates a low risk of bias, yellow indicates an unclear risk of bias, and red indicates a high risk of bias.



Data Analysis

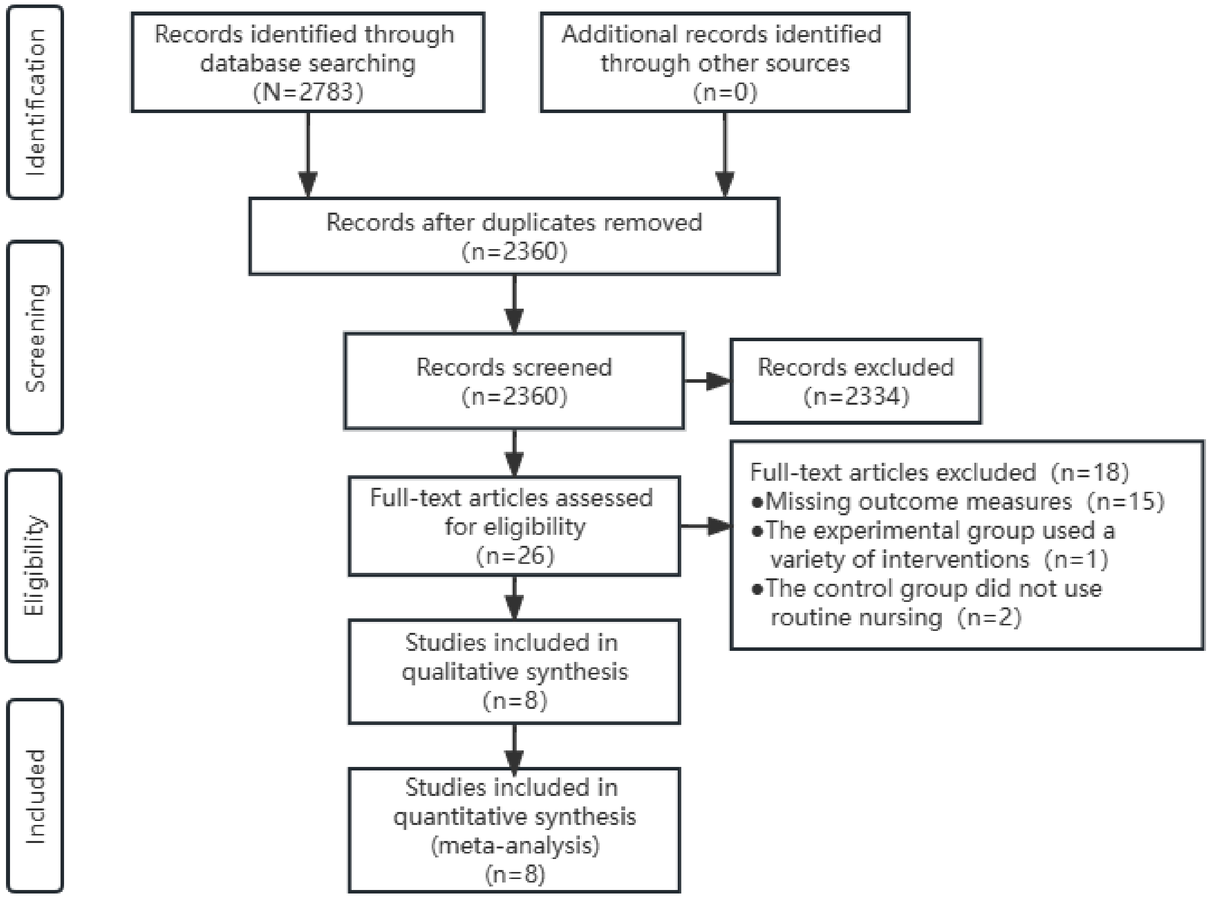
The meta-analysis was conducted using RevMan. Measures of effect are presented as odds ratios (ORs) with the 95% CI. For continuous data, we calculated the sample-size weighted mean difference (WMD). This meta-analysis was performed using the Mantel-Haenszel method or the inverse variance test. We evaluated heterogeneity with the I^2 statistic. If I^2 was ≤50%, heterogeneity was absent, and a fixed effect model was used. If I^2 was >50%, heterogeneity was present, and a random effects model was used.

Results

Study Selection Process

The search strategy identified 2783 articles from the electronic databases. In total, 423 articles were excluded because of duplication. We screened the titles and abstracts of the remaining articles and included 26 for full-text review based on the inclusion and exclusion criteria. Of these 26 studies, 8 met the inclusion criteria, and 18 studies were excluded: 15 because they were missing outcome measures, 1 because a variety of interventions were used in the experimental group, and 2 because they did not use routine nursing in the control group. Therefore, 8 studies were selected for the current meta-analysis [4,9,14-19] (Figure 2).

Figure 2. Flow chart of study selection for the meta-analysis.



Study Characteristics

The characteristics of the studies are summarized in Table 1. All included studies were RCTs. A total of 2163 participants in 8 studies were included in this meta-analysis. Except for the study by Mbuagbaw et al [19], all participants in the studies were aged 18 years or older. Study duration ranged between 1 and 12 months. SMS was used as the basis for the intervention in 6 studies. One of these studies used an mHealth intervention program that included text messages and WeChat. The remaining studies used voice calls.

Table 1. Characteristics of the included studies. All studies used routine nursing in the control group.

First author, year	Location	Participants, n (age, years)	Recruitment period (duration)	Intervention	Outcome measures
Ruan, 2017 [4]	Hengyang, China	100 (≥18)	Mar 2013-Mar 2014 (6 months)	SMS[a]	ART[b] adherence measured by VAS[c], Community Programs for Clinical Research on AIDS Antiretroviral Medication Self-Report, and CD4 cell count
Guo, 2018 [14]	South China	53 (≥18)	Oct 2016-Mar 2017 (3 months)	SMS and WeChat	CD4 cell count
Shet, 2014 [15]	South India	631 (18-60)	Jul 2010-Aug 2011 (6 months)	Customized motivational voice call	ART adherence measured by pill count
Sherman, 2020 [16]	South Florida, US	94 (>18)	Sept 2011-Apr 2014 (3-6 months)	Automated 1-way medication reminders delivered via SMS	ART adherence measured by VAS and CD4 cell count
Lester, 2010 [17]	Kenya	538 (>18)	May 2007-Oct 2008 (12 months)	SMS	ART adherence measured by self-report
Sabin, 2015 [9]	Guangxi, China	119 (≥18)	Dec 2012-Apr 2013 (6 months)	SMS	ART adherence measured by a medication device
Pop-Eleches, 2011 [18]	Kenya	428 (>18)	Jun 2007-Aug 2008 (3-12 months)	SMS	ART adherence measured by a medication event monitoring system and CD4 cell count
Mbuagbaw, 2013 [19]	Cameroon	200 (≥21)	Nov 2010-Dec 2010 (3-6 months)	Weekly standardized motivational text message	VAS and self-reported adherence

[a]SMS: short message service.

[b]ART: antiretroviral therapy.

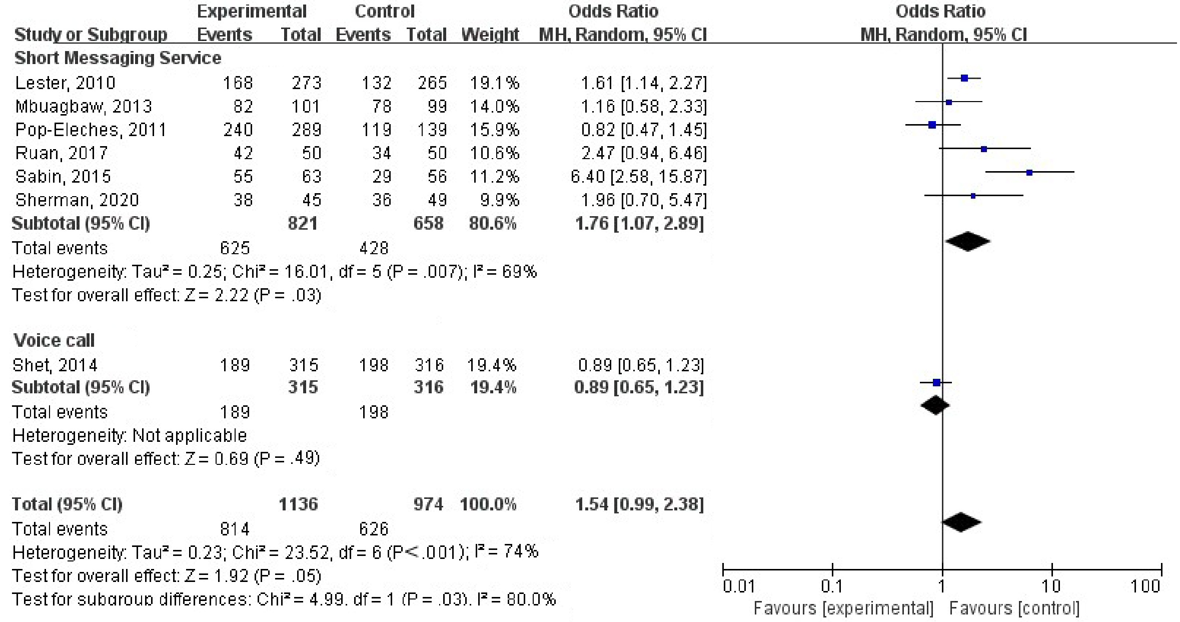
[c]VAS: visual analog scale.

Meta-analysis

Medication Adherence

Adherence to ART was measured as a primary outcome in 7 studies. The method and frequency of measuring adherence varied across the studies. The details are listed in Table 1. A random effects model was used for a meta-analysis of the effects of various intervention measures and routine nursing; the outcome was not statistically significant (OR 1.54, 95% CI 0.99-2.38; *P*=.05). There was also evidence of heterogeneity among the studies (I^2=74%; tau^2=0.23; *P*<.001; Figure 3). In the subgroups, only SMS interventions significantly increased adherence to ART (OR 1.76, 95% CI 1.07-2.89; *P*=.03).

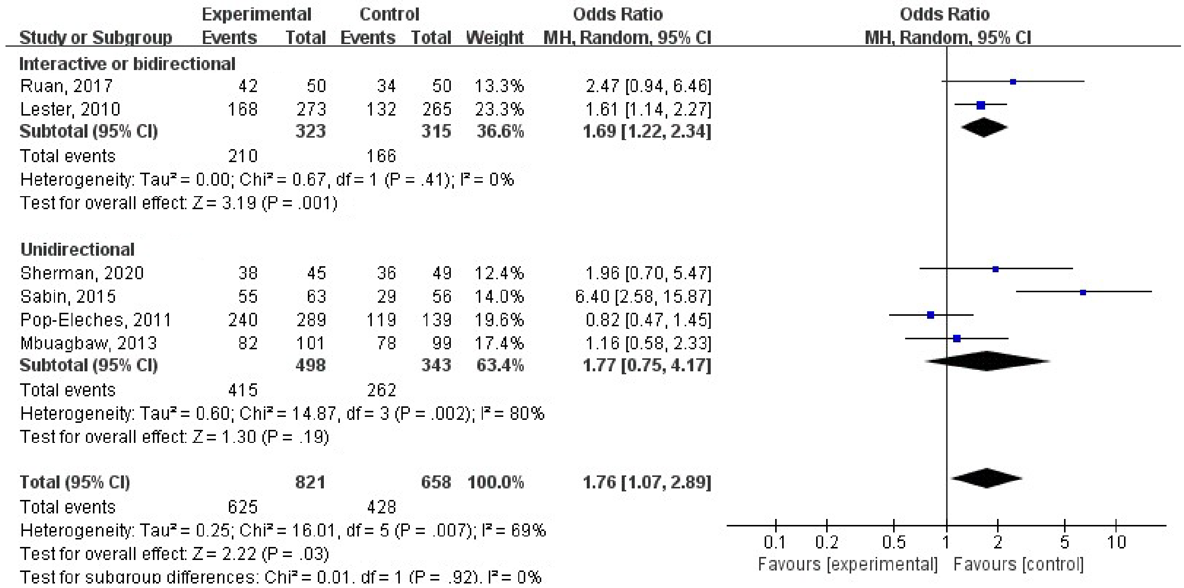
Figure 3. Forest plot of odds ratios with 95% CIs for the effect of various intervention measures and routine nursing on adherence to antiretroviral therapy. MH: Mantel-Haenszel method.



Medication Adherence With SMS Intervention

Six studies were included in a meta-analysis of the effect of SMS on adherence to ART; this showed that SMS could improve adherence (OR 1.76, 95% CI 1.07-2.89; *P*=.03) but also revealed considerable heterogeneity among the included studies (I^2=69%; tau^2=0.25; *P*=.007; Figure 4). In the subgroups, only interactive or bidirectional SMS interventions could significantly increase ART adherence (OR 1.69, 95% CI 1.22-2.34; *P*=.001). However, these studies did not show statistical heterogeneity (I^2=0%; tau^2=0.00; *P*=.41). A subgroup analysis of studies with unidirectional SMS interventions showed no statistical heterogeneity, but the analysis also showed a lack of effect in improving adherence (Figure 4).

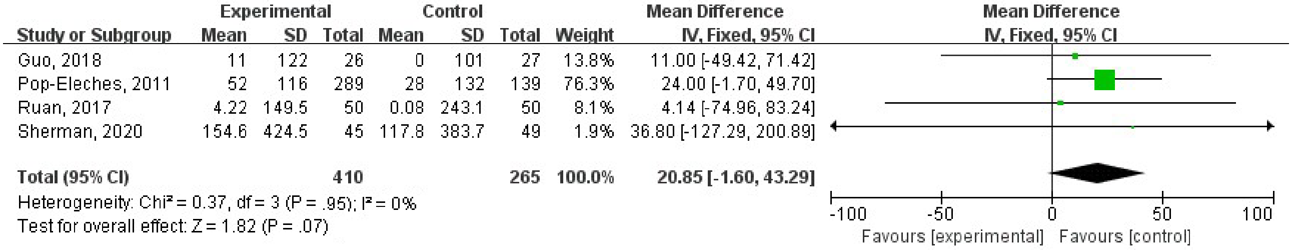
Figure 4. Forest plot of odds ratios with 95% CIs for the effect of short message service interventions on adherence to antiretroviral therapy. MH: Mantel-Haenszel.



CD4 Cell Count

Four studies reported CD4 cell count as a secondary outcome of medication adherence. Combining the differences in CD4 cell count before and after the interventions revealed no statistical heterogeneity among the studies (I^2=0%; tau^2=0.37; *P*=.95; Figure 5). Meta-analysis showed that CD4 cell count measures after mHealth interventions revealed no significant difference in medication adherence among HIV patients compared with routine nursing (WMD=20.85, 95% CI 1.60-43.29; *P*=.07; Figure 5). Only 2 studies reported viral load as an outcome to evaluate the intervention effect, so we did not perform a meta-analysis.

Figure 5. Forest plot of pooled odds ratios with 95% CIs for the effect of mHealth interventions on CD4 cell count. IV: inverse variance.



Discussion

Principal Findings

A total of 2163 participants in 8 studies were included in this meta-analysis. The main result of the meta-analysis was that the pooled OR was 1.54. However, the outcome was not statistically significant, and there was considerable heterogeneity among the studies (I^2=74%). Within-study heterogeneity reduces study robustness and relevance [20]. Our current results are different from those of a 2015 study [21]. That study found that mHealth interventions did seem to have been beneficial. We speculate that one of the possible reasons for this difference is that the number of articles included in our study was limited. Also, the different studies used a variety of methods to measure results. However, compared with the 2015 study, this meta-analysis combined the outcomes (separately for primary and secondary outcomes) to increase the reliability of the results.

A subgroup analysis showed that SMS interventions improved adherence to ART. Further analysis suggested that interactive or bidirectional SMS interventions could enhance intervention effects. This result matches that of a 2014 study [22]. Interactive or bidirectional SMS could increase medication adherence by enhancing engagement and the patient-provider relationship. Follow-up research could further study the content, time, and frequency of text messages. In this study, due to limitations arising from incomplete reporting of the relevant content, these aspects of the intervention were not analyzed.

CD4 cell count and viral load are good indicators of treatment success [23]. Several previous reviews did not obtain the same results as this study for CD4 cell count. One study [22] showed that compared to a control group, a group receiving text message–based support was more likely to maintain an adherence threshold at follow-up and meet the clinical goal of a higher CD4 cell count. However, another study [24], like ours, did not obtain this result. Our meta-analysis of the 4 studies that reported CD4 cell count showed considerable heterogeneity and no significant pooled mean difference. This may be attributable to the heterogeneity of the studies. We did not perform a meta-analysis of studies that measured viral load, as there was an insufficient number of these studies.

The WHO recommends mHealth strategies for improving ART adherence [25]. At the same time, against the background of the coronavirus epidemic, telemedicine has gradually continued to develop [26]. Currently, 95% of people use mobile phones and 77% of people use smartphones in different parts of the world [27]; mHealth has shown promise in increasing the accessibility of self-management interventions [28] and improving HIV health outcomes [6]. At the same time, research has indicated that patients living with HIV are interested in mobile apps to support HIV self-management [29]. However, most current mHealth interventions lack functionality, offering only medication reminders [28] or voice calls. Therefore, more comprehensive mHealth interventions that address multiple self-management needs of patients living with HIV are needed [30]. At the same time, the implementation of ART interventions in real-world clinical settings has been severely limited by a lack of the resources required to initiate and maintain the interventions [31], such as staff time, training, and ongoing supervision. Future research should focus on how to apply personalized mHealth interventions to the management of patients living with HIV.

Limitations

There are several limitations of the current review. The interventions used in the included studies differed in form and frequency. At the same time, these studies used diverse methods for measuring their primary outcomes. This may have produced bias. The robustness and relevance of results increase with the number of distinct outcome measures that show the same result [20]. However, few of the included studies reported CD4 cell count or viral load, and our analysis of these outcomes is thus insufficient.

Conclusion

Interactive or bidirectional SMS interventions can enhance intervention effects. However, whether mHealth can improve adherence to ART in patients with HIV is a question that needs further study. Owing to a lack of staff time, training, and ongoing supervision, there is still much work to be done to use mHealth in the clinic for ART adherence among patients living with HIV.

Abstract

Background: Chronic pain (CP) is 1 of the leading causes of disability worldwide and represents a significant burden on individual, social, and economic aspects. Potential tools, such as mobile health (mHealth) systems, are emerging for the self-management of patients with CP.

Objective: A systematic review was conducted to analyze the effects of mHealth interventions on CP management, based on pain intensity, quality of life (QoL), and functional disability assessment, compared to conventional treatment or nonintervention.

Methods: PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) guidelines were followed to conduct a systematic review of randomized controlled trials (RCTs) published in PubMed, Web of Science, Scopus, and Physiotherapy Evidence Database (PEDro) databases from February to March 2022. No filters were used. The eligibility criteria were RCTs of adults (≥18 years old) with CP, intervened with mHealth systems based on mobile apps for monitoring pain and health-related outcomes, for pain and behavioral self-management, and for performing therapeutic approaches, compared to conventional treatments (physical, occupational, and psychological therapies; usual medical care; and education) or nonintervention, reporting pain intensity, QoL, and functional disability. The methodological quality and risk of bias (RoB) were assessed using the Checklist for Measuring Quality, the Oxford Centre for Evidence-Based Medicine Levels of Evidence, and the Cochrane RoB 2.0 tool.

Results: In total, 22 RCTs, involving 2641 patients with different CP conditions listed in the *International Classification of Diseases 11th Revision* (ICD-11), including chronic low back pain (CLBP), chronic musculoskeletal pain (CMSP), chronic neck pain (CNP), unspecified CP, chronic pelvic pain (CPP), fibromyalgia (FM), interstitial cystitis/bladder pain syndrome (IC/BPS), irritable bowel syndrome (IBS), and osteoarthritis (OA). A total of 23 mHealth systems were used to conduct a variety of CP self-management strategies, among which monitoring pain and symptoms and home-based exercise programs were the most used. Beneficial effects of the use of mHealth systems in reducing pain intensity (CNP, FM, IC/BPS, and OA), QoL (CLBP, CNP, IBS, and OA), and functional disability (CLBP, CMSP, CNP, and OA) were found. Most of the included studies (18/22, 82%) reported medium methodological quality and were considered as highly recommendable; in addition, 7/22 (32%) studies had a low RoB, 10/22 (45%) had some concerns, and 5/22 (23%) had a high RoB.

Conclusions: The use of mHealth systems indicated positive effects for pain intensity in CNP, FM, IC/BPS, and OA; for QoL in CLBP, CNP, IBS, and OA; and for functional disability in CLBP, CMSP, CNP, and OA. Thus, mHealth seems to be an alternative to improving pain-related outcomes and QoL and could be part of multimodal strategies for CP self-management. High-quality studies are needed to merge the evidence and recommendations of the use of mHealth systems for CP management.

Introduction

Chronic pain (CP) is a leading cause of disability worldwide [1], affecting approximately 20% of the global population [2]. Moreover, in developed countries, up to 1 of 5 adults suffers from CP of any type [3]. This condition implies a substantial burden for people, and it also has a social and economic impact on health care systems and employment activity [2]. In fact, although the direct health care costs of managing CP conditions are important, the indirect costs, such as disability compensation and work absenteeism, are higher [4].

CP is defined as pain that persists or recurs for longer than 3 months, including a broad range of pain conditions collected in the *International Classification of Diseases 11th Revision* (ICD-11) [5]. It is a new and pragmatic classification system to apply in primary care and clinical settings for specialized pain management [6]. Current pain management interventions are based on multimodal and biopsychosocial models, which include pain education programs, exercise programs, cognitive and behavioral strategies, relaxation techniques, goal setting strategies, self-monitoring symptoms, and self-tailoring strategies [7-9]. Moreover, emotional distress, functional disability, and sleep disturbances are closely linked to the perception of pain and the pain-related outcomes in patients with CP [10,11]. Therefore, strategies for CP management should address all biopsychosocial aspects of this health condition.

Recently, innovative and potential alternatives to support the self-management of patients with CP have emerged, such as mobile device–based health care, or mobile health (mHealth) [12]. mHealth involves the practice of medicine and public health based on mobile devices to improve and promote health status [13]. According to the target of mHealth systems in CP, they can be grouped into 3 categories [12,14]: (1) education, including general information about pain, symptom identification, and treatment planning; (2) monitoring, tracking daily pain episodes and severity, symptoms, mood, activity, and medication use; and (3) treatment, involving several management strategies. These systems empower patients to become more engaged and encourage self-management [15], improving some pain-related outcomes. In line with this, several pain-related apps have been identified from scientific databases and app stores for the management of a wide range of pain (chronic and acute) conditions [16,17]. Nevertheless, there is a lack of scientific and health professional support in many of the mHealth systems, highlighting the need for developing appropriate apps based on the patient's requirements, also in the management of CP [18].

The available evidence points out promising effects of internet-delivered interventions on different biopsychosocial aspects of CP. Gandy et al [19] studied the use of these interventions using any type of device and technology for CP, showing small effects on pain intensity and disability outcomes in patients with mixed CP conditions, chronic low back pain (CLBP), fibromyalgia (FM), arthritic conditions, peripheral neuropathy, spinal cord injury, migraine, and chronic pancreatitis. In a similar vein, Moman et al [14] discussed the effects of both electronic health (eHealth), based on web apps, and mHealth technologies in patients with CP (general CP, CLBP, FM, and osteoarthritis [OA]), showing significant improvements in pain intensity outcomes at short-term follow-up. Nevertheless, the study was mainly based on eHealth systems, and few findings were obtained from mobile apps. Du et al [20] analyzed the use of web-health-based interventions and mHealth interventions in patients with CLBP, showing better effects on both pain and disability outcomes in favor of mHealth systems. According to the effects of mHealth, a recent review [21] evaluated the effectiveness of app-based interventions on several CP conditions (general CP, CLBP, chronic neck pain (CNP), rheumatoid arthritis, OA, menstrual pain, frozen shoulder pain, and migraine), stating that these apps are significantly more effective, with a small effect size in reducing pain in comparison to control groups. Thurnheer et al [22] analyzed the efficacy of app usage in the management of patients with cancer and noncancer pain (chronic cancer pain, general CP, CLBP, CNP, menstrual pain, and acute pain), reporting beneficial effects on pain, particularly in an out-clinic setting. The evidence of the use of mHealth systems is still emerging and focusing mainly on its effects on pain intensity. Moreover, commonly studied pain conditions (cancer and noncancer pain) and different types of pain (acute and chronic) are mixed, leading to heterogeneity in their findings.

In view of this background and to the best of our knowledge, none of the published reviews has examined the effects of the use of mHealth systems on pain intensity along with the effects on the functional disability and quality of life (QoL) of patients with CP. Therefore, the main purpose of this systematic review is to determine the effects of the use of mHealth systems on different CP conditions listed in the ICD-11, based on the improvement of pain intensity, QoL, and functional disability, according to the findings reported with randomized controlled trials (RCTs). Furthermore, we provide an overview of the available mHealth systems for CP management, their purposes, and their features.

Methods

Study Design

The protocol of this systematic review was registered on the International Prospective Register of Systematic Reviews (PROSPERO) database (CRD42022315808) [23]. It was conducted following the 2020 PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for systematic reviews of RCTs [24].

Search Strategy

The search strategy was based on CP diseases according to the ICD-11 [25]. The search was conducted from February to March 2022 in the following databases: PubMed, Web of Science, Scopus, and Physiotherapy Evidence Database (PEDro). The search strategy was first developed for the PubMed database using Medical Subject Headings, and it was adapted for other databases. The search was not filtered either by language or by date of publication. The search strategy for each database is provided in Multimedia Appendix 1.

Eligibility Criteria

The eligibility criteria were defined according to the PICOS (Population, Intervention, Comparison, Outcomes, Study type) framework [26]. The population included adults (≥18 years old) with any CP condition listed in the ICD-11 [25]. Interventions were mHealth systems based on mobile apps (smartphone or tablet) used for monitoring pain and health-related outcomes, for pain and behavioral self-management, and for performing therapeutic approaches. The rationale for including monitoring apps as an intervention was their effects on modifying the user's behavior, expectation, and performance for disease management or health promotion [27]. Some of the apps' features for promoting behavior changes are reminders and notifications, tracking activity, goal planning, and tailored information [28]. For comparison, the control group included conventional treatments (physical, occupational, and psychological therapies; care medical; and education) or nonintervention. Primary outcomes were based on pain intensity, QoL, and functional disability, and only RCTs were included as study designs.

Studies with a sample of children or adolescents; including a pain condition with a duration less than 3 months; based on the management of cancer-related pain or pre- and postsurgery trauma interventions (eg, knee arthroplasty, carpal tunnel syndrome); including websites, text messages, or other devices (eg, smartwatches, laptops); and those in which all studied groups used the mHealth system for the intervention were excluded.

Study Selection Process

After retrieving the documents from different databases, duplicated documents were removed using Rayyan QCRI (Qatar Computing Research Institute) [29] and manual screening. Studies were first screened by title and abstract by 2 researchers (authors MML and JAMM) according to the eligibility criteria. Next, the full text of potentially relevant papers was reviewed by MML and JAMM to decide whether they should be included in the analysis. Disagreements were discussed and resolved by consensus with a third researcher (author IF).

Data Extraction

The following data were extracted from the included studies: author, year of publication, and country; CP conditions; total number of participants; demographic information, including age and gender, for each study group; intervention details (type, follow-up assessments, and total study duration); and primary and secondary outcomes, as well as outcome measurements or tools. Furthermore, data of the main findings related to pain intensity, QoL, and functional disability were collected. Finally, specific information about the purpose and main features of the mHealth systems used as interventions was identified.

Risk of Bias, Methodological Quality, and Level of Evidence Assessment

First, the risk of bias (RoB) was assessed using the Cochrane RoB 2.0 tool [30], including 5 domains and an overall judgment. The 5 domains are (1) bias arising from the randomization process, (2) bias due to deviations from intended interventions, (3) bias due to missing outcome data, (4) bias in measurement of the outcome, and (5) bias in selection of the reported result. Each domain was categorized as "low risk," "high risk," or "unclear risk" based on the answers to signaling questions. An overall RoB assessment of the RCTs was performed following the recommendations in the guidance document.

Second, the Checklist for Measuring Quality [31] was used. It includes 26 items categorized by 5 subscales: reporting (9 items), external validity (3 items), bias (7 items), confounding (6 items), and power (1 item). Each item is scored 0 or 1, except for 1 item in the reporting subscale whose score ranges from 0 to 2 and the single item in the power subscale whose score ranges from 0 to 5, with a maximum overall score of 31. A score less than 50% indicates low methodological quality, 50%-65% indicates medium methodological quality, and >65% indicates high methodological quality.

Finally, the levels of evidence were reported according to the 2011 Oxford Centre for Evidence-Based Medicine (OCEBM), concerning the subject area or clinical setting and the study design involving the clinical question [32]. The level of evidence ranged from 1 (strong evidence) to 5 (weak evidence).

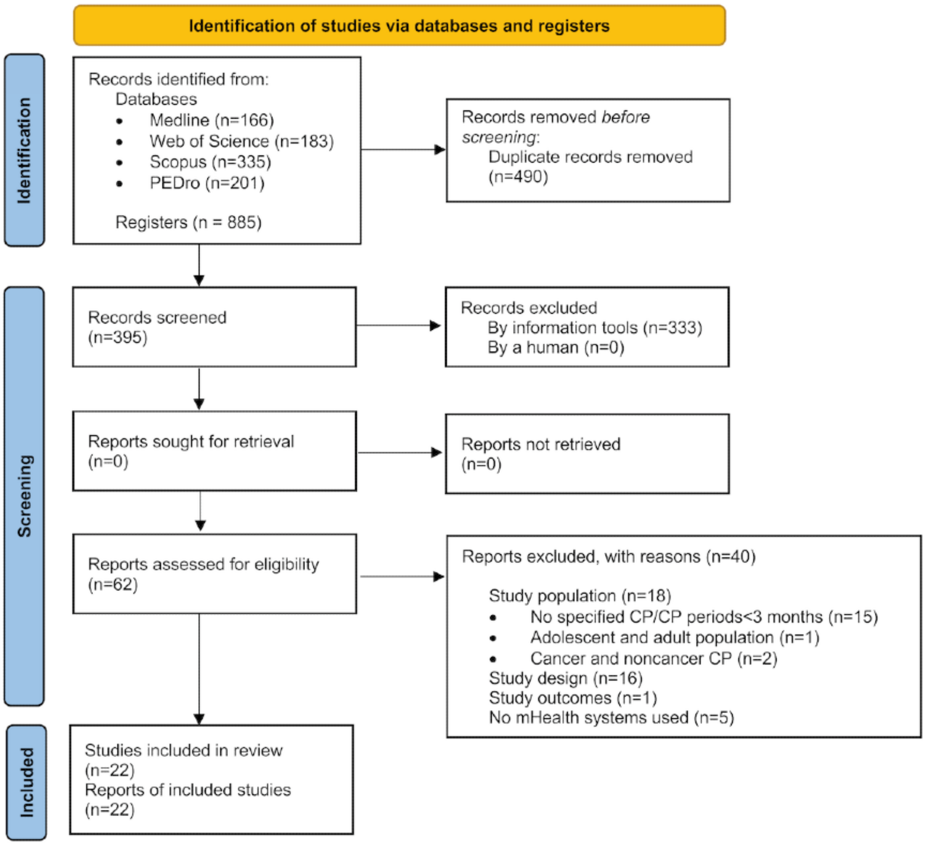
These assessments were performed by 2 authors (MML and JAMM), and the discrepancies were solved by agreement with a third researcher (author AS). These discrepancies appeared mainly in the RoB assessment, specifically in some questions related to deviations from intended interventions and measurement of outcomes. We also discussed some items of the Checklist for Measuring Quality corresponding to external (source population) and internal (blinding and concealment) validity and the power effect.

Results

Study Selection

A total of 885 studies were retrieved from the systematic literature review, of which 490 (55.4%) were duplicates and so deleted automatically. After the first screening by title and abstract, 62/395 (15.7%) studies were selected for full-text reviewing. According to the pre-established selection criteria, a total of 22 (35.5%) studies were finally included in the qualitative analysis. The full screening process and the main reasons for exclusion are shown in Figure 1.

Figure 1. Information flow diagram of the selection process of the systematic review. CP: chronic pain; mHealth: mobile health; PEDro: Physiotherapy Evidence Database.



Risk of Bias, Methodological Quality, and Level of Evidence

Regarding the results of RoB assessment by domain, 18/22 (82%) studies had a low RoB for the random allocation domain and 16/22 (73%) studies had a RoB for the missing outcome data domain. For the second (bias due to deviations from intended interventions) and fourth (measurement of outcomes) domains, 11 (50%) and 14 (64%) studies had some concerns, respectively. Last, in the selection of the reported results domain, 16 (73%) studies had a low RoB but 3 (14%) studies had a high RoB. For overall judgment, 7/22 (32%) studies had a low RoB for their outcomes, 10/22 (45%) studies had some concerns, and 5/22 (23%) studies had a high RoB.

Regarding the Checklist for Measuring Quality, 18 (82%) studies [33-50] reported medium methodological quality (between 50% and 65%), and the rest [51-54] scored high on methodological quality (>65%). Based on the clinical settings of the included studies, which concern therapy or treatment, the OCEBM level of evidence was based on systematic reviews of RCTs or, failing that, individual RCTs with narrow 95% CIs. Thus, all included papers yielded an OCEBM level of 2 for a clinical question of treatment benefits, considering them as highly recommendable.

Detailed results of the RoB assessment are shown in Figures 2 and 3. The methodological quality and the level of evidence and degrees of recommendation of the included studies are detailed in Multimedia Appendix 2 [33-54] .

Study Characteristics

The main characteristics of the studies included are shown in Table 1. Publication dates ranged from 2015 to 2022. A total of 2641 patients with CP were involved in this present systematic review, 70.6% (1793/2539) being female. The average age was 38.93 (SD 59.29) years, excluding 1 (5%) study [47] in which this information was not available.

According to CP conditions listed in the ICD-11, OA is the condition most studied in the literature, followed by CLBP [41,47,52,53] and CNP [40,49,51,54]. The lowest studies were chronic pelvic pain (CPP) [44] and interstitial cystitis/bladder pain syndrome (IC/BPS) [50].

Table 1. Study characteristics.

Characteristics	Value
Year of publication (N=22), n (%)	
2015-2018	6 (27.3)

[k]OA: osteoarthritis.
[l]mHealth: mobile health.
[m]PA: physical activity.
[n]CBT: cognitive behavioral therapy.
[o]QoL: quality of life.

Types of mHealth and Comparison Interventions

Several approaches for the self-management of patients with CP involved mHealth systems. On the one hand, we found the monitorization of pain-related variables and symptoms as part of the interventions, either isolated [37,38,41,48] or in combination with other management strategies [39,40,42,47,49,50]. Similarly, the tracking of physical activity (PA) parameters (daily PA and mobility, PA-related goals achieved, and adherence) was also used in 11 (50%) studies [33,35,37,40,41,43,45,49,51-53] aiming to record PA-related goals and to enhance PA performance and behaviors. On the other hand, self-management of CP focused on home-based PA programs as the most common intervention [33,35,39,40,45,49,51,53,55], including a wide variety of exercises, both general and specific for this population. Other common self-management approaches were educational sessions and materials [34-36,45-47,50,55]. Less frequent strategies were cognitive behavioral therapy (CBT) [43,46,47,54] and relaxation and mind-body techniques [43,44,46,54,55]. A total of 23 mHealth systems were used for monitoring [37,38,41,48,52], treatment strategies [34,36,44,46,54], and a combination of both [33,35,39,40,42,43,45,47,49-51,53]. Detailed information about the mHealth systems, their purpose of use, and the principal features are summarized in Multimedia Appendix 3.

In the control groups, interventions were based on usual health care (medical and physical therapies), being the most common comparison intervention [35,37,38,41,44,45,47-54]. Other papers performed the same intervention in both groups, one using mHealth and the other using traditional methods [33,34,36,39,42]. Finally, only 3 (14%) studies [40,43,46] did not involve any intervention.

Study Outcomes and Measurement Tools Used

Pain intensity was assessed in a total of 17 (77%) studies (N=1780). The numeric rating scale (NRS) [33,37,38,45,52-54] and the visual analogue scale (VAS) [40-42,48-51] were the most used. Regarding the OA condition, the Knee injury and Osteoarthritis Outcome Score (KOOS), the Hip injury and Osteoarthritis Outcome Score (HOOS), and the Western Ontario and McMaster (WOMAC) questionnaires were specific tools also used to assess pain intensity [34,35,39].

There was a wide range of tools used in 15 (68%) studies (N=1744) for assessing the QoL. The most repeated instruments were the 36-item Short Form Health Survey (SF-36) [34,41,43,49-51], followed by the EuroQoL-5D [35,48].

In the case of functional disability [33-35,38,39,41-45,47-53], 17 (77%) studies (N=1928) assessed it. Although there are different tools for assessing this outcome, they usually focus on a specific condition (Multimedia Appendix 3). For example, for patients with CNP [49,51], the Neck Disability Index (NDI) was used; for patients with FM, the Fibromyalgia Impact Questionnaire (FIQ) [42,48] was used; and for patients with OA, WOMAC [33,34,45], KOOK [35,39] and HOOS [35] were used.

Effects of mHealth Interventions vs Control Groups

To provide an overview of the differences found between mHealth interventions and control groups in the included studies, a visual representation is shown in Tables 2-5. The "*" sign indicates significance in favor of the mHealth intervention group, and the "=" sign indicates no significant differences between groups. No significant differences in favor of the control groups were reported.

Results of home-based PA programs delivered by mHealth systems led to a significant improvement in pain intensity in patients with CNP [49,51] and OA [35,45] when compared to usual care. Likewise, this type of intervention had significant effects on functional disability [35,45,49,51,53], but only Abadiyan et al [51] showed significant differences in the QoL between groups. In addition, when home-based PA programs delivered by mHealth systems were compared with similar traditional methods, a significant improvement in favor of mHealth for pain intensity [33], QoL, and functional disability outcomes [39] was observed in patients with OA and CNP. Nevertheless, no significant differences were obtained for any of the outcomes measured in patients with FM [42].

In relation to educational interventions based on mHealth, improvements in the QoL in OA [34], IBS [36], and IC/BPS [50] conditions were observed when compared either to usual care or to similar intervention by traditional methods. This intervention also showed improvements in functionality and pain intensity in patients with OA [34] but not for pain intensity in patients with IC/BPS [50].

CBT based on mHealth systems showed some significant improvements in QoL [46,47] and functional disability [47] in favor of the mHealth group when compared to usual care or no intervention. Nevertheless, this intervention neither reduced pain intensity in CNP [54] nor improved the QoL and functional disability in CP significantly [43].

Finally, the results of mHealth interventions focused on monitoring pain and symptoms, compared to usual care, were inconclusive. Thus, significant improvements in reducing pain were reported for patients with OA [37] and FM [48] but not for those with CMSP [38] and CLBP [41]. In patients with CMSP and CLBP, functional disability outcomes significantly improved in favor of mHealth groups [38,41], while those diagnosed with FM did not achieve significant improvements in this outcome [48]. No significant changes in the overall QoL were observed between groups with this type of intervention [41,48].

Other interventions, such as isolated monitoring of PA parameters [52] and mindfulness meditation alone [44], did not show significant differences between the mHealth and control groups for any of the studied outcomes.

With regard to the reporting of adverse events or treatment reactions of the studied interventions, only 6 (27%) of the 22 studies [37,38,45,50,51,54] provided this information, of which only 1 (17%) [54] recorded serious adverse events (cancer, sudden hearing loss, nerve injury and spinal tap, tonsillectomy, and accident causing a fracture), but none of them was considered related to the trial intervention.

Table 2. Characteristics of participants and study interventions (studies 1-11).

Study	CP[a] condition	Participants, N, intervention group (IG), n (%), control group (CG), n (%); age (years), mean (SD); gender (% female)	Intervention: mHealth[b]	Intervention: Control	Total study duration (weeks); follow-up period
Alasfour and Almarwani [33]	Knee OA[c]	N=40; 54.40 (4.33); 100% IG: n=20; 53.65 (3.96); 100% CG: n=20; 55.15 (4.64); 100%	Home-based PA[d] program (lower-limb-strengthening exercises) with the My Dear Knee app; also, exercise adherence and completed sessions recorded by the app	Home-based PA program through paper handouts	6; 3rd and 6th weeks
Arfaei Chitkar et al [34]	Knee OA	N=60; 58.17 (7.55); 100% IG: n=31; 57.84 (8.63); 100% CG: n=29; 58.52 (6.33); 100%	Educational content through the mobile app; usual medical care	Educational content without the app; usual medical care	8; 2nd month

Discussion

Principal Findings

This study provided an overview of the use of mHealth systems for the self-management of patients with different CP conditions. To the best of our knowledge, this is the first systematic review that identifies the available mHealth interventions and their effects on pain intensity, QoL, and functional disability in patients with CP. Results showed that some interventions based on mHealth systems have beneficial effects on reducing pain and functional disability and improving the QoL. Thus, the scientific evidence suggests that these systems could be a promising alternative in CP self-management through multimodal approaches.

Regarding the analyzed outcomes, 9 of the 17 studies assessing pain intensity [33-35,37,40,45,48,49,51] showed significant effects in reducing pain in favor of mHealth groups. There are several systematic reviews and meta-analyses that support these findings. Pfeifer et al [21] showed that mHealth apps are more effective in reducing pain when compared to control interventions in patients with different CP conditions, such as general CP, CLBP, CNP, arthritis (rheumatoid and OA), menstrual pain, frozen shoulder pain, and migraine. Nevertheless, the authors stated that most of the included studies used cointerventions (eg, physiotherapy, self-management booklets, pharmacological approach, and wearable activity monitors), in addition to using mHealth systems. Likewise, Moman et al [14] observed significant short- and intermediate-term improvements in pain-related outcomes in patients with CP, CLBP, FM and OA, and Thurnheer et al [22] reported a decrease in pain severity in patients with several CP diagnoses (chronic cancer pain, general CP, CLBP, CNP, menstrual pain, and also acute pain) using mobile apps for their management. Furthermore, focusing on the CP condition, Du et al [20] indicated that mHealth-based self-management programs for reducing pain show clinically important effects. Similarly, Chen et al [56] showed that the use of mobile apps for delivering PA programs is associated with significant pain relief in patients with knee OA or chronic knee pain.

Regarding the QoL, improvements were observed in 7 of 15 studies [34,36,39,46,47,50,51] involving several CP conditions (OA, CNP, CLBP, IBS, and IC/BPS). This result agrees with a previous systematic review [22] reporting that patients using a mHealth app for their self-management have a higher QoL compared to patients not using that system. Nevertheless, in the meta-analysis carried out by Chen et al [56], when analyzing the type of technology used for delivering PA programs, they observed that the use of the web is associated with significant improvements in the QoL in patients with knee OA or chronic knee pain, but the use of mobile apps or smartphones is not. This may be because only few of the studies included in this meta-analysis used mobile apps to deliver the interventions, making it difficult to examine the effects of this type of technology.

In the case of functional disability, we found some significant differences between mHealth and control groups in patients with musculoskeletal pain (CLBP [41,47,53], CNP [49,51], and CMSP [38]) and OA [34,35,45]. Nevertheless, these findings are not in line with the available literature. Chen et al [56] did not find evidence for a significant improvement in physical function with technology-supported PA programs. Likewise, results of meta-analyses of telehealth-based interventions, including mHealth and eHealth systems, have suggested that these interventions have no significant effects on physical functionality [14] and disability [57] at short- and intermediate-term follow-up. However, these results are provided by different technology-based interventions and not specifically mHealth systems, which are more recent technologies not sufficiently researched yet.

The types of intervention of the studies included in this systematic review were home-based PA programs, education, CBT, mind-body therapies, and monitoring. This is in line with a large review of the recommendations from clinical practice guidelines (CPG) for musculoskeletal pain, where 3 pillar interventions were identified as key self-management approaches: education, PA, and psychosocial therapies [58]. Similarly, Geraghty et al [59] analyzed the available self-management interventions for chronic widespread pain, with PA programs and medical information being the 2 most common components, followed by psychological approaches. Our findings reported that depending on the type of interventions carried out by mHealth, there are differences in their effects on study outcomes. In this regard, home-based PA programs and education, combined or isolated, showed significant effects on all outcomes compared to other interventions, especially in the case of functional disability. We also found that PA programs and education are commonly considered as cointerventions.

The use of PA as a clinical intervention is suggested as being adequate for several of the conditions included in this systematic review. In patients with OA, it showed a moderate effect on physical functioning, with high patient acceptability and limited side effects, being strongly recommended as conservative management [60]. Similarly, van Doormaal et al [61] reported that PA reduces pain and improves physical function and QoL, with strong-to-moderate evidence. Finally, the CPG for OA include specific exercise programs as core treatment of the nonsurgical management of this condition [58,62]. Moreover, for CLBP and CNP self-management, PA showed significant improvements in pain intensity and functional disability outcomes and slightly more effects on the QoL. In line with this, Bertozzi et al [63] and Price et al [64] reported significant improvement effects of PA programs on CNP in the short and intermediate terms. Nevertheless, both studies have mentioned that the effects of PA are not maintained in the long term, although no high-quality trials are available [63,64]. In the case of FM, although only Yuan et al [42] performed a home-based PA program, this type of intervention is strongly recommended in clinical guidelines for the management of this pathology [65,66]. In fact, previous evidence supports the effectiveness of different modalities of exercise (aerobic, strength, and functional training) in common symptoms of FM and QoL [67].

Education is also considered an essential component of conservative management. In fact, the included studies on several CP conditions applied this approach in isolation or in combination with other interventions, showing improvements in pain-related outcomes, functional disability, and QoL. Education usually includes information about the condition, its prognosis, possible consequences, associated factors, the importance of maintaining a healthy lifestyle, and self-care management options [58,60]. Education promotes feelings of hope and optimism and a positive expectation of the treatment benefits in patients with CP [62].

As previously mentioned, another key purpose of the CPG was to address the psychosocial factors related to CP, for which the internet-delivered interventions may be 1 means of increasing remote access to psychological care. In fact, the previous literature shows beneficial effects of internet-delivered cognitive and behavioral interventions for CP on pain intensity, disability, mood states, and QoL, supporting the use of technological devices for pain management outcomes [19,68]. In that line, CBT is the most studied and used and is especially important in some CP conditions, such as FM [65]. Evidence showed that patients with FM who received CBT showed reduced pain and improved health-related QoL and functional disability more than patients receiving usual care, no treatment, or other nonpharmacological interventions [69]. Similarly, Mascarenhas et al [70] found high-quality evidence in favor of CBT for pain in the short term but with a small effect size that did not reach the minimum clinically important change. Although CBT is a common treatment strategy in FM, the studies included in our systematic review did not apply this type of intervention for FM. However, CBT was applied to patients with both IBS and IC/BPS, showing improvements in QoL and functional disability outcomes. Guidelines recommend that the management of these CP conditions should include multimodal behavioral, physical, and psychological techniques [71].

Other self-management interventions delivered by mHealth systems found in the studies included in this review were the monitoring of pain, other symptoms (mood states, disease stages and impact, and adverse events), and PA parameters, isolated or as cointerventions of other therapies. In addition, mind-body components encompassing meditation, mindfulness, and relaxation techniques were found. Nevertheless, the results of these strategies were heterogeneous, showing only some slight differences when compared to usual care or similar intervention by traditional methods. Thus, it suggests that these interventions have insufficient evidence in CP to provide conclusive findings.

Regarding the overall methodological quality of the studies included, almost all of them reported medium methodological quality according to the Checklist for Measuring Quality. Nevertheless, some items related to internal and external validity were frequently scored as “null” or “unable to determine,” which could limit the interpretation and generalization of the results. Likewise, the results of the Cochrane RoB 2.0 assessment tool showed some concerns and a high RoB in the domain related to deviations from intended interventions due to the nature of the study design itself. Lack of blinding of participants is a common issue reported in research where the implementation of interventions depends on the participants, making it difficult to blind them. Similarly, lack of blinding of outcome assessors poses some concerns and a high RoB in the measurement outcome domain, which could also influence the interpretation of findings. Therefore, a future RCT should address these issues to strengthen the evidence on mHealth-based interventions for the self-management of patients with CP.

Study Limitations and Recommendations for Future Research

Although this systematic review provides a wide perspective on the use of mHealth for self-management of CP, some limitations should be remarked. First, due to the inclusion criteria of the study population, the heterogeneity among CP conditions and patient characteristics makes generalization of the findings not suitable for a specific CP condition. In addition, the high heterogeneity in terms of study interventions and outcome measures makes a meta-analysis not congruent enough to extract a quantitative synthesis of the findings. Third, due to the nature of the RCT, patients in most studies were aware of the interventions, so the effect of a placebo cannot be rejected and could suppose a risk of performance bias. Similarly, the lack of blinding outcome assessors poses a risk of detection bias, which could influence the interpretation of results. Therefore, future research with higher quality in these methodological aspects is needed. Fourth, in some studies, the sample size was small, in addition to losses to follow-up during ongoing research, which could limit the interpretation of the results and limit the drawing of conclusive evidence. Last, because we focused our study on the adult population with CP conditions, the review did not provide information about the effects that the mHealth systems might have on children and adolescents. This could be of interest for future research, as this type of intervention may be attractive and motivating for those populations who are currently familiar with the use of mobile technologies.

Conclusion

This systematic review analyzed the effects of mHealth systems on self-management interventions in patients with different CP conditions, showing beneficial effects on pain intensity, QoL, and functional disability. Concretely, mHealth systems showed positive effects on pain intensity in CNP, FM, IC/BPS, and OA; on the QoL in CLBP, CNP, IBS, and OA; and on functional disability in CLBP, CMSP, CNP, and OA. No statistically significant changes for any of the study outcomes were observed in patients with unspecific CP and CPP. Despite the methodological limitations, mHealth systems seem to be a promising alternative for the management of patients with CP through a biopsychosocial framework. Indeed, there is a wide variety of mHealth systems for the management of CP, ranging from the monitoring of pain and symptoms to therapeutic approaches, mainly based on exercise, education, and psychosocial components. However, further clinical studies of high methodological quality are needed to consolidate the scientific evidence and recommendations for the use of mHealth systems in patients with CP.

Abstract

Background: Since the era of smartphones started in early 2007, they have steadily turned into an accepted part of our lives. Poor sleep is a health problem that needs to be closely monitored before it causes severe mental health problems, such as anxiety or depression. Sleep disorders (eg, acute insomnia) can also develop to chronic insomnia if not treated early. More specifically, mental health problems have been recognized to have casual links to anxiety, depression, heart disease, obesity, dementia, diabetes, and cancer. Several researchers have used mobile sensors to monitor sleep and to study changes in individual mood that may cause depression and anxiety.

Objective: Extreme sleepiness and insomnia not only influence physical health, they also have a significant impact on mental health, such as by causing depression, which has a prevalence of 18% to 21% among young adults aged 16 to 24 in the United Kingdom. The main body of this narrative review explores how passive data collection through smartphone sensors can be used in predicting anxiety and depression.

Methods: A narrative review of the English language literature was performed. We investigated the use of smartphone sensors as a method of collecting data from individuals, regardless of whether the data source was active or passive. Articles were found from a search of Google Scholar records (from 2013 to 2020) with keywords including "mobile phone," "mobile applications," "health apps," "insomnia," "mental health," "sleep monitoring," "depression," "anxiety," "sleep disorder," "lack of sleep," "digital phenotyping," "mobile sensing," "smartphone sensors," and "sleep detector."

Results: The 12 articles presented in this paper explain the current practices of using smartphone sensors for tracking sleep patterns and detecting changes in mental health, especially depression and anxiety over a period of time. Several researchers have been exploring technological methods to detect sleep using smartphone sensors. Researchers have also investigated changes in smartphone sensors and linked them with mental health and well-being.

Conclusions: The conducted review provides an overview of the possibilities of using smartphone sensors unobtrusively to collect data related to sleeping pattern, depression, and anxiety. This provides a unique research opportunity to use smartphone sensors to detect insomnia and provide early detection or intervention for mental health problems such as depression and anxiety if insomnia is detected.

Introduction

Background

Insomnia is defined as inadequate sleep, with the most common causes being poor sleep conditions and stress [1]. It has also been defined as the presence of long sleep latency, also called sleep onset latency, the elapsed time from being fully awake to sleeping [2]. Sleep latency differs from person to person. Sleep latency and how quickly we reach rapid eye movement (REM) sleep can be indicators of the quantity and quality of sleep. Good sleep quality is measured by the time falling asleep (the ideal is 15 to 20 minutes), the ability to stay asleep all night without waking up, and the ability to spend at least 85% of the time asleep rather than awake [3,4].

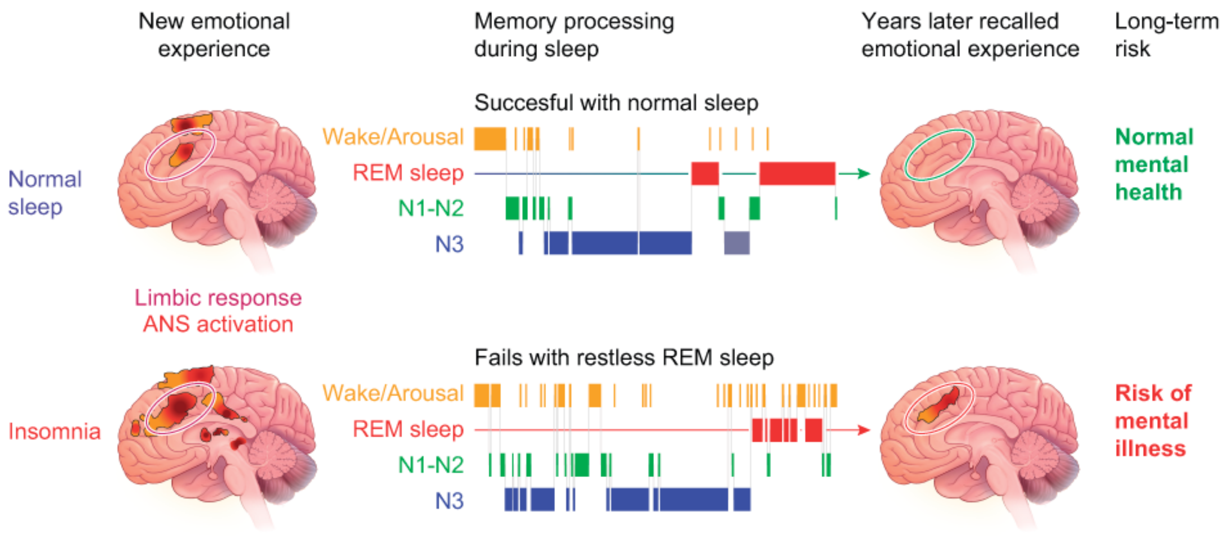
About 40% of people who are diagnosed with insomnia symptoms also report mental health problems [5]. Mental health problems and insomnia are linked in significant ways, where insomnia is a common diagnostic symptom for depression and anxiety [5]. Compared to the longstanding perspective that regarded sleep issues as related to symptoms of mental problems, there is growing research evidence that the relationship between mental disorders and insomnia is problematic and includes bidirectional causation.

The Risk of Insomnia

Mendelson et al [6] were the first to publish findings on this topic; they found that over 90% of depressed patients complained about impaired sleep quality. Several early epidemiological studies found similar strong associations: Ford and Kamerow [7], in 1989, found that people with chronic insomnia were 40 times more likely to have major depression and 6 times more likely to have an anxiety disorder. Mellinger et al [8], in 1985, found that there was a significant association between insomnia and depression. This led to the generally accepted concept that insomnia is one of the core symptoms of psychopathology.

Insomnia and depression share multiple underlying mechanisms. Both conditions have been shown to be triggered by psychosocial stressors, which can then cause overactivity of arousal-inducing neurons in the central nervous system (CNS) compared to the sleep-promoting areas, leading to hyperarousal (Figure 1) [9,10]. Another hypothesis is that insomnia could disrupt synaptic plasticity and neural network function, both of which could precipitate depression [11].

Figure 1. Brain mechanisms of insomnia (adapted from Someren [9], with permission from the American Physiological Society). ANS: autonomic nervous system; REM: rapid eye movement.



More recent studies started to find that insomnia can be an independent indicator for depression. This is highlighted by a 2011 meta-analysis by Baglioni et al [12] of 21 longitudinal epidemiological studies, which found “an overall odds ratio for insomnia to predict depression” of 2.60 (95% CI 1.98-3.42). Results from a 2016 meta-analysis were consistent with these findings (risk ratio 2.27, 95% CI 1.89-2.71) [13]. The recent evidence triggered a change in international guidelines, with insomnia being included in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, a commonly used diagnostic tool, as an independent disorder. This therefore means that insomnia, although still very closely linked to depression, is no longer classified as “primary” or “secondary” and is now considered a disorder in its own right [14,15].

Nyer et al [16] conducted a study to explore the association of sleep disturbance and depressive symptoms in 287 college students with depressive symptoms. The study assumed that students with depressive symptoms and sleep disturbance would have a significant burden of psychiatric symptoms compared to those who had depressive symptoms without sleep disturbance. The study addressed its aims by using different self-report scales, such as the Beck Depression and Anxiety inventory [17,18], the Beck Hopelessness Scale [19], the Anxiety Symptoms Questionnaire [20], the Massachusetts General Hospital Cognitive and Physical Functioning questionnaire [21], and the Quality-Of-Life Enjoyment and Satisfaction questionnaire [22]. For all measures, descriptive statistics showed that the total number of students who had depression with sleep disturbance was 220, and the remaining 67 students had depression without sleep disturbance problems. The results further showed that students who had depressive symptoms with sleep disturbance experienced a significant burden of anxiety symptoms compared to those with depressive symptoms without sleep disturbance [16].

A similar study conducted by Samaranayake et al [23] among university students found that a large number of students were affected by depression and anxiety due to sleep disorders. A total of 1933 students completed a self-report survey. The study found that 39.4% of the students had a sleep disorder lasting over a month. Moreover, depression and anxiety were present in 17.3% and 19.7% of students, respectively, and 7.3% of the students had thought of self-harm.

Studies have shown the close relationship between sleep disorders and mental health problems. Poor sleep quality, defined as waking up frequently during the night, may cause mental health issues such as depression and anxiety. Also, mental health problems could affect an individual's sleep pattern. Anxiety due to worries or repetitive thoughts might keep their brain awake. These symptoms have to occur at least 3 times a week over a period of at least 3 months in order to be diagnosed as insomnia disorder [11]. Furthermore, studies have shown that insomnia is associated with an increased risk of depression.

Methods

The main research criterion we looked at in the publications was the use of smartphone sensors to track sleep. We excluded studies that monitored sleep using other tools, such as wearable devices, electroencephalography headsets, or dream headbands. The reason for excluding these factors was the possibility of finding a method that can track sleep unobtrusively. According to Deloitte's seventh annual mobile consumer survey, around 79% of young adults check their phones before going to sleep [24].

We looked at different studies that monitored sleep using smartphone sensors. The total sample population was up to 205 university students and adults. The designed studies used the Android operating system to collect the data. We categorized the studies based on whether they monitored sleep with a single or multiple sensors.

Anxiety and depression are common, with a prevalence of 18% to 21% among young adults aged 16 to 24 in the United Kingdom [25]. As we wanted to study the relationship between poor sleep and anxiety and depression, we looked to a range of different studies that used mobile sensors to detect individuals' behavior. They predicted changes in mood using behavioral signals such as location, mobility, speech pattern, phone use, and activities. We excluded papers that discussed other mental health issues, such as bipolar disorder or schizophrenia, and articles that examined changes in mood using other methods, such as physiological and social signals.

Results

In the field of measuring sleep via smartphone sensors, we found a total of 7 published articles that used mobile sensors to passively collect data [8,14,26-30]. A total of 5 articles discussed the use of mobile sensors to track depression and anxiety [31-35].

Smartphone Sensors for Sleep Detection

With the widening reach of technology, several groups have carried out sleep studies relying on smartphone sensors [36-38]. The accelerometer embedded in every smartphone has been used to measure phone (hence body) movement to understand sleep stage [27]. Room environment conditions can be measured and monitored by other smartphone sensors to estimate sleep quality. Room environmental variables that can be measured by smartphone sensors to assess the quality of the environment include noise [27,39,40], luminosity or darkness [40], and temperature [41]. Screen on/off timing has been used in several studies as an indicator of sleeping time and duration [27,28,30]. Microphone sensors can also measure an individual's snoring, which might impact their sleep quality [26]. Snoring can lead to fragmented and unrefreshing sleep, which often causes poor daytime functioning (tiredness and sleepiness) [41]; moreover, snoring is common among people aged 60 years or older [42,43].

Single-Sensor Method

The iSleep app, which was developed by Hao et al [26], aims to replace wearable devices in sleep tracking by relying on the built-in microphone. The algorithm was able to classify several types of extraneous noise, such as that from fans and air conditioners. However, in order to collect sleep events, the user is required to turn on the app and place the phone in a certain location, and this requires user intervention on a daily basis. That means that in order to calculate sleep duration, the user needs to manually start and close the app. Two matrices (snoring and coughing detection) are used to evaluate the accuracy of the app. During the experiment, the smartphone or tablet is used to collect acoustic data and should be placed 1.5 meters away. A second omnidirectional microphone attached on the headboard and connected to a laptop collects high-quality audio. The microphone should be placed 5 meters away from the bed to avoid noises coming from the laptop fan that might impact the quality of the collected data. Additionally, an iPod is used to record any movement on the bed. The iSleep app uses microphone sensors to collect data related to sleep pattern without considering privacy-sensitive data sets from the user's smartphone. However, the complicated procedure used to detect sleeping patterns will be difficult to implement in daily life, as it requires a detailed room setup and user intervention, which may be difficult for young adults. Also, although the app has been tested among young adults aged between 20 and 30 years, the prevalence of snoring among young adults is only around 10%, although it increases with age [42,43].

A “tappigraphy” sensor has also been used to measure sleeping patterns [29]. Tappigraphy involves measuring touchscreen events and comparing them with both actigraphy and a daily sleep diary. The study design is based on calculating the number of times the user touches their phone and follows a 24-hour sleep-wake cycle. The longest period of not using the phone is considered to be sleeping time. Tappigraphy overestimates sleeping time compared to actigraphy when a low number of touchscreen touches are measured per day [29]. The sample size of this study was 79 users aged between 16 and 45 years. The large variation in the subjects' age may have made the data collected an inaccurate reflection of reality, as students and workers have different phone-use styles. Usually, older people spend less time using their phone compared to younger people [44]. The 24-hour sleep-wake cycle might also not have been accurate, especially if the user was a worker or a student, as sometimes, they may need to avoid using their phone during working or class time, affecting the accuracy of predictions of sleeping time, whether this was during the day or the night.

Mobile apps that use screen on/off events to measure sleeping pattern have been discussed in several research papers [28,30,38]. A study based on computing circadian rhythm focused on detecting the chronotype, which means the activity and sleep preferences of an individual within a 24-hour period, and the impact of social jet lag on sleep duration using an unobtrusive and low-cost method based on on/off screen sensors among 9 subjects aged between 19 and 25 years [28]. In order to obtain accurate results, the sleep duration was calculated using a ground truth determined by sleep diaries that were collected daily from participants. When comparing the app performance with the sleep-diary data, there was less than 45 minutes of error. The study showed that participants with an early chronotype experienced the most social jet lag, due to social pressure applied by people with later chronotypes on weekends. However, the study was only interested in determining sleep onset that happened between late night and early morning, without taking into consideration individual preferences. For example, international students who have different sleep times in their home country may adjust their sleep time to be able to contact their family and friends when they are available.

The Know Addiction app [38] was developed to monitor the link between circadian rhythm and individual sleeping patterns using smartphone screen on/off events during a predetermined sleeping window; this window was the period between 10 PM and 10 AM among 61 subjects who were non–shift workers and aged between 20 and 56 years. The app collected total sleep duration according to different parameters. The 3 parameters that were used to measure sleeping pattern were as follows: reactive use episode, proactive use episode, and nonuse episode. A reactive use episode was defined as any notification within 1 minute prior to a screen-on event. In contrast, a proactive use episode was defined as no notifications within 1 minute prior to a screen-on event. The app excluded all reactive use episodes in the sleep indicators calculation. The third parameter was nonuse episodes, defined as a screen on/off event. Sleeping time was determined by measuring the maximal nonuse episode within the predetermined sleeping window. Overall, the study results showed that total daily duration of smartphone use was statistically significantly correlated with delayed sleep onset (correlation 0.0808, 95% CI 0.0434-0.1182; $P<.05$) The study was limited to tracking sleeping patterns and did not attempt to measure other health or mental health issues. However, the predetermined sleeping window of 10 PM to 10 AM could not accurately estimate all individuals' sleep duration, as having mental health problems such as depression or anxiety means that sleep may not occur during the defined sleeping time window. An individual with depression symptoms would prefer to sleep for a longer time than the estimated sleeping time window.

The iSenseSleep app [30] lists all screen on/off events and then analyzes them to estimate sleep duration; it was validated in different groups (4 working mothers and 10 university students). The algorithm provides a list of all time points related to sleep episodes; the iSenseSleep app then considers the longest period to be the sleeping time, ignoring any disturbance that is less than 5 minutes. The app was designed to estimate sleeping time occurring during the night from 10 PM onwards. The app was designed to estimate sleep duration during the normal sleeping time, ignoring those who have changes in their sleeping pattern, for example, weekdays versus weekend days, where the sleeping time may differ. The iSenseSleep app estimates the wake-up time by checking the last screen-on event in the morning that was at least 4 hours since the last screen-off event. The app was able to predict sleep duration with an average error of 24 (SD 17) minutes (7%, SD 4% of the total duration). The estimation of sleep duration was more accurate among university students than working mothers, with an average error of 68 minutes (17% of the total) and 83 minutes (20% of the total), respectively. However, the iSenseSleep app was only used for 2 days to predict the sleeping pattern of the user for the rest of the nights, and that may not reflect the reality of changes in their sleeping pattern over time, especially for people who have problems with depression and anxiety.

Although the above studies conducted their research to understand individual sleeping patterns based on screen on/off events and tappigraphy, sleep quality was not determined in these studies. Sleep quality measures disturbance time, which is when the user wakes up in the middle of the night before going back to sleep. The user can also be asked to enter their sleeping time for working days and weekend days, so their sleeping pattern and sleep quality can be accurately predicted.

Multiple Sensor Modalities

Chen et al [27] developed Best Effort Sleep (BES), an Android mobile app to estimate sleep duration without user intervention by collecting data from multiple mobile sensors, including the light sensor and the microphone, as well from phone use and whether the device was in stationary mode (ie, not moving). The authors also developed another mobile app, known as Sleep With the Phone (SWP). SWP was developed to collect sleeping data using the accelerometer, with a strict protocol the user needs to follow in order to ensure accuracy while collecting the data, which includes placing the phone on the pillow when the user intends to sleep. Over 1 week with 8 participants, the accuracy of the BES app was tested with SWP and other commercial wearable systems, such as a Jawbone wristband and Zeo headband. When evaluating the accuracy of sleep monitoring using BES, SWP, Jawbone, and Zeo, the authors found that BES achieved a sleep duration error of plus or minus 42 minutes. The use of BES can be considered as an ideal approach to sleep monitoring in terms of its low cost and reduced need for user intervention to record the data, avoiding putting a burden on the user. However, room environment observations might not be considered a good predictor to rely on when predicting sleeping time, as some people may sleep while the room light is turned on. In addition, in the case that the user forgets to recharge the phone, the app will consider that the user is sleeping, as it is in the phone-off mode. The study showed that light and phone-off features contributed to lowering error.

Toss ’N’ Turn (TNT) is an Android mobile app developed to investigate how smartphones can detect bedtime, wake time, and sleep duration without requiring changes in people’s behavior and thus estimate the regularity of sleep quality [36]. A total of 27 participants were studied who were aged between 20 and 59 years. The algorithm observes the sensor logs for the accelerometer, screen on/off events, light, microphone, and battery in a 10-minute window to classify a sleep or not-sleep state. It then eliminates possible sleep detection errors, such as noise or disturbance states, between quiet and stationary situations. The app produces errors of plus or minus 35 minutes, 31 minutes, and 49 minutes in detecting bedtime, wake time, and sleep duration, respectively. However, when the mobile battery is low, the app will stop collecting data, and using multiple sensors can reduce the battery life. The study showed that changes in the screen status (ie, on/off events) and accelerometer were related to wake time, while changes in the light sensor were not always related.

Both studies (ie, BES and TNT) used multiple sensors to understand sleeping patterns, but apps that are based on multiple sensors can reduce the battery life. In addition, both studies showed that the presence of an accelerometer and screen on/off events provided good results in predicting sleeping time, while light sensors could vary in predicting the sleeping pattern. Moreover, the studies used microphone sensors to collect data without leveraging the privacy and sensitivity of the collected data from the users’ smartphones.

Table 1 shows a summary of methods to determine sleep duration; column 3 shows the sample size for validation and column 4 shows the duration of the validation study.

Earlier studies have used unobtrusive methods to predict sleeping patterns without user intervention and have used various sensors to predict sleeping time and various techniques to determine sleep duration and quality. Moreover, earlier papers [28,30,38] have shown that sleep duration, bedtime, and wake time could be identified over a significant period with screen on/off events instead of complex sensors that require additional software, use protocols, or collect sensitive data, such as from the microphone.

Table 1. Studies of mobile sensors to monitor sleep.

Smartphone Sensors for Detecting Depression and Anxiety

The interest in studying the effectiveness of using smartphones for tracking individuals’ sleeping patterns and activities and the relationship with mental well-being has increased at a brisk pace. Over this period of technological advancement, a considerable amount of literature has been published using mobile sensors to categorize mental health and well-being. These studies have used mobile sensors to collect behavioral signals and later relate them to mental health problems.

GPS has been used to study mental health problems such as depression [32,33,35]. These studies discussed a correlation between physical activities and mental health problems. DeMasi et al [32] aimed to track depression symptoms using GPS. Sleep duration was measured by estimating the longest period an individual was not physically active after 9 PM and individual physical activities during the day. A total of 47 undergraduate students installed the app over an 8-week period and completed a self-report survey related to depression and bipolar symptoms. The study showed a positive correlation between physical activities and estimated mental health status. There were limitations to activity recognition, especially that the smartphone was not in a fixed position, participants performed nonstandard activities, and the phones were set down, such as when they were left in a gym locker. Sleep duration and sleep disturbance could not be identified with a single sensor such as GPS.

Saeb et al [33] performed a study of 40 adult subjects over a 2-week period to detect daily life behavior and depression symptoms using GPS, including circadian movement (over 24 hours), location variance, and use of phone features. The data were collected and compared with self-report surveys. The accuracy achieved from this study in predicting depression symptoms through GPS and phone use was 86.5%. A similar study was conducted to study changes in mental health by tracking individuals' activities and sleeping patterns using mobile sensors [31]. This study aimed to understand changes in depression and stress level using data collected from smartphone sensors. The data were collected from 47 young adults over a 10-week period. GPS was used to track individual daily activities while sleep duration was tracked based on light, microphone data, mobile use, and accelerometer data. The study used the algorithm developed for BES [27] to calculate sleep duration. Self-report surveys of stress and depression were collected on a daily basis. The result of the analysis showed a correlation between individual activities and sleep duration with daily stress and depression level.

StudentLife is an app that is run on smartphones and wearable devices [31,34]. The study was conducted for a 10-week period among a single class of 48 students whose age was between 19 and 30 years. The study aimed to track the engagement and performance of students on an individual level. StudentLife used different types of smartphone sensors, such as the accelerometer, microphone, light sensor, and GPS [31,34]. The microphone was coded to capture sounds every 2 minutes. In contrast, GPS was activated every 10 minutes to calculate the total daily distance moved by the individual. The accelerometer embedded in the smartphone was used to detect the ratio of movement versus being stationary. The study used data retrieved from device lock duration, the accelerometer, the microphone, and the light sensor to calculate sleep duration. A self-report was used to measure mental health status and depression (with the Patient Health Questionnaire-9) [45], perceived stress [46], flourishing [47], and loneliness scales [48]. However, the study did not consider that not carrying the phone during the day would prevent the app from accurately predicting data. For example, if the user left the phone at home, all the data from the microphone and accelerometer would not be collected on that day, and the system would assume that the person was stationary and quiet, which was interpreted as sleeping. In consequence, the predicted mental health state would not be accurate. Other difficulties arose from the app measuring sleep duration using the light level. If the user was from a high-latitude location, which is dark for most of the day, then the app would consider the dark time to be sleeping time. Also, if the user preferred to sleep while keeping the room light on, it would not predict bedtime and sleeping duration accurately.

From the previous studies, we can see that the proliferation of digital technologies and mobile sensors can provide a feasible and unobtrusive method to continuously collect behavioral data from individuals, which can help in better understanding the mental health condition of individuals. Using accelerometers and other phone [31,33] features has been shown to be an efficient way of understanding individuals' behavior and mental well-being.

Discussion

Principal Findings

Mental health problems and sleep are linked in significant ways. Compared to the longstanding perspective that sleep issues are symptoms of mental problems, there is growing research evidence that the relationship between mental disorders and sleep is problematic and includes bidirectional causation.

Many people may not be aware of how their sleeping pattern can impact their health and well-being, seeking treatment only when physical and mental symptoms have started to manifest. Furthermore, both children and adults are reluctant to seek help, with only 1 in 3 receiving treatments for common mental health problems. These reasons, along with the increasing difficulty of accessing primary care services, leave room for an alternative method of insomnia identification. Smartphone sensor technologies in users' phones may be a suitable method to track sleeping patterns and early sleep disorders. Using these technologies may prevent more serious symptoms arising.

Research has demonstrated the effectiveness of using mobile phone sensors to record personal data and predict mental health and well-being. Several apps have been developed to track behavioral signals and link them with individual mental health and well-being. These apps are based on wearable and nonwearable devices that collect data using accelerometers, microphones, light sensors, and screen on/off events.

Conclusion

This review describes the effectiveness of several sleep apps that have been used to track insomnia, which can cause depression and anxiety. Furthermore, the studies in this review found that using smartphone sensors to detect mental health problems can be useful for monitoring behavioral patterns that can cause depressive symptoms. Further study is needed in this area to understand the feasibility of using mobile sensors to track sleep disorders and provide early intervention and treatment when insomnia is detected, so as to reduce mental health problems.

Abstract

Background: To solve the disadvantages of traditional fetal monitoring such as time-consuming, cumbersome steps and low coverage, it is paramount to develop remote fetal monitoring. Remote fetal monitoring expands time and space, which is expected to popularize fetal monitoring in remote areas with the low availability of health services. Pregnant women can transmit fetal monitoring data from remote monitoring terminals to the central monitoring station so that doctors can interpret it remotely and detect fetal hypoxia in time. Fetal monitoring involving remote technology has also been carried out, but with some conflicting results.

Objective: The review aimed to (1) examine the efficacy of remote fetal monitoring in improving maternal-fetal outcomes and (2) identify research gaps in the field to make recommendations for future research.

Methods: We did a systematic literature search with PubMed, Cochrane Library, Web of Science, Embase, MEDLINE, CINAHL, ProQuest Dissertations and Theses Global, ClinicalTrials.gov, and Open Grey in March 2022. Randomized controlled trials or quasi-experimental trials of remote fetal monitoring were identified. Two reviewers independently searched articles, extracted data, and assessed each study. Primary outcomes (maternal-fetal outcomes) and secondary outcomes (health care usage) were presented as relative risks or mean difference. The review was registered on PROSPERO as CRD42020165038.

Results: Of the 9337 retrieved literature, 9 studies were included in the systematic review and meta-analysis (n=1128). Compared with a control group, remote fetal monitoring reduced the risk of neonatal asphyxia (risk ratio 0.66, 95% CI 0.45-0.97; P=.04), with a low heterogeneity of 24%. Other maternal-fetal outcomes did not differ significantly between remote fetal monitoring and routine fetal monitoring, such as cesarean section (P=.21; I^2=0%), induced labor (P=.50; I^2=0%), instrumental vaginal birth (P=.45; I^2=0%), spontaneous delivery (P=.85; I^2=0%), gestational weeks at delivery (P=.35; I^2=0%), premature delivery (P=.47; I^2=0%), and low birth weight (P=.71; I^2=0%). Only 2 studies performed a cost analysis, stating that remote fetal monitoring can contribute to reductions in health care costs when compared with conventional care. In addition, remote fetal monitoring might affect the number of visits and duration in the hospital, but it was not possible to draw definite conclusions about the effects due to the limited number of studies.

Conclusions: Remote fetal monitoring seems to reduce the incidence of neonatal asphyxia and health care costs compared with routine fetal monitoring. To strengthen the claims on the efficacy of remote fetal monitoring, further well-designed studies are necessary, especially in high-risk pregnant women, such as pregnant women with diabetes, pregnant women with hypertension, and so forth.

KEYWORDS

remote fetal monitoring; maternal outcomes; fetal outcomes; review

Introduction

Fetal safety has always been a top priority for perinatal care. According to the World Health Organization, as of 2019, there were an estimated 2 million stillbirths, most of which can be prevented by safe and quality care, timely emergency care, and accurate recording [1]. Fetal monitoring is the primary means of monitoring to assess fetal safety and contributes to reducing the risk of stillbirth by detecting fetal hypoxia as early as possible [2,3]. Previous studies have repeatedly demonstrated the clinical value of fetal monitoring in reducing adverse perinatal outcomes (eg, neonatal cerebral palsy, hypoxic-ischemic encephalopathy, or stillbirth) [4,5].

Traditional antenatal care is resource intensive and not friendly to underserved settings. Beyond that, routine prenatal monitoring is only suitable for hospital settings, which means that pregnant women require regular outpatient follow-up [6]. Recurrent outpatient visits also pose additional travel risks (eg, falls, collisions, and bumps), especially for high-risk pregnant women. Telemedicine refers to the long-distance transmission of medical information between medical workers and patients through telecommunication technology [7], which has many potential advantages such as reducing outpatient time, alleviating the shortage of medical resources, reducing transportation costs and medical costs, and so forth [8-10]. Remote monitoring using telephones, websites, portable devices, and so forth during pregnancy is becoming more and more popular [11,12].

Systematic reviews have demonstrated the feasibility and superiority of telemedicine in obstetrics [13], focusing on blood pressure (BP) management [14,15], blood glucose management [16], and weight management [17] during pregnancy. However, we are not yet clear about the benefits or dangers of remote fetal monitoring. The primary objective of this systematic review was to assess the effectiveness of remote fetal monitoring for improving maternal-fetal outcomes. In addition, we also sought to analyze the cost-effectiveness of remote fetal monitoring compared to conventional prenatal monitoring.

Methods

Reporting Standards

This systematic review and meta-analysis was carried out according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines of 2009 [18] and was registered on PROSPERO as CRD42020165038.

Literature Retrieval

In total, 9 web-based databases were searched in March 2022, including PubMed (January 1966-March 2022), Cochrane Library (January 1947-March 2022), Web of Science (January 1990-Mar 2022), Embase (January 1974-March 2022), MEDLINE (January 1950-March 2022), CINAHL (January 1982-March 2022), ProQuest Dissertations and Theses Global (January 1899-March 2022), ClinicalTrials.gov (January 1997-March 2022), and Open Grey (January 1980-March 2022). Search terms generated from the inspection of relevant papers were wielded to search for eligible studies, such as fetal, remote, telemetry, monitor, and so forth. The full search strategy was available in Multimedia Appendix 1 and was rerun before the final analysis.

Inclusion Criteria

Studies were considered eligible if they simultaneously met the following criteria: (1) pregnant women; (2) randomized controlled trials (RCTs) or quasi-experimental trials; (3) fetal monitoring data were transmitted to the central monitoring station by remote monitoring terminals; and (4) outcomes included at least 1 maternal-fetal outcome or health resource usage. There were no restrictions on language, nationality, or publication status.

Exclusion Criteria

Studies meeting any of the following criteria were excluded: (1) no control group in the study; (2) comparative studies of 2 or more remote monitoring technologies; and (3) the full text was still unavailable after contacting the original authors. Studies were not excluded due to monitoring settings (hospital, home, community setting, or mixed).

Outcome Measures

The primary outcomes were maternal-fetal outcomes (cesarean section, induced labor or miscarriage, instrumental vaginal birth, spontaneous delivery, gestational weeks at delivery, premature delivery, birth weight, and so on). The secondary outcomes were health care usage, which was assessed by on-site appointments, home visits, duration in the hospital, prenatal costs, and so on.

Study Selection

A 3-step screening identified articles that met the inclusion and exclusion criteria were literature retrieval, preliminary screening (title and abstract), and full-text screening. Literature retrieval was conducted by 2 investigators. All searched articles were uploaded into the reference management tool of EndNote. Articles with the same author, year, title, and so on were identified and removed by EndNote. Subsequently, 2 independent investigators (SYL and QY) selected all articles by evaluating the title and abstract after the removal of duplicates. Finally, the same 2 investigators (SYL and QY) identified the ultimately eligible articles by screening independently the full text according to the inclusion and exclusion criteria. In addition, the first author (SYL) hand-searched the references of the ultimately included literature to identify further publications. Any discrepancies and disagreements were finally resolved by consultation with a third reviewer (YL). We also contacted the original authors for verification if there were any uncertain technical types.

Data Extraction

Data from included studies were extracted by SYL and then cross-checked by another author (QY). A standardized data extraction form was designed by the research team and included the following data: (1) basic information of included studies (first author, year of publication, country, and study design); (2) characteristics of participants (maternal age, gestational weeks, sample size, and attrition rate); (3) characteristics of interventions (trial settings, duration of the intervention, monitoring personnel, monitoring content, feedback types, and technical support); and (4) outcomes measurement (maternal-fetal outcomes and health care usage). For insufficient data, we contacted the original authors via email. The standardized data extraction form was available in Multimedia Appendix 2.

Quality Assessment

Independently, the quality of eligible studies was assessed by 2 reviewers (SYL and QY) according to the Cochrane Risk of Bias Tool [19], which consisted of 7 items (random sequence generation, allocation concealment, blinding of participants and personnel, blinding of outcome assessment, incomplete outcome data, selective reporting, and other bias) with the responses of “low risk,” “high risk,” and “unclear risk.” The research was considered high quality with a low risk score on at least 4 domains, which must include 3 key domains (random sequence generation, allocation concealment, and incomplete outcome data) [20]. Consensuses between 2 investigators (SYL and QY) were reached by discussion with a third reviewer (YL).

Data Synthesis and Statistical Analysis

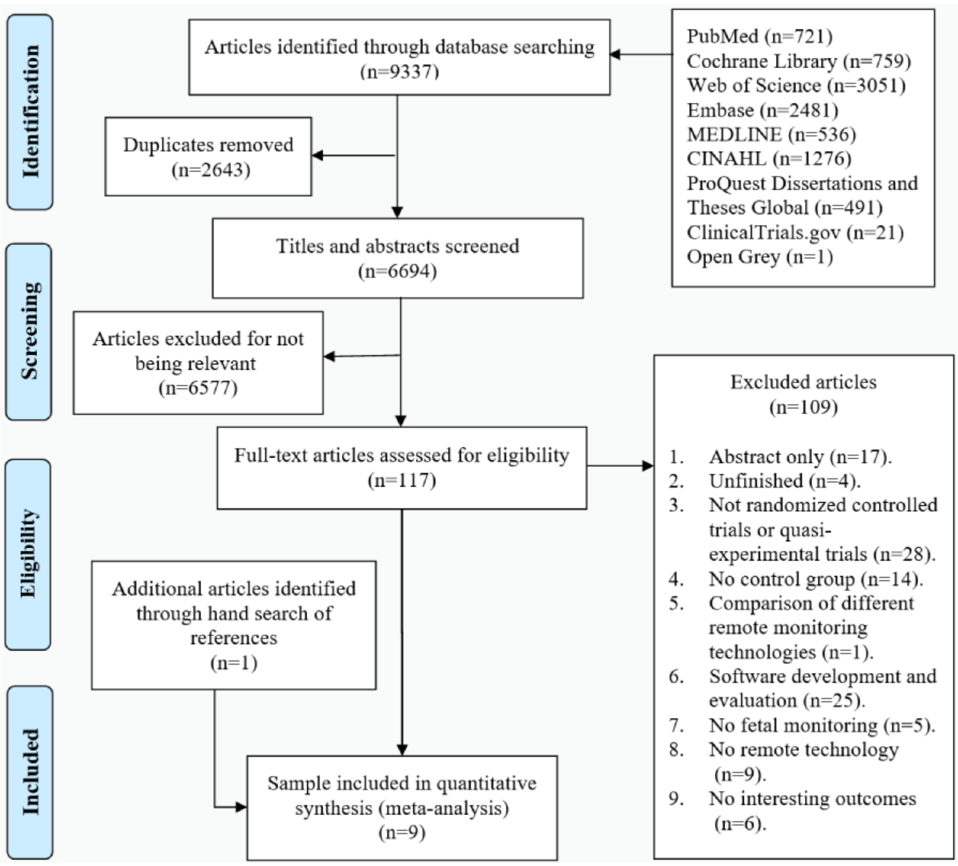
Quantitative analysis of included studies was carried out in Review Manager (RevMan) software (version 5.4). Continuous variables were presented as mean difference (MD), and dichotomous variables were described as risk ratio (RR) with a 95% CI. The statistical heterogeneity of selected studies was assessed by the chi-square test combined with I^2. Heterogeneity was divided into nonsignificant heterogeneity (I^2 ranging from 0% to 40%), moderate heterogeneity (I^2 ranging from 30% to 60%), substantial heterogeneity (I^2 ranging from 50% to 90%) and considerable heterogeneity (I^2 ranging from 75% to 100%) [19]. When I^2<40%, the fixed-effects model was adopted; otherwise, a random effect model was considered. In addition, sensitivity analysis and subgroup analysis were used to explore the sources of heterogeneity if needed.

Results

Study Selection

A total of 9337 studies were initially retrieved by searching 9 databases. After the 3-step screening, 8 studies met the inclusion and exclusion criteria. From a manual search of related references, 1 additional study was included. Finally, 9 RCTs were included in the systematic review and meta-analysis. The results of 1 study were published in 2 articles [21,22]. The detailed flow diagram of study selection is shown in Figure 1.

Figure 1. Flow diagram of study selection.



Study Characteristics

The characteristics of 9 RCTs are outlined in Table 1, involving 1128 participants from 6 countries. Seven studies were from developed countries (1 from the United States [23], 3 from the United Kingdom [24-26], 2 from the Netherlands [21,22], and 1 from Finland [27]). Only 2 studies were performed in developing countries (1 from China [28] and 1 from Mexico [29]). Eight of the screened studies were monocentric, and 1 was multicenter [26]. On the duration of interventions, 7 studies were carried out in the prenatal period [21-23,25,26,28,29], and 2 studies were conducted during labor [24,27]. In terms of participants, most of the included studies recruited high-risk pregnant women [21,22,25,26], and the remaining studies recruited low-risk pregnant women [23], late pregnant women [28], and pregnant women facing labor [24,25], respectively. The pooled mean age of pregnant women was 29.28 (SD 5.03) years in 6 RCTs [21-23,25-27].

Table 1. Characteristics of included studies.

Author, year, country	Study design	Participants	Duration	Sample, N	Attrition rate (%)	Major characterization	Major results
Butler Tobah et al, 2019, United States [23]	2-arm RCT,[a] monocentric	Low-risk pregnancies (IG：29.5±3.3 years; CG：29.7±3.6 years)	<13 weeks of gestation to deliver	IG[b]: N=134; CG[c]: N=133	11	IG: OB Nest care (8 on-site appointments, 6 remote visits via phone or web-based communication) CG: usual care (12 prescheduled prenatal clinic appointments)	Pregnancy outcomes (cesarean, delivery, miscarriage, and preterm delivery); neonatal outcomes (low birth weight, and neonatal asphyxia); health care usage (on-site appointments, remote visits, and inpatient days)
Wang et al, 2019, China [28]	2-arm RCT, monocentric	Late pregnancies (IG：22-40 years; CG：22-38 years)	36-41 weeks of gestation to deliver	IG: N=80; CG: N=80	0	IG: remote FHR[d] monitoring (3-4 times daily); CG: own fetal movement count (3 times daily) and routine outpatient FHR monitoring	Neonatal outcomes (neonatal asphyxia and nonstress test）

Dawson et al, 1999, United Kingdom [26]	2-arm RCT, multicenter	High-risk pregnancies (IG：25.7 ± 5.0 years; CG：27.2 ± 6.3 years)	12 weeks of gestation to deliver	IG: N=43; CG: N=38	0	IG: domiciliary monitoring daily via DFM[e] system; CG: conventional care (standard midwifery visits)	Pregnancy outcomes (weeks of gestation at delivery, spontaneous delivery, cesarean delivery, operative vaginal delivery, and induced labor); neonatal outcomes (neonatal asphyxia); health care usage (on-site appointments, home visits, inpatient days, and cost-effectiveness)
Birnie et al, 1997, the Netherlands [21]	2-arm RCT, monocentric	High-risk pregnancies (IG：29.6±5.8 years; CG：30.9±5.8 years)	32-43 weeks of gestation to deliver	IG: N=76; CG: N=74	0	IG: domiciliary monitoring daily via portable cardiotocography; CG: in-hospital monitoring daily	Pregnancy outcomes (weeks of gestation at delivery, cesarean delivery, and induced labor); neonatal outcomes (birth weight); health care usage (inpatient days and cost-effectiveness)
Monincx et al, 1997, the Netherlands [22]	2-arm RCT, monocentric	High-risk pregnancies (IG：29.6±5.8 years; CG：30.9±5.8 years)	32-43 weeks of gestation to deliver	IG: N=76; CG: N=74	0	IG: domiciliary monitoring daily via portable cardiotocography; CG: in-hospital monitoring daily	Pregnancy outcomes (spontaneous delivery, operative vaginal delivery, and perinatal mortality); neonatal outcomes (neonatal asphyxia and neurological optimality scores)
Dawson et al, 1989, United Kingdom [25]	2-arm RCT, monocentric	High-risk pregnancies (IG：28.78±5.85 years; CG：26.06±3.51 years)	26-41 weeks of gestation to deliver	IG: N=40; CG: N=17	5	IG: domiciliary monitoring daily via DFM system; CG: conventional hospital care	Pregnancy outcomes (weeks of gestation at delivery, cesarean delivery, and induced labor)

Author, year, country	Study design	Participants	Duration	Sample, N	Attrition rate (%)	Major characterization	Major results
Calvert et al, 1982, United Kingdom [24]	3-arm RCT, monocentric	Patients facing labor (≤37 weeks of gestation)	During labor	IG: N=100; CG: N=100	0	IG: remote monitor cardiotocography (patients could get out of bed to walk or sit); CG: conventional bedside cardiotocography	Pregnancy outcomes (spontaneous delivery, cesarean delivery, and operative vaginal delivery); Neonatal outcomes (neonatal asphyxia)
Haukkamaa et al, 1982, Finland [27]	2-arm RCT, monocentric	Patients facing labor (IG: 28.35±3.75 years; CG: 28.1±3.7 years)	During labor	IG: N=31; CG: N=29	0	IG: FHR monitored by telemetry (patients were encouraged to sit or walk); CG: FHR monitored by conventional cardiotocography	Pregnancy outcomes (cesarean delivery, operative vaginal delivery, and induced labor)

[a]RCT: randomized controlled trial.

[b]IG: intervention group.

[c]CG: control group.

[d]FHR: fetal heart rate.

[e]DFM: domiciliary fetal monitoring.

Characteristics of Interventions

The characteristics of interventions are described in Table 2. Most of the included studies were undertaken at home [21-23,25,26,28], with 3 exceptions occurring in rural clinics [29] and hospitals [24,27]. Pregnant women in the control groups received "conventional care," including routine outpatient monitoring, in-hospital monitoring, or conventional bedside cardiotocography. Pregnant women in the intervention groups received remote fetal monitoring with web, Bluetooth, or telephone. Of the included studies, 5 RCTs only supervised fetal heart rate [24-28], and the remaining 4 RCTs monitored extra BP [21-23,29], blood glucose [29], height [29], weight [29], or temperature [21,22].

The frequency of fetal monitoring and guidance varied among the included studies as did the form of feedback. Due to the different stages of pregnancy, the frequency of fetal monitoring ranged from 3 to 4 times daily to biweekly. There were many ways to achieve one-to-one, personalized, and exclusive guidance, including phone visits, on-site appointments, or family visits. In addition, 2 other studies, which occurred during labor, used the obstetrical telemetry system to remotely monitor the fetus in real time [24,27]. During the birth process, the pregnant women in the conventional group were nursed in bed, whereas those with telemetry equipment were encouraged to get out of bed to walk or sit on a chair.

Table 2. Characteristics of interventions.

Author, year, country	Monitoring personnel	Monitoring locus	Monitoring content	Feedback	Technical support
Butler Tobah et al, 2019, United States [23]	Patient, nurse, and obstetrician	Domiciliary	FHR,[a] BP[b]	• Transmission of data via a phone or the institution's electronic medical record system • Personalized guidance by telephone visits or on-site appointments	Home digital sphygmomanometer, handheld fetal Doppler, and patient web portal
Wang et al 2019, China [28]	Patient and obstetrician	Domiciliary	FHR	• Transmission of data via phone • Personalized guidance via telephone if necessary	Portable intelligent medical terminal system
Tapia-Conyer et al, 2015, Mexico [29]	Nurse and obstetrician	Rural clinics	FHR, BP, blood glucose, height, and weight	• Transmission of data through a Bluetooth interface and web access • Personalized consultations via fetal monitoring visits	MiBebe fetal remote monitor prototype, Bluetooth, and patient web portal
Dawson et al 1999, United Kingdom [26]	Patient, community midwife	Domiciliary	FHR	• Transmission of data via telephone using modems • Personalized surveillance and care for each pregnant woman	DFM[c] system
Birnie et al 1997, the Netherlands [21]	Investigator, midwife, and physician	Domiciliary	FHR, BP, and temperature	• Transmission of data via telephone • Personalized consultations via telephone if necessary	Portable cardiotocography and public telephone network
Monincx et al 1997, the Netherlands [22]	Investigator, midwife, and physician	Domiciliary	FHR, BP, and temperature	• Transmission of data via telephone • Personalized consultations via telephone if necessary	Portable cardiotocography and public telephone network
Dawson et al 1989, United Kingdom [25]	Patient, midwife	Domiciliary	FHR	• Transmission of data via telephone fetal monitoring systems • Personalized guidance via regular family visits	DFM system
Calvert et al 1982, United Kingdom [24]	Midwife	Hospital	FHR	• Transmission of data via an obstetrical telemetry system	Obstetrical telemetry system
Haukkamaa et al 1982, Finland [27]	Midwife	Hospital	FHR	• Transmission of data via an obstetrical telemetry system	Obstetrical telemetry system

[a]FHR: fetal heart rate.

[b]BP: blood pressure.

[c]DFM: domiciliary fetal monitoring.

Risk of Bias

Overall, the quality of included studies was moderate, 4 of which (44%) were high-quality research [21-23,26]. The studies showed the main bias in the blinding of participants and personnel, which might be caused by the nature of interventions. In addition, 1 study (11%) showed a high risk of bias for random sequence generation because of grouping according to the hospital number [24]. Fortunately, all outcomes were obtained from medical records, so the outcome assessment would not be influenced by the lack of blinding. Based on the above reasons, the blinding of outcome assessment of included studies was assessed as "low risk of bias." Three RCTs (22%) reported clear data loss, with attrition of 11% [23], 12% [29], and 5% [25], respectively. One of the studies had a relatively large difference in attrition between the groups (20% and 4%, respectively), and it was unclear whether the loss to follow-up varied [29]. Three studies (22%) used intention-to-analysis [21-23] (Figures 2 and 3).

Figure 2. Risk of bias in each study.

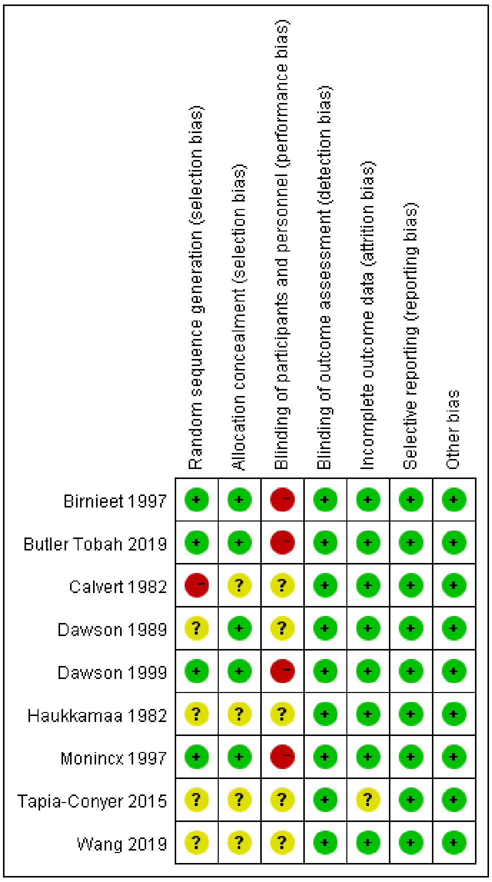

Figure 3. Overall risk of each type of bias.

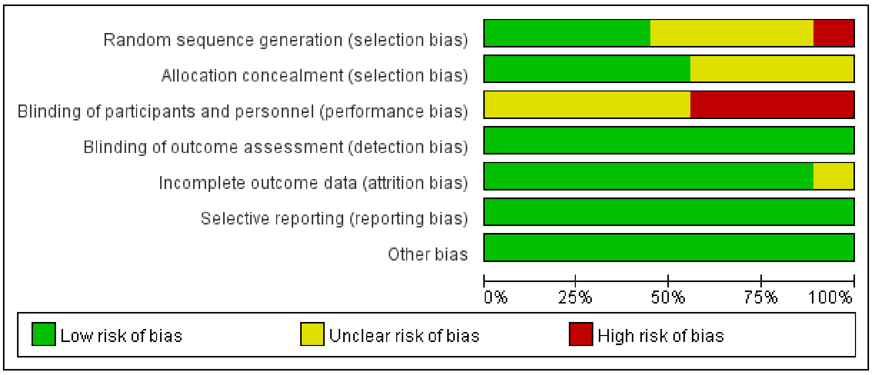

Synthesis of Results

The review extracted 8 maternal-fetal outcomes and the pooled analyses are presented in Table 3.

Table 3. Effect estimates of 8 outcomes.

Outcomes	Studies, n	Participants, n	Statistical methods	Effect estimates
Cesarean section	6	815	Risk ratio (M-H,[a] fixed, 95% CI)	0.81 (0.59 to 1.12)
Neonatal asphyxia	5	859	Risk ratio (M-H, fixed, 95% CI)	0.66 (0.45 to 0.97)[b]
Instrumental vaginal birth	4	492	Risk ratio (M-H, fixed, 95% CI)	1.21 (0.74 to 1.98)
Induced labor	4	348	Risk ratio (M-H, fixed, 95% CI)	0.90 (0.66 to 1.22)
Spontaneous delivery	3	432	Risk ratio (M-H, fixed, 95% CI)	0.99 (0.89 to 1.10)
Gestational weeks at delivery	3	288	Mean difference (IV,[c] fixed, 95% CI)	−0.28 (−0.86 to 0.30)
Premature delivery	2	420	Risk ratio (M-H, fixed, 95% CI)	0.80 (0.44 to 1.46)
Low birth weight	2	420	Risk ratio (M-H, fixed, 95% CI)	1.20 (0.45 to 3.20)

[a]M-H: Mantel-Haenszel.

[b]Statistically significant at *P*=.04 level.

[c]IV: inverse variance.

Maternal Outcomes

Cesarean section was the most assessed in the included studies, involving 815 pregnant women from 6 RCTs [21,23-27]. Under the fixed effect model, the pooled results showed a nonsignificant difference between the intervention group and the control group (RR 0.81, 95% CI 0.59-1.12; *P*=.21), without any heterogeneity (I^2=0%; *P*=.93; Figure 4).

Instrumental vaginal birth was mentioned in 4 studies involving 492 pregnant women [22,24,26,27]. There was no evidence of heterogeneity when pooling the 4 studies (I^2=0%; *P*=.88). With a fixed effect model, the prevalence of instrumental vaginal birth did not significantly differ between the remote monitoring group and the routine monitoring group (RR 1.21, 95% CI 0.74-1.98; *P*=.45; Figure 5).

Four RCTs (n=348) reported induced labor with an overall rate of 32% [21,25-27]. Moreover, no significant difference (RR 0.90, 95% CI 0.66-1.22; *P*=.50) between groups and the heterogeneity (I^2=0%; *P*=.42) in pooling 4 studies was demonstrated (Figure 6).

Similarly, no significant difference was found in the risk of spontaneous delivery (RR 0.99, 95% CI 0.89‐1.10; *P*=.85) [22,24,26] or premature delivery (RR 0.80, 95% CI 0.44‐1.46; *P*=.47) [23,29], both with no heterogeneity (I^2=0%; *P*=.68 and *P*=.45, respectively; Figures 7 and 8). For gestational weeks at delivery, the overall effect of 3 studies [21,25,26] was also insignificant (MD −0.28, 95% CI −0.86 to 0.30; *P*=.35) in the absence of heterogeneity (I^2=0%; *P*=.68; Figure 9).

Figure 4. Forest plot of cesarean section.

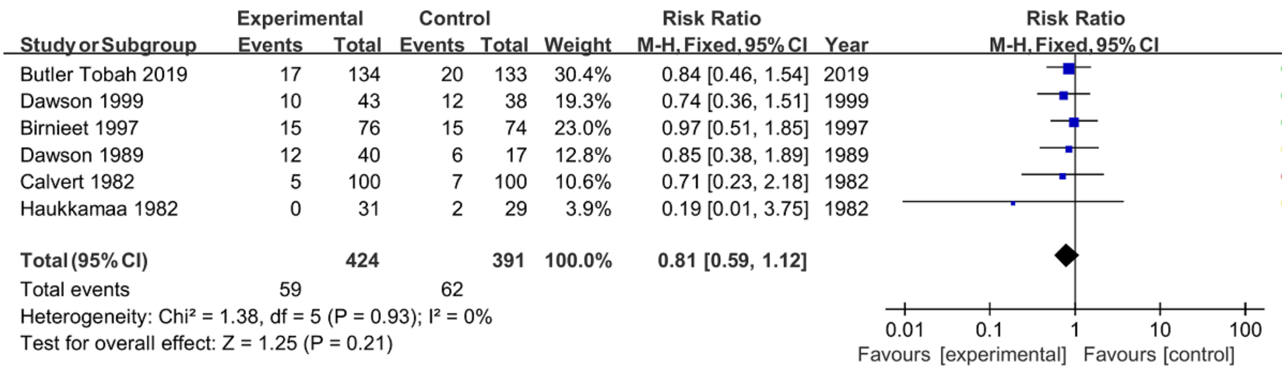

Figure 5. Forest plot of instrumental vaginal birth.

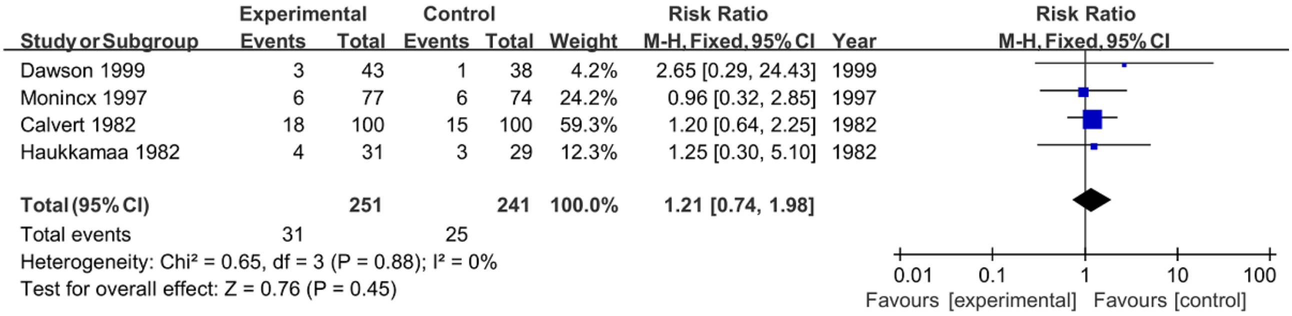

Figure 6. Forest plot of induced labor.

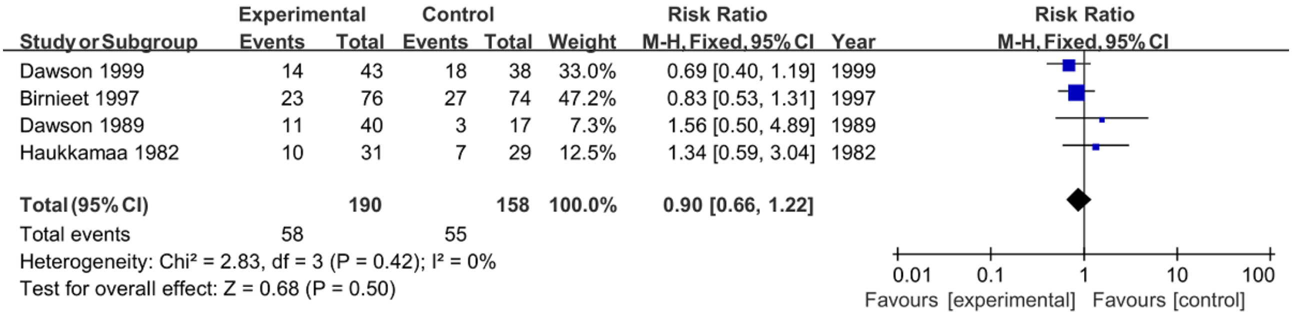

Figure 7. Forest plot of spontaneous delivery.

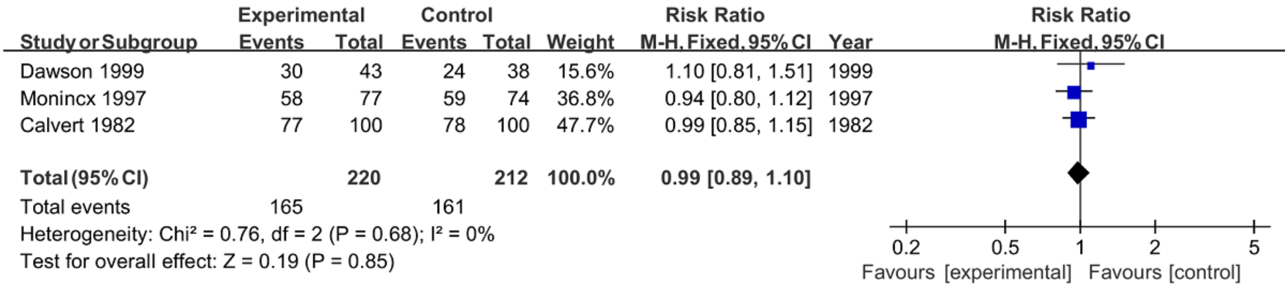

Figure 8. Forest plot of premature delivery.

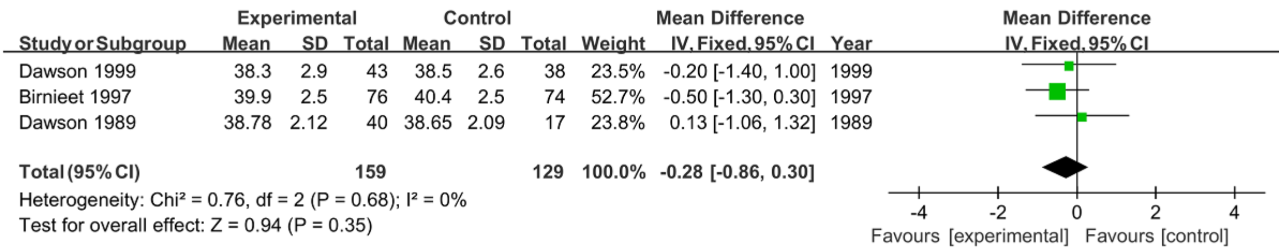
Figure 9. Forest plot of gestational weeks at delivery.



Outcomes of Infants

Five studies (n=859) compared the incidence of neonatal asphyxia between the intervention group and the control groups, with an overall prevalence of 11% [22-24,26,28]. Furthermore, the overall effect of neonatal asphyxia was significant, and the combined risk ratio was 0.66 (95% CI 0.45-0.97; *P*=.04) with an acceptable heterogeneity across studies (I^2=24%; *P*=.26; Figure 10).

For low birth weight, the pooled results of 2 studies involving 420 newborns showed that no significant difference was discovered between the intervention group and the control group (RR 1.20, 95% CI 0.45-3.20; *P*=.71), without any heterogeneity (I^2=0%; *P*=.41; Figure 11) [23,29].

Figure 10. Forest plot of neonatal asphyxia.

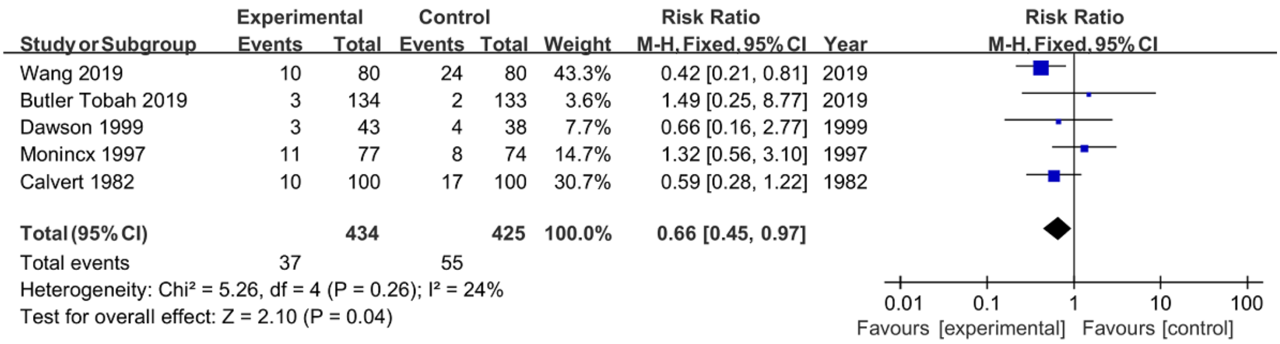


Figure 11. Forest plot of low birth weight.

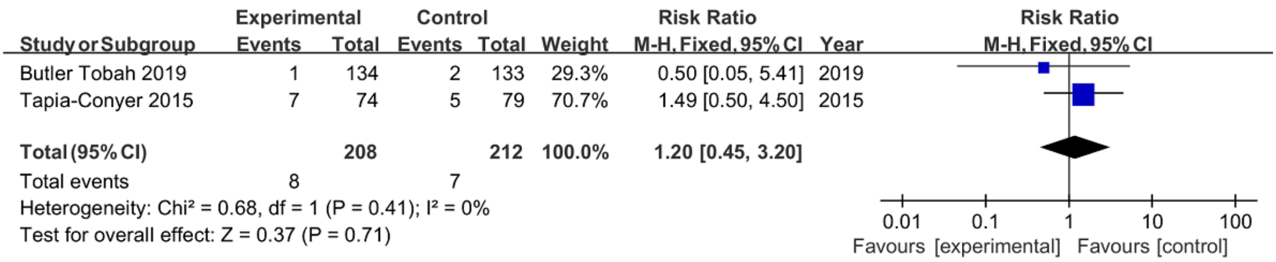

Health Care Usage

The outcomes of health care usage were investigated in 3 studies [21,23,26], involving the number of on-site appointments or home visits, duration in hospital, medical cost, and so on. However, none of them was suitable for meta-analysis due to heterogeneity of evaluation methods and assessment timing or to a lack of sufficient data.

Butler Tobah et al [23] reported that compared with conventional nursing, the number of on-site appointments with clinicians and nurses decreased significantly in the intervention group (11.25 vs 14.69 visits; *P*<.01), while the duration of time spent on coordinating care and connected care appointments by phone or on the internet was higher in the intervention group (401.20 vs 167.10 minutes per woman; *P*<.01). Similarly, Dawson et al [26] also reported that the remote group received more home visits (3.7 vs 1.4 visits; *P*=.002) and longer home visits (33.5 vs 12.8 minutes per visit; *P*<.001). There was no significant difference in the number of antenatal clinic visits between the 2 groups (2.4 vs 3.2 visits; *P*=.11) [26]. For antenatal inpatient days, Dawson et al [26] found there were no significant differences between the 2 groups (3.58 vs 5.13 days; *P*=.12), whereas Birnie et al [21] reported longer hospital stays in the control group (1 vs 7 days; *P*<.001). Furthermore, no significant differences in hospital length of stay after delivery [21,23] were observed across groups.

Two studies reported cost-effectiveness [21,26]. Birnie et al [21] indicated that domiciliary monitoring had lower prenatal costs than in-hospital monitoring (US $1521 vs US $3558 per woman; *P*<.001), mainly focusing on nursing care, domiciliary monitoring, and informal family care. Dawson et al [26] also supported that the total cost of domiciliary care was €223.83 (US $239.89 in 2023) per woman less than that of conventional care, consisting of community midwife (time and travel), home monitoring equipment (capital cost and maintenance), lost productive output (women and partners), and antenatal clinic attendances (visits, ultrasound scans, and antenatal inpatient care) [26].

Discussion

Principal Findings

As far as we know, this is the first article to quantitatively analyze the effects of remote fetal monitoring. The systematic review and meta-analysis highlighted that remote fetal monitoring significantly reduced the risk of neonatal asphyxia by 34%. Beyond that, remote fetal monitoring was also beneficial for reducing prenatal costs, which showed some potential for greater cost-effectiveness.

Comparison With Prior Studies

In previous reviews, the superiority of obstetric remote monitoring has also been repeatedly emphasized because of real-time, periodic, and remote monitoring [3,30,31]. By integrating 14 studies involving blood glucose, fetal heart rate, and uterine activity, Lanssens et al found that remote monitoring reduced low neonatal birth weight and neonatal intensive care unit admissions, as well as prolonged gestational age [31]. Likewise, a recent systematic review, focusing on obstetric remote monitoring of BP, uterine contractions, weight, heart rate, and so forth also supported that telemonitoring during pregnancy had great potential for promoting better pregnancy outcomes [3]. However, due to limited research on prenatal remote monitoring, no further quantitative analysis was carried out in the above reviews.

This systematic review and meta-analysis, the first to focus remote monitoring on the fetus, revealed that remote fetal monitoring reduced the risk of neonatal asphyxia by 34%. Remote fetal monitoring can identify signs of fetal hypoxia in time by monitoring wherever and whenever, which is essential to reduce neonatal asphyxia, especially in high-risk pregnant women [32]. In terms of cost-effectiveness, only 2 RCTs out of 9 studies reported cost-effectiveness [21,26]. Both demonstrated that remote monitoring significantly reduced prenatal costs, which was consistent with previous studies [31,33,34]. In Lanssens' [31] review, 2 retrospective studies found that remote monitoring significantly reduced health care costs. In the studies reviewed, cost analysis focused on health care costs, patient costs, caregiver costs, and productivity costs. Remote fetal monitoring had additional equipment costs and maintenance costs, but in the long run, it saved much more than that, such as time costs, travel costs, or outpatient costs.

In addition, the disadvantages of remote fetal monitoring remained controversial, such as whether additional cesarean sections would be added. In this regard, this meta-analysis covering 9 studies found no consistent evidence of adverse effects on maternal and infant outcomes, with a small heterogeneity ranging from 0% to 24%. This might be related to accurate guidance from midwives or obstetricians on the remote monitoring team. Nonetheless, a recent review in 2019 evaluated information involving decreased fetal movement in 24 mobile applications, revealing that the information varied widely and lacked evidence-based clinical advice [35]. Accurate information about fetal movement is essential for improving maternal and infant outcomes. Therefore, it is recommended that health care personnel cooperate with software developers to jointly develop high-quality prenatal education tools, which will help to promote more pregnant women to obtain timely and accurate guidance.

Notably, in the current systematic review and meta-analysis, 7 of the 9 studies were carried out in developed countries, which were inseparable from the rich medical resources and advanced medical technologies of developed countries. The latest global figures showed that in 2020, there were 26 and 17 deaths per 1000 live births in low- and middle-income countries (LMICs), respectively. However, in high-income countries, the rate only stood at 3 per 1000 [36]. Given the higher perinatal mortality rate, the need for remote fetal monitoring in developing countries may be more urgent. Furthermore, a recent review focused on LMICs concluded that mobile technology can overcome economic and geographic barriers by transmitting clinical information collected using low-cost devices, thereby increasing the perinatal care coverage of LMICs [5]. It can be argued that remote fetal monitoring supported by mobile technology appears to have greater potential in LMICs, where antenatal care services need to be improved. Therefore, we encourage remote fetal monitoring in LMICs to alleviate the shortage of medical resources and further complement the benefits of remote fetal monitoring.

Suggestions for Clinical Practice

This systematic review has demonstrated that remote fetal monitoring has a significant effect on improving maternal and infant outcomes, but this does not mean that remote fetal monitoring can replace face-to-face communication between doctors and patients, which is necessary for shared decision-making. Remote monitoring breaks through the barriers of time and distance, so it is reasonable as an effective complement to traditional outpatient monitoring [37]. Especially during the COVID-19 pandemic, pregnant women, as a high-risk group, should not gather in outpatient clinics for a long time. At this time, remote fetal monitoring not only realizes noncontact medical services but also ensures the safety of mothers and babies. Unfortunately, remote fetal monitoring is rarely implemented in developing countries, especially in areas with limited medical resources [3]. Therefore, the development and implementation of remote monitoring technology urgently need to be put on the agenda. Aside from the technical issues, another concern of remote fetal monitoring is that authentication rules, reimbursement policies, data security, legal responsibilities, and so forth are not yet clear [38]. Although remote fetal monitoring has not yet shown adverse consequences, it is still necessary to conduct relevant research cautiously in combination with the local medical level.

Limitations

There were some limitations worth noting. The diversity of pregnant women in the current systematic review was the major limitation, involving low-risk pregnancies, high-risk pregnancies, late pregnancies, and patients facing labor. Future research can continue to explore which types of pregnant women are more suitable for remote fetal monitoring. In addition, several RCTs included in this meta-analysis were relatively old, which might limit the direct applicability of the evidence to current clinical practice. Finally, due to the limited literature, it was difficult to quantitatively analyze the efficacy of remote fetal monitoring in health resource usage. Future studies are expected to assess the cost-effectiveness of remote fetal monitoring, including implementation costs (technology costs, medical costs, etc), intervention costs (patient resource costs, commuting costs, etc), and downstream costs (productivity costs, future costs, etc) [39]. Likewise, the number of consultations, length of hospital stay, and patient compliance or satisfaction cannot be ignored and need to be explored further.

Conclusions

The present systematic review and meta-analysis of 9 studies highlighted that remote fetal monitoring had a favorable effect on reducing neonatal asphyxia. Remote fetal monitoring has not yet found hidden dangers, but more large-scale, multicenter, and high-quality studies are still expected to explore its safety and efficacy. At the same time, more research is also recommended to further carry out the cost analysis of remote fetal monitoring, which will help alleviate the huge medical expenses.

Abstract

Background: Community health workers (CHWs) have become essential to the promotion of healthy behaviors, yet their work is complicated by challenges both within and beyond their control. These challenges include resistance to the change of existing behaviors, disbelief of health messages, limited community health literacy, insufficient CHW communication skills and knowledge, lack of community interest and respect for CHWs, and CHWs' lack of adequate supplies. The rising penetration of "smart" technology (eg, smartphones and tablets) in low- and middle-income countries facilitates the use of portable electronic devices in the field.

Objective: This scoping review examines to what extent mobile health in the form of smart devices may enhance the delivery of public health messages in CHW-client interactions, thereby addressing the aforementioned challenges and inducing client behavior change.

Methods: We conducted a structured search of the PubMed and LILACS databases using subject heading terms in 4 categories: technology user, technology device, use of technology, and outcome. Eligibility criteria included publication since January 2007, CHWs delivering a health message aided by a smart device, and face-to-face communication between CHWs and clients. Eligible studies were analyzed qualitatively using a modified version of the Partners in Health conceptual framework.

Results: We identified 12 eligible studies, 10 (83%) of which used qualitative or mixed methods approaches. We found that smart devices mitigate challenges encountered by CHWs by improving their knowledge, motivation, and creativity (eg, through self-made videos); their status within the community; and the credibility of their health messages. The technology stimulated interest in both CHWs and clients—and sometimes even in bystanders and neighbors. Media content produced locally or reflecting local customs was strongly embraced. Yet, the effect of smart devices on the quality of CHW-client interactions was inconclusive. Interactions suffered as CHWs were tempted to replace educational conversations with clients by passively watching video content. Furthermore, a series of technical difficulties experienced especially by older and less educated CHWs compromised some of the advantages brought about by mobile devices. Adequate CHW training ameliorated these difficulties. Only 1 study (8%) considered client health behavior change as an end point, thus revealing a major research gap.

Conclusions: Smart mobile devices may augment CHWs' field performance and enhance face-to-face interactions with clients, yet they also generate new challenges. The available evidence is scarce, mostly qualitative, and focused on a limited range of health outcomes. Future research should include larger-scale interventions across a wide range of health outcomes and feature client health behavior change as an end point.

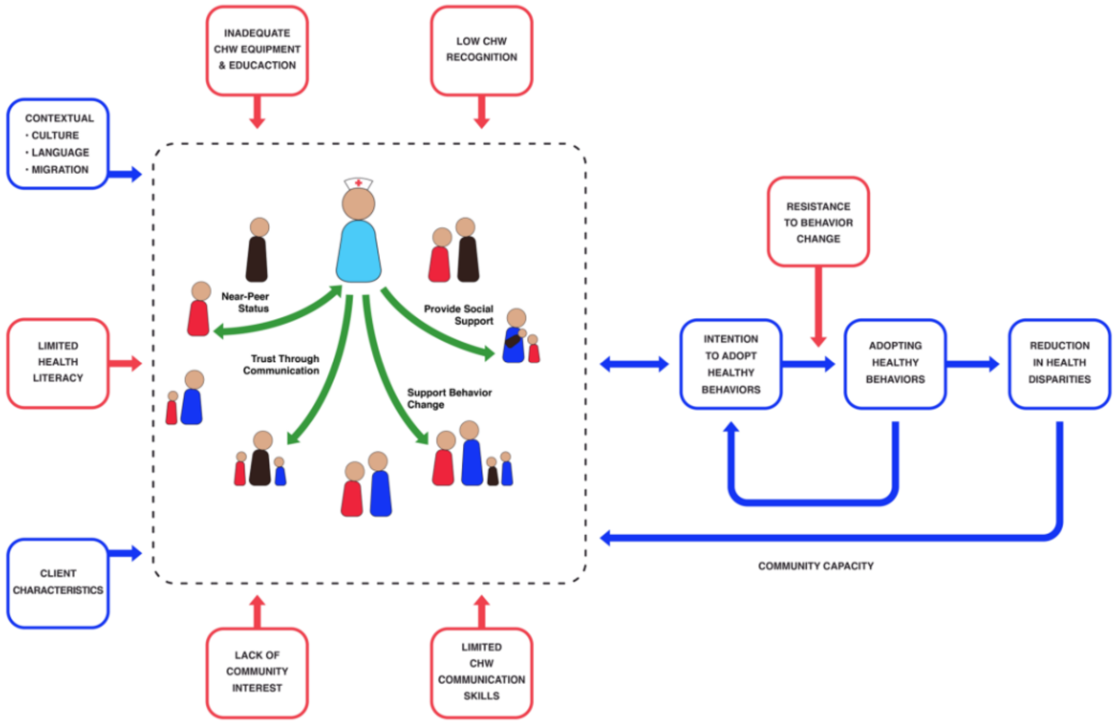
Introduction

Community health workers (CHWs) have become central to health promotion activities, with more than 5 million CHWs working worldwide in 2014 [1]. In part, CHWs' impact is a result of speaking the local language and identifying with the community they serve. Therefore, they have the potential to convey health messages more effectively than other health cadres [2] and may be able to "improve key health-related behaviors" [1]. Katigbak and colleagues [3] have developed the Partners in Health conceptual framework for how CHWs can facilitate the adoption of healthy behaviors. In this framework, client characteristics, the environment, and CHW activities reciprocally influence each other to generate behavior change. Nevertheless, factors both within and beyond CHWs' control can impede their health promotion activities. Based on the literature cited below, we have identified challenges to CHW health promotion activities and have integrated them into the Partners in Health framework (Figure 1).

Figure 1. Conceptual framework of facilitators and barriers to community health workers (CHWs) and patients acting as partners in health. Challenges to the CHW-client interaction are shown in red (adapted from Katigbak et al [3] with permission from the American Journal of Public Health).



One challenge is the way humans manage change, as promoting healthy behavior often entails encouraging changes in existing behavior. Since multiple social, emotional, and cognitive factors interact to mediate [4] and sustain behavior change [5], harmful behaviors are often resistant to change. A second challenge to promoting healthy behaviors is community literacy. In particular, limited health literacy, the ability to comprehend and act on health-related information, is associated with negative health outcomes [6,7] and may complicate health message uptake. In contrast, adequate health literacy can promote healthy behaviors, such as physical activity, by increasing knowledge and self-efficacy related to these behaviors, resulting in positive health outcomes [7]. While low health literacy is certainly a problem in higher-income countries [6], it constitutes a larger problem in low- and middle-income countries (LMIC). For example, basic literacy in many sub-Saharan African countries ranges from 24% to 60% [8].

Other challenges relate to the characteristics of CHWs and their interaction with community members. These include insufficient CHW communication skills [9]. In addition, a lack of community participation and interest, CHWs' own limitations in understanding complex health information due to low levels of education, a lack of respect for CHW knowledge, and disbelief in health promotion messages may complicate the work of CHWs [10]. The lack of community recognition and the low community status of CHWs may pose additional challenges [11], and this problem may be aggravated if CHWs lack adequate supplies and equipment [12]. Facing these challenges, CHWs have demanded educational communication materials that can be carried to the households they visit [9] and suggested using media to reinforce health messages [10].

Mobile electronic media—in particular "smart" devices such as smartphones and tablets—may constitute powerful tools to deliver public health messages. Smart devices can provide learning via videos or mobile apps, providing information through multiple modes (eg, verbally and visually). Learners presented with visual information in addition to verbal information generate a multimedia effect that deepens learning [13]. Dual coding theory suggests that this deeper learning occurs because learners process visual and verbal information separately and then select pieces of information from each before unifying them into a coherent mental representation of knowledge [14]. This theory has been used to optimize multimedia learning materials for e-learning [15] and medical education [16].

The rapidly rising smartphone ownership in LMIC [17] presents an opportunity for increased access to health-related information and resources extending health system reach [18]. However, the comparatively low penetration of smart devices in low-income settings may limit their usefulness as health promotion vehicles; in several sub-Saharan African countries, adult smartphone ownership is less than 20% [17]. Equipping CHWs with mobile smart devices provides an intermediate solution, allowing electronic multimedia education to be accessed even in low device-penetration communities. For example, tablet-displayed videos have transmitted agricultural knowledge and induced abstractive learning in rural Uganda [19].

Given the potential of smart devices as health promotion vehicles, equipping CHWs with such devices may address several of the aforementioned health promotion challenges. Past reviews of mobile health (mHealth) and CHWs have not focused specifically on the use of mHealth as a health promotion tool. Braun and colleagues' [20] review of CHW mHealth use concentrated on how mHealth improved intra-CHW communication and learning. Hall and colleagues' [21] review of mHealth interventions in LMIC included client education and behavior change but focused on the role of mHealth in improving treatment adherence and appointment compliance rather than multimedia applications. Källander and colleagues' [22] review considered SMS text messaging rather than multimedia applications, while the review by White et al [23] focused on how mHealth improved CHW-patient communication broadly but did not focus specifically on educational uses. Thus, there has not been a systematic review of how smart mobile devices can facilitate the delivery of public health messages by CHWs.

Accordingly, we conducted a scoping review of how multimedia features of smart mobile devices have been used to enhance knowledge transfer and behavior change by CHWs. We excluded distance-based media approaches such as SMS text messaging, automated voice messages, and phone calls and focused instead on studies involving direct face-to-face communication between CHWs and community members. Our fundamental question is whether smart mobile devices can enhance CHW face-to-face delivery of public health messages and thereby enhance client health behavior change. The aim of this study was to identify the type of evidence available, point out knowledge gaps, and indicate possible directions for future research. Given these objectives, we deemed a scoping review approach as the most suitable [24].

Methods

Following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-analyses extension for Scoping Reviews) methodology [25], we used a scoping approach to review the literature published between January 1, 2007, and January 5, 2022. The start date was chosen because the first publicly available smartphones using capacitive touch screens were released in 2007 (tablet computers became more common after 2010). The search was performed in English, but no articles were excluded from the full-text assessment if they were published in another language. We consulted the PubMed and LILACS databases, modifying White and colleagues' [23] strategy to capture the intersection of 4 search categories: technology user, technology device, use of technology, and outcome.

We defined our "technology users" as CHWs using smart devices to deliver public health messages and client recipients. As definitions for CHWs vary [26], we employed the common definition used in a World Health Organization study group review, in that CHWs should be "members of the communities where they work, should be selected by the communities, should be answerable to the communities for their activities, should be supported by the health system but not necessarily a part of its organization, and have shorter training than professional workers" [27]. Clients are defined as community and household members of any age or gender who receive a health message outside the context of health facilities.

For "technology device" and "use of technology," we focused on digital content requiring portable computer-like "smart" devices that distinguish themselves from regular cell phones by the ability to run apps, show video content, and connect to the internet. We excluded technological features not requiring "smart" devices that can be used by traditional cell phones, (eg, SMS text messages, automated voice messages, and phone calls). We also required direct, person-to-person communication between CHWs and clients (as opposed to CHWs sending messages from a distance) since we were interested in whether technology enhances the effectiveness of person-to-person communication. The person-to-person communication had to be primary health education (ie, the delivery of a preventative health message such as the promotion of healthy behaviors). We excluded secondary prevention messages such as treatment dissemination or medication reminders. Finally, we included any qualitative or quantitative "outcome" that allowed us to assess the effectiveness, advantages, or disadvantages of the use of smart devices for health promotion from the viewpoint of any stakeholder.

For each category, we identified relevant Medical Subject Headings (MeSH) for PubMed and the corresponding multilingual Descriptores en Ciencias de la Salud in LILACS. The complete search process including all MeSH terms used is shown in Multimedia Appendix 1. For each article fulfilling the inclusion criteria, we screened all references for other potentially relevant articles and used Google Scholar to search for relevant publications citing these included studies, as well as additional publications by the same authors.

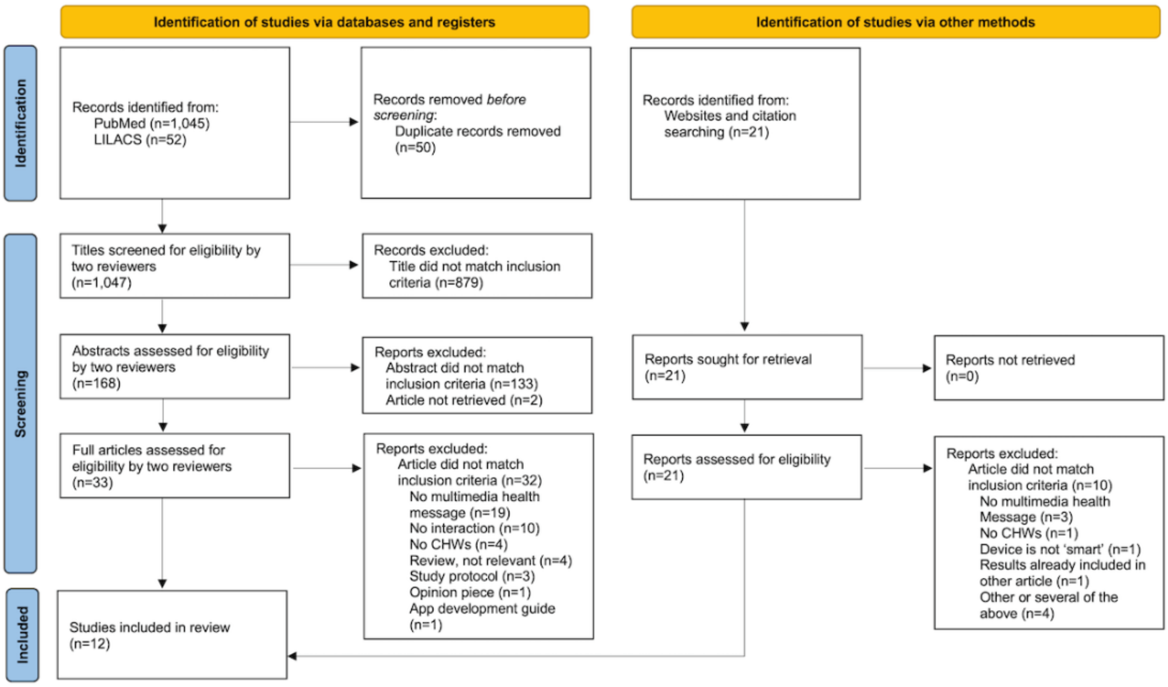
Details of all articles found through these searches were extracted to a spreadsheet and deduplicated. Two authors (MG and FS) independently screened the article titles and abstracts for relevance with respect to the inclusion criteria defined above. If deemed relevant by at least 1 of the 2 authors, the article was included in the following stage of review. The same authors then independently reviewed the full text of all retained articles from the abstract screen. All full-text articles deemed relevant by at least 1 of the 2 authors were then discussed in-depth to reach the final agreement on inclusion. Disagreements were resolved through mutual consent or consultation with a third author (GH). We grouped all included studies by methodology, extracting methods and findings into tables, and used these to qualitatively describe the literature in the context of our original conceptual framework. The PRISMA-ScR checklist [25] that guided our approach can be found in Multimedia Appendix 2.

Results

Identified Articles

The PubMed search yielded 1045 results, and the LILACS search 52, all but 2 (96%) of them duplicates of PubMed articles. Of all articles in either database, 168 articles (16%) were included after the title review, 33 (3%) after the abstract review, and 4 after the full paper review. Of these, 1 was chosen to be included in the results of this publication. From the Google Scholar search and reference screenings, 21 additional abstracts were selected, 11 (52%) of which met our inclusion criteria. All 11 studies were included. Hence, of the 1118 initially identified studies (1068 after deduplication), 12 (1%) were retained for analysis (Figure 2 [28]).

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-analyses) flow diagram for review articles. Reasons for exclusion do not sum to total because some categories overlap. CHW: community health worker.



Overview of Studies

The included studies—all published between 2010 and 2021—were conducted in South Africa [29,30], Nigeria [31], Burkina Faso [32], Lesotho [33-35], and India [36-40] (Table 1). Among them, 9 (75%) studies were rural, 2 (17%) urban, and 1 (8%) both. Moreover, 2 (17%) studies were quantitative, 7 (58%) were qualitative, and 3 (25%) were a combination of both. Five (42%) articles were published in peer-reviewed journals, and 7 (58%) were conference papers. Eight (67%) studies addressed maternal and child health (MCH), 1 (8%) addressed polio immunization, and 3 studies (25%) included multiple health themes. Moreover, 11 (92%) studies included between 7 and 81 CHW participants. Of these, CHWs were the sole or primary participants in 6 (50%) studies; in other cases, they constituted 1 group of participants, alongside mothers, field staff, or mobile shop/laptop owners. The remaining 1 (8%) study examined only clients. Note that sample sizes reported both in the text and Table 1 refer to the participants relevant to our research question and in some cases do not reflect the overall sample size of all participants featured in the study.

Table 1. Overview of studies.

[a]MOVIE: Mobile Video Intervention for Exclusive Breastfeeding.

[b]RCT: randomized controlled trial.

[c]CHW: community health worker.

Quantitative Assessments

Birukila et al [31] assessed the acceptance of videos containing messages to promote polio immunization in rural and urban Nigeria. The videos—described as pictorial, digitalized flipcharts—were shown to parents and caregivers in 21,242 households on CHWs' smartphones. Almost all (99.9%) of the 11,612 caregivers who watched the videos claimed that these videos met their health information needs, and 85.4% of the 12,418 mobile phone owners agreed to receive the videos via Bluetooth. Over the study period, CHWs shared the videos around 100 times a day.

The only randomized controlled trial (RCT) we encountered was the intervention by Adam et al [30] in South Africa, wherein 1502 pregnant mothers were randomized into 2 groups. The control group received standard of care (SOC) home-based infant feeding counseling by CHWs. Using tablets, the intervention group was shown videos on infant feeding in addition to the SOC. No differences in behavior (infant feeding practices) were observed between the groups at 1 month and 5 months follow-up, but the videos had replaced around 40% of the CHWs' face-to-face counseling, thereby freeing up time for other health-related tasks. The small increase in maternal knowledge, observed at the 1-month follow-up, was no longer present after 5 months.

Qualitative and Mixed Assessments

Ramachandran et al [38] evaluated portable multimedia content in rural India. In their study, 7 CHWs used smartphones to show educational videos on maternal health and anemia to pregnant women during weekly household visits. Some of the material was produced by CHWs and featured influential community members. CHWs approached the videos with enthusiasm, yet older CHWs struggled with the technical features of the smartphones. The devices were often used in a noninteractive manner due to a lack of training. However, CHW coaching mitigated these issues. A written test administered before and after the intervention revealed improvements in CHW knowledge of pregnancy danger signs and self-efficacy after the intervention.

Treatman et al [39] developed a smartphone app featuring culturally appropriate color illustrations and audio recordings in the local language containing health messages about topics in MCH. In their study, 8 CHWs in rural India tested the app and were then interviewed. The audio messages were considered more significant than the illustrations; an engaging speaker was deemed especially important. CHWs described the devices as fun to use and impressive to clients, who considered the health messages credible and trustworthy. CHWs preferred the phones over other job aides since they were easier to carry. However, CHWs doubted the effectiveness of the multimedia content if presented without facilitation and thus highlighted the importance of interaction with clients. Moreover, smartphones appeared inept for use in noisy environments or with groups of clients.

In urban South Africa, Coetzee et al [29] provided 24 CHWs with tablets to show videos to pregnant women and mothers during home visits. Pre- and postintervention focus groups were conducted. The tablets increased CHW motivation by amplifying the perceived importance of their work. The videos stimulated clients' interest and attention, improved CHW credibility and time efficiency, and triggered interest even among nontargeted household members. However, some CHWs worried about tablet theft and their credibility and social status being compromised by insufficient technologic capability. Sometimes, tablets were regarded as a means to avoid interaction with clients, especially when CHWs were tired. Moreover, some clients were concerned that the tablets might be recording them, compromising confidentiality.

Molapo et al [33-35] carried out a series of qualitative assessments based on interviews, focus groups, and observations in Lesotho, one of which [33] also contained a quantitative component. In the first intervention [35], a computer application allowed rural trainers of CHWs to create educational videos with local content transferable to the smartphones of 15 CHWs via Bluetooth. Repeated video views helped CHWs deepen their knowledge, and CHWs requested video material deemed especially important. Surprisingly, CHWs not only used the videos for their own education, as was intended, but they also shared them with community members and peers who did not possess smartphones. The health workers experienced a sense of pride, respect from others, and empowerment, and the videos helped them talk about topics that made them feel uncomfortable, such as sexual health.

During the second intervention [34], the existing video content was improved through community feedback. Since CHWs had started showing the videos to community members, their trainers created videos catered to this purpose. Different versions of the application were tested in the field by 54 CHWs, each equipped with a smartphone. CHWs usually showed the videos to groups of clients; they disliked pausing the videos for feedback or questions because the interruptions limited their perceived professionality.

In the last of the 3 interventions, Molapo et al [33] analyzed the results of their 17 months of fieldwork both qualitatively and quantitatively using log data of video views. The 42 CHWs preferred to watch the videos to completion and interact with their clients afterward instead of pausing the videos. Older CHWs handled the smartphones as well as their younger peers after appropriate instructions. In general, CHWs found the smartphones easy to use, though a lack of English literacy sometimes caused problems. Explicit graphic images, such as in videos about sexually transmitted infections, were popular and triggered discussion. The average number of views per video per CHW declined 24% to 87% percent in 16 months, which the authors attribute to a waning novelty effect. However, video views tended to increase shortly after CHW educational workshops, with views increasing for around 3 months. The number of views per video depended on the video's perceived importance and individual features, with a preference for videos showing influential community members.

In the study by Kumar et al [37] spanning 24 months, Indian CHWs showed educational videos on MCH to community members in 84 rural villages during monthly group gatherings. These events became so popular that CHWs began to organize them independently, thereby exceeding the researchers' expectations. The videos were played on small, battery-powered projectors; they facilitated CHWs' explanations, generated discussions, and highly elevated their social status. The latter was especially true for videos starring CHWs, giving them "celebrity status" [37]. Locally filmed videos were the most popular, as community members could relate to the content. Other advantages included the videos' repeatability and credibility boost for health messages.

Vashistha et al [40] attempted to identify the most effective means of distributing offline health videos on personal mobile phones. They equipped 81 CHWs, 84 mobile shop owners, and 71 laptop owners in rural India with videos promoting MCH. The videos featured unique phone numbers, and viewers were urged to call if they liked the video. The number of calls was recorded, and callbacks were conducted to gather viewers' opinions. By the end of the 14-week study period, mobile shop owners had distributed the video material to 6 times as many clients compared to laptop owners and CHWs. However, the number of calls received from videos distributed by CHWs far exceeded the calls from those disseminated by mobile shop or laptop owners. The authors provided 3 reasons for this finding: the CHWs had stronger ties with their clients, they were considered experts in their domain, and they seemed to have emphasized the importance of making the phone calls. CHWs regarded the technology as an effective way to enable clients to learn, review, and share health-related knowledge.

Gopalakrishnan et al [36] developed a software for smartphones and tested how its use would affect CHW-client interactions. In their study, 32 CHWs showed videos with health messages on MCH to 55 clients during home visits. Postintervention interviews revealed a divergence in the software's perceived utility between CHWs and beneficiaries; some initial technical difficulties notwithstanding, the former reported increases in CHW authority, the credibility of health messages, client attention, and the involvement of key household decision makers. They also noted a positive impact on behavior change (vaccination rates). However, for most beneficiaries, the software failed to improve interactions with CHWs. On the contrary, CHW-client interactions were harmed by rushed and short visits and the failure of CHWs to mediate interactions appropriately.

Finally, Isler et al [32] adapted a series of videos related to MCH and nutrition from 1 cultural setting (South Africa) to another (Burkina Faso). Animated videos with South African content and design received input from Burkanese CHWs and clients and were then modified to represent the Burkina Faso cultural, linguistic, and physical setting. Clients emphasized that the characters portrayed should reflect community members in appearance, behavior, and financial situation. Moreover, they recommended acknowledging local household structures and hierarchies during video presentations. The ease of tablet usage varied by CHW education and age. Some CHWs expressed technical concerns and preferred reducing the amount of information transmitted in each video viewing session.

Discussion

Principal Findings

Studies to date have been conducted in India and across Africa and have largely evaluated the practicability of smartphones or tablets as health promotion vehicles. Despite the diversity of study designs and cultural contexts, the studies have common findings regarding both the ability of mHealth to alleviate some challenges encountered by CHWs and some key drawbacks, such as equivocal effects on CHW-client interactions and frequent technical difficulties in the field. While locally produced media content proved popular, the potential of smart devices as catalysts for health behavior change remains elusive and merits larger-scale, quantitative interventions in the future.

Overcoming Challenges

mHealth technologies may mitigate some of the challenges experienced by CHWs in the promotion of healthy behaviors. mHealth can increase CHW health knowledge [35,38], thereby addressing CHWs' own educational deficits. CHWs themselves stressed that the ability to carry mobile videos helped them remember crucial health concepts [35], an assertion verified objectively in a written test [38]. Increased CHW health knowledge should benefit their interactions with clients and increase clients' respect for the health workers and their work.

As a novel technology, mHealth use by CHWs may stimulate community interest [29-32,35-37,39]. Clients, bystanders, and neighbors were interested mHealth deliveries [29,39], as were CHWs not possessing electronic devices [35]. While this interest may wane over time as recipients become accustomed to the technology, it appears possible to rekindle interest through the introduction of new material [33]. Constant innovations (in the form of new videos, apps, etc) may therefore be necessary to maintain interest. The rising personal ownership of mobile electronic devices in LMIC may limit such novelty effects in the future, making the case for constant technological or creative progress even stronger.

Part of the creativity required for this progress may well be shown by the CHWs themselves, as the introduction of the technology motivated them [29,38] and was overall enjoyable [39]. CHWs became innovative in the development of new media [38] and took ownership of the technology, for example, by independently organizing events going beyond the aims set out by the researchers [37]. At times, CHW motivation also extended to influential community members who became involved in the projects [38]. The increased levels of CHW motivation may be explained to some extent by their elevated levels of self-efficacy [38] and community recognition [29,30,35-37]. The mHealth technology gave CHWs a sense of pride and empowerment [35] and elevated their social status [30,37]. This, in turn, affected the extent to which clients accepted health messages, as they considered them trustworthy and credible [29,30,37,39]. Thus, by boosting CHW motivation, self-efficacy, and community status and by raising the credibility of health messages, mHealth may help CHWs promote healthy behaviors more effectively in their interactions with clients. However, the question remains whether these interactions improved with the use of mobile technology.

CHW-Client Interactions

The impact of mHealth on CHW-client interactions was ambivalent. On the one hand, CHWs sometimes viewed smart devices as complementary to their interaction with clients [39]. For instance, CHW-moderated group video sessions generated considerable discussion [37]. Devices were particularly beneficial for sensitive topics such as sexual health [35]. On the other hand, CHWs also used portable media to replace client conversations [29,30,38], for example, because they did not know what else to do [38], they were tired [29], or they wanted to save time [30]. In other cases, CHWs preferred to interact with clients only after the videos had played until completion [33,34]. Beneficiaries frequently considered video-assisted health promotion sessions as rushed or too short [36]. In 1 study [36], there was a considerable divergence in how CHWs and clients assessed the use of smartphones; while CHWs embraced them, beneficiaries criticized the quality of interactions. This suggests that mHealth-facilitated health promotion may simplify CHWs' work by replacing discussions with screen time—at the expense of clients' experience.

Personal interaction with clients is one of the factors that distinguish CHWs from other health-promoting agents. It is thus questionable whether mHealth can benefit CHWs' health-promoting efforts should the quality of face-to-face interactions be undermined. However, appropriate CHW training in how to use videos to stimulate discussions may reduce or eliminate the risk of noninteraction, as 1 study showed [38]. Further research should focus on mHealth's influence on the quality of CHW-client interactions and how a stimulating synergy between technology and interactions can be achieved.

Technical Difficulties

Even the best electronic device is of no avail if a CHW lacks the knowledge on how to use it. Some CHWs initially struggled when using portable media [32,36,38]. Younger CHWs generally adapted more quickly than their older colleagues [32,38], and higher education levels facilitated the adoption of the technology [32,38]. Due to the technological challenges, CHWs reported feeling anxious [29], nervous [32], and even worried about their community status being compromised [29,34]. However, the technical difficulties were reduced after CHWs received appropriate training [33,38], and even older CHWs learned to use the devices as effectively as their younger peers [33]. Having overcome the initial problems, CHWs enjoyed using the devices [33,39], considered touchscreens user friendly [33], and preferred portable devices over other, bulkier job aides [39]. Some CHWs reported that their skillful usage of the technology enhanced their perceived authority in the community [30]. Hence, proper CHW instruction is the key to converting smart devices from stressors and sources of discomfort into pleasant companions at work.

Go Local

Both CHWs and clients highlighted the importance of the media featuring local content [32,35,37-39]. When given the opportunity to create their own educational videos, CHWs chose to include testimonials from influential community members [38]. Videos featuring sequences of CHWs raised their social status in the community and enabled clients to identify with the content [37]. Clients preferred locally filmed videos over those shot in different locations [37]. The inclusion of locally appropriate color illustrations and the local language was also appreciated by clients [32,39], who emphasized that animated video content should resemble the local population in appearance and behaviors [32]. Hence, mHealth promotional strategies should adopt local features to maximize client identification with the material. Locally produced content thus has the potential to affect health behaviors more powerfully than material conceptualized elsewhere.

Client Learning and Behaviors

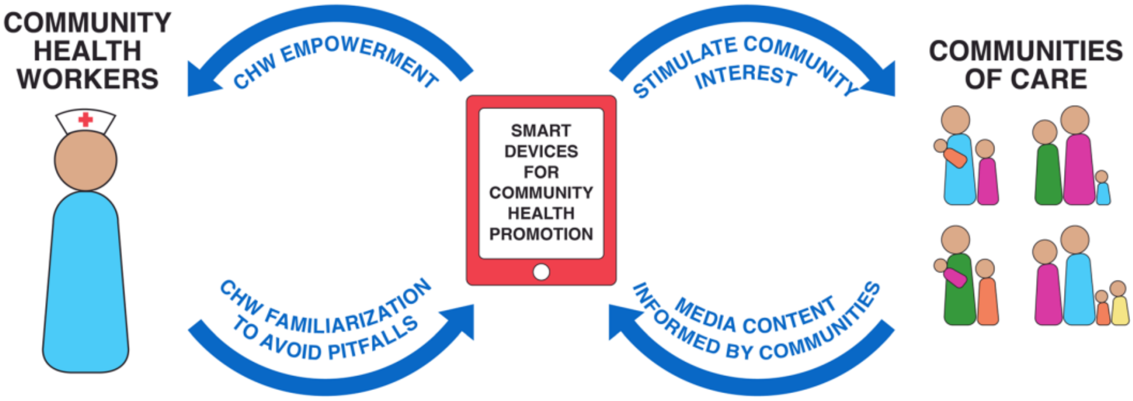
Perhaps the most important question in the context of mHealth and health promotion is whether mHealth helps CHWs improve clients' health behaviors. The reviewed literature contained almost no evidence relating to changes in clients' behaviors or process measures such as behavioral intent or health knowledge. Both clients [31] and CHWs [29,40] regarded the portable devices as enriching educational tools for the recipients of the interventions. Some CHWs provided anecdotal evidence that the use of the devices could have contributed to the adoption of health behaviors such as vaccinations [36]. However, only 1 (8%) of the 12 studies featured behavior change as an end point [30]. In this long-term RCT, the researchers observed no effect of the mHealth video intervention on health behaviors and only a small positive effect on health knowledge [30]. Thus, the potential of mHealth to bring about behavior change when employed by CHWs remains unclear.

Looking Ahead

The studies included in this review contain valuable information on the impact of mobile electronic devices on the delivery of health messages by CHWs. mHealth can empower CHWs and potentially help alleviate many challenges faced in the field. By stimulating community interest, health messages may be conveyed more effectively. Media content informed by the targeted communities themselves has been shown to be especially persuasive. However, the use of mobile media will always require careful training to maximize benefits and minimize potential pitfalls. CHWs should be familiarized with the technology and instructed on employing it as a complement to their interactions with clients, not as a replacement thereof. If used appropriately, smart devices may catalyze health promotion, benefitting CHWs and clients alike (Figure 3).

Nevertheless, our primary research question—whether mHealth improves CHW-led face-to-face delivery of public health messages and behavior change interventions—remains unanswered. Notably, all but 2 (83%) of the studies in this review are qualitative. While these are invaluable for planning, improvement, and evaluation, more large-scale quantitative studies, such as the included RCT [30], are needed with behavior change end points. In addition, 8 (67%) of the 12 studies in this review focus on MCH. This reflects the importance of MCH in low-income settings, but a wider scope of mHealth assessments would be desirable.

Figure 3. Smart devices as catalysts for community health promotion.



Limitations

Our review has some limitations. First, we only used 2 databases which, while wide-ranging in scope, did not capture all the relevant published studies we finally used. Therefore, we may have missed other published studies. Second, capturing all relevant research in this fast-moving field is difficult, as highlighted by most of the included work being only available as conference papers. These findings suggest the importance of future updates to this review.

Conclusions

Novel technological improvements may increase the effectiveness of CHW-led promotion of healthy behaviors. In this review, we show that smart mobile devices have the potential to enhance face-to-face interactions between CHWs and their clients, as these job aides address many of the challenges that CHWs commonly encounter in the field. However, we also find that the available evidence on our research question is scarce, largely qualitative, and focused on a limited scope of health outcomes. In particular, it is unclear whether mHealth helps CHWs change clients' health behaviors. Moreover, the impact of employing mHealth in the field is not all positive, as smart devices may burden CHWs with technological difficulties and lead them to act more passively in their interactions with clients. Further research is required to develop interventions to address this issue, along with large-scale quantitative interventions across a wider range of health outcomes to determine the full potential for interactive mHealth interventions to support CHW behavior change work in low-resource settings.

Acknowledgments

This research was funded in whole, or in part, by the Wellcome Trust through a personal fellowship to GH (Grant 210479/Z/18/Z). For the purpose of open access, the author has applied a CC BY public copyright license to any author-accepted manuscript version arising from this submission. Additional funding has been received from research grants from the European Union (Horizon 2020 and European Institute of Innovation and Technology Health), German Research Foundation (Deutsche Forschungsgemeinschaft), US National Institutes of Health, German Ministry of Education and Research, Alexander von Humboldt Foundation, Else-Kröner-Fresenius-Foundation, and the World Health Organization.

Authors' Contributions

GH, TB, and MG conceived and designed the study. MG screened the titles, abstracts, and full texts and led the quality assessment, data extraction, and drafting of the manuscript. FS screened titles, abstracts, and full texts and participated in quality assessment and data extraction. GH judged over disagreements. MG, GH, FS, MA, AV, and JG interpreted the results and participated in the manuscript drafts and finalization. All authors approved the final manuscript.

Abstract

Background: Globally, 81% of youth do not meet the physical activity (PA) guidelines. Youth of families with a low socioeconomic position are less likely to meet the recommended PA guidelines. Mobile health (mHealth) interventions are preferred by youth over traditional in-person approaches and are in line with their media preferences. Despite the promise of mHealth interventions in promoting PA, a common challenge is to engage users in the long term or effectively. Earlier reviews highlighted the association of different design features (eg, notifications and rewards) with engagement among adults. However, little is known about which design features are important for increasing engagement among youth.

Objective: To inform the design process of future mHealth tools, it is important to investigate the design features that can yield effective user engagement. This systematic review aimed to identify which design features are associated with engagement in mHealth PA interventions among youth who were aged between 4 and 18 years.

Methods: A systematic search was conducted in EBSCOhost (MEDLINE, APA PsycINFO, and Psychology & Behavioral Sciences Collection) and Scopus. Qualitative and quantitative studies were included if they documented design features associated with engagement. Design features and related behavior change techniques and engagement measures were extracted. Study quality was assessed according to the Mixed Method Assessment Tool, and one-third of all screening and data extraction were double coded by a second reviewer.

Results: Studies (n=21) showed that various features were associated with engagement, such as a clear interface, rewards, multiplayer game mode, social interaction, variety of challenges with personalized difficulty level, self-monitoring, and variety of customization options among others, including self-set goals, personalized feedback, progress, and a narrative. In contrast, various features need to be carefully considered while designing mHealth PA interventions, such as sounds, competition, instructions, notifications, virtual maps, or self-monitoring, facilitated by manual input. In addition, technical functionality can be considered as a prerequisite for engagement. Research addressing youth from low socioeconomic position families is very limited with regard to engagement in mHealth apps.

Conclusions: Mismatches between different design features in terms of target group, study design, and content translation from behavior change techniques to design features are highlighted and set up in a design guideline and future research agenda.

systematic review; youth; physical activity; design features; engagement; mHealth; mobile health; mobile phone

Introduction

Background

Physical activity (PA) in youth is associated with a variety of health benefits [1], including physical [2] and mental health benefits [3]. Despite the health benefits, 81% of youth (ie, those in childhood and adolescence) globally do not meet the PA guidelines [4,5] of daily 60 minutes of moderate- to vigorous-intensity physical activity (MVPA) and vigorous activities 3 days per week [1]. In Europe, only 19% of adolescents comply with the MVPA guidelines, and higher family affluence is associated with higher levels of MVPA [6]. Moreover, PA in youth is reported to track into adulthood, underlying the importance of promoting PA in the youth [7,8]. Also, the youth of families with a low socioeconomic position (SEP) are less likely to meet the recommended PA guidelines [9,10]. Therefore, effective and socially acceptable PA interventions are needed [11], especially among youth of families with a low SEP. SEP is often measured in terms of education (attainment), income, and occupation status, which are often interrelated and related to the social and economic resources available [12].

Mobile health (mHealth) tools such as smartphone apps can be cost-effective [13] in changing total PA [14,15] and daily steps [14]. mHealth interventions are preferred by youth over traditional in-person approaches [16-18] and are in line with preferences of youth, with regard to multimedia formats (ie, text, sound, and video) [19]. Mobile devices and apps have gained popularity in the daily life of increasingly younger age groups of youth, starting at the age of 3 or 4 years already [20-24]. Families of young children, especially those with a low-SEP background, indicate concern about inappropriate content [20], which might suggest that appropriate content might rather be supported by guardians. Appropriate content may refer to different forms of app use that might not necessarily increase current screen time use, as the design of the mHealth intervention may have considered a limited use time frame, only stimulating sporadic screen time (eg, integration to the direct physical environment to stimulate children to go outside and be physically active instead of the requirement of using the digital tool when being physically active) or stimulating the co-use of young children and guardians [25]. Earlier systematic reviews indicated that currently, foremost, adults are included in mHealth effectiveness studies, and limited research has been conducted among youth [26]. People with high SEP compared with people with low SEP report foremost positive health effects of the same digital intervention [27]. Apps are primarily designed for people with high SEP, and people with low SEP are often reported as being difficult to reach [28]. In contrast to mHealth apps, youth from low-SEP families engage in more screen time [29] and are more involved on the web [30] and active [31] gaming. This suggests that approaching youth with low SEP via apps (eg, screen and games) can be useful and beneficial, yet other ingredients (eg, tailoring) are needed to reach them effectively in mHealth apps [32].

Despite the promise of digital or mHealth interventions in promoting PA [26], a common challenge is to engage users in the long term [14] or effectively [26]. With regard to including people with a low-SEP background in research, studies identified challenges in reaching the target group [33] and engaging them in research [28] and in the digital health intervention [34]. In addition, eHealth and mHealth studies focus on a general target group and often do not research subgroups (ie, low-SEP groups) [35].

Engagement refers to the involvement and motivation of the user in the intervention [36]. It refers to “(1) the extent (e.g., amount, frequency, duration, depth) of usage and (2) the subjective experience characterized by attention, interest and affect” (ie, enjoyment) [37]. Attention refers to the degree of focus or absorption versus distraction in the intervention. Interest refers to feelings of interest or fascination versus boredom with the intervention. Enjoyment reflects the enjoyable experience of fun or pleasure versus frustration and annoyance while using the intervention [37,38]. Engagement can contribute to the overall effectiveness of digital interventions [26,39], meaning that to be effective, it is important that the user experiences a sufficient degree of engagement. The extent of use or dose is less predictive of engagement than the subjective experience to achieve the intended outcomes of the intervention (ie, effective engagement) [40]. This means that frequently engaging with the intervention is not always required to be effectively engaged with the intervention or the behavior eventually.

Currently, engagement is still not commonly reported in terms of use data (ie, extent) [26] and experience data (ie, subjective engagement) [41]. To improve intervention exposure and related intervention efficacy, it is important to better understand the design features (ie, active ingredients of an app that are in best cases informed by theory and translated into design, often referred to as “persuasive features,” features, and elements) contributing to engagement [26]. A review of commercial apps indicated low engagement scores and suggested investigating features that improve engagement with an app among youth [42], as the features may differ with those studied in adults [37]. Earlier studies reported a common decline in app use over time and called for investigating features that contribute to intervention uptake and engagement [14,26] also among particular subgroups, such as people with a low-SEP background [27,32,43,44]. For example, research among low-SEP groups indicated that frustration with particular design features and navigations (eg, data log) hampered app use [45].

When designing mHealth interventions, several active ingredients, otherwise indicated as behavior change techniques (BCTs), are applied and translated to app features to foster behavior change. In addition to low engagement scores, existing reviews reveal that a limited number of BCTs, such as instructions, encouragement, rewards, and feedback on performance, which are essential components of interventions to promote behavior change [46], are currently applied in mHealth apps [42]. BCTs can be directly translated into gamification or app features (eg, goal-setting translated into challenges), here referred to as design features [47]. Studies suggest that applying either a larger number of BCTs [42]—particular BCTs (eg, self-monitoring, feedback, goal-setting, rewards, reminders, and social support under certain circumstances) or a particular combination of BCTs (eg, problem-solving and rewards) [48]—may contribute to engagement in digital interventions [44,47,48].

Objective

To inform the design process of future mHealth tools, it is important to investigate the design features that can yield effective user engagement. Research has demonstrated that for adults, user guidance, well-designed reminders, self-monitoring, positive feedback, rewards (eg, lottery), goal-setting, personalization, social networking, and health message framing [43,44,49] were associated with higher user engagement. However, most studies included adult samples, targeted mental health instead of PA among adolescents, or did not focus on low-SEP groups [50-52]. To our knowledge, no systematic review that primarily seeks to identify design features in mHealth PA intervention among youth, especially youth from low-SEP families that have been associated with engagement, has yet been conducted. Therefore, this systematic review aimed to identify which features are associated with engagement in mHealth PA interventions among youth who were aged between 4 and 18 years. This could help inform app developers and (digital) behavior change intervention researchers to better integrate engagement during the design process of mobile behavioral change interventions.

Methods

Systematic Review

The research protocol of the review was registered with the International Prospective Register of Systematic Reviews (PROSPERO; #CRD42021254989). Reporting complied with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; Multimedia Appendix 1 [53]) statement [54].

Search Strategy

A systematic search was conducted on June 2, 2021, updated on June 24, 2022, and included the following databases: EBSCOhost (MEDLINE, APA PsycINFO, and Psychology & Behavioral Sciences Collection) and Scopus. The search terms that included synonyms relating to engagement and the population (youth), the intervention (mHealth), and outcome (PA) were informed by earlier reviews [37,55,56] and were eventually reviewed by an academic librarian. Multimedia Appendix 2 provides the complete search terms and synonyms used.

Eligibility Criteria

Quantitative, qualitative, and mixed methods studies were included in the review, as engagement is an emerging field of research, and the aim of this review was to gain a broad overview of features that are considered engaging. Available full-text research articles or conference papers were eligible in case they (1) described the development (ie, user-testing) or evaluation of an mHealth intervention (or more broadly the use of healthy lifestyles as long as specific information about PA could be retrieved), designed for PA promotion; (2) reported on the extent of use or subjective experience; (3) reported an association (ie, relation of design features with engagement, either assessed qualitatively and referred to "self-perceived association" or quantitatively referred to "association"); (4) included an intervention that was designed for healthy youth who were aged between 4 and 18 years (in line with Dutch PA guidelines [57] and in line with the increasing popularity of mobile devices in the daily life of [increasingly younger] youth) [20-24] or if the mean sample age was within this range; (5) were written in English; and (6) were published between 2010 and 2021 (owing to the smartphone use increase among youth, the use of mHealth interventions has been increasing since 2010).

Papers were excluded in case they (1) included a PA intervention that was not mobile based; (2) did not report on the extent of use or subjective experience; (3) did not report an association between a particular intervention feature and engagement; and (4) included either a study population of children who were aged <4 years, adults, or older adults or a population whose mean sample age was not within the range of 4 to 18 years (in line with Dutch national PA recommendation age range). Moreover, editorials, opinion papers, case studies, research protocols, design papers not including any user-testing, book chapters, systematic reviews, or meta-analyses were excluded (Textbox 1).

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Population
  - Youth was defined as individuals who were:
    - healthy
    - aged between 4 and 18 years or the mean age of sample in the same age range
- Intervention
  - Physical activity mobile health interventions that are:
    - developed (ie, offered for user-testing) or evaluated
    - mobile
    - designed for physical activity promotion (or healthy lifestyle, including physical activity)
    - designed for the target group of youth (4-18 years old)
- Comparison
  - Not applicable
- Outcome
  - Drivers of the extent of use or subjective experience with regard to physical activity
- Study type
  - Quantitative, qualitative, and mixed methods studies that:
    - report on behavioral or subjective engagement
    - report a relation or association between the particular feature and engagement
    - are original and available full-text research articles or conference paper

Exclusion criteria

- Population
  - Youth in disease recovery and rehabilitation, experiencing a chronic disease (ie, overweight, obesity, and diabetes)
  - Children aged <4 years or mean age not within the age range of 4 to 18 years and adults or older adults
- Intervention
  - Physical activity interventions that:
    - were still in the early development phase (ie, not offering an app but, for example, only a general discussion about apps, paper mock-ups)
    - used different formats than mobile
    - only included wearables (eg, smartwatches) without a mobile health app
- Comparison
  - Not applicable
- Outcome
  - No drivers of the extent of use or subjective experience with regard to physical activity
- Study type
  - Quantitative, qualitative, and mixed methods studies that:
    - do not report on behavioral or subjective engagement
    - do not report a relation or association between the particular feature and engagement, for example, engagement is only described in general without any relation to the particular feature

- are editorials, opinion papers, case studies, research protocols, or design papers not including any user-testing, book chapters, systematic review, or meta-analysis

Screening and Data Extraction

All the papers identified through the searches were downloaded into Rayyan software (Rayyan Systems Inc), a systematic review software, and duplicates were removed. A multistep strategy was applied. First, titles and abstracts were screened, followed by full-text reading to determine eligibility (DO). One-third of the titles and abstracts and full texts were reviewed by a second reviewer (KB). Interrater reliability for the titles and abstracts and full texts was substantial and moderate (Cohen κ=0.73 and Cohen κ=0.54), respectively. Disagreements regarding the title and abstract and full texts were resolved through discussion between the reviewers (DO and KB). Any disagreement between the 2 reviewers was discussed, and a third reviewer (AS) was consulted if necessary.

Data extraction was completed by both reviewers (DO and KB). Disagreement regarding data extraction was resolved through discussion between the reviewers (DO and KB). Background information (1-3) was extracted by one reviewer (DO), and the rest of the data (4-7) were extracted by two reviewers (DO and KB): (1) publication information (author and year); (2) study information (country and target group [number, percentage of female, percentage of people of low SEP, mean age, and age range]), and 3) app description (name, device, operating system, aim, and theory used; based on the mHealth taxonomy) [58]; (4) engagement measures (engagement measure or definition); (5) presence of BCT and, if present, behavioral change measures (based on the ABACUS scale) [59]; (6) design features (type of feature and 1 feature vs multiple features); and (7) association with engagement (short summary of association of particular features and engagement). The engagement measure of the original individual study was extracted (ie, usability, motivation, enjoyment, and liking) and then coded according to attention (ie, paying attention to mHealth app), interest (ie, feeling interested in mHealth app), and enjoyment (ie, experiencing enjoyment while using it; Textbox 2) [37].

As the researchers of this study were not aware of one framework of design features, 3 (digital) behavior scientist researchers (AS, LW, and MS) developed a coding frame to code all design features based on earlier studies on PA apps; gamification (ie, application of any features [eg, badges, points, avatars etc] in a nongame setting); and game research (ie, full-fledged and rule-based games) [61]. Free codes were created if they did not suit 1 category. Owing to the design process of translating BCTs into design features, obviously, overlap between the features and BCTs occurs (ie, goals vs goal-setting). Design features were coded as interface esthetics, challenges, narrative, levels, feedback, monitoring, customization or personalization, reinforcement, navigation, goals, social, progress, and credibility (Textbox 3).

Textbox 2. Coding scheme of engagement and definitions.

Interest

- Experiencing interest, boredom, fascination, intrigue, or indifference [37]
- Cognitive state that is occurring spontaneously and relates to liking and willful engagement [60]

Attention

- Experiencing focus, inattention, absorption, distraction, or mindfulness [37]
- Cognitive state of focused awareness and relates to focalization and concentration [60]

Enjoyment

- Experiencing frustration, annoyance, enjoyment, fun, or pleasure [37]
- Relates to the sensory experience and relates to pleasure and activation [60]

Textbox 3. Coding framework for design features and definitions.

Interface esthetics

- Graphics, color, sound, music, and language [55,56]

Challenges

- “Time-limited goals or competitions” [55,62-64]

Narrative

- Story [54,61,63]
- Levels [55,62,64]
- Feedback [55,56,62,63]

Monitoring

- Self-monitoring, monitoring, and tracking of user’s behavior (eg, smartphone sensor and wearable) [55,56,63,65]

Customization or personalization

- Assessment of user’s characteristics and provision of personal information and avatars [55,56,62,63]

Reinforcement

- Reminders and rewards (badges, points, unlockable content [“access to enhanced functionality or content for accumulating experience or achieving a specific goal”], leaderboard, certificates, medals, cash or gifts, congratulation messages, and updates) [55,56,62-65]

Navigation

- Navigation support (menu bar, search bar, etc), instructions, and guidance [55,56]

Goals

- “Performance-based measures and targets,” either set by the app or by the user itself [55,63-65]

Social

- Social messages (communicating with others), “performance is publicly displayed,” community, competition (compete with each other), and collaboration (work together) [55,56,62-65]

Progress

- Progress, achievement, and levels [55,62-64]

Credibility

- Absence of advertisement, credible sources or information, privacy policy, and password protection [56,63]

Quality Assessment

Quality was assessed according to the Mixed Method Assessment Tool [66], and it was not used as a basis for study exclusion but to support the interpretation of results (Multimedia Appendix 3 [67-87]). All the studies were coded by 1 reviewer (DO), and one-third of the studies were double coded (KB). Interrater reliability was substantial (κ=0.63). Any disagreement between the 2 reviewers was discussed, and a third reviewer (AS) was consulted if necessary.

Synthesis of Results

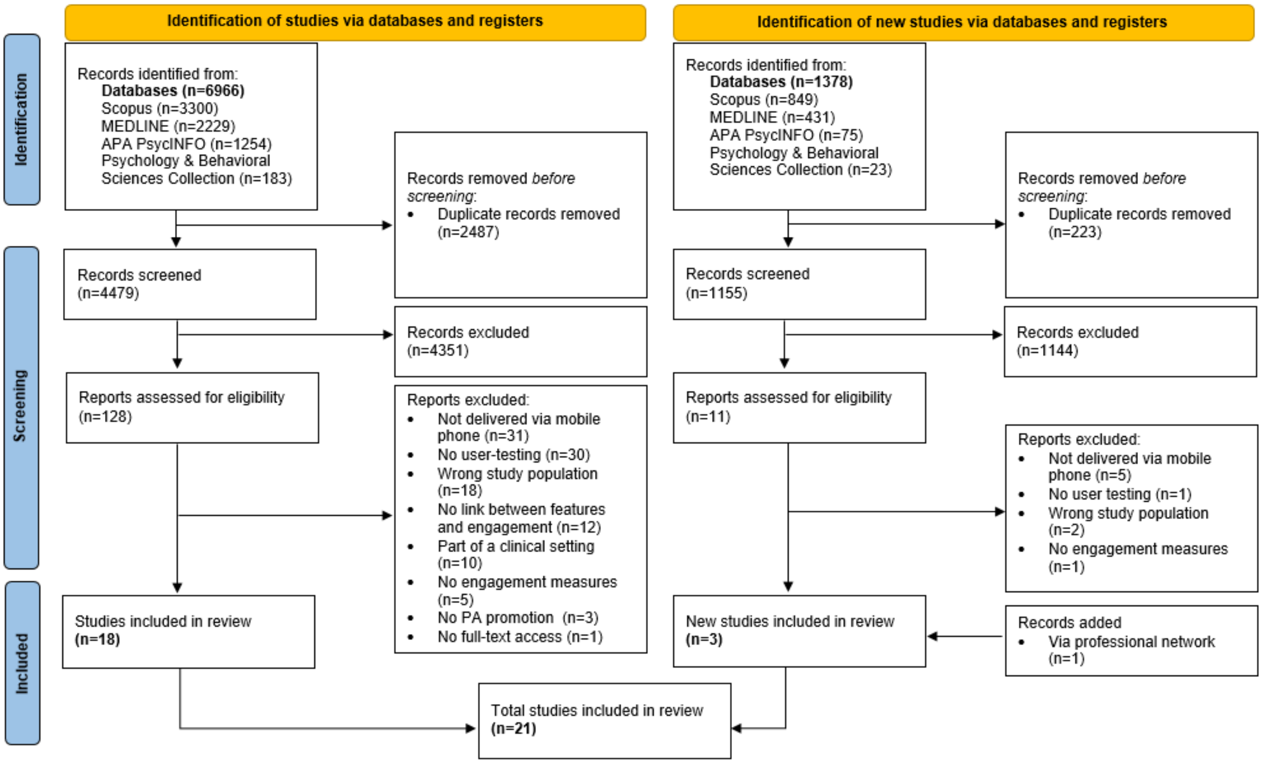
A systematic narrative format [88] structured around the design features that were associated with engagement was applied. All the features that have been actually tested (ie, user-testing) were reported. In case the same study also provided suggestions by participants to further develop the app (ie, hypothetical design features not tested but suggested), this was marked explicitly as a suggestion. In addition, the presence or absence of BCTs was outlined, indicating whether theories had been applied in the design phase of design features or not. A subgroup analysis was conducted for youth from low-SEP families. The categorization of SEP was derived from the classification of the original studies. Research results were not grouped by the origin of the data (ie, qualitative, quantitative, or mixed methods), but it was indicated explicitly for each research outcome.

Results

Description of Included Studies

In total, 21 studies were included in this review (Figure 1). The studies originated from different countries (15) and were conducted in Europe (n=10), North America (n=4), Australia (n=3), Asia (n=3), and South America (n=1). These studies were published between 2012 and 2021. Mobile interventions were used and evaluated by youth who were aged between 3 and 18 years. Sample sizes ranged from 5 to 354 youths, with a total sample size of 1443 youths. All the studies retrieved informed consents from parents and youth participants, except for 5 studies that only collected consent from the youth participants alone [67,68] or from the school principal [70], were conducted in parent-child dyads [69], or did not clearly state this [71]. Studies included different engagement measures varying from acceptability, experience, usability, motivation, feasibility, enjoyment, engagement, satisfaction, or interest. When categorizing the measures in terms of interest, attention, or enjoyment, most studies (15/21, 71%) measured solely interest, especially in terms of features that were in general liked by the users. A combination of interest and attention (2/21, 10%), solely attention (1/21, 5%), solely enjoyment (1/21, 5%), or solely engagement (2/21, 10%) was rarely studied. Engagement was mainly measured as the primary outcome in some studies (14/21, 67%). Most studies (12/21, 57%) used a mixed methods design, ranging from posttest prototype studies to quasi-experimental studies to randomized controlled trials, mixed with designs such as qualitative exit interviews, focus groups, or think-aloud studies. In total, 24% (5/21) of studies included a qualitative study design (interview and focus group study), and 19% (4/21) of studies included a quantitative study design (experimental design with quantitative survey). Studies relevant to this review included qualitative data (10/21, 48%), quantitative data (4/21, 19%), or mixed methods data (7/21, 33%) to determine the association between design features and engagement.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart illustrating the inclusion and exclusion of studies. PA: physical activity.



On the basis of Mixed Method Assessment Tool [66], the quality of the included studies was mixed. In general, the studies that measured engagement as the primary study outcome had a moderate to high quality, especially scoring high on transparency regarding the data collection methods and analysis. Studies that focused on engagement as a secondary outcome scored rather low on the quality of the study design applicable to measure engagement (eg, including nonvalidated methods such as a number of open exit questions in a larger randomized controlled trial), although the studies scored high on the design (eg, randomized controlled trial) to measure the primary outcome (eg, PA).

mHealth Interventions

In general, the mobile interventions tested in the included studies (N=21) were either developed for commercial purposes (n=4, 19%) or for study purposes (n=17, 81%). Most of the interventions (14/21, 67%) were designed to improve PA behavior. In addition, 33% (7/21) of studies focused also on additional health behaviors associated with a healthy lifestyle (eg, nutrition or sleep) in addition to PA behavior. The studies included different types of mHealth interventions, ranging from mobile games (10/21, 48%) to mobile apps (8/21, 38%) to mobile text messaging systems (3/21, 14%). Mobile games mainly focused on PA (9/10, 90% studies); included different PA activities (ie, ranging from simple arm movements such as swinging arm to complex full-body movement such as running); and applied different inputs (ie, ranging from manual input to camera data to Bluetooth, GPS, or PA sensor data). Games ranged from short-term activities (eg, push-ups) to long-term gameplay (eg, location-based treasure hunt games). Mobile apps ranged from narrative-driven PA guidance to GPS-tracking information. Mobile text messaging systems especially focused on generating and adapting goal-setting, facilitating self-monitoring, and providing feedback [72,73] and informative content (ie, quizzes and factoids) [74]. Furthermore, 67% (2/3) of the studies focused also on health behaviors other than PA (Multimedia Appendix 4 [67-87]). The interventions tested in the included studies were perceived as engaging by the youth. Youth liked to play games that aimed to increase their PA level and evaluated apps or text messaging systems as easy to use and supportive in improving PA or lifestyle behaviors. Multiple studies (6/21, 29%) found that poor functionality and technical issues are considered a barrier for engagement with mobile interventions [67,68,75-77] and suggested to include technical improvements [76].

In the following section, all the design features are summarized, starting with the design feature researched most often. A detailed overview of the results is presented in Table 1. All tested design features (ie, features offered to participants via an app and actually tested) are outlined as an association between the particular design feature and engagement (either as self-perceived association in qualitative studies or as tested association in quantitative studies). In case the participants provided further suggestions on design features that might be included in a future version (ie, feature not tested or only hypothetical), it was explicitly referred to as a suggestion. The results section concludes with a subanalysis on BCTs and low-SEP subgroups.

Table 1. Design features and association with user engagement.

Details	Association (ie, tested)	Suggestion (ie, hypothetical)
Interface aesthetics		
Language		
PA[a] and nutrition messages (ranging from information to quizzes)	[74][b,c] [67][b,d] [74][b,c]	[67][d]
Familiar content	[74][c,e]	N/A[f]
Short messages	[78][b,g] [74][b,c]	N/A
Cheerful and personal tone	[78][b,g] [74][b,c]	N/A
Visual		
Clearly presented text	[68][b]	N/A
Large text blocks and complicated language	[68][e,g]	N/A
Clear and realistic visualization (eg, infographics, figures, tables, pictures, symbols, and videos)	[79][b,g] [68][b,g]	[68][g] [67][d] [76][c] [77][d]
Quality not reflecting reality	[70][e,g]	N/A
Sound		
Sounds associated with arm movements or game activities	[75,80][b,c]	N/A
Sounds associated with every click	[81][e,g]	N/A
Monotone and robotic voice	[75][c,e]	N/A
General interface		
Lack of sophistication	[75][c,e] [79][e,g]	N/A
Reinforcement		
Rewards		
Tangible rewards (prize, medal, new Pokémon, and healthy real-world actions)	[75,82][b,c] [78][b,g]	[83][c] [78][g]
Intangible rewards (achievement, encouragement, evolving Pokémon, and comparisons)	[70,81][b,g] [82,84][b,c]	N/A
Messages		
Messages sent at random times, maximum frequency <2 times per day	[74][b,c]	N/A
Frequency and timing of messages	[78][e,g]	N/A
Receiving reminders	[79][g,h]	N/A
Reinforcement		
Leaderboard	[76][h,c] [87][h,d] [85][e,c]	N/A
Navigation		
PA instructions		
Instructions on PA (eg, video)	[67][b,d]	[71][g] [86][c]
Textual and unclear instructions on physical missions	[71][e,g] [83,85,86][c,e]	N/A
In-app instructions		
Clear and intuitive in-app instructions	[84][b,c]	[80][c]
Written manual and unclear instructions	[78][e,g] [76][c,e]	N/A
Layout		
Straightforward and simple layout	[84][b,c]	[67][d] [83][c]
Scrolling to find information	[68][e,g]	N/A

Details	Association (ie, tested)	Suggestion (ie, hypothetical)
Lack of logical flow between different modules	[68][e,g]	N/A
Navigation		
Finding and recognizing items on a map	[70][e,g]	N/A
Difficulty reading the map	[76][c,e]	N/A
Controls reacting slowly	[78][e,g] [85][c,e]	N/A
Social		
Multiplayer		
Socializing and multiplayer capabilities (eg, friends)	[80][b,c] [70,78,81][b,g]	[76,80,82][c] [71][d]
Social messages		
Sharing results and postings	[78][b,g] [83][b,c]	N/A
Social networking	[84][c,e]	N/A
Replying messages or chat	[74][b,c]	[82][c]
Competition		
Competing against classmates	[71][g,h] [82][c,h] [87][d,h]	N/A
Competing with friends	[87][d,h] [78][b,g]	N/A
Cooperation		
Cooperation and togetherness	[82][b,c]	[82][c]
Challenges		
Types of challenges		
Searching for items (eg, QR codes, bombs, Pokémon, and tags)	[70,71,81][b,g] [82][b,c]	N/A
PA missions	[84][b,c] [69,71,78][b,g]	N/A
Variety		
Repetitive game with lack of progression or clear end goal	[78][e,g]	N/A
Larger variety of actions (eg, special events, season-themed challenges, and new missions or minigames)	N/A	[78][g] [76,82][c] [77][d]
Difficulty level		
Difficulty level of the challenges that suit a player's skill level	[81][b,g]	[80][c]
Time limit		
Time given (to diffuse bombs)	[70][g,h]	N/A
Monitoring		
Manual input		
Manual input of multiple activities or behaviors	[68,69][e,g]	N/A
Remembering multiple behaviors	[79][e,g]	N/A
Run logs and PA diary	[84][b,c] [67][b,d]	N/A
Device		
Monitoring via phone (eg, SMS text messaging and smartphone)	[73][b,d] [71][b,g]	N/A
Monitoring via external sensor (eg, pedometer, wearables, and heart rate monitor)	[73][b,d] [71][b,g]	N/A
Monitoring with real-time information	[83][b,c] [77][d,h]	N/A
Self-monitoring		

Details	Association (ie, tested)	Suggestion (ie, hypothetical)
Self-reflection	[72][c,h]	N/A
Ability to track multiple behaviors	[79][g,h]	N/A
Goals		
Self-set goals		
Personal, self-selected goals	[67][b,d] [78,79][b,g] [76][c,h]	N/A
Type of goals		
Choosing between different types of goals	[84][b,c]	N/A
Goals helped to perform PA	[83][b,c] [67][b,d]	N/A
Goals		
Goal reminders	[72,76][b,c]	N/A
Customization		
Types of customization		
Ability to customize user account, own music, choosing the type of PA, and personal goals	[78,79][b,g] [83,84][b,c]	[83][c]

Interface Esthetics

Clear and short messages with positive and personal tone and relevant content were associated with engagement in youth [67,74,78]. Engagement was hampered by lack of sophistication in the interface (eg, game graphics, sound effects, and camera use) [75,79]. Youth preferred a clear and understandable layout [67,68,76] and text with clear headlines and a large font size supported with infographics, figures, and tables [68]. The design of progress graphs was identified as an important contributor to engagement in terms of readability [79]. Too much text or large text blocks, as well as heavy and complicated language, were considered to hamper usability [68]. Participants suggested to include more pictures, symbols, and videos to make the app more attractive [68]; improved or realistic visuals [67,76,77]; or general interfaces [76]. Youth liked sounds that were associated with their movements or game activities [75,80]. However, robotic and monotonic voices [75] or sound associated with clicks could negatively impact engagement [81].

Reinforcement

Youth enjoyed winning tangible rewards [70,75,78,82] and suggested offering rewards (ie, in apps that have not introduced rewards earlier) [78,83]. Intangible rewards (eg, feeling of achievement [81] and encouragement [84]) were especially interesting for the youth. Messages that were sent at random times were preferred over messages sent at preset times. The preferred frequency of the messages was less than twice per day [74]. In the study by Martin et al [78], participants expressed concerns about the frequency and timing of messages. The timing should be appropriate, for example, not receiving messages at a moment when one is not able to act on the messages [74,78]. Mixed results with regard to leaderboards were noted. Youth enjoyed leaderboards when beating persons placed above them but they did not enjoy being at the top of the leaderboard. In addition, leaderboards could lead to too much competition that could result in teasing [76]. In another study, adolescents particularly indicated that they missed seeing the other player's scores [85].

Navigation

Instructions related on the one hand to instructions of the in-app functions and on the other hand to instructions related to PA activities. In both cases, well-outlined instructions could support engagement [67,84], and suggestions were made to design clear, simple, and intuitive instructions [80] with the addition of visual components [71,86]. Unclear instructions on requested movements [83,85,86] or unclear [76] textual [71,78] instructions could hamper engagement. The wish for clear instructions had been underlined by a straightforward and simple layout [67,68,83,84]. Working with a map was considered difficult [70,76]. Laine and Suk [70] reported that the quality of the map tile was perceived as poor, which made it difficult to identify one's current location. In addition, Robertson et al [76] reported that children experienced difficulties in understanding the map representation in the game interface. Interestingly, both studies integrated the Google Maps (Google Inc) services, which hampered PA and interrupted engagement. To find and recognize targets, the map resolution and targets should be clear. Furthermore, controls facilitating navigation through the app were negatively associated with engagement in case they were reacting slowly [78,85].

Social

Multiplayer gameplay was considered important for engaging, socializing [80,81], and playing with friends [70] and setting challenges for friends [78]. In different studies, multiplayer gameplay was suggested to include in future versions of the app [76,77,80,82]. However, competing with friends revealed mixed results. Martin et al [78] found a positive association with engagement [78], and as outlined previously, leaderboards could affect high competition (see *Reinforcement* section); however, when competition was compared with cooperation, the latter was preferred [71,82,87]. This was also quantitatively assessed by Nuijten et al [87], who found that intergroup competition (ie, collaboration within class and competing against other classes) increased engagement in comparison with intragroup competition (ie, individual competition). Competing with others was suggested by youth for future app versions [80].

Cooperation and togetherness were considered important during gameplay [82,87], and an extension to collaborate with others was suggested for future app versions [82]. Social interaction in terms of messages to the research team [74], postings [83], and sharing results [78] was considered to contribute to engagement. A chat function [82] or a social platform [80] was suggested for a future app version. Direito et al [84] described that children seldom or never used the social networking features and disliked sharing their runs or status updates.

Challenges

Youth suggested increasing the variety of actions or (mini) games available, indicating that they liked a wide variety of challenges to choose from when playing a game [77,78]. In addition, the new content was considered important, for example, season-themed challenges or special events [76,78,82]. Youth liked activities organized around a hunt, including activities of finding and scanning objects [70,71,81,82] or missions, for example, PA-related workout missions [69,71,78,84]. Youth liked games that made a connection between energy expenditure in real life and the energy level in a game [78]. Repetitive challenges with a lack of progression or clear end goals negatively impacted engagement [78]. The difficulty level of the challenges needed to fit the users' level [80,81], as challenges that were not adjusted to a younger age appeared to negatively impact young kids' enjoyment [81]. This finding was supported by the study done by Arteaga et al [80], in which children suggested including multiple challenges that fit the different levels of individual players. The study by Laine and Suk [70] reported mixed results regarding a time limit paired with challenges.

Monitoring

Manual input hampered engagement [68,69,79], although youth liked to make use of logbooks [84] and diaries [67]. Using devices [71,73] to track real-time information was appreciated and perceived as useful [77,83]. Youth endorsed the self-monitoring function but had complaints relating to discomfort while wearing the monitoring device [72]. The accelerometer that was used in this study was not part of the intervention but was used to measure the PA outcome. The perceived discomfort might have influenced the use of the intervention. Including the function to track multiple health behaviors, on the one hand, engaged youth but, on the other hand, challenged them by the need to remember multiple behaviors [79].

Goals

Self-set goals were considered important [67,76,78,79]. However, choosing a goal was considered cognitively challenging [76]. Specific goals on PA or different types of goals were considered to contribute to engagement [67,83,84]. The feeling of achieving a goal contributed to enjoyment [76]. Reminders to set goals were considered useful [72].

Customization

Youth liked to customize their accounts (eg, removing features such as friends, goal-setting, and training plans) [79,83]; choose the type of PA they wanted to perform [83]; sort their personal goals [78]; and listen to their own music [84]. Youth in general suggested including the possibility of customizing one's account [83].

Youth liked to engage with avatars [69], and children (10-12 years old) suggested including dragons (35%), followed by a dinosaur (25%), and suggested to upgrade their avatar with personal equipment [69].

Feedback

Participants considered regular feedback on achievements and goals [67], which is individualized and in real time to contribute to engagement [79,83]. However, feedback based on dynamic tailoring did not reveal to contribute to overall engagement but contributed to narrative sensation (ie, feeling of presence) [77]. Feedback that was shared via SMS text messaging and presented in graphs was highly valued [67,73].

PA Input

Youth enjoyed upper-body movements [80] compared with full-body movement such as running. However, requiring running to proceed in the game achieved mixed results (ie, facilitating and hampering) on engagement [70,71,81].

Narrative

Youth liked the addition of a narrative, including a variety of characters [78,80,84] and settings [78] that are realistic [80], and the addition of a (complex) story, which was suggested by various studies [70,80,86].

Levels

Gradually increasing levels [84] were considered important, and higher upgrade levels, referring to unlocking new levels as the player proceeds, were suggested to be added [69].

Credibility

Youth found it important to receive information from a credible source as nutrition professionals [74].

Other Features

Youth suggested including additional push notifications [80] and reducing the GPS latency [76].

Included BCTs

In total, 19% (4/21) of the studies did not include any reference to BCTs [68,71,82,86]; 19% (4/21) of studies did only include a reference to BCTs in the results [70,73,74,80]; and 33% (7/21) of studies did include a reference to BCTs in the methods and results; however, they did not particularly refer to it as BCT [67,69,75,77,78,84,87]. Furthermore, 29% (6/21) of studies included a particular reference to BCTs and included the outline of the BCT in the methods and results [72,76,79,81,83,85]. In general, 57% (12/21) of studies included theory in the development of the app (4/21, 19% excluded as apps developed for commercial purposes). In addition, 81% (17/21) of studies included several BCTs (ranging from 2-10), which were partly related to the design features outlined in Table 1. The particular BCTs were not adopted in Table 1, as they have been translated into design features. The BCTs that were most often mentioned were feedback (11/21, 52%), social comparison (11/21, 52%), goal-setting (10/21, 48%), rewards (10/21, 48%), monitoring (9/21, 43%), and encouragement (6/21, 29%).

Subanalysis SEP

In total, 29% (6/21) of the studies (all from countries that form the Global North) included a substantial target population of low SEP [72,75-77,86,87]; however, 33% (2/6) of studies eventually included a large percentage of high-SEP children (34% to 75%) [72,76]. In only 33% (2/6) of studies [75,76], the SEP was indicated as a direct study aim, and in 33% (2/6) of studies [77,86], a mix in SEP was desired. Low SEP was defined differently (ie, neighborhood site, family income, family affluence, parents’ education level, and youth education level), which made it difficult to compare studies, and engaging design features were not presented for different SEP categories. Therefore, subanalysis of the different design features could not be conducted.

Discussion

Principal Findings

This systematic review presents the results of 21 studies that assessed the associations between features and engagement with mHealth PA interventions. According to our knowledge, this is the first mHealth intervention review that focused on PA and youth, with an additional focus on low-SEP background.

The results showed that various design features, such as a clear interface; rewards; multiplayer game mode; facilitation of social interaction; variety of challenges with personalized difficulty level; self-monitoring options; and a variety of customization options among others, including self-set goals, personalized feedback, progress, and a narrative, were positively associated with engagement. In contrast, various features, such as sounds, leaderboards, competition, instructions, timing of messages or notifications, maps, or self-monitoring facilitated by manual input, that have been negatively associated with engagement need to be carefully considered while designing mHealth PA interventions. In addition, technical functionality can be considered as a prerequisite for engagement.

When comparing the results with those of research in adults, several features are shared, such as a simple and structured interface, tailored and positive feedback on PA levels [43,44,89,90], progress [90], well-designed reminders (eg, timing and frequency of notifications) [26,43,44,89], rewards [43,44,49,91-93], self-monitoring [26,43,44], goal-setting, [43,44], clear navigation [43,44], accurate tracking function [43], personalization (eg, goals) [94], and the offer of a variety of features [43,95]. Technical difficulties were also negatively influencing engagement in adults [43,89].

Several features that have been in particular noted for adults, yet not in this review on youth, are credential sources, adequate privacy settings [43], and content preventing the occurrence of surprises [26,43]. Sharing accomplishments via social media was considered less engaging in adults [90] than in youth. Although the studies among youth provided mixed results on competition, literature on adults suggests including competition [44,90], leaderboards [91], and hierarchical status (eg, progressive status report) [91]. In gamification research, leaderboards are considered the most common feature implemented (alongside points, goals, and progress) [96,97], and this seems to be considered with care when addressing youth for PA promotion. In studies including adults, no direct links with narratives, avatars, a hunt, difficulties with manual input, sounds, or virtual location maps were found. Research on using these design features for interventions in youth is limited, according to the results of this review.

This review focused on design features that have been tested by youth and included hypothetical or suggested features of the same studies but did not extend the search to studies that only provided ideas or suggestions that have not been tested (ie, cocreation study on app development without user-testing). Earlier studies have indicated that what users may request and what they actually engage with in practice do not have to match [44,98]. In the studies in this review, several features were tested and included as further suggestions, which may underline the importance of the match between what youth would like to have included and what they actually engage with. The following results are in line with existing research on app development (ie, no user-testing) among youth: (1) clear user interface esthetics (ie, youthful visuals) [99,100]; (2) rewards, referring to a fair reward system [100,101], rewards that progressively increase [102], and social rewards (ie, storybooks with interactive questions) [103]; and (3) multiplayer mode, facilitating competition [55,100] and comparison (eg, leaderboards) [55], as well as cooperation [103,104]. Several features that have been suggested and tested in the studies included in this review were not found in existing research, and these include (1) chat functions (although with mixed results), (2) increasing difficulty level, (3) customizing user content, and (4) adding a variety of avatars and characters. In addition, several features have been suggested but have not been tested, and these include (1) meaningful information [99,100], including PA-related tips and plans [101], and (2) variety and content updates [102].

Features that have been solely suggested in this review (ie, not tested) relate to (1) adding video and moving figures that navigate the PA and app instructions, (2) adding a storyline, and (3) including additional push notifications. Other research suggests that a clear navigation that is self-explanatory is important [99], yet that notifications evoke mixed results on engagement [101]. Features that have been suggested in other research, but not in this review, include (1) in-app events [104] and (2) GPS and map editors [105,106]. This review contributes to the body of research and highlights that although maps can be suggested by youth, they can be very challenging when applied in practice, risking hampering engagement. Additional features that especially could hamper engagement include a small number of available minigames [106], no instant feedback [102] or personalized feedback by email [101], lengthy texts, and difficult navigation [99]. Future studies are needed to conduct experimental testing on features that yield inconclusive evidence so far among others competition, leaderboards, and notifications, as it may be possible that the results may differ for different subgroups of youth. We recommend that designers and health researchers consider designing a clear interface and an appropriate and fair reward system, enabling social interaction, and providing a variety of content, which is preferably customizable.

Earlier research indicates how a variety of design features are designed and implemented in mobile apps [65,107]. This is also indicated in other research outlining the challenges of how BCTs are operationalized [65,108-110]. In other words, the content or the active ingredient of the intervention may still differ by how it is delivered, in which context, or in which combinations (ie, design features, including gamification elements and BCTs) it is applied [111]. An ontology, as proposed by West and Michie [112], and tools such as SciModeller that integrate multiple pieces of empirical data [113] can eventually contribute to this knowledge and help researchers and mHealth developers apply and build on this knowledge. This review focused on whether the app design has been informed by or has been based on relating BCTs or behavioral theories and concluded that BCTs are often not outlined in detail, and there is no particular translation of BCTs to app content. This review only included 33% (7/21) of studies that made a clear translation from a particular BCT to a design feature. A scoping review not only summarized the challenges in mHealth design in translating BCTs to an mHealth feature but also raised challenges with regard to integrating ideas from different perspectives (ie, BCTs, user needs, and stakeholder views), which can result in conflicting ideas [110]. Existing research on mHealth, focusing on app features, BCTs, or both, points to the challenge of mapping which features or BCTs work in isolation or in combination with others [47,114]. Furthermore, a wide applicability exists with regard to creating design features that are often designed from scratch. In light of the Open Digital Health initiative [115], we recommend making mHealth apps and data accessible to be able to reuse or continue working on existing design features that have been proven to be effective for engagement. By this, we can start mapping working design features for different user groups in different contexts [115,116].

Different systematic reviews focusing on the effectiveness of mHealth interventions have also focused on BCTs. However, a large number of the reviews map the number of BCTs that have been included in an intervention [42,117] or the BCTs that have been included [42,117]. However, there is dearth of research that identifies the individual or interaction effects of design features or BCTs in mHealth interventions among youth. Several studies have identified that modeling is an effective BCT for children. With regard to adolescents, providing consequences for behavior, providing information on others' approval, facilitating intention formation, self-monitoring, using behavioral contract [118], and providing individualization support [25] were positive predictors of PA effect size. Providing instructions was negatively predictive of study effect size [118]. In future reviews, it would be interesting to map the similarities and differences between design features that contribute to engagement in the mHealth intervention (ie, microengagement) and BCTs that contribute to the behavioral change effectiveness (ie, macroengagement) to identify effective design features [40]. However, limited BCTs are researched in effectiveness studies, especially among youth [119]. Therefore, more individual studies are needed before this comparison can be made. Future studies may, therefore, test the effectiveness of individual BCTs and combinations of BCTs on behavioral changes in factorial designs [120] in youth. Future studies should also consider testing both microengagement and macroengagement in the same mHealth intervention [40] to better inform how to increase engagement in the mHealth intervention (ie, microengagement) and translate this to behavioral change, which can be engaged in the long term in the absence of any intervention (ie, macroengagement).

This review underlines that research addressing youth from low-SEP families is very limited with regard to engagement in mHealth apps. Although it is often argued that apps can be a suitable platform to reach diverse groups of youth, it is striking that only 7 studies have been identified that aim to involve youth from different SEP backgrounds. Unfortunately, it was not possible to conduct a subanalysis because the features were not directly linked to the SEP position. Studies that succeeded in addressing a large percentage of children with low SEP recruited participants via schools [49,77,86]. From this review, it cannot be directly derived which recruitment strategy leads to lower percentages of children with low SEP, as especially, the measures of low SEP differ greatly. We advocate for more research that includes youth from low-SEP families early in the development phase and user-testing and suggest recruiting youth from low-SEP background via schools. Further research in adults suggested that personal contact between study staff and participants is essential and that community sites (comparable with school settings) created a sense of community and support [121]. Thereby, youth who have the potential to book the greatest health gains (ie, often youth with low-SEP or low-PA levels) are addressed appropriately, which may contribute to reducing health inequalities and the digital divide [44]. A scoping review highlighted the need to further investigate user engagement studies in low-SEP groups and called for future in-depth formative studies [95]. Existing research indicates that multimedia, personalization, variation, and gamification [95], such as competition [116], can contribute to engagement in mHealth apps among young adults with low-SEP backgrounds. We advocate to start testing these features in youth with low SEP.

In this review, we identified a heterogeneity of engagement measures, which has also been identified in earlier reviews [55,60,114,122,123]. In addition, several measures only reflect one construct of engagement and do not measure the multidimensional concept of engagement [55]. Furthermore, research studies included in this review did not distinguish between different features that can be considered in different stages of engagement. Research suggests that engagement is a dynamic process rather than a state, although it is often measured as a state (ie, 1 postintervention questionnaire on engagement instead of cyclic measurement) [124]. On the basis of earlier research, it may however be stated that features such as a clear interface are especially important for the initial stage of engagement (ie, attention grabbing) [124]. Features that sustain engagement may relate to social interaction, a variety of challenges with personalized difficulty level, self-monitoring and customization options, and narratives [77]. Disengaging may relate to certain types of sounds, leaderboards, instructions, messages or notifications, competition, and self-monitoring facilitated by manual input. Features that reengaged or nonengaged users have not been identified in this review. However, for example, Janko et al [69] discussed unlockable avatars and upgrading levels as possible features that may contribute to reengagement. Research on young adults indicated that users did not engage (ie, nonengagement) owing to low uptake of the intervention among peers [49]. The reasons for disengagement mentioned in this review relate to factors outside the mHealth intervention (eg, holidays, competing after-school activities, weather, school policies, and unstructured or leisure settings) [76,77,81,83,87], yet nonadherence has not been linked to design features. Future research is needed to identify particular features in different stages of engagement to grasp engagement as a multidimensional and dynamic process [124]. Thereby, designers can improve design features according to the stage of engagement (eg, include particular features to reengage users and prevent them from sustained disengagement). Furthermore, engagement may also be related to the setting in which the mHealth tool is implemented. The activity that competes with the mHealth tool is central. Earlier research indicated that pupils tend to choose to engage with an mHealth tool in order not to participate in class in a school setting [125]. In comparison, mHealth tools are often challenged in leisure time, and the competition with other apps or leisure activities is central [126,127]. Future studies should focus on the implementation of mHealth tool and investigate differences in engagement in either voluntary versus more obligatory settings.

In terms of comparability, the Persuasive Systems Design (PSD) model could have helped map the different design features. PSD is often used in research to outline persuasive design elements. The model maps different persuasive design elements in primary task support, dialogue support, system credibility support, and social support. When comparing the PSD model with the coding scheme applied in this systematic review, a number of similarities can be identified. In terms of primary task support, navigation (PSD model: tunneling), personalization, and self-monitoring are identified. In terms of dialogue support, rewards, messages (PSD model: reminders), and interface aesthetics (PSD model: liking) can be identified. Liking is very broadly defined as "visually attractive" in the PSD model and has been criticized in earlier research [128]. It finds more detail in the coding of our systematic review (ie, interplay of interface elements such as sounds, visuals, and language). In terms of system credibility support, only credibility (PSD model: expertise) can be identified. In terms of social support, reinforcement (PSD model: social comparison), social messages (PSD model: social facilitation), cooperation, and competition can be identified. Design features that are difficult to code in terms of the PSD model are challenges, levels, feedback, avatars, and narratives and are predominately game elements and refer to achievement- and immersion-based features [96]. These have also been identified in earlier research, distinguishing their research from the PSD model [129,130]. On the one hand, this emphasizes the challenge to identify and apply a complete list of design elements. As a proposed solution, Geuens et al [128] created a website that derived from the PSD model and mapped a working list of adaptable features. However, it should be noted that this list is currently not complete in terms of gamification elements. On the other hand, the large number of similarities between the PSD model and the coding frame of this systematic review suggest that various research studies may have found (to a certain degree) a consensus on design features. A revision of the PSD model, adapted by, for example, gamification elements, could help create an updated list of design features that are widely applicable to designers and researchers.

Strengths and Limitations

As identified in an earlier review [55], this review included a larger number of studies reporting the foremost positive associations, which may bias the overview in features that are either unrelated or negatively associated and may not be reported (ie, publication bias). In addition, the strength of associations has not been included in the individual studies, owing to a lack of high-quality experimental studies. In addition, heterogeneity among studies with regard to engagement measures was identified, making direct comparison challenging; this has also been identified in earlier studies [114]. This systematic review maps a large number of features that are associated with engagement individually. The interaction of different features and their effect on engagement is still not researched and needs to be considered in future engagement studies, for example, experimental factorial designs [41]. Individual studies included small sample sizes, and only a small number of studies focused on low SEP. Using different SEP measures and mixing them with high-SEP measures made it challenging to compare studies and prevented us from conducting a subanalysis based on the SEP background. Therefore, the findings might not be transferable to low-SEP groups and this underlines the need for future research. In addition, the variability in SEP measures made it difficult to standardize SEP thresholds and compare between countries, as youth from a low-SEP background may not be equivalent in terms of studies and countries, and disparity occurs even in different parts of one country. Studies that included SEP measures were exclusively from countries of the Global North, emphasizing that in general, a minority of studies focused on the Global South (4/21, 19%), and none focused on SEP. As the search was limited to English, this review may not have included all available and relevant research on this topic. Earlier research outlines the differences in the effectiveness of mHealth intervention on behavioral outcomes and engagement among very young children and older children. Research further suggests that preferences for design features may differ between different age groups of youth. This systematic review did not cluster for different age groups because of the limited number of studies that, for example, focus on the very young children (aged <4 years) [25]. More individual studies are needed among very young children to identify whether age differences exist. Earlier research suggests that gender differences in games may exist [131-137]. None of the included studies in this systematic review distinguished between gender for design features in mHealth interventions. In future research, it can therefore be considered to investigate possible differences in future user-testing. The quality of the studies was mixed, indicating in general that study designs with regard to measuring engagement need to evolve. Especially, studies that focus on engagement as a secondary outcome need to operationalize engagement clearly and report the methods transparently. In this review, no validated design feature taxonomy has been used for coding, although it was based on existing overviews of design features [114]. In this review, all study designs were included, and this provided a comprehensive overview of relating research on engagement and triangulated evidence. This is the first review identifying mHealth design features among youth with the aim of promoting PA. This review was based on the PRISMA guidelines and succeeded in providing a coherent overview of all nuances relating to a good quality assessment and high interrater reliability.

Conclusions

The results indicate that a clear interface; an appropriate and fair reward system; social interaction; and a variety of app content (ie, missions, content, and characters) that are preferably customizable can contribute to engagement in mHealth PA interventions for youth. Design features, such as sounds, competition, instructions, notifications, virtual maps, or self-monitoring facilitated by manual input, that were negatively associated with engagement need to be carefully considered when designing mHealth PA interventions. In addition, technical functionality can be considered a prerequisite for engagement. Research addressing youth from low-SEP families is very limited with regard to engagement in mHealth apps, and design features often lack a sufficient degree of operationalization based on behavioral change theories or techniques. Future studies are needed to further test design features in youth, particularly youth from low-SEP families, and to evolve engagement measures.

Acknowledgments

This review was supported by the mVital@2040 project, which is a part of the Vitality Academy and connected to the EWUU Alliance (Eindhoven University of Technology, Wageningen University & Research, Utrecht University, and University Medical Centre Utrecht). The project and AS were funded by the Wageningen University & Research. MS initiated and acquired the funding for the mVital@2040 project.

Authors' Contributions

AS was responsible for leading all stages of the review. AS established the research protocol, which was reviewed by MS and LHHW. DO conducted the search and data extraction under the supervision of LHHW and drafted the first version of the methods and results. KB served as the second reviewer for search and data extraction. The search was updated by AS. AS was responsible for drafting the manuscript, which was written together with MS, LHHW, and EdV. The manuscript was eventually reviewed and adapted by MS, LHHW, EdV, DO, and KB.

Abstract

Background: Health care professionals are increasingly using smartphones in clinical care. Smartphone use can affect patient quality of care and clinical outcomes.

Objective: This scoping review aimed to describe how physicians use smartphones and mobile apps in clinical settings.

Methods: We conducted a scoping review using the Joanna Briggs Institute methodology and reported the results according to PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines. We used the following databases in our literature search: MEDLINE, Embase, Cochrane Library, Web of Science, Google Scholar, and gray literature for studies published since 2010. An additional search was also performed by scanning the reference lists of included studies. A narrative synthesis approach was used.

Results: A total of 10 studies, published between 2016 and 2021, were included in this review. Of these studies, 8 used surveys and 2 used surveys with focus group study designs to explore smartphone use, its adoption, experience of using it, and views on the use of smartphones among physicians. There were studies with only general practitioners (n=3), studies with only specialists (n=3), and studies with both general practitioners and specialists (n=4). Physicians use smartphones and mobile apps for communication (n=9), clinical decision-making (n=7), drug compendium (n=7), medical education and training (n=7), maintaining health records (n=4), managing time (n=4), and monitoring patients (n=2) in clinical practice. The Medscape medical app was frequently used for information gathering. WhatsApp, a nonmedical app, was commonly used for physician-patient communication. The commonly reported barriers were lack of regulatory oversight, privacy concerns, and limited Wi-Fi or internet access. The commonly reported facilitator was convenience and having access to evidence-based medicine, clinical decision-making support, and a wide array of apps.

Conclusions: Smartphones and mobile apps were used for communication, medical education and training, clinical decision-making, and drug compendia in most studies. Although the benefits of smartphones and mobile apps for physicians at work were promising, there were concerns about patient privacy and confidentiality. Legislation is urgently needed to protect the liability of health care professionals using smartphones.

Introduction

Background

The use of smartphones has become increasingly indispensable [1]. This technology has revolutionized how people live, learn, work, communicate, and entertain themselves [2]. The use of smartphones among health care professionals is also widespread and affects the clinical care they provide [3]. Studies in various settings reported that most health care professionals use smartphones daily in their practice [4-8].

Smartphones and mobile apps offer an important and diverse set of clinical tools for health care professionals. They enable direct communication with colleagues and patients, instant access to medical knowledge, education, remote patient management, research, and digital diagnostics, to name a few [2]. However, the widespread adoption and use of smartphones in medical practice can affect the quality of care [9,10]. There are concerns about the impact of smartphones on professionalism, patient safety, and data confidentiality as well as the trustworthiness of sources accessed via smartphones [6-8,11-14].

The use of smartphones may vary between different groups of health care professionals and in different settings. For instance, some studies report that medical journal mobile apps are more commonly used by physicians than by nurses [15,16]. In contrast, medical calculators or drug compendium apps are used by both physicians and nurses [7,16]. Many medical mobile apps targeting health care professionals are available, and their number is growing. Studies have reported that the daily use of medical apps ranges from 1 to 20 minutes among physicians [7]. Knowing what types of apps are commonly used by various health care professionals can help discern their needs, guide the future evaluation of the quality of such apps, and inform the development of new apps.

Objectives

A growing number of studies are exploring the use of smartphones among health care professionals as well as their experiences and perceptions of the role of smartphones in clinical care [4,6,7,9-11,13-15,17-22]. However, to date, there are no existing scoping reviews, systematic reviews, and research syntheses available on this topic. Our objective was to collate and describe how smartphones and mobile apps were used by physicians, specifically, specialists and family physicians, within clinical settings. We presented the barriers, facilitators, and opinions of physicians regarding smartphones and mobile apps.

Methods

Overview

A scoping review was conducted using the Joanna Briggs Institute methodology and reported according to PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [23]. The scoping review methodology consisted of five key steps: (1) identifying the research question; (2) identifying relevant studies; (3) study selection; (4) charting the data; and (5) collating, summarizing, and reporting the results. The study protocol was registered in the Open Science Framework registries [24].

Step 1: Identifying the Research Question

This review aimed to collate and describe studies focusing on the use of smartphones among physicians. The overarching question for this scoping review was as follows: "How do physicians use smartphones in clinical practice?" More specifically, the research questions for this scoping review are as follows:

- What are the smartphone apps and features physicians access and why?
- How do physicians use their smartphones as an information source?
- What are physicians' opinions of the impact of smartphones on clinical care?

Step 2: Identifying Relevant Studies

We developed the MEDLINE (Ovid) search strategy collaboratively and iteratively with support from an experienced medical librarian. The search strategy was guided by relevant articles identified from previous manual searches, based on our research questions, and eligibility criteria (Multimedia Appendix 1). The same strategy was adopted to search for applicable studies in Embase, Cochrane Library, and Web of Science. Similar to previous studies, we also searched the reference lists of the included studies and gray literature in the first 10 pages of the search results in Google Scholar using the search terms in our search strategy and titles of the included studies [25,26]. Only studies published in the English language were included. Results were imported to EndNote 20 (Clarivate Analytics) [27].

The included studies in this review had to meet the inclusion and exclusion criteria presented in Textbox 1. We included studies published between January 2010 and January 2022 to capture data that aligned with the proliferation of smartphone ownership [28]. This review aimed to understand practicing physicians', defined as specialists, and family physicians' use of smartphones in clinical settings. Owing to the differences in training needs between medical trainees and nontrainees, medical trainees were excluded [29].

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Studies focusing on the use of smartphones among physicians defined as specialists and family physicians
- Studies exploring the use of mobile apps and the use of social media if this is done explicitly using smartphones (only if the motivation for use was physician driven)
- Studies focusing on personal smartphones, organizationally provided smartphones, or both
- Studies focusing on a mix of physicians if more than 50% of the physicians were specialists and family physicians
- Survey, observational, mixed methods, or qualitative studies
- Published between January 2010 and January 2022
- Printed in the English language

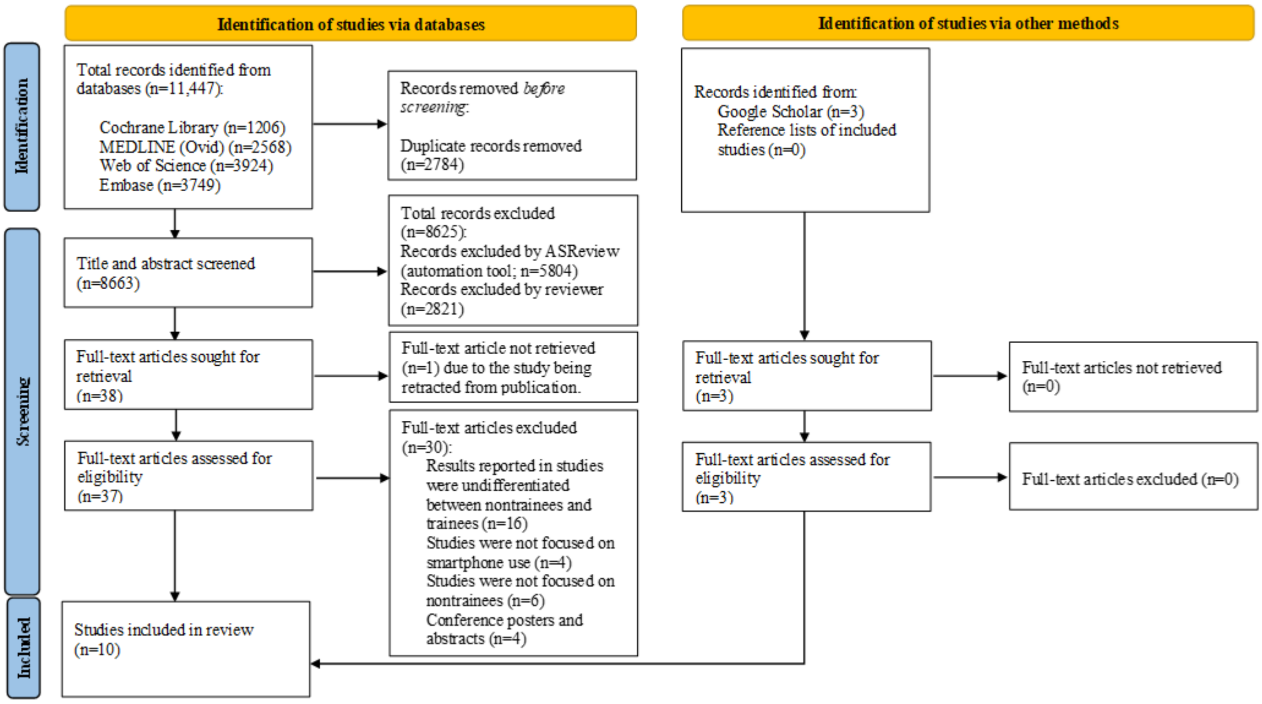
Exclusion criteria

- Studies that focused on patients, medical students, medical trainees, medical residents, house officers, health intervention, or medical education
- If the smartphones were implemented for research purposes
- Studies that focused on infection control of personal smartphones
- Editorials, opinion pieces, conference posters, and abstracts

Step 3: Study Selection

Studies were identified using the search criteria presented in Textbox 1. The search results from different electronic databases were combined in a single EndNote (Clarivate Analytics) library [27], and duplicate records were removed. The first reviewer (MLM) independently screened titles and abstracts on ASReview v1.0 (ASReview Lab) [30] to identify studies that potentially met the inclusion criteria. Only 33% of the titles and abstracts were screened. This was 1 rule that was predetermined and adhered to before screening commenced on ASReview [30]. This rule was set based on a study that found that 95% of eligible studies would be found after screening between 8% and 33% of studies on ASReview [31]. In parallel, a second reviewer (ABSBM) independently screened all titles and abstracts, including 33% of titles and abstracts that were screened by MLM on Covidence (Veritas Health Innovation) [32] to identify studies that potentially met the inclusion criteria. Disagreements on the included titles and abstracts were resolved through discussion between the first and second reviewers. Conflicts between the 2 reviewers were resolved through consensus, and when required, a third reviewer (Ahmad Ishqi Jabir) acted as an arbiter. In total, 2 reviewers (MLM and ABSBM) independently retrieved the full texts of the included titles and abstracts and read and assessed the studies against the eligibility criteria. Disagreements on the included full-text articles were resolved through discussion between the first and second reviewers. Conflicts between the 2 reviewers were resolved through consensus, and when required, a third reviewer (AIJ) acted as an arbiter. A total of 2 reviewers (MLM and ABSBM) independently extracted the data for each included study using a structured data extraction form. Figure 1 shows a flow diagram of the article selection process.

Figure 1. Flow diagram for the article selection process.



Step 4: Charting the Data

After the screening process was completed, EndNote Library [27] was set up to share articles between the reviewers. A data charting form was created using Microsoft Excel and used to extract data from the included studies. The data extracted from each study included the name of the first authors, year of publication, title, aims of the study, study design, study location, study time frame, sample size, participant characteristics, type of smartphone used, and study findings (Multimedia Appendix 2 [5,22,33-40]). Adapted from previous studies by Lee and De Jong [41,42], the data extracted from the included studies were categorized into functions, benefits, and challenges of smartphones and mobile apps for health care professionals. We used coding frames from these studies, as they captured data that were aligned with the proliferation of smartphone ownership. The data charting form was piloted by 2 reviewers (MLM and ABSBM), with 4 studies either different in study designs or population specialties to ensure consistent, reliable, and efficient data extraction. Conflicts between the 2 reviewers were resolved through consensus, and when required, a third reviewer (AIJ) served as an arbiter.

Step 5: Collating, Summarizing, and Reporting the Results

A comprehensive summary of the included studies, number of studies, study design, data collection methods, population types, and the aims of the study were presented. The use of smartphones was organized according to themes presented in a previous paper [41]. The framework we developed was aligned with all our research questions. The collated findings were ownership rates, type of mobile apps used, type of information sources used, type of websites accessed, use of smartphones for contact with colleagues and patients, and physicians' experiences of using smartphones. Relationships between population characteristics and the use of smartphones (differences in the use of smartphones among physicians in primary and secondary care) were identified. A narrative synthesis of the findings without the use of a qualitative analysis program was presented.

Results

Search Findings

Database searches yielded 11,447 records, and another 3 records were retrieved from the gray literature source. After removing 2784 duplicates, 8663 titles and abstracts were screened. Title and abstract screening led to the exclusion of 8625 records, resulting in 40 full texts that needed to be assessed for eligibility. Of these, 30 articles were excluded, resulting in 10 studies for the review (Figure 1). We used a sensitive search strategy that aimed to retrieve all relevant research in this novel area and as such had a high number of citations initially. We then screened citations in parallel and independently to ensure the reliability of our screening.

Study Characteristics

The 10 studies included in this review (Table 1 [5,22,33-40]) were conducted across 9 countries and published between 2016 and 2021. The study data collection time frames were reported in 4 studies [5,22,37,38], and data were collected between 2014 and 2019. Of the 10 included studies, 8 (80%) used surveys [5,22,33-38] and 2 (20%) used surveys with focus groups study designs [39,40]. A total of 3 studies recruited only general practitioners (GPs) [22,33,39], another 3 studies recruited only specialists [34,35,37], and 4 studies recruited both GPs and specialists [5,36,38,40]. The participants in the remaining studies were addressed as anesthetist consultants [34], pediatricians [35], specialists, or surgeons. Overall, 4 studies did not provide information on their clinical settings [5,33,35,36], 2 studies were conducted in hospitals [34,38], and the remaining studies were conducted in community health centers [22], large university surgical departments [37], rural practices [39], and health institutions [40]. The characteristics and details of the included studies on the use of smartphones and mobile apps by physicians are presented in Tables 1 and 2 (Multimedia Appendix 2). One study reported that physicians possessed more than 6 different work-related mobile apps on their smartphones [34]. Another study reported that most GPs had 1 to 3 medical apps, with very few owning more than 4 [22]. Only 1 study found that young GPs (aged <35 years) were more likely to own smartphones [22]. Another study found that younger physicians (aged ≤44 years) were less likely to allow their patients to communicate with them via the internet or phone, and they used medical apps more often [5]. One study reported that 10% (5/50) of physicians used organizationally provided smartphones, whereas the rest used personal smartphones for clinical use [38]. The results are presented in Tables 1 and 2 and are consistent with the PRISMA-ScR guidelines [43].

[a]GP: general practitioner.

[b]This information was not reported in this study.

[c]The number of studies was calculated based on the majority reported under sex and type of smartphone used. For instance, if a study reported more males than females being recruited, we counted it as "Mostly males." Similarly, there are a number of studies on the type of smartphones used.

Table 2. Smartphones and mobile apps used by physicians.

Purpose of smartphone use	Examples of mobile apps and features used
Communication	WhatsApp [5,36,40], Google Hangout [40], Facebook [5,36], YouTube [36], SMS text messaging [36], email [22,36,37], voice calling [37], and instant messaging [33,37,39]
Information seeking and management	
Clinical decision-making	Medscape [35,36,40], UpToDate [35,40], Nature [40], MedCalc [5,40], Das28 [40], Diagnostic assistance tools [38], Prognosis [40], Dxsarus [40], Laborwerte [5], Labormedizin Pocket [5], and medical calculators [38]
Health record maintenance	Enil [40], Meddata [40], E-nabiz [40], PACSapp [40], Acibadem [40], and coding and billing [42]
Medical education and training	Twitter [34], Medscape [35,36,40], OrthoApp [40], Vcell [40], UpToDate [35,40], PubMed [36], and Nature [40]
Reference tools	UpToDate [35], Medscape [35,36], Cepilaç [40], Diagnosia [5], Embryotox [5], Antibiotika (Thalhammer) [5], Arzneimittel Pocket [5], Eponyms [40], and PubMed [36]
Clinical care	
Patient monitoring	Apple Health [37], Instant health rate [37], and Fitwell [37]
Time management	Google Calendar [40]

Communication

Of the 10 included studies, 7 (70%) reported the use of smartphones and mobile apps for communication [5,22,33,36,37,39,40]. One study reported that participants allowed their patients to contact them by phone and via web-based communication tools [5]. However, the study did not report on the smartphone features or apps used. Another study reported that smartphones allowed faster access to information, especially for communication among peers [40]. More than half of the physicians preferred using smartphones and mobile apps over other alternatives for communication with other physicians [36]. Of the 10 studies, 3 (30%) did not explicitly report how smartphones and mobile apps were used by physicians for communication [34,35,38]. One study reported using smartphones to contact other specialists for referrals or advice [34], another study reported using smartphones for communication [38], and the last study did not report on communication at all [35].

Information Seeking and Management

Of the 10 included studies, 7 (70%) reported the use of mobile apps for medical education and training [5,34-38,40]. Of the 7 studies, 3 did not provide examples of mobile apps used by GPs and specialists in medical education and training [5,37,38]. Of the 3 studies, 1 reported that most physicians perceived that they were provided with reliable clinical content and continuing medical education when using mobile apps for medical education and training [5]. Another study reported that most surgeons felt that texting improved the educational experience of their trainees [37]. Of the 10 studies, 7 (70%) reported the use of mobile apps for clinical decision-making [5,22,34-36,38,40]. Of the 7 studies, 1 reported that anesthetists used mobile apps for clinical algorithms, clinical planning, and assessment [34]. Another study reported that mobile apps for disease diagnosis were used by GPs [22], but the identity of the mobile apps used was not provided in those 2 studies.

Frequent use of drug compendium apps was reported in 7 studies [5,22,34-36,38,40]. A total of 4 studies found that the most frequent type of medical apps used by physicians were drug compendium apps [5,22,34,40]. The other most common types of reference tools were the literature search portals [5,22,35,36,38] and medical literature [5,22,34-36]. These were followed by medical journals [34-36], medical news [5,35,36], and medical textbooks [5,40]. Of the 7 studies, 1 reported that anesthetists used mobile apps for drug compendium, prescription, and dosing, and academic journals [34]. However, no examples of the mobile apps used were provided in this study. Another study reported that the Diagnosia and Embryotox medical apps were most often used [5]. Physicians were less familiar with medical apps such as Antibiotika (Thalhammer) from Germany, MedCalc (United States), Laborwerte (Germany), Arzneimittel Pocket (Germany), and Labormedizin Pocket (Germany) [5].

Of the 10 included studies, 4 (40%) reported the use of mobile apps for health record maintenance to access local appointment systems developed by their local health ministry [5,34,38,40]. Of the 4 studies, 1 reported the types of smartphone apps used by anesthetists, including apps for billing and accessing patient results and those that allowed access to hospital electronic medical records [34]. Another study reported that Enlil (Turkey), a national hospital management information system, was the most used app [40]. It was followed by other medical health recording systems from Turkey, such as Meddata, E-nabiz, PACSapp, and Acibadem [40].

Clinical Care

The use of mobile apps for time management was reported in 40% (4/10) of the included studies [22,34,35,40]. Only 1 study reported Google Calendar as the most used app among GPs, followed by the default mobile calendar and appointment app [40]. The other 3 studies did not provide examples of mobile apps used for time management [22,34,35].

Only 20% (2/10) of studies reported the use of mobile apps for patient monitoring [38,40]. According to Sezgin et al [40], patient-monitoring apps were the least prevalent among all mobile apps. Examples of the types of patient-monitoring smartphone apps provided in that study were pedometers, calorie trackers, and heart rate and information tracker tools (cardiograph) [40]. The study also reported that patients had been using the tracking apps and sharing them with their physicians [40]. Teferi et al [38] reported using an app to document the procedures for patient monitoring.

Smartphone Features Used and Web Access by Physicians

Of the 10 studies, only 1 (10%) reported the use of built-in features in the smartphone, such as torchlight, stopwatch, and camera [34]. The same study also reported the use of a smartphone to distract pediatric patients [34]. However, the study did not report on how the smartphone features were used by physicians.

A total of 2 studies reported that physicians used nonmedical apps more frequently than medical apps [22,42]. These nonmedical apps were used by physicians for calendar [22] and web access [22,42]. Overall, 4 studies reported on the use of smartphones for web access [22,35,38,40]. However, 3 of the 4 studies neither reported the reasons for physicians to access the internet nor stated the websites that were accessed [22,38,40]. Web browsers and search engines were also used for medical information searches, sometimes outperforming medical apps [40].

Barriers to the Use of Smartphones and Mobile Apps by Physicians

Overview

In addition to depicting the use of smartphones and mobile apps by physicians, many studies have described the factors that prevented physicians from using smartphones. This review found a wide variety of barriers to the use of smartphones and mobile apps by physicians, including the infringement of patient privacy and confidentiality, lack of regulatory oversight, negative impact on physician-patient and collegial relationships, quality concerns, limited Wi-Fi or internet access, lack of workplace integration, and lack of smartphone savviness.

Infringement of Patient Privacy and Confidentiality

The potential confidentiality breach of patient privacy was the most common barrier to the use of smartphones and mobile apps by physicians [33,36,37,39,40]. Only one study reported on privacy concerns, which included the fear of sending the message to the wrong person or number and the uncertainty around the receipt of the messages [33]. The lack of security and control over the apps' content were also perceived to be risks related to the infringement of patient privacy and confidentiality when using smartphones and mobile apps for communication at work [40]. However, the study did not report the names of these apps.

Lack of Regulatory Oversight

The included studies also addressed barriers to the regulation of smartphones and mobile apps used by physicians [33,37,39,40]. One study reported that only 27% of GPs have a written text policy for texting patients [33]. GPs who used texts always documented patient consent, and when texting medically sensitive information, they always obtained specific consent [33,39]. In the hospital setting, some physicians were unaware that they had any organizational policy on the use of smartphones [34] and sharing patient information via text messages [37]. Most surgeons in 1 study agreed that texting patient-related information should be regulated by a hospital policy (74%) or legislation (57%) [37].

Negative Impact on Physician-Patient and Collegial Relationships

Several studies in this review referenced barriers related to professional relationships. Hofer and Haluza [5] reported that employees were not allowed to use their smartphones at work, as it was found to be disruptive to the relationship with patients during consultation. It was also reported that, among consultant anesthetists with more than 3 years of experience as a consultant, up to 27% agreed that their smartphone was a distraction from their work [34]. However, none of those with less than 3 years in post believed that their smartphones were a distraction from their work [34]. In addition to distraction, GPs found that text messaging increased patient anxiety [39]. Some physicians also reported feeling uncomfortable using smartphones in front of patients [40].

Quality Concerns

Another reported barrier was concern about the quality of the information provided by medical apps [5,40]. For example, physicians expected professional organizations to inform evidence-based medical apps, including assessing the quality of medical information in the medical apps recommended by the organization [5].

Limited Wi-Fi or Internet Access

In total, 2 studies reported limited internet access as a barrier [5,36]. Physicians mentioned that they would use many more apps if smartphone reception was better in the hospital [5]. Hence, they suggested that the availability of an offline version of an app is important [5].

Lack of Workplace Integration

Sezgin et al [40] also raised the issue of the lack of extensive use of smartphones and mobile apps in the hospital system. This has been demonstrated by the lack of interoperability between the use of smartphones and other hospital devices [40].

Lack of Smartphone Savviness

Only one study reported the lack of advanced skills as a barrier to the use of smartphones and mobile apps [40]. For example, some physicians indicated that they were not aware and unsure of the appropriate apps that could be used to help them with their daily clinical tasks. Their lack of knowledge on smartphone use prevented them from using it in clinical settings.

Facilitators for the Use of Smartphones and Mobile Apps by Physicians

Overview

Numerous studies have reported on the facilitators for the use of smartphones and mobile apps by physicians. Facilitators included convenience and access to evidence-based medicine and clinical decision-making support. One study reported that smartphones and mobile apps were useful for conducting research. However, the authors did not elaborate further [36]. The user-friendliness of medical apps was perceived to facilitate the ease of use of mobile apps [5].

Convenience

Physicians used smartphones and mobile apps primarily for convenience [5,33,34,36,37,39,40]. For example, flexible communication channels [5,33,34,36,37,40] as well as a selection of powerful apps to accomplish a variety of tasks at work were readily available [5,36]. Portability [36,41], rapid access to information [37], and multimedia resources [5,36,41] were also examples of convenience.

Access to Evidence-Based Medicine and Clinical Decision-making Support

Access to various evidence-based and clinical decision-making support mobile apps was highlighted as a facilitator in this review [5,34,40]. The evidence-based medical mobile apps included apps for medical education and training and reference tools, as listed in Table 2.

Discussion

Summary of Key Findings

According to the studies included in this review, physicians primarily use smartphones and mobile apps for communication, medical education and training, clinical decision-making, and accessing the drug compendium. Medscape was frequently mentioned as a medical app used for information gathering. WhatsApp has been widely reported as a nonmedical app used for physician-physician and physician-patient communication. The most common barriers reported in the included studies were the risk of infringing on patient privacy and confidentiality, lack of regulatory oversight, limited Wi-Fi or internet access, the lack of extensive use of mobile apps in the hospital system, and the lack of smartphone savviness. The most common facilitators reported in the included studies were the availability of having flexible communication methods, easy access to evidence-based medicine, clinical decision-making support, availability of mobile app choices to accomplish many different purposes at work, and portability.

We found that physicians are more likely to use smartphones for work-related purposes because of the increasing availability of mobile apps. Prior studies showed that only 13% of physicians used their smartphones to watch web-based videos weekly for professional purposes, and continuing medical education activities were the most frequently viewed content [44]. However, this review found that studies frequently reported the daily and weekly use of smartphones and mobile apps by physicians [5,22,40]. In addition, smartphones and mobile apps were widely used not only for medical education and training but also for communication, clinical decision-making, and reference tools. We found mixed views regarding the use of smartphones for work-related purposes as a distraction for physicians [5,34]. For instance, physicians believe that using a smartphone during a consultation could negatively affect the patient-physician relationship [5]. This finding is consistent with a recent systematic review on the effect of web-based information-seeking behavior on the physician-patient relationship [45]. Another study found a correlation between the number of years of experience as a specialist and whether smartphones were perceived as a distraction [34]. Younger physicians tended to use smartphones more and were more likely to accept them in the workplace [34]. This was also found to be consistent with a recent systematic review of distraction with smartphones during nursing care [46]. Future research should conduct a review on the distraction of smartphones from physicians in the clinical setting and perhaps derive a precise estimate of the effect that smartphone distraction has on clinical care outcomes.

Our review identified some challenges to the use of smartphones and mobile apps by physicians. First, we found that physicians were unaware of their hospital's policy [41] on the use of smartphones at work. Only a minority of GPs had written a text policy for texting patients [32]. As a result, while our review found that most GPs who used text messaging always documented patient consent when texting medically sensitive information [33], there remains the potential for a breach in confidentiality. Although previous studies have suggested that the use of strong authentication mechanisms helps to mitigate the risks of a breach [47,48], we found evidence that not all physicians had their smartphones encrypted or password protected, and others were unsure whether their smartphones were encrypted [37].

Physicians are increasingly using instant messaging tools, such as WhatsApp, Facebook, and Google Hangout, for physician-physician and physician-patient communications. However, using social media at work may result in the mingling of personal and hospital data. Most social media tools mentioned in our review are not Health Insurance Portability and Accountability Act compliant, which aims to protect patient privacy and ensure the integrity of sensitive medical information [49]. Despite the absence of Health Insurance Portability and Accountability Act–specific regulations for smartphones and apps, some organizations have developed recommendations and guidelines for mobile security measures [49-53]. A previous study [47] suggested that educating health care professionals about the available hospital policy on the use of smartphones at work could be useful in implementing the policy. However, our review revealed a lack of direction for ideal smartphone use at work. Consequently, it might be helpful to have a policy or legislation that provides comprehensive guidance on authentication, access control, chain of responsibility, data ownership, allowed devices, acceptable use, training, and noncompliance with the use of smartphones and mobile apps [47,54]. Compliance with the legislation of smartphone use at work should be considered in the future during the appraisal process of health care professionals.

This review found that physicians use evidence-based medical apps because they provide instant access to evidence. One example of such an app is the evidence-based point-of-care information summaries [5,34,40]. Point-of-care information summaries are defined as medical compendia specifically designed to deliver predigested, rapidly accessible, comprehensive, periodically updated, and evidence-based information (and possibly guidance) to clinicians [55]. Our review found that Medscape and UpToDate were the most commonly reported evidence-based point-of-care information summaries apps. However, health care organizations lack information on the use of evidence-based medical apps [5]. They were unaware of the reliability of evidence-based information provided by medical apps [5]. To ensure quality and safety, the use of medical apps must undergo rigorous evaluation, validation, and development of best practice standards [40]. Therefore, as a means of mitigating the use of non–evidence-based information in clinical practice, future research should assess the quality of evidence within medical apps to support health care professionals to be more confident when using such apps for practice. In addition, the findings from such research may inform policy on the audit and regulation of medical apps.

There were some limitations when conducting this scoping review. As 8 (80%) of the 10 studies used quantitative methods such as surveys to gather data, deep descriptions and examples to provide an in-depth understanding of smartphones and mobile app use were limited [5,22,33-38]. In addition, only English-language studies were included in this narrative synthesis. Although our classification of data was determined through detailed analysis, team discussions, and consensus, there may be themes that we have overlooked. However, as our comprehensive analysis was based on a commonly used framework on smartphone use by health care professionals, missing out on themes may have been minimized [41].

Implication of the Findings

Physicians use smartphones and mobile apps for communication, clinical decision-making, drug compendium, medical education and training, maintaining health records, managing time, and monitoring patients in clinical practice. However, we found several gaps related to the use of smartphones and mobile apps by physicians at work. These gaps are the lack of regulatory oversight either at a hospital or at a government level, that is, the need to address concerns about the risks of infringement of patient privacy and confidentiality when using smartphones and mobile apps for communication of patient information. There is a need to identify medical apps that provide reliable clinical information and nonmedical apps that can be used for communication by physicians at work. We also found that the use of smartphones differs in different subgroups, such as participants of different ages, sexes, and work experience. Therefore, there may be possible implications on the association of the characteristics of participants with the use of smartphones and mobile apps. Future studies should explore the associations between smartphone use with clinical practice. Future research should also provide more information about smartphone use in clinical practice, including whether smartphones were used for work-related or personal purposes, how smartphone features and apps were used, and how health care professionals communicate using smartphones.

Conclusions

Our review found literature reporting on the use of smartphones and mobile apps for communication, medical education and training, clinical decision-making, and drug compendia. Challenges related to the use of smartphones and mobile apps include the lack of patient privacy and confidentiality and regulatory oversight. The benefits of smartphones and mobile apps for physicians at work include the availability of having flexible communication methods and mobile app choices to accomplish many different purposes at work, easy access to evidence-based medicine and clinical decision-making support, and portability. Physicians commonly use Medscape and WhatsApp mobile apps. Future research should address patient privacy issues, as well as legislation related to smartphone and mobile apps in clinical practice.

Acknowledgments

The authors would like to thank Ms Yasmin Lynda Munro from the Medical Library (Nanyang Technological University) for her help in developing the search strategy. The authors would also like to thank Ahmad Ishqi Jabir, a research associate from Lee Kong Chian School of Medicine (Nanyang Technological University), for his advice on the use of artificial intelligence for the study selection. This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Authors' Contributions

LTC conceived the idea of the review. ML and ABSBM screened the studies and extracted data. ML synthesized the findings and wrote the manuscript. LTC, HES, ESL, and ABSBM provided insightful feedback on the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The Internet of Things (IoT) has become integrated into everyday life, with devices becoming permanent fixtures in many homes. As countries face increasing pressure on their health care systems, smart home technologies have the potential to support population health through continuous behavioral monitoring.

Objective: This scoping review aims to provide insight into this evolving field of research by surveying the current technologies and applications for in-home health monitoring.

Methods: Peer-reviewed papers from 2008 to 2021 related to smart home technologies for health care were extracted from 4 databases (PubMed, Scopus, ScienceDirect, and CINAHL); 49 papers met the inclusion criteria and were analyzed.

Results: Most of the studies were from Europe and North America. The largest proportion of the studies were proof of concept or pilot studies. Approximately 78% (38/49) of the studies used real human participants, most of whom were older females. Demographic data were often missing. Nearly 60% (29/49) of the studies reported on the health status of the participants. Results were primarily reported in engineering and technology journals. Almost 62% (30/49) of the studies used passive infrared sensors to report on motion detection where data were primarily binary. There were numerous data analysis, management, and machine learning techniques employed. The primary challenges reported by authors were differentiating between multiple participants in a single space, technology interoperability, and data security and privacy.

Conclusions: This scoping review synthesizes the current state of research on smart home technologies for health care. We were able to identify multiple trends and knowledge gaps—in particular, the lack of collaboration across disciplines. Technological development dominates over the human-centric part of the equation. During the preparation of this scoping review, we noted that the health care research papers lacked a concrete definition of a smart home, and based on the available evidence and the identified gaps, we propose a new definition for a smart home for health care. Smart home technology is growing rapidly, and interdisciplinary approaches will be needed to ensure integration into the health sector.

Introduction

Smart home technology is rapidly becoming a permanent fixture in our everyday lives. Globally, there are 175 million connected smart homes—a number projected to continue rising. Smart home technology employs the Internet of Things (IoT) concept to interconnect and share data among household devices across a Wi-Fi–based wireless network [1]. Through connection and automated action, smart homes provide convenience and comfort to homeowners [2-4]. Smart devices can include video monitors, motion sensors, alarms, smart planners or calendars, and thermostats. Data can be leveraged for a variety of purposes, including energy saving [5], security and safety [6], fall detection [7], light management [8], and fire detection [7]. However, the benefits of smart home technology run deeper than the superficial hype of comfort and convenience. These may be the solutions to our health care crisis.

The COVID-19 pandemic revealed what many health professionals already suspected: our health care system is overburdened. Our aging population places increased demand on the health care system. Many services are inaccessible to remote communities. Long-term care homes face high mortality and morbidity. To relieve an overwhelmed system, health care is turning to technology [9]—specifically, the application of smart home devices to support independent living. Through continuous behavioral monitoring, IoT devices can be harnessed to detect, diagnose, and monitor health conditions. At the community level, the collection and analysis of sensor data could inform public health initiatives. Interdisciplinary research teams are already working on the application of smart devices in health care. For example, smart wearable trackers, passive infrared sensors, and chair occupancy sensors deliver daily insights into the physical activity levels. Smart thermostats and bed occupancy sensors have been used to track sleep patterns. As physical activity and sleep are good overall health predictors, these can be powerful tools for motivating healthy behavioral changes [10]. The application of machine learning to these systems can be used for behavior change detection [11,12]. Applications can include monitoring the onset and progression of age-related diseases [10], detection of hazardous events (such as falls), and analyzing behavioral impacts following health interventions such as cancer treatments or physical therapy [12]. Information exchange with primary health care providers and caregivers will strengthen health care delivery. Public health authorities could also assess, in real time, the implications of COVID-19 lockdown policies at the population level. These data can be used to inform care delivery, support evidence-based policy making, and enhance care strategies in real time.

The main advantage of using IoT technologies is that they provide objective data in real time. Sensor data are collected passively without human effort; one can go about their day, forgetting about the device. The data are therefore less prone to performance and recall biases compared to the traditional data collection methods. As data are collected continuously and uploaded to the cloud storage, they are immediately available for analysis. The analysis can be conducted automatically, and the resulting insights can be shared immediately with users. The development and deployment of smart home technology for health care will require the concerted effort of an interdisciplinary research team: combining expertise in technology, engineering, and health care. Despite the potential of smart home solutions to health challenges, their real-world implementation continues to be scarce. There is a need to understand the current state of research in smart home technology for health care. Existing reviews on the application of smart home technology in health care are limited [2,3]. Here, we present a scoping review to address this need. The goal was to synthesize the literature on how smart home technologies are being used for health care within the home and community. This study also aims to identify gaps or opportunities in smart home technology to inform practice, policy making, and research. Our review was guided by the following research questions:

1. What smart home technologies are currently being used to monitor health care indicators in vulnerable populations at home or in the community?
2. What types of information are these sensors gathering?
3. What insights can be generated from these data sets?

Our extensive database search led to the identification of 49 peer-reviewed publications on smart home technology for health care, which met our inclusion criteria. We were able to identify multiple research trends and knowledge gaps and provide insight into the next steps needed to propel the field forward.

Methods

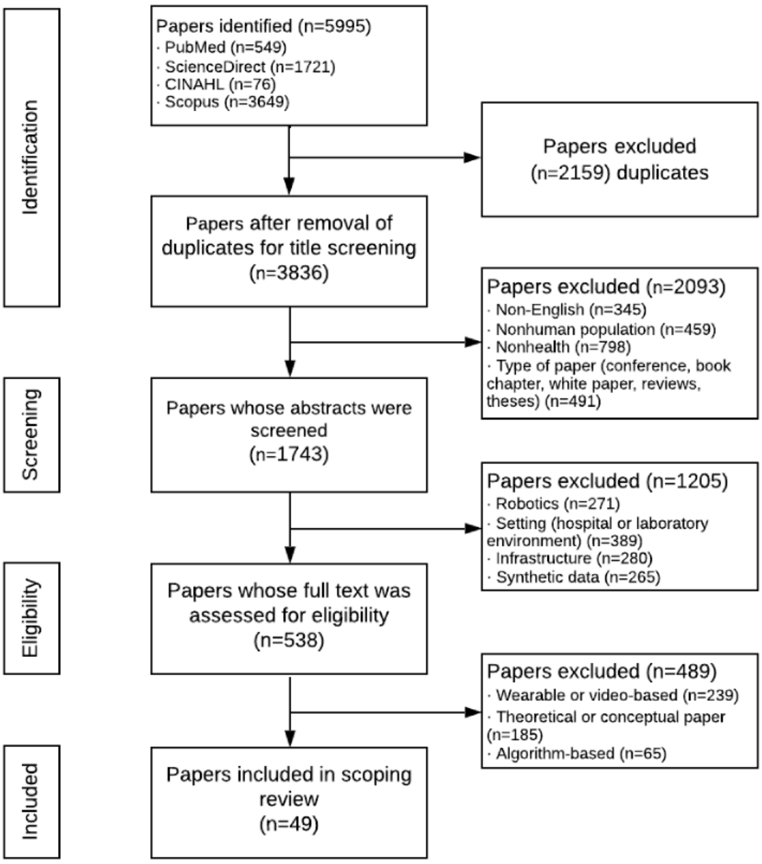
Data Sources and Search Strategy

This scoping review is based on the widely accepted framework by Arksey and O'Malley [13]. This framework was selected because it allows for the inclusion of various methodological designs across an interdisciplinary field. We searched for papers across 4 databases: PubMed, Scopus, ScienceDirect, and CINAHL. The search terms utilized are presented in Table S1 of Multimedia Appendix 1; they briefly encompassed the following search terms: health, monitor, smart home, ambient assisted living, active assisted living, and AAL. We limited our search to papers published between January 2008 and August 2021. Only peer-reviewed papers published in English were included. Of note, the term "surveillance" was not used in the search query, as its inclusion returned hundreds of results outside of the scope of this research project. A total of 5995 potential papers were identified using the search queries.

Paper Selection Process

Papers were organized into Mendeley and Zotero reference managers. Following the removal of 2159 duplicate papers, 3836 papers remained for title screening (Figure 1). Paper selection was further refined by ensuring that paper titles contained one of our keywords as mentioned above. AO and KSS each reviewed half of the papers. Papers not in English and those not related to humans were excluded: papers related to animal, agricultural, or biology research were excluded. Further, conference papers, book chapters, white papers, reviews, and theses were removed. Following title screening, 1743 papers were selected for abstract review by AO and KSS in Mendeley. AO and KSS screened the abstracts to ensure that the papers focused on remote sensor technology and its application in a home setting. Papers that used synthetic data or described infrastructure architecture or were in hospital or laboratory settings were excluded. The remaining 538 papers proceeded to full-text screening and were transitioned to Zotero for file management due to software issues in Mendeley. Studies using wearables or video-based technologies, theoretical or conceptual papers, and algorithm-based technologies were removed. Both authors independently and unanimously agreed on the inclusion of 29 papers with an additional 97 papers with conflicting votes. These papers were discussed on a case-by-case basis until a unanimous decision was reached. Of the 97 papers that had conflicting votes, 20 papers were included in this review. Thus, 49 papers were found to be eligible for the final scoping review. The selected papers were saved in a database, and a master chart was built by AO and KSS to summarize the key information for subsequent analysis.

Figure 1. Systematic study selection using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart.



Results

Selection and Characterization of Studies on Smart Home Technologies

To gain an understanding of the types of smart home technologies being used and the information collected, we conducted a literature search across 4 databases (PubMed, Scopus, ScienceDirect, and CINAHL) between January 2008 and August 2021 by using the queries outlined in Table S1 of Multimedia Appendix 1. A total of 49 papers met the inclusion criteria for this scoping review (Table 1). Among the types of studies conducted, 31% (13/49) were pilot studies, 14% (7/49) were proof of concept, 12% (6/49) were algorithm evaluations, 10% (5/49) were proposals, 8% (4/49) were technical validations, 8% (4/49) were case studies, 6% (3/49) were method evaluations, 6% (3/49) were longitudinal studies, 4% (2/49) were platform evaluations, 2% (1/49) were randomized controlled trials, and 2% (1/49) were qualitative studies. When we examined the country of origin for each paper, we found that most of the studies were conducted in western societies, with 47% (23/49) of the papers originating from Europe and 35% (17/49) from North America. Few studies were conducted in Asia (6/49, 12%), Africa (2/49, 4%), and Oceania (1/49, 2%).

We observed an increase in the number of publications in recent years: 71% (35/49) of the papers were published within the last 5 years (2015-2020), while only 29% (14/49) of the papers were published before 2015. All the studies were either directly or indirectly associated with academic institutions. When classified based on a publication's domain, 64% (31/49) of the selected papers were published primarily in the fields of engineering and computer science, 18% (9/49) were published in biomedical engineering and health informatics journals, and 18% (9/49) were published in health-related journals (Figure 2 and Table S2 of Multimedia Appendix 1).

Figure 2. Journals of the published papers reviewed in this study.

Population Demographics

As it is common practice in computer science or engineering research to use simulated data for platform or algorithm evaluation, we first categorized the studies based on the source of their data. Approximately 78% (38/49) of the papers used data collected from human participants, and the remaining 22% (11/49) of the studies used simulated data (Table 1). The age of the participants ranged from 18 to 93 years. Of the 38 studies that utilized human participants, 63% (31/49) reported participant age, but only 33% (16/49) indicated the gender of the participants. Of those that did report gender, female participants were nearly 3 times more prevalent than male participants (425 females vs 145 males). Volunteer participants were typically students recruited from the researcher's institution or patients from memory care units and assisted-living residents. Of the papers on human participants, 79% (30/49) reported the health status of the participants.

Study Settings and Parameters

The 49 papers included in this review can be broadly divided into 2 groups: 41% (20/49) approached the use of IoT for health purposes and 59% (29/49) used IoT for technological validations. The primary research focus was recognizing human mobility patterns (Table 2; complete data in Table S3 of Multimedia Appendix 1). Study length ranged from a single day of data collection to 8 years. Data were collected primarily in real-world settings, including smart apartments or smart workplaces. One of the studies used simulated home environments [39]. If the study took place in an apartment, the number of rooms typically used was between 2 and 3. Typically, there was only a single occupant in the study location.

Table 2. Technical components of the selected studies with outcomes.

Type of study, reference	Primary focus	Outcome measure	Algorithm	Type of data
Pilot study				
Chen et al [14], Dasios et al [24], Yu et al [26]	Independent living for the older population who may or may not have chronic diseases	Activity, fall detection, indoor motion	Statistical analysis of the machine learning algorithm	Binary sensors: motion, light, temperature, humidity,
Marcelino et al [25]	e-Service provision	Physical, medical, social interaction by audio-visual communication with service providers	Qualitative and quantitative data analysis	Interview questionnaire
Proof of concept				
Alberdi Aramendi et al [10], Kim et al [27], Hassan et al [28], Shirali et al [29], Jung [30], Alsina-Pagès et al [31], Mahmoud et al [32]	From 2013 to 2020, the proof of concept improved from synthetic data to real-world data, single individual to multi-individual, but the objectives more or less—the same activity recognition, anomaly detection, pattern recognition to improve the quality of life of older individuals	Motion or presence data	Binary sensor data, machine learning algorithm-support vector machine as the typical model with many of the studies; the recent study used the parallel activity log inference algorithm	Sensor data
Algorithm evaluation				
Jakkula and Cook [33], Rashidi et al [34], Singla et al [35], Damodaran et al [36], Hamad et al [37], Enshaeifar et al [38]	All the studies tried to recognize normal activity patterns and anomaly detection	Motion or presence data, device-free solutions based on radio signals like home Wi-Fi 802.11 channel state information	Machine learning and deep learning algorithms	Passive infrared sensors
Proposal				
Ros et al [39], Navarro et al [40], Gayathri et al [41], Kwon et al [42], Taiwo and Ezugwo [43]	Activity recognition of the individual	Mobility pattern recognition	Machine learning, deep learning algorithms	Binary sensor and acoustic sensor data
Technical validation				
Mora et al [44], Bassoli et al [45], Schlebusch [46], Virone et al [47]	Active assisted living monitoring, intelligent toilet seat, differentiate regular patterns, and identify abnormalities in household activities	Passive infrared sensors, magnetic contact, bed occupancy, chair occupancy, toilet presence, fridge sensor, electrocardiogram and bioimpedance spectroscopy measurements, behavioral monitoring by presence data	Behavior explanatory models, sensor profiles, multivariate habits clusters, R-peak detection, software for automatic measurement of circadian activity deviation/circadian activity rhythms	Motion sensor data, electrocardiogram, bioimpedance spectroscopy, passive infrared sensor
Case studies				
Sprint et al [12], Lazarou et al [48], Hercog et al [49], Yang and Hsu [50]	Behavior change detection, home monitoring system, activity recognition, effective active home automation solution based on open-source home automation software, and wireless, custom-developed, Wi-Fi–based hardware	Activity change, sleep, physical activity, and activities of daily living, automatic classification of activities of daily living, system functionality	CASAS[a] middleware	Motion, light, temperature, door, motion, presence, utility usage sensors, passive infrared/current sensors
Method evalution				

Type of study, reference	Primary focus	Outcome measure	Algorithm	Type of data
Yao et al [51], Fleury et al [52], Fiorini et al [53]	Activity recognition	Automatic classification of activities of daily living	Support vector machine, unsupervised machine learning, rule-based reasoning method for activity recognition	Location, temperature, sound, postural transitions and walk periods, motion sensor, location, activity, motion
Longitudinal study				
Fritz et al [54], Austin et al [55], Lyons et al [56]	Remote monitoring of pain, loneliness	Recognize pain-associated behaviors	Machine learning algorithm, isolation forest (forest) anomaly detection algorithm, decision tree classifier, logistic regression classifier	Passive infrared–based sensor data, light, temperature, humidity
Platform evaluation				
Junnila et al [57], Lamprinakos et al [58]	Remote patient monitoring using home health or telehealth	Interoperability/adaptability, which can accommodate different types of sensors	Rule-based ontological framework, partial human monitoring is required	Passive infrared–based sensor data
Qualitative study				
Cahill et al [59]	Identify and validate the requirements for new technology enabling resident wellness and person-centered care delivery in a residential care environment	State of environment and state of care delivery, state of resident	Qualitative data analysis and machine learning algorithm	Sensor and interview data
Randomized controlled trial (secondary data analysis)				
Mora et al [1]	Internet of Things–based home monitoring for older patients with stroke	Behavioral aspects-bed/rest patterns, toilet usage, room presence, and many others	Regression framework and anomaly detection, unsupervised clustering techniques	Sensor data

[a]CASAS: Center for Advanced Studies in Adaptive Systems

Data Collection and Analysis

To determine which smart home technologies were being used, sensors were grouped into 16 main categories (Table 3): utilization of space (bed and chair occupancy, toilet, fridge, kitchen, or GPS), human vitals (blood pressure, electrocardiography, blood glucose, heart rate, or respiratory rate), and environmental sensors (light, air temperature, humidity, sound, airflow, smoke, carbon monoxide, gas, or flooding). Nearly 62% (30/49) of the studies used passive infrared sensors to report on motion detection. As motion detectors and object presence sensors primarily record binary (yes/no) data, it was unsurprising that this data type was the most reported in the studies examined. Quantitative data were reported in many papers. Audiovisual (sound, light), vital indicators (heart rate, respiratory, blood glucose, body temperature), and environmental conditions (room temperature, humidity) typically record quantitative data. Finally, several papers reported spatiotemporal data typical of GPS sensors.

As smart home data collection produces large quantities of data, data management software is frequently employed. Examining the papers, we found SQL [34,35,56,57] and MYSQL [24,25,55] were frequently used to organize the data. MATLAB and Python were used for data analysis and visualization by nearly all the studies. Various statistical methods were used for data analysis, including descriptive statistics, model building, machine learning, and deep learning. Descriptive statistics were primarily used to describe the demographic characteristics of the study participants, whereas multidomain approaches [52], longitudinal linear mixed-effect regression [55], and out-of-sample cross-validation methods [55] were used for statistical models.

As 41% (20/49) of the papers reported the use of machine learning algorithms, we sought to determine which algorithms were more commonly employed. Clustering in 5 studies [1,28,30,34,53] and Hidden Markov Model in 4 studies [23,30,34,39] were the most used in data analysis to identify a regular pattern and predict future patterns. The other algorithms used in the studies were decision tree emerging pattern [11,25,27], clustering conditional random field [37,51], context-aware reasoning [28,42], fuzzy logic [41,49], k-nearest neighbors [10,51], logistic regression classifier [51,55], AdaBoost [10], Bayes network [27], boosting model using ensemble [42], circadian activity rhythms [47], multi-Hidden Markov Model [34], multiple regression model [42], multivariate habits cluster [44], ontological modelling [41], software for automatic measurement of circadian activity deviation [47], and support vector machines [52].

Nearly 14% (7/49) of the papers used deep learning methods, which included artificial neural networks [40], activity recognition using the discontinuous varied-order sequential model [34], latent trajectory models [56], longitudinal linear mixed-effect regression recurrent neural networks [55], open pass neural networks [60], recurrent neural networks [32], and multilayer perceptron [10]. One study used mixed methods and included a thematic analysis of the quantitative data [25]. Another study used the activity discovery method [34], and yet another conducted qualitative data analysis by using a mixed methods approach [25]. Some studies used induction algorithms, behavioral monitoring systems, rapid iterative testing and evaluation [15], or QRS recognition [57] for electrocardiography.

Table 3. Types of sensors, data characteristics, and their association with health.

Sensor type	Data type	Health indicator/proxy
Motion: passive infrared sensors, radiofrequency identification, magnetic switches	Any movement within the room, door movement	Physical activity/speed/quality of physical health/sleep
Presence	Any movement within the room, indoor movement	Physical activity/gait speed/quality of physical health/sleep
Temperature	Temperature of room, temperature of stove/oven	Body temperature, health quality/activity-sleep/awake/sedentary
Light	Luminosity (lux)	Sleep/active
Sound/microphone	Noise	Sleep/active
Humidity	Indoor environment	Indoor environment
Biosensors	Fall detection	Activity/alert
Plug sensors	Appliance use: television, fridge, kitchen appliance, medicine dispenser	Activity
Body position sensors	Activity	Activity
Carbon monoxide	Indoor environment	Indoor environment
Flooding sensors	Water use/consumption	Indoor environment
Gas sensors	Use of gas in the kitchen	Indoor environment
Smoke detector	Indoor environment	Indoor environment
Pressure sensor/smart tiles/pressure pad	Bed movement, gait speed, chair movement	Sleep time/quality
Electrocardiogram patch	Heart health	Heart health
Airflow sensors	Room environment	Indoor environment
SpO_2	Oxygen saturation of blood	Heart health/lung health
Blood pressure	Heart health	Heart health
Heart rate	Heart health	Heart health
Respiratory rate	Lung health	Lung health
Blood glucose sensors	General health	Diabetes
Smart weighing scale	Body weight	Weight
Pedometer	Walking	Physical activity
Contact sensors	Usage of a phone book, cooking pot, medicine container	Activity analysis
GPS	Location	Location
Wi-Fi signal	Indoor activity	Location
Smart seismic sensor	Floor vibration	Activity analysis, including fall

Outcome Measures

All the studies reported that IoT improved the quality of care, increased participants' sense of comfort, enabled early detection, and increased participants' understanding of the impact of health events on overall health. The health indicators specifically measured through smart home technologies included fall detection [24], functional health decline/improvement [10], high-level activities of daily living/instrumental activities of daily living [34,35,48,50,59,61-63], leisure services [59], loneliness [55], medical services [17,21,30,64], patient health status [17,21,30,64], perception [58], physical activity [48], sedentary behaviors [24,62], medication adherence [62], movement patterns [29], sequence of gestures [61], sleep

[12,48,56], eating habits [10,24,57,62], situational awareness [30], social engagement [56], time spent outside the home [55], and overall well-being [24].

Limitations and Challenges in the Studies

To gain insight into future research needs in the field of smart home technologies, we extracted information pertaining to the challenges and limitations self-reported by researchers. In the 49 studies, the biggest challenge faced by the researchers was differentiating between multiple participants in a single space. The second challenge identified was the lack of technology interoperability and the ability to scale up. The third challenge identified was linked to data security and privacy. The additional challenges identified by the researchers included calibration of the sensors, cost of technology and data management, data streaming and integration, data velocity, data volume, difficulty differentiating activities, generalization of activities, and demographic discrepancies (data collected from young volunteers, while algorithms were designed for the older population). Heterogeneity, installation of the sensors, lack of patient motivation, large numbers of nodes, limited data bandwidth, limited indoor activities, malfunctioning sensors, privacy, sample size, security, service quality, user acceptance, and varying levels of data accuracy were also noted as challenges.

Discussion

Key Findings

Existing reviews on the application of smart home technology for health care are limited [2,3]. If at all present, they focus on a very specific specialty within health care, such as geriatric care [65], dementia [66,67], fall prevention [68], or pregnancy [69]. This scoping review aims to address this knowledge gap by elucidating how smart home technologies are being used for health care within the home and community. An extensive database search revealed 49 peer-reviewed publications, which met our inclusion criteria. A wide variety of sensors were used to meet the differing needs in each study. Passive infrared sensors, which report on motion detection, were the most studied smart home technology for health and report primarily binary data. Multiple studies quantified measurable health indicators (eg, heart rate, blood pressure, sleep, physical activity). Reported data were mostly organized using SQL or MYSQL. As expected, diverse data analyses and statistical methods, including machine learning and deep learning, were applied to big data analysis. Of note, although some studies were performed in home settings, none were unobtrusive or zero effort. There were often disruptions to daily routines or participants were required to log activities [70].

We recognize that there are several limitations to our study and that potentially relevant publications may have been overlooked due to the constraints in our search queries and inclusion criteria. As smart home technologies are often developed by the technology industry, not all work is likely published in peer-reviewed journals. Furthermore, our use of the query term “smart home” may have excluded relevant research settings in a community or an institution. For the purposes of this scoping review, database searches were conducted in August 2021. Due to the rapid nature of this field of research, new insights may have emerged since the initial search.

Defining a “Smart Home” for Health Care

During the preparation of this scoping review, we noted that the health care research papers lacked a concrete definition for a smart home. Based on the available evidence and the identified gaps, we propose the following definition for a smart home for health care.

A smart home for health care can be defined as a home equipped with smart sensors using Bluetooth, Wi-Fi, or similar technology, not restricted to IoT, to automate, regulate, and monitor home occupants’ physical health, mental health, and environments within the home. The focus must be on convenience, safety, and improvement of one’s quality of life, to address the needs of the individual, caregivers, and health professionals.

Sociodemographic Inequalities

The studies included in this review were predominantly performed in western societies. This bias could be due to our requirement that studies should be published in English. However, it is known that high-income nations dominate the field of smart home technology. This could be due to several factors. First, western countries are trending toward an aging population, and thus, the interest in assisted living technologies is higher [71]. Second, low- and middle-income countries are focused on reducing mortality and morbidity related to infectious diseases; therefore, their resources are not focused on the needs of an aging population [72-74]. To address global health and knowledge inequalities, researchers and funding bodies must ensure that low- and middle-income countries have the resources to benefit from health technologies. Future research should prioritize including study participants in nonwestern societies.

Computer science or engineering research often use simulated data due to budget, staffing, and time constraints. Traditional technical training does not consider health outcomes and overlooks the social determinants of health. Without health care experts as part of the research team, many are unaware of the importance of reporting the demographic characteristics of human study participants. This was reflected in our scoping review, as many of the included studies failed to report this information. Of those that did report demographics, we found that female participants were more prevalent, being nearly 3 times more likely to have been studied than male participants. This was unexpected, given that research is typically dominated by male participants [75,76]. Some potential reasons for this variance could be that women live longer [77], are more likely to live in assisted care units [78], are more likely to participate in studies [79], or have altruistic considerations [80]. Moreover, the use of simulated data despite the availability of actual data highlights the need for better access to high-quality data.

The Intersection of Health and Technology

Smart home technology is a rapidly growing interdisciplinary field at the intersection of health, information technology, and engineering [81]. Yet, our scoping review highlighted a strong bias toward publication within primarily engineering and information technology journals. Many of the papers included in this scoping review contained highly technical language, tools, and databases. However, the primary audience is the health care field. Although we acknowledge that much of the technology is in its early stages, with research focused on technical challenges (data handling, analysis, storage, security, and privacy), this finding highlights a lack of collaboration between health and technical fields. Future work must address this gap—fostering interdisciplinary research teams with a broad spectrum of skills and domain knowledge experts. The involvement of health professionals in smart home technology research will ensure that these tools are relevant and bolster their successful implementation.

Technological Challenges

Interoperability was a commonly noted challenge faced by researchers. Technology is constantly being upgraded and improved with new products continually hitting the market. As diverse companies compete to create the latest technology, interoperability becomes an issue. Because there are no standardized guidelines, companies develop their own unique protocols and architectures for handling data, which contribute to incompatibility across the IoT landscape. The result is a jungle of systems that are confusing and intimidating to navigate for many non–tech-savvy individuals. One must subscribe to a single system that may not meet all their needs, grapple with the inconvenience of systems that do not communicate seamlessly, or implement third-party software or hardware to bridge the gap. There is a need to continue to develop solutions that allow these systems to integrate and communicate with one another. Similarly, the other 2 challenges faced by the researchers were differentiating individuals within a multiparticipant household and data security and privacy. Health care technology brings a new layer of complexity due to risks associated with personally identified data, health data, privacy, data rights, and ethical considerations [82].

Data Quality

Some of the studies [18,27,55] examined here had insufficient data quality to make their research findings relevant in the health care field. In many cases, the number of study participants was minimal and lacked demographic information. The quality of many of the sensors used in a home setting is lesser than that of the instruments used in a clinical setting, often diminishing the value of the data. Additionally, some of the technologies were not diagnostic tools at all because the health indicators were not quantifiable (video or audio). Other health conditions such as loneliness or mental health cannot be quantified and thus must be measured through the integration of multiple proxy indicators. The challenges of data integration will likely be addressed with continued improvements in artificial intelligence. Here, we have highlighted the existing research on the application of smart home technology to improve health and revealed multiple gaps in our knowledge. The IoT has ushered in a period of ultraconnectivity [83], converting commercial, off-the-shelf sensors like smart Wi-Fi thermostats and wearable devices into vital sources of health data. With the collaborative efforts of technology experts and health care professionals, we have the potential to leverage these data to improve physical and mental health.

Conclusion

Smart home technology has the potential to improve the quality of life by monitoring health indicators in vulnerable persons. Despite their potential, there is still a lack of large-scale utilization of these technologies for health care. A scoping review of the existing literature enabled us to identify the types of sensors and the data being explored. The trends and knowledge gaps identified here will invite new progress in remote patient monitoring in public health. This kind of a care system can support and complement medical interventions to improve population health.

Acknowledgments

We would like to thank Adson Rocha for helping with screening, charting, and providing input throughout the process and the Ubiquitous Health Technology Lab (UbiLab) volunteers, namely, Clarisse Misola, Nadia Somani, Arjun Mehta, Chaeyoon Jeong, Thianna Edwards, Kunal Karhanis, and Harneet Dhillon, for their timely help whenever and wherever required. We would like to thank the Natural Sciences and Energy Research Council, ecobee, and The Mathematics of Information Technology and Complex Systems (MITACS) for supporting this work.

Conflicts of Interest

None declared.

Abstract

Background: Self-management plays a critical role in maintaining and improving the health of persons with spinal cord injury (SCI). Despite their potential, existing mobile health (mHealth) self-management support (SMS) tools for SCI have not been comprehensively described in terms of their characteristics and approaches. It is important to have an overview of these tools to know how best to select, further develop, and improve them.

Objective: The objective of this systematic literature review was to identify mHealth SMS tools for SCI and summarize their characteristics and approaches to offering SMS.

Methods: A systematic review of the literature published between January 2010 and March 2022 was conducted across 8 bibliographic databases. The data synthesis was guided by the self-management task taxonomy by Corbin and Strauss, the self-management skill taxonomy by Lorig and Holman, and the Practical Reviews in Self-Management Support taxonomy. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) standards guided the reporting.

Results: A total of 24 publications reporting on 19 mHealth SMS tools for SCI were included. These tools were introduced from 2015 onward and used various mHealth technologies and multimedia formats to provide SMS using 9 methods identified by the Practical Reviews in Self-Management Support taxonomy (eg, social support and lifestyle advice and support). The identified tools focused on common SCI self-management areas (eg, bowel, bladder, and pain management) and overlooked areas such as sexual dysfunction problems and environmental problems, including barriers in the built environment. Most tools (12/19, 63%) unexpectedly supported a single self-management task instead of all 3 tasks (ie, medical, role, and emotional management), and emotional management tasks had very little support. All self-management skills (eg, problem-solving, decision-making, and action planning) had coverage, but a single tool addressed resource use. The identified mHealth SMS tools were similar in terms of number, introduction period, geographical distribution, and technical sophistication compared with SMS tools for other chronic conditions.

Conclusions: This systematic literature review provides one of the first descriptions of mHealth SMS tools for SCI in terms of their characteristics and approaches to offering SMS. This study's findings highlight a need for increased coverage of key SMS for SCI components; adopting comparable usability, user experience, and accessibility evaluation methods; and related research to provide more detailed reporting. Future research should consider other data sources such as app stores and technology-centric bibliographic databases to complement this compilation by identifying other possibly overlooked mHealth SMS tools. A consideration of this study's findings is expected to support the selection, development, and improvement of mHealth SMS tools for SCI.

Introduction

Background

Spinal cord injury (SCI) is a complex chronic health condition that carries a high health, economic, and social burden for those affected and their families. SCI can be traumatic or nontraumatic in nature and is characterized by the loss or impairment of motor, sensory, or autonomic functions below the level of the injury [1]. Frequent health complications include pressure injury, urinary tract infections, bowel dysfunction, mental health conditions, pulmonary complications, pain, and sexual dysfunction [2,3]. The limitations in functioning caused by SCIs are largely dependent on the neurological level and severity of the injury, associated comorbidities and complications, the age of onset, available health and social care resources, and the presence of barriers or facilitators in the person's environment [1]. Similarly, wider participation in society is also made difficult without a concerted effort to pursue further education or sustainable employment, sufficient financial support, and the alleviation of comorbidities [4].

Self-management plays a critical role in maintaining and improving the health of persons with SCI [5]. It is widely understood as the ability of an individual to manage the symptoms, treatment, biopsychosocial consequences, and lifestyle changes inherent to living with a chronic health condition [6]. Corbin and Strauss [7] introduced 3 tasks, namely, medical, role, and emotional management, that describe how people with chronic health conditions manage their health. Lorig and Holman [8] described 6 key skills that support the execution of these tasks: problem-solving, decision-making, resource use, forming patient-provider partnerships, action planning, and self-tailoring. Pearce et al [9] argued that self-management is nonetheless not the sole responsibility of persons affected by chronic health conditions and proposed the Practical Reviews in Self-Management Support (PRISMS) taxonomy to highlight 14 self-management support (SMS) activities such as the provision of social support and equipment. SMS is often provided in the form of traditional institutional and paper-based options [6]. However, technology-based SMS options help overcome traditional barriers of distance, time, and high economic costs and are increasingly becoming available for SCI [10,11].

The use of technology-based SMS for chronic conditions has expanded with the widespread adoption of mobile health (mHealth) technology [10]. Compared with early desktop computer–based technologies, mHealth provides more person-centered, available, accessible, and scalable tools [12]. It introduces the use of mobile and wireless information and communications technologies, including geospatial services, movement, light and proximity sensors, and Bluetooth technology, bundled into mobile devices, apps, and wearable technologies, among other similar products, to support meeting health needs [13]. In the context of SMS, this could involve using a mobile device to receive visual, auditory, and tactile-based reminders to perform a health behavior (eg, taking medication), self-monitor health status (eg, recording vital signs), learn from web-based informational resources, and secure social support from online peer groups [9,14]. mHealth is well positioned to benefit from the high adoption rates among persons with SCI. Over 87% of participants with traumatic SCI in a 2018 study indicated that they were mobile internet users, which represented a 35% increase from 2012 [15] and a 12% higher rate than the global mobile internet subscription rate in 2019 [16]. An increase in the global user base has also been attributed to the recent pandemic [17], which is also expected to have a similar impact among persons with SCI in the last 2 years.

Nonetheless, to the best of our knowledge, the available mHealth SMS for SCI has not been comprehensively compiled. Reviews on the closest related topics have focused on accessing telerehabilitation [10], telehealth care [18], and telecounseling [19-21] outside clinical settings but have not adequately considered SMS and, with the exception of one study [10], mHealth. The latest review was also completed in early 2016, which does not account for the expected rapid increase in the development of mHealth options over the last 6 years. Therefore, it is important to have an overview of available mHealth SMS options for SCI.

Objectives

The objective of this systematic literature review was to identify and summarize the mHealth SMS tools developed for SCI. It aimed to describe their volume, features, evidence base, and reporting and recommend future directions for the development, evaluation, and reporting of these tools. Articulating data on effectiveness, gaps in coverage, usability shortcomings, and impact is expected to help patients and clinicians with selecting tools and support researchers and developers in optimizing existing tools or deciding and planning the development of new ones.

Methods

Overview

A systematic review was conducted to identify and summarize the mHealth SMS tools for SCI. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [22] and the extension for searching [23] were used to guide reporting (Multimedia Appendix 1). The inclusion of an assessment of methodological quality for other types of observational studies overlooked by the study protocol [24] was the single protocol deviation observed.

Search Strategy

MEDLINE, Academic Search Premier, LISTA, Business Source Premier, Scopus, CINAHL Complete, PsycINFO, and Web of Science Core Collection were searched using keywords for SCI and mHealth (Multimedia Appendix 2). The reference lists of included articles were also hand searched.

Eligibility Criteria

Publications were eligible for inclusion if they described an mHealth [13] SMS tool [6] for SCI. Eligible mHealth SMS tools were optimized for access from mobile devices to help accommodate the accessibility needs of people with SCI and were intended for use outside a clinical setting or not dependent on assistance from others to obtain benefits. Publications including primary research studies, books, and gray literature (eg, conference proceedings, theses, government documents, and professional publications) made available in the English language between January 2010 and March 2022 were considered. Gray literature such as commentaries and letters to the editor that were unlikely to discuss mHealth SMS tools for SCI in sufficient detail were not considered.

Eligibility Assessment

In total, 3 researchers (AV, MD, and RMB), including a health scientist, psychologist, and health technologist, were involved in screening. They attended a training workshop to help ensure consistency in screening using the web-based service Rayyan (Rayyan Systems Inc) [25] without its artificial intelligence–based features. The screeners completed a training set of 100 publications. Conflicting screening decisions (ie, *include*, *maybe*, or *exclude*) were discussed to clarify any misunderstandings. A total of 2 screeners were then randomly assigned a screening set of titles and abstracts. A third screener afterward performed a second screening of 29% (29/100) of the publications. In total, 2 screeners (AV and RMB) conducted eligibility checks on the full texts. Screening was independently conducted to reduce the risk of reviewer bias [26], and conflicting screening decisions were resolved collaboratively.

Risk-of-Bias Assessment

The same researchers who conducted the screening (RMB and AV), along with a rehabilitation physician (VS), independently evaluated the risk of bias for the included studies based on recommendations from Ma et al [27] and according to the assessment strategy shown in Textbox 1. Disagreements in evaluations were resolved collaboratively.

Textbox 1. Strategy for risk-of-bias assessment.

Experimental studies

- Revised version of the Cochrane Collaboration tool for assessing risk of bias in randomized trials [28]

Mixed methods studies

- Mixed Methods Appraisal Tool for systematic mixed studies reviews [29]

Other observational studies

- Joanna Briggs Institute Checklist for Analytical Cross-Sectional Studies [30]

Qualitative studies

- Joanna Briggs Institute Checklist for Qualitative Research [31]

Quasi-experimental studies

- Joanna Briggs Institute Checklist for Quasi-Experimental Studies [32]

Data Extraction and Synthesis

MD and RMB completed the data extraction. These researchers attended a training workshop to help ensure consistency and reliability using a web-based data extraction form. This form was discussed and modified for increased clarity. One researcher extracted data from the included publications, another reviewed and verified the extracted data, and discrepancies were resolved collaboratively. The extracted data were collated and summarized by 2 researchers (RMB and AV) using a descriptive synthesis. The analysis of frequencies, except for publication characteristics, only considered unique data extracted from publications focusing on the same mHealth option. The synthesis of evaluative information considered usability [33] and user experience [34]. Data extraction and synthesis were also guided by frameworks for self-management tasks [7] and skills [8], as detailed in Textbox 2, and support activities [9]. Aspects of SMS for SCI that were targeted by the included mHealth tools [35] were described using emergent themes.

Textbox 2. Self-management task and skill frameworks.

Self-management tasks [7]

- Medical management
  - Making health-related appointments, following treatment plans, tracking symptoms, and taking medication as directed
- Role management
  - Organizing and coordinating the various everyday roles and responsibilities related to work, family, community, and self-care and adapting these roles as needed
- Emotional management
  - Regulating and coping with emotions resulting from living with a condition in a healthy and effective manner

Self-management skills [8]

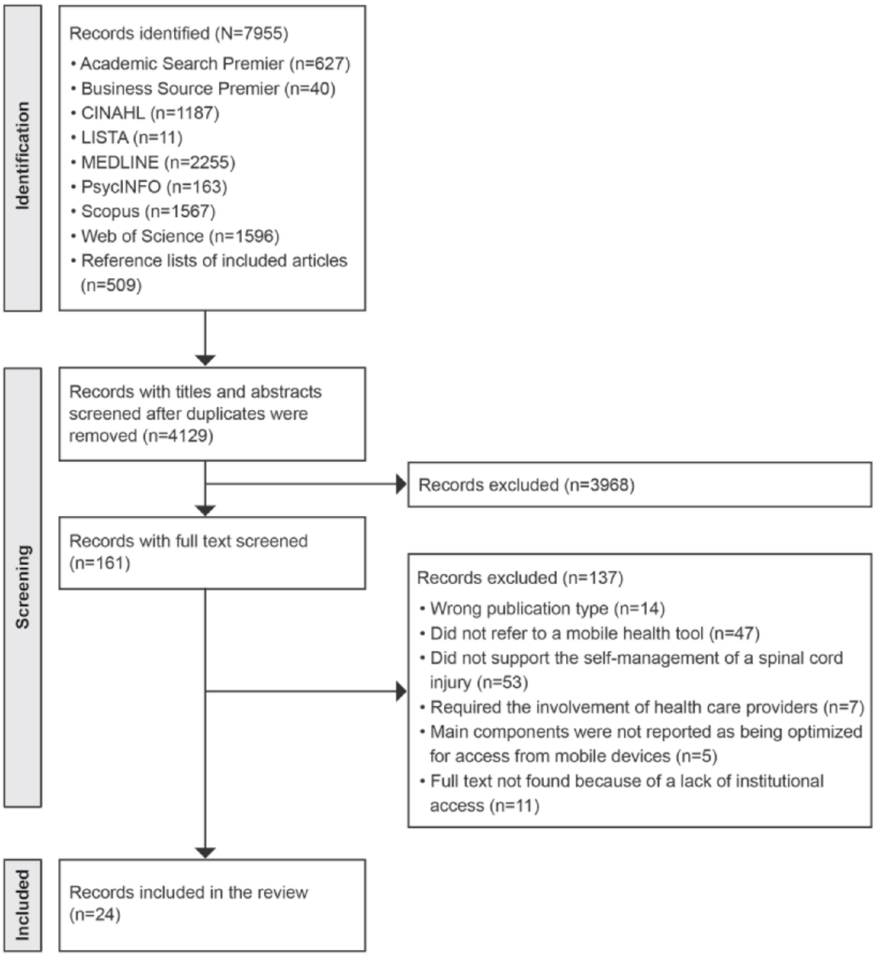
- Problem-solving
  - Identifying problems and finding, implementing, and evaluating solutions
- Decision-making
  - Weighing options and choosing the best course of action in response to changes in their condition
- Resource use
  - Finding and effectively using resources
- Forming patient-provider partnerships
  - Learning from and partnering with health care professionals to understand the patterns experienced with a condition, make informed decisions, and discuss related issues
- Action planning
  - Developing a realistic action plan that can be confidently used to achieve a set goal
- Self-tailoring
  - Developing and implementing personalized self-management strategies as needed

Results

Overview

A total of 24 publications [36-59] were included, and Figure 1 details the methodological process.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the review search, selection, and inclusion process.



Characteristics of the Included Publications

The 24 included publications comprised 20 (83%) studies [36,37,40,42-57,59], 3 (12%) reports [38,39,58], and 1 (4%) protocol paper [41] (Table S1 Multimedia Appendix 3). The included publications primarily aimed to describe and develop mHealth tools (10/24, 42%) [38,39,43,45,46,48,54,56-58], evaluate implementation factors (9/24, 38%) [37,40,45,46,49,50,54,55,57], evaluate usability and user experience (7/24, 29%) [45-48,52-54] and effectiveness (6/24, 25%) [36,41,42,44,51,54], and describe stakeholder perspectives (1/24, 4%). The included publications were published between 2015 and 2022, and most (18/24, 75%) were published from 2018 onward [41-57,59]. The research teams were mainly based in North America (15/24, 62%) [38,40-42,44-47,50,52,53,55,56,58,59], followed by Europe (6/24, 25%) [36,37,48,49,54,57], Asia (2/24, 8%) [43,51], and Europe and Asia (1/24, 4%) [39].

Of the 20 included studies, 7 (35%) were quasi-experimental [37,42,43,50,51,53,57], 5 (25%) were mixed methods [46-48,54], 4 (20%) were qualitative [49,52,56,59], 2 (10%) were observational [45,55], and 2 (10%) were experimental [36,44]. The risk of bias was deemed low in just over half (11/20, 55%) of the included studies [44,45,47,49,51,52,55-57,59] (Multimedia Appendix 4 [36-59]). No studies were excluded based on the risk assessment. Study participants experienced various limitations in body functions, including musculoskeletal and movement-related functions [37,39,43], sensory functions and pain [36,47,51,59], urination and defecation [40,45,47,50,58,59], skin [38,45-50,52,53,59], sleep [54], and functions that help manage the psychological and social demands of daily life [44,45,47,54,59]. The sample sizes of the 20 included studies ranged from 4 to 75 participants where reported [36,37,40,42-57,59]. The age range of the study participants was 18 to 81 years, and most study participants were male (232/396, 59%) where reported (19/20, 95%) [36,37,40,42,44-57,59].

Characteristics of the Underlying mHealth Technology

A total of 19 mHealth tools were identified (Table 1 and Table S2 Multimedia Appendix 3). In total, 4% (1/24) of the publications focused on 2 tools [37], 12% (3/24) focused on 1 tool [41,47,50], and 2 sets of 2 focused on 1 tool equally (2/24, 8%) [40,48,49,58]. In total, 4 tools were unnamed (4/24, 17%) [38,40,43,48,49]. The included publications documented mHealth tools mainly at their testing stage (10/19, 53%) [36,40,43-45,47,50-52,54,55,58], followed by the developmental (6/19, 32%) [38,39,41,46,48,56,59], proof-of-concept (3/19, 16%) [37,42,49], proposal (1/19, 5%) [57], and launch (1/19, 5%) [53] stages.

The design and development of the included mHealth tools followed phases largely characteristic of user-centered design as the process was iterative and sought to understand users, the relevant tasks they needed to perform, and the environment of use (10/19, 53%) [36,39,40,44,46,47,50-52,54,57,59]. Participatory design, in which stakeholders are encouraged to make substantial contributions to design decisions, was used to a lesser extent (3/19, 16%) [45,48,49,56]. A total of 32% (6/19) of the publications [37,38,42,43,53,55] did not describe the design process adopted.

The primary technologies used were apps (16/19, 84%) [37-39,41-55,57,59], mobile-optimized websites (2/19, 11%) [40,56,58], and a glove (ie, wearable; 1/19, 5%) [36]. These technologies were mainly connected to mobile phones (10/19, 53%) [39,42-44,46,48,49,51,53,54,57], followed by tablets (7/19, 37%) [37,39,41,45,47,50,52,54,55], unspecified mobile devices (4/19, 21%) [36,38,40,56,58], pressure mats (2/19, 11%) [46,53], smartwatches (ie, wearable; 2/19, 11%) [42,55], smart garments (ie, wearable; 1/19, 5%) [39], and Raspberry Pi (1/19, 5%) [46].

The Android mobile operating system was the most frequently chosen (8/19, 42%) [39,41-44,48,50,53,57], closely followed by iOS (7/19, 37%) [37,38,45-47,52,53]. A total of 11% (2/19) of the tools used both operating systems [41,47,50,53], 11% (2/19) were operating system–agnostic [40,56,58], and 21% (4/19) did not report this information [36,51,54,55]. Further requirements regarding the device and operating system version and full language and country availability were largely vague or absent and could not be extracted.

When reported, devices required a display (18/19, 95%) [37-48,50-57,59], internet connectivity (12/19, 63%) [38,40,43-46,48,51,53-56], audio (6/19, 32%) [36,39,45,48,55,57], camera (5/19, 26%) [37,43-45,48], Bluetooth (5/19, 26%) [36,39,42,46,53], reminder features (5/19, 26%) [38,43,44,48,54], accelerometer sensor (4/19, 21%) [38,42,43,57], notification features (4/19, 21%) [38,39,42,46], messaging (3/19, 16%) [44,45,48], and cloud storage (1/19, 5%) [38]. Table 2 summarizes each requirement of the included mHealth tools. Multimedia Appendix 5 [36-59] organizes each requirement by self-management tasks, skills, and support components and tasks.

Table 1. Number of mobile health (mHealth) tools introduced per year (n=19).

Year of introduction	mHealth tools, n (%)
2015	3 (16)
2016	2 (11)
2017	0 (0)
2018	0 (0)
2019	7 (37)
2020	3 (16)
2021	3 (16)
2022	1 (5)

Table 2. Device requirements of the included mobile health tools (n=19).

Device requirement and citation	Description of use	Frequency, n (%)
Display [37-59]	Used for presenting the mobile device's user interface in visual and tactile form	18 (95)
Internet connectivity [38,40,43-46,48,49,51,53-56,58]	Used for accessing web-based information, having voice and video calls, and sending and storing information via the web	12 (63)
Audio [36,39,45,48,49,55,57]	Used for listening to multimedia content with sound, creating audio messages, and having voice calls	6 (32)
Bluetooth [36,39,42,46,53]	Used for exchanging data over short distances between mobile devices and paired technologies	5 (26)
Camera [37,43-45,48,49]	Used for having video calls and capturing still images	5 (26)
Reminders [38,43,44,48,49,54]	Used for alerting users to participate in a planned activity	5 (26)
Accelerometer [38,42,43,57]	Embedded in a smartphone or wearable (eg, smartwatch) and used for motion sensing	4 (21)
Notifications [38,39,42,46]	Used for informing users of available mobile technology information updates via audio, visual, and tactile indicators	4 (21)
Messaging [44,45,48,49]	Used for multimedia communication via the internet	3 (16)
Cloud storage [38]	Used for data storage	1 (5)

Characteristics of Approaches Providing SMS for SCI

The mHealth tools supported the completion of all self-management tasks (Table 3). Emotional management had little support (3/19, 16%) [44,47,54,59] compared with medical (14/19, 74%) [36-39,41,43,44,46-50,53-56,58,59] and role (12/19, 63%) [38,40-42,45,47-52,54,56-59] management tasks. Most mHealth tools supported 1 self-management task (12/19, 63%) [36,37,39,42,43,45,46,51-53,55,57], followed by 26% (5/19) supporting 2 self-management tasks [38,40,44,48,49,56,58] and 11% (2/19) supporting 3 self-management tasks [41,47,50,54,59].

The mHealth tools supported the practice of all self-management skills (Table 4). The top 4 self-management skills were supported more than the average number of times. These 4 represented 84% (31/37) of the total number of times that self-management skills were supported. Most mHealth tools (7/19, 37%) supported 1 self-management skill [41,44,47-51,56,57,59], followed by 32% (6/19) supporting 2 self-management tasks [38,40,43,45,54,55,58] and 3 self-management tasks [36,37,39,42,46,52,53].

The mHealth tools incorporated 64% (9/14) of the PRISMS support components (Table 5). The top 4 components were incorporated more than the average number of times. These 4 represented 74% (35/47) of the total number of times that the components were incorporated. Most mHealth tools (8/19, 42%) incorporated 1 support component [36,37,39,42,46,52,53,55], followed by 21% (4/19) incorporating 4 support components [40,44,51,54,58], 16% (3/19) incorporating 3 support components [38,45,48,49], and 11% (2/19) incorporating 2 support components [43,57] and 5 support components [41,47,50,56,59]. These 10 components largely focused on supporting pressure injury prevention, physical activity promotion, and bladder management (Table 3). The lowest focus was placed on spasticity management, autonomic dysreflexia management, sleep management, and shoulder posture monitoring (Table 6).

The adopted self-management approaches were individualized only or combined with a group-based approach. Individualized approaches included multimedia educational content (eg, audio, text, images, and video), real-time behavioral visualizations or illustrations, textual or haptic feedback, personalized physical movement plans, games, 2-way messaging with health care professionals, content requiring active end-user engagement (eg, diary), and progress-tracking features (16/19, 84%) [36-39,41-53,55,57,59]. Combined approaches included forums and progress-tracking leaderboards (3/19, 16%) [40,54,56,58].

The included mHealth tools were intended mostly for use in nonclinical (ie, home and community environment) settings (17/19, 89%) [37-39,42-46,48,51-58], and only 11% (2/19) were also intended for use in clinical settings [36,41,47,50,59]. The adopted approaches largely relied on research (14/19, 74%) [36,42,44-48,51,52,54,55,58], followed by theory (5/19, 26%) [38,39,41,43,56] and expertise (1/19, 5%) [57]. Approaches targeting therapeutic exercise for legs [43] and shoulder posture monitoring [39] solely relied on theory. The provision of training and practice for everyday activities that targeted therapeutic exercise for the hands was the only approach that was without an app [36].

Table 3. Characteristics of approaches providing self-management support for spinal cord injury (SCI; n=19).

mHealth tool name, citation, and country availability	Self-management focus areas	Relevant self-management tasks	Relevant self-management skills	Relevant self-management support components
AW-Shift[a] [53], United States	Pressure injury management	Medical management	Decision-making	Monitoring of the condition with feedback

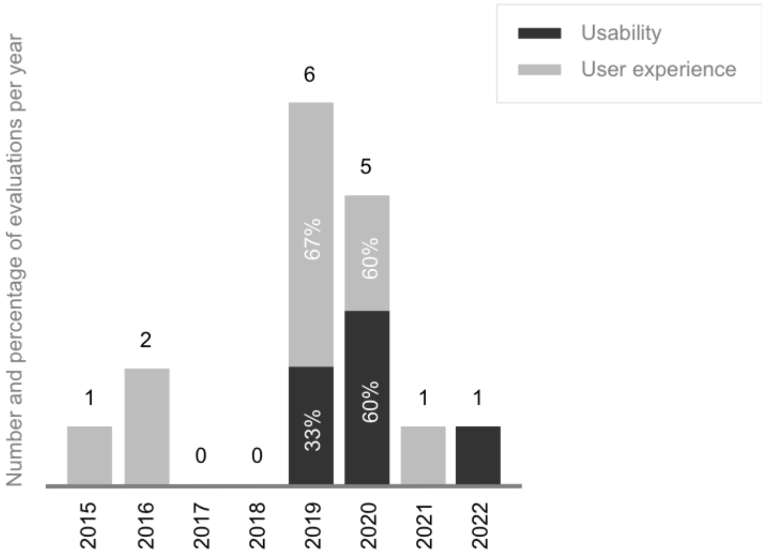
Evaluation of mHealth SMS for SCI

The included studies reported a significant change in trunk control [37], urinary tract infections [44], hand sensory functions [36], self-management for neurogenic bladder dysfunction [40], and bowel management confidence [50] (Table 1). No significant changes in urinary tract leakage and infections or pain [51] and psychosocial-related outcomes [44] were observed. None of the included studies published before 2019 (6/20, 30%) had the primary aim of evaluating usability or user experience. The included studies that conducted these evaluations increased 4-fold during the last 4 years (15/18, 83%) [45-48,51,54,56] compared with the previous period (3/18, 17%) [37,39,40] (Figure 2). When evaluated by 58% (14/24) of the included publications [37,40,43,45-49,51,52,54,56,57,59], interviews, focus groups, surveys, and field studies were used. A widely adopted instrument (eg, the System Usability Scale; 4/14, 29%) [46-48,54] was seldom used for evaluating usability or user experience (Table 3). All evaluations relied on empirical methods involving participants with SCI. The results from the usability evaluations were largely *very good* (6/12, 50%) [37,40,45-48,51], followed by those indicating *good* (3/12, 25%)

[46-48] and *poor* (1/12, 8%) [54] usability. The user experience evaluations were mostly *good* (3/4, 75%) [43,46,57] and *very good* (1/4, 25%) [51]. Other evaluations of usability [56,59] and user experience [49,52] generated 12 change requests from study participants regarding design, content, and functionality. No accessibility evaluations were reported.

Figure 2. Temporal distribution of mobile health tool evaluation.



Discussion

Principal Findings and Comparison With Prior Work

The 24 included publications introduced 19 mHealth SMS tools for SCI since 2015 using various mHealth technologies and multimedia formats. The findings support the notion that the adoption of mHealth SMS tools for SCI is a growing area of interest [10]. The findings are similar to those of reviews of a comparable period identifying 23 heart failure– [60]; 21 cardiovascular disease– [61]; 23 HIV-, AIDS-, or HIV and AIDS– [62]; and 17 Parkinson disease–related [63] mHealth SMS tools that were introduced from 2012 onward. The geographical distribution of the tools in the included publications is also similar to that in these reviews, with the large majority of tools being introduced in North America and Europe except in the case of HIV or AIDS [62], where no tools introduced in Europe were reported.

mHealth Technologies Underlying SMS for SCI

A review of mHealth SMS tools for heart failure [60] reported that 48% of the identified tools benefited from a participatory design approach compared with 16% (3/19) in this review. However, as evidenced in the study by Allin et al [64], adopting participatory design for the development of mHealth SMS tools for SCI is instrumental in highlighting accessibility, design, and information quality concerns and developing potential solutions in response. Nonetheless, research also highlights that a participatory design approach does not guarantee sustained engagement [64]. The remaining reviews did not report the approach adopted for designing the identified tools, which is similar to 32% (6/19) of the tools identified in this review. Unlike comparable reviews [61,62], our review found a nearly equal operating system share between Android and iOS despite the former being the most used by a large margin [65]. Unlike comparable reviews [61,63] except for that by Mehraeen et al [62], widely used wearable devices (eg, smartwatches) were not identified in this review despite their demonstrated potential for health self-management. This likely results partially from the difficulty to accurately measure physical activity in persons with SCI using wearables [66]. The identified device requirements are also common features found in many mobile devices, which allowed for the easy adoption of these tools and which were also present in and similarly used by the tools identified in comparable reviews.

Approaches to SMS for SCI

The lack of support for all 3 self-management tasks (ie, medical, role, and emotional) was unexpected as SMS tools should aim to include content that addresses all of them [8]. The lack of support for emotional management was unexpectedly pronounced given that managing the psychological demands of SCI and other chronic conditions is a core task for those affected [67]. Compared with the 10 most common problems reported by persons with SCI [68,69], the included mHealth tools largely addressed similar problems but prioritized them differently. For example, pressure injury was ranked much lower by people with SCI than the high level of coverage this complication had in the included mHealth tools. Moreover, the included mHealth tools did not address environmental problems such as barriers in the built environment and sexual dysfunction problems. Compared with non–mHealth-based self-management interventions identified in a recent scoping review [70], the identified mHealth tools reflected a very similar level of focus on SCI symptoms. Except for sexual functions, the identified mHealth tools considered many additional symptoms and health self-management options in comparison. The interventions and mHealth tools identified in this review similarly ascertained the provision of *information about the condition and/or its management* as being the most common PRISMS support component offered. However, the findings from the recent scoping review and this review differ in their coverage of the remaining PRISMS components and self-management skills. This is likely partially due to mHealth being more suited for offering *practical support with adherence*, *monitoring of the condition with feedback*, and *provision of easy access to advice or support when needed*, for example, compared with alternative methods (eg, paper- and desktop computer–based options). The recent scoping review [70] also found that most self-management interventions following an SCI were individualized or combined with a group-based approach. The identified mHealth tools used more sophisticated but comparable formats with alternative self-management interventions [70].

Evaluation of mHealth SMS Tools for SCI

mHealth tools require a high level of usability to ensure that they can be easily used over time without expending unwarranted effort. Comparable reviews have reported a lower percentage of usability evaluations for hypertension (2/21, 10%) [71], diabetes (14/31, 45%) [72], and heart failure (9/18, 50%) [73] than that reported by the included studies. Although the usability of the included tools was generally ranked positively, the failure to use standardized measurement instruments makes it difficult to ascertain what exactly was measured and compare with findings from similar studies. Comparable reviews have reported a slightly higher adoption of standardized instruments for usability evaluations for diabetes (6/31, 19%) [72] and heart failure (4/18, 22%) [73]. Comparable studies investigating user experience of self-management tools were few [74,75], similarly revealed positive results [74], did not adopt widely used assessment instruments [74], and benefited from qualitative methods to gain insights into improvements [74,75].

Implications for Future Practice and Research

More effort is needed to develop mHealth SMS tools for SCI with consideration for incorporating all self-management tasks and undersupported self-management skills and support components. New approaches that can bridge the observed fragmentation of SMS provided by mHealth tools for SCI should be pursued. For example, mHealth SMS tools for chronic health conditions share several common features, and a reference architecture could be of benefit for the efficient and cost-effective development of mHealth SMS tools for SCI, other chronic health conditions, or a combination of these. These technologies are shaped by their underlying technical frameworks as much as by their features. Decisions regarding the design, development, and implementation of mHealth tools need to be reported in detail and investigated to inform future decision-making regarding mHealth tools. Usability and user experience evaluations should use commonly adopted instruments, including the System Usability Scale [76]; the Usefulness, Satisfaction, and Ease of Use Questionnaire [77]; and the Post-Study System Usability Questionnaire [78], to enhance the validity of evaluations and comparability of findings. Furthermore, empirical methods such as usability testing with users should be complemented by other methods [79], including expert inspections and automated evaluations, to improve the validity of these evaluations. Considering and reporting the supported level of functioning by an mHealth tool is essential given the considerable accessibility needs of people with SCI (eg, difficulties associated with sensory and motor impairments). Similar reviews should include more technology-centric databases, for example, the one from the Institute of Electrical and Electronics Engineers, in their search strategy. A systematic search of the most used app stores can complement this review's findings by identifying and evaluating SMS apps for SCI that are available to the public.

Limitations

The included publications were unlikely to account for all available mHealth SMS tools for SCI. Furthermore, one of the identified apps was retired from the Apple App Store (ie, Assisted Weight Shift) [53], another was retired from the Google Play Store (ie, Pop Flux) [37], and a single app was available from both digital distribution platforms (eg, Interactive Mobile Health and Rehabilitation) [44]. Nonetheless, this systematic literature review is necessary to comprehensively account for these tools. The mHealth tools were also insufficiently described by the included studies, and this prevented a deeper evaluation. For example, despite notable differences in the cost and features of mobile devices using the Android and iOS operating systems, it was difficult to understand how the operating system was chosen without a rationale being provided, especially when their adoption rates were almost the same. Information about the intervention, such as its name; details about primary and secondary users, including lesion type and injury etiology; the design process followed; and minimum hardware and software requirements, was vaguely reported or absent and could have provided valuable insight. For example, it might have indicated a fuller coverage of self-management tasks. This inadequate reporting might also reflect publication restrictions regarding word limits and alternative focus topics where authors instead strategically prioritize other details. Despite these shortcomings in reporting, the included studies still provided more relevant details than tools identified via other means, such as app store descriptions. The publication year restriction could have excluded otherwise eligible mHealth tools, but the findings from this study and the latest review on a related topic [10] strongly suggest that very few or no tools would have been missed as a result. Only considering mobile-optimized web-based services for inclusion likely reduced the number of web-based mHealth tools included, but it is an essential feature given the accessibility needs of people with SCIs. Usability and user experience evaluations were limited as they relied on empirical evaluations, which typically focus on testing select system tasks with users instead of all possible tasks. However, the focus is often on essential tasks, and the practice reduces costs such as time, money, and effort to conduct the evaluation [79].

Conclusions

This systematic literature review provides one of the first overviews of mHealth SMS tools for SCI and represents one of the first steps in a wider research agenda aiming to comprehensively account for these tools. This review identified 19 mHealth tools reported across the 24 included publications and an increasing development trend. A synthesis of these findings highlighted the need for mHealth to support key underserviced SMS components for SCI, more standardized or commonly used evaluation methods for usability and user experience, and more detailed reporting that includes key technical details and decisions that shape the mHealth tool. Future research is encouraged to consider other sources for the identification of mHealth SMS tools for SCI, such as app stores and more technology-centric bibliographic databases, to complement this compilation.

Abstract

Background: Mobile health (mHealth) apps can promote physical activity; however, the pragmatic nature (ie, how well research translates into real-world settings) of these studies is unknown. The impact of study design choices, for example, intervention duration, on intervention effect sizes is also understudied.

Objective: This review and meta-analysis aims to describe the pragmatic nature of recent mHealth interventions for promoting physical activity and examine the associations between study effect size and pragmatic study design choices.

Methods: The PubMed, Scopus, Web of Science, and PsycINFO databases were searched until April 2020. Studies were eligible if they incorporated apps as the primary intervention, were conducted in health promotion or preventive care settings, included a device-based physical activity outcome, and used randomized study designs. Studies were assessed using the Reach, Effectiveness, Adoption, Implementation, Maintenance (RE-AIM) and Pragmatic-Explanatory Continuum Indicator Summary-2 (PRECIS-2) frameworks. Study effect sizes were summarized using random effect models, and meta-regression was used to examine treatment effect heterogeneity by study characteristics.

Results: Overall, 3555 participants were included across 22 interventions, with sample sizes ranging from 27 to 833 (mean 161.6, SD 193.9, median 93) participants. The study populations' mean age ranged from 10.6 to 61.5 (mean 39.6, SD 6.5) years, and the proportion of males included across all studies was 42.8% (1521/3555). Additionally, intervention lengths varied from 2 weeks to 6 months (mean 60.9, SD 34.9 days). The primary app- or device-based physical activity outcome differed among interventions: most interventions (17/22, 77%) used activity monitors or fitness trackers, whereas the rest (5/22, 23%) used app-based accelerometry measures. Data reporting across the RE-AIM framework was low (5.64/31, 18%) and varied within specific dimensions (Reach=44%; Effectiveness=52%; Adoption=3%; Implementation=10%; Maintenance=12.4%). PRECIS-2 results indicated that most study designs (14/22, 63%) were *equally explanatory and pragmatic*, with an overall PRECIS-2 score across all interventions of 2.93/5 (SD 0.54). The most pragmatic dimension was *flexibility (adherence)*, with an average score of 3.73 (SD 0.92), whereas *follow-up*, *organization*, and *flexibility (delivery)* appeared more explanatory with means of 2.18 (SD 0.75), 2.36 (SD 1.07), and 2.41 (SD 0.72), respectively. An overall positive treatment effect was observed (Cohen *d*=0.29, 95% CI 0.13-0.46). Meta-regression analyses revealed that more pragmatic studies (−0.81, 95% CI −1.36 to −0.25) were associated with smaller increases in physical activity. Treatment effect sizes were homogenous across study duration, participants' age and gender, and RE-AIM scores.

Conclusions: App-based mHealth physical activity studies continue to underreport several key study characteristics and have limited pragmatic use and generalizability. In addition, more pragmatic interventions observe smaller treatment effects, whereas study duration appears to be unrelated to the effect size. Future app-based studies should more comprehensively report real-world applicability, and more pragmatic approaches are needed for maximal population health impacts.

Introduction

Background

Regular physical activity can combat numerous chronic conditions and is associated with reduced premature mortality [1,2]. Despite these benefits, behavioral interventions and public policy have been largely unsuccessful in promoting higher physical activity among the general population. Worldwide, 28% of individuals are currently classified as insufficiently active [3], and physical inactivity has an estimated annual health care cost of >US $50 billion globally [4]. Thus, increasing physical activity across the world is an important economic and public health objective that requires scalable and pragmatic strategies [5].

Mobile health (mHealth) tools are one promising approach for improving health care delivery and scaling behavioral interventions worldwide [6,7]. Mobile app–based platforms can be particularly effective at increasing intervention accessibility and cost-effectiveness, and they offer the ability to tailor intervention methods to individuals' unique needs [8-10]. Accordingly, the use of app-based mHealth tools in health care has rapidly increased since 2008 [10,11], and several review papers have recently highlighted the important potential role of app-based interventions for improving global physical activity levels [12-14]. In addition, app-based interventions saw a large relative increase in publications compared with SMS text messaging, telehealth, or web-based interventions [14], making app-based interventions one of the most popular new clinical tools [15] and an important intervention approach to review to inform current and future researchers, as well as health care providers (eg, general practitioners).

Despite the growth of research using app-based tools to promote physical activity, there is limited evidence that app-based interventions for increasing physical activity have been widely adopted by policy makers or integrated into clinical or other practice settings [16,17]. One potential explanation for this lack of real-world application is that this research has generally centered on internal validity (ie, reliability or accuracy of the outcomes) over external validity (ie, generalizability or applicability of results) [18,19]. In other words, the existing research has emphasized explanatory approaches rather than more pragmatic study designs [20]. Explanatory studies measure whether an intervention has a beneficial effect under ideal and thoroughly controlled circumstances and, therefore, substantially differ from real-world conditions (eg, restrictive selection of study sample and control of intervention delivery). Pragmatic study designs can determine the effect of an intervention under more realistic conditions by maximizing external validity (eg, broad and inclusive eligibility criteria and flexibility in intervention delivery) [20-23]. Studies are not strictly dichotomous in their design; instead, they are situated along the explanatory-pragmatic continuum [21,22,24]. Essentially, the challenge is to strike a balance between a highly effective program and whether it can be integrated into practice settings. mHealth interventions have the unique advantages of leveraging automation, data-informed decision-making, and other technological components that might aid in adherence to the core elements (eg, key ingredients or mechanism of change) while scaling out [25].

Existing systematic reviews of mHealth studies have broadly called for increased pragmatism [18,26,27]; however, only one research review has specifically explored the generalizability and applicability of app-based physical activity interventions [16]. However, the results were limited by the insufficient reporting of external validity factors within the included studies. Thus, the review authors were not able to determine the generalizability of the findings and recommended that future mHealth researchers better report all study characteristics [16]. Specific study design characteristics, such as the study sample's demographics (eg, average age and gender) and the duration of the intervention, are important dimensions to evaluate when determining the generalizability of a study's findings to the full population.

Given the continued growth of app-based physical activity interventions [14] and the lack of clarity surrounding the pragmatic nature of these approaches, we conducted a systematic review and meta-analysis of mHealth apps for physical activity promotion.

Objective

Our primary aim was to analyze the degree to which these interventions reported the study characteristics necessary to inform generalizability and applicability and to assess the explanatory versus pragmatic nature of these studies. Our secondary aim was to explore the association between study design characteristics (eg, explanatory vs pragmatic, intervention duration, and participant demographics) and the observed effect sizes on participants' physical activity.

Methods

Protocol and Registration

This review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Multimedia Appendix 1) [28,29].

Search Strategy and Study Selection

We conducted a systematic search in 4 electronic databases on April 4, 2020: PubMed, Scopus, Web of Science, and PsycINFO. The search combined synonyms and keywords related to an app-based mHealth intervention for promoting physical activity (Table 1; Multimedia Appendix 2). We attempted to control for language bias by using a search strategy without language restriction (ie, no selective inclusion of trials published in English) [30]. In addition to these databases, the list of papers discussed by relevant systematic reviews [8,31-40] was examined to identify any further eligible studies.

Table 1. Search strategy used in PubMed on April 4, 2020.

Search category	Search term
mHealth[a]	mHealth OR mobile health OR m-health OR activity tracker OR fitness tracker OR wearable OR tablet OR personal digital assistant OR pda OR short message service OR sms OR text message OR android OR iphone OR iOS OR mobile phone OR cellphone OR cell phone OR cellular phone OR cellular telephone OR mobile telephone OR smart-phone OR smartphone OR mobile application OR mobile app

Combined	mHealth AND Physical activity AND Intervention AND Study design

[a]mHealth: mobile health.

[b]RCT: randomized controlled trial.

[c]PCT: practical clinical trial.

The included studies were limited to app-based physical activity interventions that were published in a peer-reviewed journal between January 2012 and April 2020 that primarily targeted physical activity and at most one other behavioral outcome and that presented quantitative outcome data. We further restricted our review to studies that collected device-based physical activity measures, as opposed to self-reported measures because device-based measures are frequently observed to be more reliable [41,42] and the use of physical activity–monitoring devices has become more commonplace in the real world [43], demonstrating the feasibility, acceptability, and pragmatism of these intervention tools. A complete list of the eligibility criteria is presented in Table 2. We obtained additional data sources (when available) such as the study protocol, the CONSORT (Consolidated Standards of Reporting Trials) checklist, or any other publicly available information from the corresponding authors provided via an email invitation to assess the Reach, Effectiveness, Adoption, Implementation, Maintenance (RE-AIM) framework for internal and external validity factors [44,45] and the Pragmatic-Explanatory Continuum Indicator Summary-2 (PRECIS-2) tool for evaluating interventions' pragmatism [24]. Specifically, this email contained a brief description of our study, and then asked, "In order to comprehensively evaluate the reporting of RE-AIM and PRECIS-2 criteria, we are also extracting data from study protocols and companion articles (eg, qualitative or quantitative methods measuring implementation). Would you be willing to help us by providing these additional resources?"

All records from the databases and supplementary searches were managed using the Microsoft EndNote X9 (Clarivate) reference manager software. After removing duplicates, we exported the records to Abstrackr (Brown University) for semiautomatic citation screening [46]. The relevance of the titles and abstracts was independently assessed by 2 authors (BP and JMH). Each eligible full text was independently reviewed by 2 researchers (SMH and MPB). Discrepancies were resolved through discussion between the screening authors. Any remaining conflicts were discussed among the other authors (CS, DE, KW, and BP) until consensus was reached.

Table 2. Eligibility criteria.

Data type	Eligibility criteria
Population	Participants of any age participating in physical activity programs in the context of health promotion or preventive care settings were included. Studies focusing on special populations (eg, pregnant women) or studies including participants with physical or psychological morbidities preventing them from participating in physical activity were excluded.
Intervention	Stand-alone mobile apps and web apps exclusively designed for mobile devices; multicomponent interventions (eg, supported through brief counseling sessions or paired with other mHealth[a] technologies) were included as long as the app was the primary component to the intervention; interventions that targeted ≥2 health behaviors in addition to physical activity (eg, diet, sleep, and SB[b]) were excluded; apps solely used for data collection purposes or as an appointment reminder service only were not eligible.
Comparator	Active or inactive comparator arms were included; single-subject design trials were excluded.
Outcome	Device-based measures of physical activity.
Study design	RCTs[c] and randomized ecologically valid research designs (ie, practical clinical trials, RCTs); randomized pilot and feasibility studies were included.

[a]mHealth: mobile health.

[b]SB: sedentary behavior.

[c]RCT: randomized controlled trial.

Data Collection Process

General Study Characteristics

We adapted an existing extraction template [32] to collect and summarize the general study characteristics. Specifically, we collected information about the study setting and design, study population, intervention components, outcome measures, key findings, and statistical analyses performed (Multimedia Appendix 3). Two authors (BP and JMH) separately extracted additional quantitative data for the meta-analyses; discrepancies were resolved through discussion and consultation with a third author (SMH).

RE-AIM Evaluation and PRECIS-2 Assessment

We used the RE-AIM framework to describe the degree of reporting of study characteristics across 5 dimensions (ie, reach, effectiveness, adoption, implementation, and maintenance). The evaluation was assisted by a 31-item RE-AIM coding system used in a previous study [47]. We then applied the PRECIS-2 tool to compare the interventions with usual care and to identify the pragmatic versus explanatory nature of each study. Following the guidance of Loudon et al [24] and the PRECIS-2 toolkit published on the web, usual care was defined as the primary care that patients usually received for medical advice and treatment. The PRECIS-2 tool comprises 9 domains (ie, eligibility criteria, recruitment, setting, flexibility [delivery], flexibility [adherence], follow-up, primary outcome, and primary analysis), each of which is assigned a score from 1 to 5 (1 is *very explanatory* and 5 is *very pragmatic*) [24]. In accordance with previous research [47], mean scores of >3.5 were deemed *primarily pragmatic*. Values between 2.5 and 3.5 were considered *equally pragmatic and explanatory*, and scores <2.5 were rated as *primarily explanatory*.

Although both frameworks can be applied regardless of the study setting, additional modifications to these frameworks are recommended for a given setting [48]. Thus, we adapted the RE-AIM and PRECIS-2 coding sheets [49] for our setting (Multimedia Appendix 4 presents these adapted coding sheets). The final scoring by the study is presented in Multimedia Appendix 5.

Quality Assessment

For each study, we also assessed quality of the study using the revised Cochrane risk-of-bias (RoB 2.0) tool for randomized controlled trials [50]. Two authors (BP and JMH) independently performed these assessments, and any disagreements were resolved through discussion with a third author (SMH, DE, and MPB). The studies were classified as having a *low risk of bias* if all the 5 assessment domains were considered low risk. Otherwise, the studies were classified as having s*ome concerns* when concerns were raised in at least 1 of the 5 domains, or they were classified as having *high risk of bias* when at least one of the domains was judged to be at high risk. These categories were drawn from the original Cochrane RoB 2.0 tool [50].

Statistical Analyses

We used counts and percentages to summarize the general study characteristics and RE-AIM and PRECIS-2 scores for each study.

Meta-analyses were performed by using *meta* commands in Stata 16 (StataCorp) [51]. We used the standardized average treatment effect in each study's primary app- or device-based physical activity outcome (ie, minutes of moderate to vigorous physical activity or step count) to compare treatment effects across studies with different outcomes. The standardized average treatment effect (or Cohen *d*) was calculated as the difference in the mean change in primary physical activity outcome between the intervention group and the control group divided by the pooled SD of the physical activity outcome in both the intervention and control groups, with a priori interpretations [52] of trivial (<0.2), small (0.2-0.5), moderate (0.5-0.8), and large (>0.8) effects.

In addition, we tested for heterogeneous treatment effects using random-effects models estimated through restricted maximum likelihood. All the following moderating variables were log transformed to better compare the effect sizes: baseline physical activity, sample size, participants' age, participants' gender, intervention duration, RoB score, RE-AIM score, and PRECIS-2 score. Bubble plots were used to graphically examine the relationships between treatment effect size and the continuous moderating variables.

We assessed the statistical significance of treatment effect heterogeneity by using Cochran Q test and calculating the Higgins I^2 statistic [53]. The following thresholds for the interpretation of the I^2 statistic were used:0%-40%, 30%-60%, 50%-90%, or 75%-100%; these were interpreted as *not likely important*, *moderate*, *substantial*, and *considerable* heterogeneity, respectively [53].

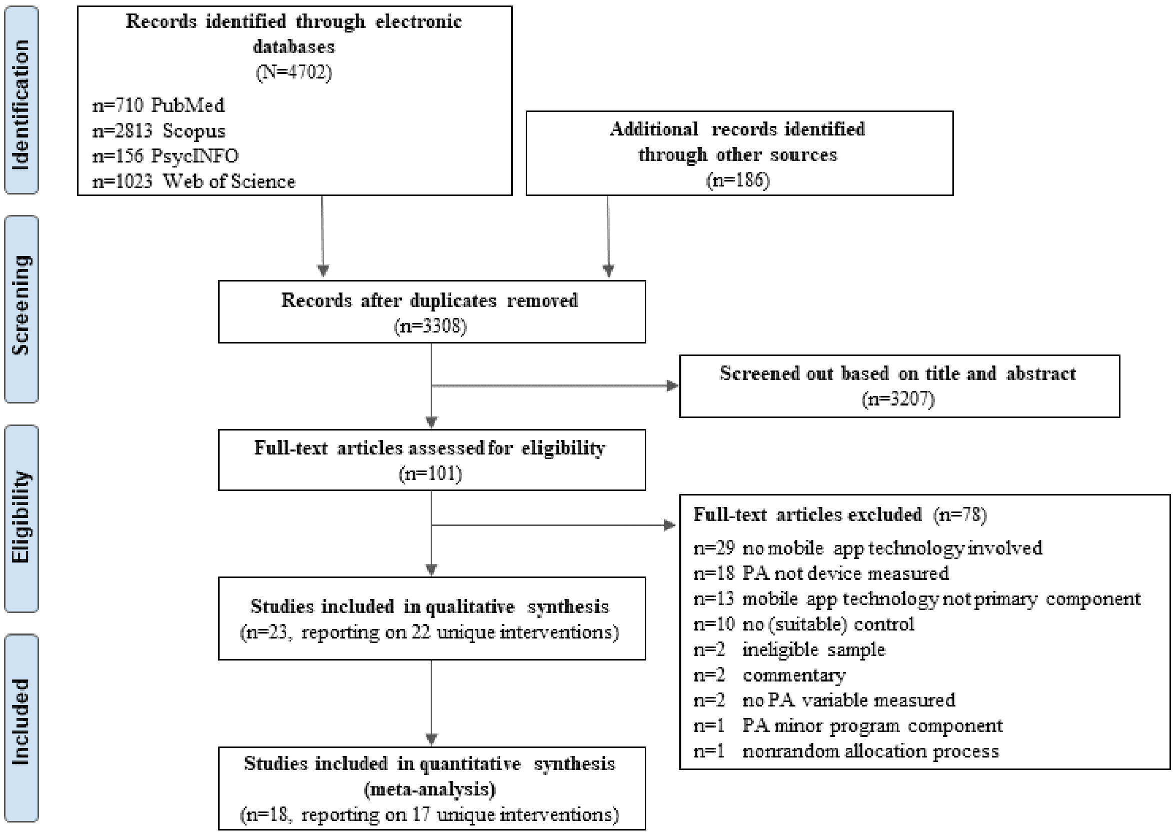
Finally, the combined impact of small-study effects and publication bias was assessed by using the trim-and-fill method and performing the Egger test using the *metafor* package [54] in R (version 3.6.3; R Foundation for Statistical Computing) [55]. The results are reported with 95% CI, and a *P* value of <.05 was considered statistically significant.

Results

Study Selection

The search yielded 3308 unique studies after duplicates were removed. Of the 3308 studies, we screened 3207 (96.95%) studies based on title and abstract, leaving 101 (3.05%) potentially relevant studies. After additional content reviews, 23 studies reporting 22 unique interventions met the eligibility criteria for inclusion in the RE-AIM and PRECIS-2 analyses. We emailed the corresponding authors of all 23 studies to request additional study information. We received responses from 52% (12/23) of the studies, and these responses either contained more information on the study (7/12, 58%) or simply stated that there was no additional information available (5/12, 42%). In total, only 74% (17/23) of these studies presented sufficient quantitative detail for inclusion in the meta-analyses. The detailed study selection process is visualized in the PRISMA flowchart (Figure 1).

Figure 1. Flowchart of study selection. PA: physical activity.



Study Characteristics

All interventions were published in English between 2012 and 2020 and were conducted in 10 countries, with most interventions (10/22, 45%) having based in the United States [56-65]. Of the 22 interventions, 21 (95%) used a randomized controlled trial design, of which 19 (90%) interventions randomized participants on an individual level and 3 (14%) interventions were randomized in clusters [66-68]. One study explicitly used a pragmatic study design [69]; 6 studies identified their trials as pilot studies [56,61,62,64,70,71], and 1 was classified as a feasibility study [72]. One study used a factorial design between multiple intervention components as part of a multiphase optimization strategy [57]. An overview of these study characteristics for each study is presented in detail in Multimedia Appendix 6.

A total of 3555 participants were included across all 22 interventions, with sample sizes ranging from 27 to 833 (mean 161.6, SD 193.9, median 93) participants. All studies were conducted in a health promotion or preventive care setting, and the most common study settings were the local community (10/22, 45%), a university or other type of school (7/22, 32%), or a clinical care setting (3/22, 14%). In addition, 10 interventions exclusively targeted insufficiently active individuals. Study populations varied in age and gender, with mean ages ranging from 10.6 to 61.5 (mean 39.6, SD 6.5) years, and the proportion of males included across all studies was 42.8% (1521/3555). Moreover, 2 studies exclusively targeted men, and 2 studies included women only.

Intervention length varied from 2 weeks to 6 months (mean 60.9, SD 34.9 days). The primary app- or device-based physical activity outcomes differed between interventions, with most interventions (17/22, 77%) using activity monitors or fitness trackers and the rest (5/22, 23%) using app-based accelerometry measures. All studies reported either moderate to vigorous physical activity, daily steps, or both measures. The comparator groups received either no intervention (10/22, 45%); a minimal intervention such as generic physical activity information (6/22, 27%); a basic app version targeting physical activity (3/22, 14%); a control app unrelated to physical activity (1/22, 5%); or a wearable activity monitor with access to its corresponding generic tracking app (2/22, 9%).

A total of 27% (6/22) of studies targeted physical activity, and 5% (1/22) of studies targeted additional health behavior outcome (ie, diet or sedentary behavior). With regard to the physical activity intervention strategies used in all studies, 27% (6/22) of studies provided brief in-person expert consultations (eg, goal setting or generic physical activity information), and 5% (1/22) of interventions included weekly telephone counseling. Most studies (19/22, 83%) also used emails and text messages as physical activity reminders or to provide participants with an activity summary.

The interventions' apps varied greatly between the studies and consisted of both commercial products and apps designed solely for research purposes. The apps included features such as physical activity tracking and self-monitoring, feedback, goal setting, social interaction, and gamification features (Multimedia Appendix 6 provides the full list of app features by intervention).

RoB Assessment

Table 3 shows the RoB in the included studies. Overall, 17% (4/23) of studies showed a *low risk*; 43% (10/23) of studies raised *some concerns*; and 39% (9/23) of studies were rated *high risk*. A lack of balance across randomized study groups in terms of baseline physical activity and gender contributed to a *high risk of bias* classification for 3 studies, and 2 other studies were considered to have a *high risk of bias* for deviating from their intended intervention design, which the authors attributed to a lack of participant engagement with the intervention's physical activity app and the intended intervention. In addition, most studies (14/22, 64%) did not provide enough information to determine whether the data were analyzed according to their prespecified data analysis plan, which resulted in them being classified as having *some concerns*.

RE-AIM Evaluation

Overview

The overall rating of sufficiently reported individual RE-AIM items across all interventions was 18% (5.64/31, SD 2.30%; Table 4). Reporting ranged from 2 to 11 of the 31 RE-AIM items. The most commonly reported items were those in the Effectiveness (2.6/5, 52%) and Reach (1.8/4, 45%) dimensions. Reported data within the Maintenance categories were observed in only 12% (1.1/9) of the interventions, and the reporting of items in the Adoption and the Implementation dimensions were found in 4% (0.3/8) and 10% (0.5/5) of the interventions, respectively. A summary of the key findings of the factors within each dimension is presented in the subsequent section.

Table 4. Inclusion of Reach, Effectiveness, Adoption, Implementation, Maintenance (RE-AIM) items across all interventions (N=22).[a,b]

RE-AIM dimension and items	Values, n (%)
Reach (44.3%)	
Exclusion criteria	17 (77)
Participation rate	16 (73)
Representativeness	6 (27)
Use of qualitative methods to understand reach and recruitment	0 (0)
Effectiveness (52.7%)	
Measure of primary outcome	22 (100)
Measure of broader outcomes (ie, QoL[c], negative outcomes)	11 (50)
Measure of robustness across subgroups	4 (18)
Measure of short-term attrition	14 (64)
Use of qualitative methods or data to understand outcomes	7 (32)
Adoption-setting (3.4%)	
Setting exclusions	2 (9)
Setting adoption rate	1 (4)
Setting representativeness	0 (0)
Use of qualitative methods to understand adoption at setting level	0 (0)
Adoption-staff (0%)	
Staff exclusions	0 (0)
Staff participation rate	0 (0)
Staff representativeness	0 (0)
Use of qualitative methods to understand staff participation	0 (0)
Implementation (10%)	
Delivered as intended	5 (23)
Adaptations to intervention	4 (18)
Cost of intervention (time or money)	0 (0)
Consistency of implementation across staff or time or settings subgroups	2 (9)
Use of qualitative methods to understand implementation	0 (0)
Maintenance-individual (9%)	
Measure of primary outcome at ≥6-mo follow-up	3 (14)
Measure of broader outcomes (ie, QoL, negative outcomes) at follow-up	2 (9)
Measure of long-term robustness across subgroups	2 (9)
Measure of long-term attrition	3 (14)
Use of qualitative methods to understand long-term effects	0 (0)
Maintenance-setting (3.4%)	
Program ongoing (≥6-mo poststudy funding)	1 (4)
Long-term program adaptations	2 (9.1)
Some discussion of sustainability of business model	0 (0)
Use of qualitative methods to understand setting-level institutionalization	0 (0)

[a]The table formatting was adapted from Burke et al [47].

[b]Overall RE-AIM was 18.2%.

[c]QoL: quality of life.

Reach

Exclusion criteria commonly included health contraindications for participating in physical activity or comprised mHealth-specific requirements (eg, specifications around technical devices). Most studies provided accurate information (ie, either n and valid denominator or percentage) on the *participation rate* (16/22, 73%) [56-60,62-66,68,69,71,72,75,78]; however, only a few (3/22, 14%) reported the sample size in relation to the total number exposed to recruitment [65,68,72], and the remaining trials reported only on the relation of the sample size to potentially eligible participants [56-60,62-64,66,69,71,75,78]. A few interventions (6/22, 27%) adequately reported the *representativeness* of the study sample. One intervention compared their sample to eligible individuals who declined participation [72], and 5 compared their sample and their target audience [58,62,66,70,71]. Comparisons were made on physical activity variables and anthropometry and fitness measures.

Effectiveness

All studies (23/23, 100%) reported a *measure of primary outcome* related to physical activity (per review eligibility criteria), and half of the interventions (11/22, 50%) addressed a *measure of broader outcomes* [56,57,60,61,65-67,69,70,72,75]. Moreover, 45% (10/22) of studies compared their physical activity–related findings to a public health goal (ie, physical activity guidelines) [56,58,62-64,71,74-76]; however, only a few studies (4/22, 18%) analyzed the *robustness across study subgroups* (eg, gender and age groups) [56,58,64,76]. Potential explanations for physical activity–related findings were explored using *qualitative research methods* in several interventions (7/22, 32%) [57,62,67-69,72,76].

Adoption

Both nonresearch and research staff participation were considered, and more participation of either nonresearch or research staff would result in a study being less pragmatic if it exceeded the usual standard of care. However, no items were reported within the dimension "Adoption-staff." Regarding "Adoption-setting," 2 studies specified *settingexclusions* (eg, unqualified staff and irregular physical education classes) [67,68]. One intervention presented a valid *setting adoption rate* [68].

Implementation

The *delivered as intended* and the *adaptations to intervention* items were infrequently addressed and were mainly of technical nature (eg, app bug or app appearance). None of the studies sufficiently reported the *cost of* intervention, meaning that costs were not addressed across all levels of the intervention or were not detailed enough (eg, app development, technical equipment, and support). The *consistency of implementation* was outlined in 2 trials (eg, fidelity checks) [58,78].

Maintenance

A few interventions (3/22, 14%) assessed a *≥6-month follow-up* measure; 2 studies reported a 6-month follow-up phase [58,66]; 1 implemented a 9-month follow-up measure [73]; and all these studies reported an accurate *long-term attrition rate*. Two studies analyzed the *long-term robustness* (eg, age and weight status) [58,73]. A *measure of broader outcomes* was reported in 2 interventions, assessing the quality of life using the 12-Item Short-Form Health Survey [58,66].

Items within the Maintenance-Setting dimension were only addressed by 3 interventions, including potential *long-term adaptations* (eg, implementing an educational app component) [56,72,74]. The sustainability of the program in the RE-AIM context was not discussed at all.

PRECIS-2 Assessment

The overall PRECIS-2 score across all interventions was 2.93/5 (SD 0.54). Of the 22 assessed interventions, 14 (64%) interventions were categorized as *equally pragmaticand explanatory* (range 2.56-3.44) [57,59,62–67,69–71,73,74,76]; 5 (23%) studies were identified as being *primarily explanatory* (range 2.00-2.44) [58,60,61,68,77]; and 3 (14%) studies were *primarily pragmatic* (range 3.56-4.44) [56,72,74].

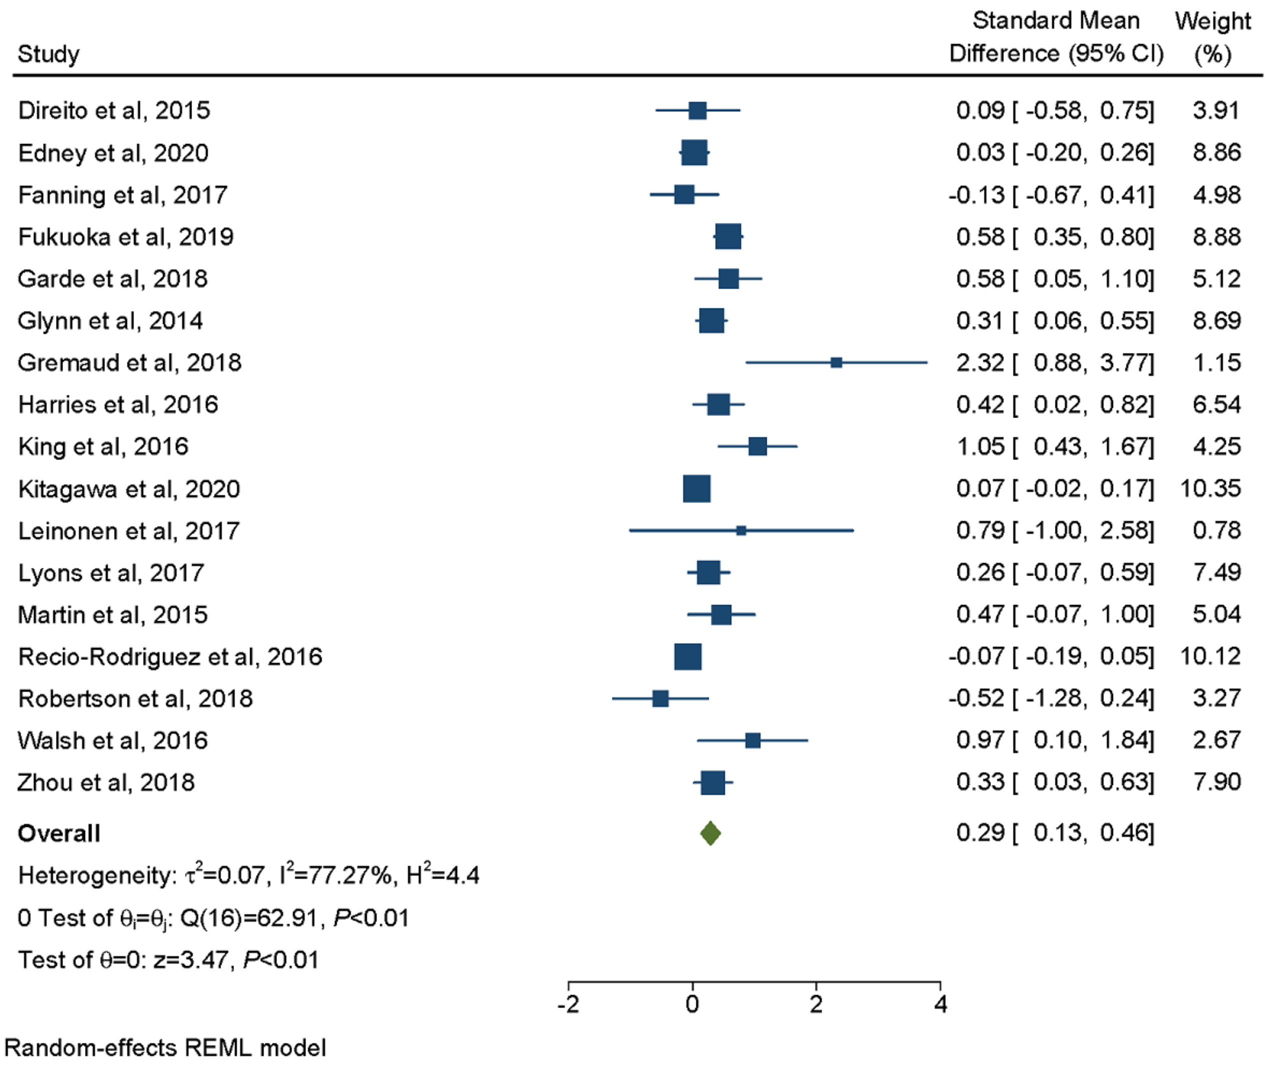
The most pragmatic dimension across all interventions was *flexibility (adherence)*, with an average score of 3.73 (SD 0.92), as demonstrated by letting the participants use the app at their convenience or lacking any measures to improve adherence. *Follow-up*, *organization*, and *flexibility (delivery)* appeared to be more explanatory, with means of 2.18 (SD 0.75), 2.36 (SD 1.07), and 2.41 (SD 0.72), respectively. For example, delivery flexibility was considered more explanatory based on in-person requirements, clinician oversight, or specific app use or compliance requirements. Domains considered equally explanatory and pragmatic were *eligibility criteria*, *recruitment*, *setting*, *primary outcome*, and *primary analysis* (range 2.95-3.45). Overall, the studies in this review were equally pragmatic and explanatory in terms of the eligibility criteria.

Meta-analysis

Overall Treatment Effect

Data from only 17 interventions were extracted for this meta-analysis because 5 interventions did not present complete outcome data (ie, they did not report SE or 95% CI). Overall, these 17 mHealth interventions significantly improved the participants' physical activity (Cohen *d*=0.29, 95% CI 0.13-0.46; Figure 2).

Figure 2. Forest plot of standardized treatment effects on physical activity with studies weighted by the inverse of the SE of the estimated treatment effect. REML: restricted maximum likelihood.



Meta-regression Analyses

Meta-regression analyses revealed a statistically significant negative association between the standardized treatment effect and the study's sample size (*P*=.01), PRECIS-2 score (*P*<.001), and study participants' baseline physical activity (*P*<.001; Table 5), that is, a larger sample size, higher PRECIS-2 score (ie, more pragmatic), and higher observed baseline physical activity levels were all associated with smaller treatment effect sizes on participants' physical activity. None of the other covariate measures (ie, intervention duration, participants' age, participants' gender, and RE-AIM score) were significantly related to changes in participants' physical activity.

To graphically depict the interaction between the treatment effect size and the continuous measure of a study's PRECIS-2 score, we created a bubble plot with studies represented by circles sized by the inverse of the SE of the estimated treatment effect (Figure 3). The plot also shows the weighted linear relationship between these study characteristics and the 95% CI for this estimated relationship.

Table 5. Meta-regression results showing the interaction between study characteristics and the standardized treatment effect on physical activity.[a]

Covariate	Standardized mean difference (95% CI)	*P* value
Log (intervention duration [days])	0.0171 (−0.0338 to 0.0680)	.51
Log (participant mean age [years])	−0.00296 (−0.224 to 0.218)	.98
Log (sample size)	−0.0616[b] (−0.111 to −0.0123)	.01
Log (percentage male)	−0.0615 (−0.266 to 0.143)	.56
Log (baseline step count)	−0.420[c] (−0.637 to −0.202)	<.001
Log (baseline MVPA[d] [minutes])	−0.199[c] (−0.288 to −0.109)	<.001
Log (PRECIS-2[e] score)	−0.805[f] (−1.361 to −0.249)	<.001
Log (RE-AIM[g] score)	−0.0277 (−0.177 to 0.122)	.72
Log (risk-of-bias score)	−0.199 (−0.406 to 0.0690)	.06

[a]All covariates were log transformed; therefore, the coefficients measure the associated change in the standardized treatment effect size from a 1% increase in the indicated variable.

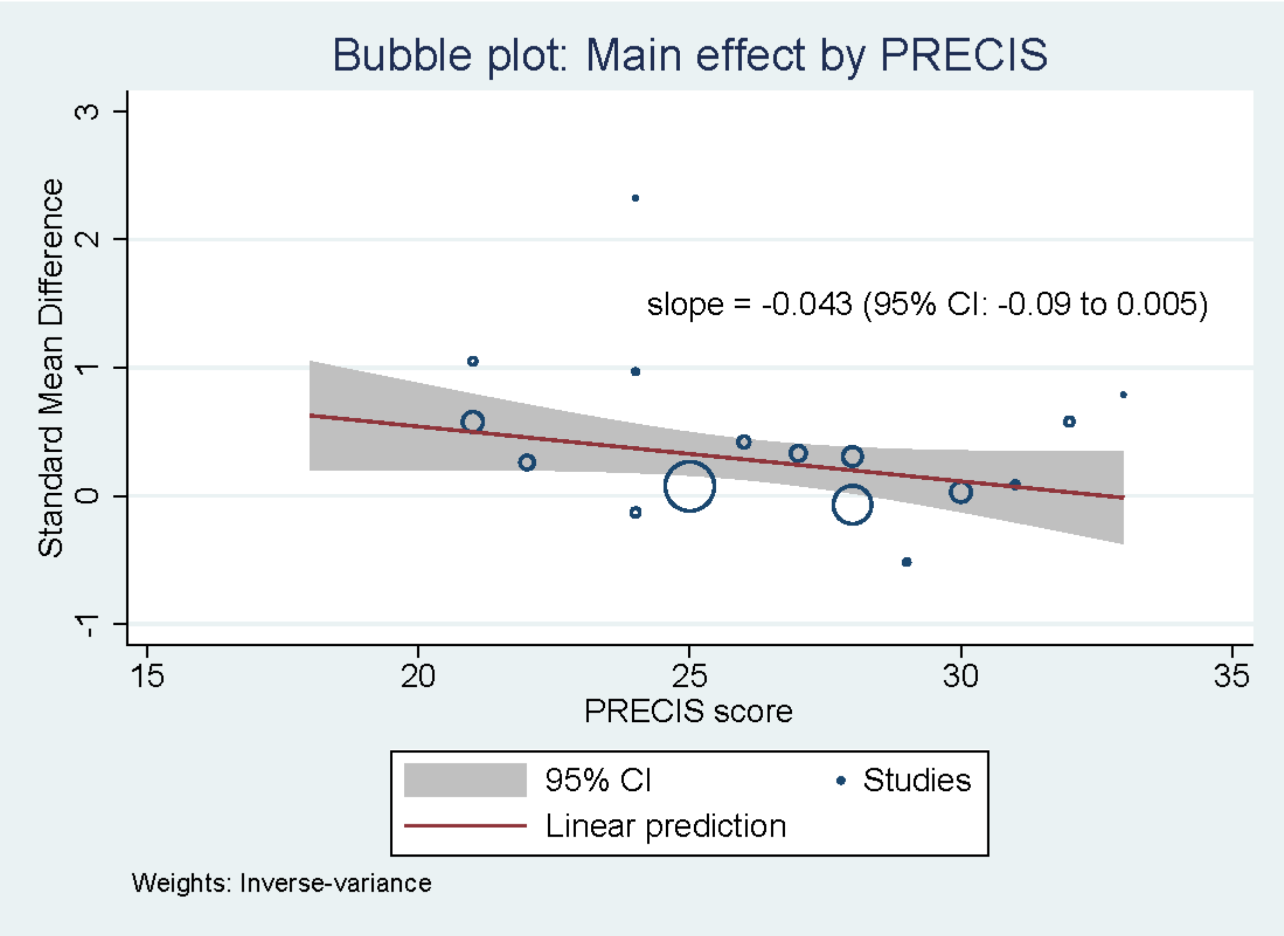
[f]*P*<.01.

[g]PRECIS-2: Pragmatic-Explanatory Continuum Indicator Summary-2.

Figure 3. Bubble plot of standardized treatment effect on Pragmatic-Explanatory Continuum Indicator Summary-2 (PRECIS-2) score (a single outlier was removed).



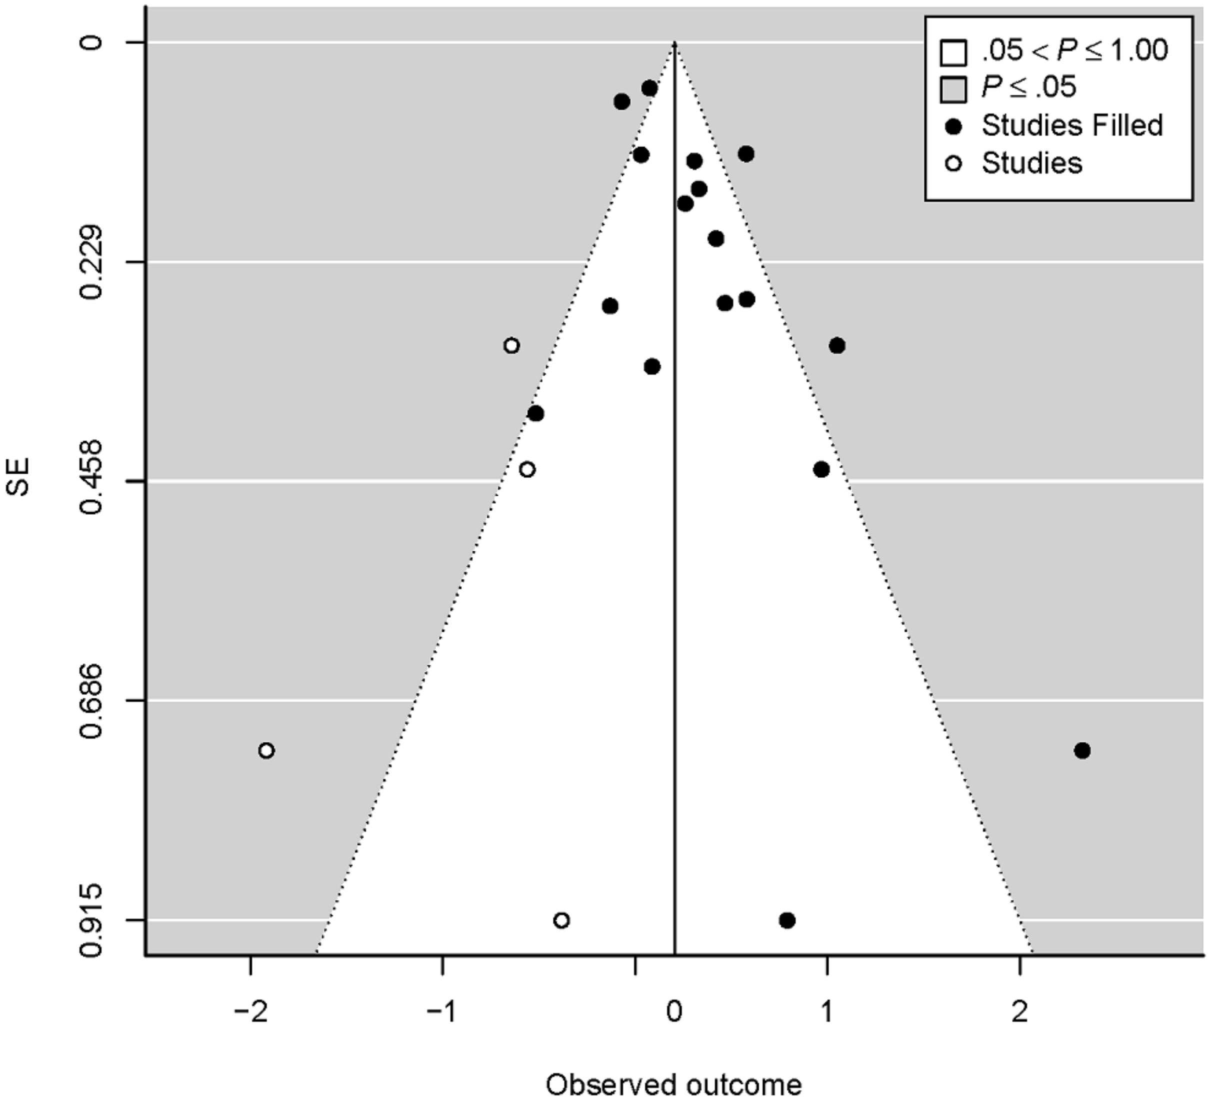
Overall Treatment Effect Heterogeneity

The meta-analysis showed considerable heterogeneity between the studies, with an I^2 value of 77.27%. The I^2 value represents the estimated percentage of variability in the results because of heterogeneity rather than chance [53]. Cochran Q test for treatment effect heterogeneity across these studies was Q_{16}=62.91, which demonstrates a statistically significant degree of heterogeneity (P<.001).

Analysis of Publication Bias and Small-Study Effects

We used the trim-and-fill method to explore the potential impact of publication bias in this literature, which estimated the number of studies missing from this literature to be 4 (SE 2.80; Figure 4). After imputing these missing studies, the overall standardized treatment effect size was slightly reduced from 0.29 (95% CI 0.13-0.46) to 0.20 (95% CI 0.01-0.40) but remained statistically significant. A high I^2 value of 83.8% indicated that the heterogeneity between studies remained at a considerable level after imputing these potentially missing studies. We then carried out the Egger test for small-study effects, which reached statistical significance under most specifications (Multimedia Appendix 7).

Figure 4. Trim-and-fill funnel plot for included studies in this meta-analysis.



Discussion

Principal Findings

Among recent studies using app-based interventions to promote physical activity, we observed a significant degree of underreporting on several RE-AIM dimensions, which limits researchers' and policy makers' ability to assess the generalizability of the research results. In addition, the interventions in this literature, in general, had more explanatory rather than pragmatic designs, which further limits our ability to forecast how successful these interventions would be in promoting physical activity if implemented among the general population. Finally, the aggregate study results showed a small but significant improvement in participants' physical activity. However, treatment effect sizes varied according to the PRECIS-2 classification, where the more pragmatic trials produced smaller treatment effects on physical activity. Taken together, these findings suggest that app-based physical activity interventions would have limited efficacy in promoting physical activity if more widely scaled and adopted among the general population, suggesting that more pragmatic study designs are needed to increase the transferability from research to practice. The recommendations provided by Blackman et al [16] should be used more widely by researchers in this literature when designing and reporting study findings.

RE-AIM Evaluation and PRECIS-2 Assessment

RE-AIM Evaluation

Our findings build on a prior review of mHealth physical activity interventions that also observed a lack of reporting on study characteristics and research findings in this literature [16]. Without sufficient information on these important study dimensions, the previous review was unable to determine the generalizability of the research findings at that time. Our more detailed and updated review demonstrates that only small improvements in transparency and the reporting of study characteristics have been achieved in mHealth physical activity research since then.

Our finding that recent mHealth physical activity studies lack transparency builds on similar observations reported in reviews of physical activity interventions using both mHealth and other intervention tools [47,49,79]. Specifically, the review by Blackman et al [16] on the mHealth physical activity literature found that few studies reported on the maintenance of intervention effects and the degree of implementation fidelity. In addition, the review by Harden et al [49] on group-based physical activity interventions showed that external validity factors were consistently underreported, and the review by Burke et al [47] on physical activity interventions for adults with spinal cord injuries found that several items within the Adoption and Maintenance dimensions of RE-AIM were not reported in any study, limiting the generalizability of these studies.

Two specific areas of underreporting in the mHealth physical activity studies that we reviewed were in the Adoption and Maintenance dimensions. The lack of reported information on the ability of health care providers to adopt these app-based physical activity intervention tool or tools significantly limits the willingness of clinicians and organizations to implement these new intervention approaches [16,47,49]. More pragmatic study designs with greater reporting of the Adoption and Maintenance dimensions are needed to increase the implementation of these mHealth tools in real-world settings. In addition, none of the studies reported sufficiently the cost of the intervention (in terms of either time or money), making it difficult to assess the benefit versus cost of these tools. Rubin et al [80] noted that prior complications experienced when integrating mHealth technologies into clinical practice have likely increased providers' hesitancy to adopt new mHealth strategies. Therefore, we believe that increased reporting of interventions' organizational requirements and costs (eg, required staff qualifications, equipment for delivery and analysis, cost of acquiring the intervention tools, and maintenance) would increase the applicability of this research.

PRECIS-2 Assessment

With regard to the PRECIS-2 results, our domain-specific assessments suggest that these recent studies testing app-based physical activity interventions tend to be primarily explanatory in nature. To combat a lack of app engagement, many studies used additional text messages or email reminders to reengage participants with the interventions' app. These additional intervention components lowered our assessment of pragmatism, as it is not clear how well these methods can be widely implemented in usual care practices. Although the apps were considered relatively pragmatic in terms of their ease of accessibility, many studies also used frequent assessments and in-person intervention components or brought participants into research-specific facilities, limiting their overall level of pragmatism. Importantly, the use of device-based physical activity measures did not influence PRECIS-2 scores, as these devices are increasingly available and integrated into usual care.

Challenges and Adaptations of RE-AIM and PRECIS-2

To address the underreporting of study characteristics, we combined the main intervention report with additional documents available on the web but found few additional study details through these additional sources; thus, we want to emphasize that a greater "consensus around the use of frameworks and checklists across scientific fields and journals" is still needed [47]. We also expanded the original RE-AIM framework to include a third scoring category (*inadequately/insufficiently reported)* but found that assessing this added nuance in reporting adds substantially more work to the review process. Therefore, we refer readers and future reviewers to the ongoing creation of domain-specific review tools [81], which will hopefully be able to strike a better balance between researcher burden and improved accuracy.

Meta-analysis

Overall, these recent app-based physical activity interventions produced small but significant increases in participants' physical activity. This finding is in line with the results of previous reviews that also found a small and significant effect of app-based interventions on promoting physical activity [31-33,82]. In addition, our meta-analysis found that study effect sizes were not significantly different between interventions with durations longer than 8 weeks compared with those with shorter durations (Multimedia Appendix 7), which suggests that duration alone is not a predictor of a successful physical activity intervention and that additional approaches and intervention tools are still needed to change and maintain physical activity increases. Finally, a few of these studies were able to demonstrate, or even assess, the maintenance of physical activity after the interventions were withdrawn. This finding emphasizes the need for an improved understanding of physical activity habits and the maintenance of initial behavioral change.

The lack of evidence for an optimal physical activity intervention duration and for the maintenance of physical activity increases has been noted in previous reviews of the mHealth literature. Contrary to our findings, Romeo et al [32] found that the most effective physical activity interventions had durations longer than 8 weeks. In addition, the review by

Schoeppe et al [33] on app-based health interventions showed the greatest effects among interventions for up to 3 months in duration. The discrepancy between our results and those of previous studies demonstrates the need for more evidence on the optimal intervention duration. With regard to the maintenance of intervention effects, a recent systematic review by Pradal-Cano et al [82] described the need for longer-term studies to observe the maintenance of intervention effects after the intervention components are withdrawn. Among the studies reviewed by Pradal-Cano et al [58,66,73], only 3 reported on the maintenance of intervention effects at least 6 months after the intervention was withdrawn, and there were fixed findings on maintenance among these studies.

Strengths and Limitations

Adapting 2 complementary implementation science tools to better understand the generalizability and applicability of app-based physical activity intervention findings is a key strength of this review; however, this review is not without limitations. First, our literature search identified a relatively small number of unique interventions, which limited the power of our statistical methods. Second, the included studies significantly varied in terms of design parameters (eg, sampling frame and intervention components) and methodological parameters (eg, outcome measures). This considerable heterogeneity was identified in the meta-analyses and indicated the difficulties in synthesizing this literature. Although we focused only on app-based physical activity interventions, most interventions incorporated additional intervention components, precluding us from isolating the individual effect of the app on physical activity. Third, our literature search was performed in 2020, and more studies using mobile apps to increase physical activity have been published since then [83-85]. Although it is beyond the scope of this paper to incorporate these studies into our complete analyses, they all provide additional evidence that mobile apps can improve physical activity. In addition, one of these recent studies reported long-term behavioral maintenance outcomes [85], which is an important step in the mHealth app literature. Another important limitation is that most included studies targeted adults (19/22, 86%), which limits the generalizability of our findings to physical activity interventions among younger and older populations. Fourth, the significant degree of underreporting of study characteristics limited our ability to assess treatment moderation by individual RE-AIM dimensions, which is an important area for future research. Finally, our statistical analyses indicated the presence of a publication bias, potentially compromising the robustness of our findings. However, subsequent trim-and-fill analyses suggested that the overall treatment effect was only slightly reduced when attempting to account for these missing studies.

Conclusions

This review highlights important limitations in the mHealth literature that uses app-based interventions to promote physical activity. Specifically, studies continue to underreport several key study characteristics that are necessary to determine the generalizability and scalability of these intervention approaches. Importantly, more pragmatic study designs are needed to help researchers and policy makers confidently implement app-based tools in standard care practice. In addition, studies with different intervention durations were equally effective in increasing physical activity, suggesting that additional intervention methods and approaches are necessary to improve the maintenance and growth of initial physical activity improvements.

Abstract

Background: Microrandomized trials (MRTs) have emerged as the gold standard for the development and evaluation of multicomponent, adaptive mobile health (mHealth) interventions. However, not much is known about the state of participant engagement measurement in MRTs of mHealth interventions.

Objective: In this scoping review, we aimed to quantify the proportion of existing or planned MRTs of mHealth interventions to date that have assessed (or have planned to assess) engagement. In addition, for the trials that have explicitly assessed (or have planned to assess) engagement, we aimed to investigate how engagement has been operationalized and to identify the factors that have been studied as determinants of engagement in MRTs of mHealth interventions.

Methods: We conducted a broad search for MRTs of mHealth interventions in 5 databases and manually searched preprint servers and trial registries. Study characteristics of each included evidence source were extracted. We coded and categorized these data to identify how engagement has been operationalized and which determinants, moderators, and covariates have been assessed in existing MRTs.

Results: Our database and manual search yielded 22 eligible evidence sources. Most of these studies (14/22, 64%) were designed to evaluate the effects of intervention components. The median sample size of the included MRTs was 110.5. At least 1 explicit measure of engagement was included in 91% (20/22) of the included MRTs. We found that objective measures such as system usage data (16/20, 80%) and sensor data (7/20, 35%) are the most common methods of measuring engagement. All studies included at least 1 measure of the physical facet of engagement, but the affective and cognitive facets of engagement have largely been neglected (only measured by 1 study each). Most studies measured engagement with the mHealth intervention (Little e) and not with the health behavior of interest (Big E). Only 6 (30%) of the 20 studies that measured engagement assessed the determinants of engagement in MRTs of mHealth interventions; notification-related variables were the most common determinants of engagement assessed (4/6, 67% studies). Of the 6 studies, 3 (50%) examined the moderators of participant engagement—2 studies investigated time-related moderators exclusively, and 1 study planned to investigate a comprehensive set of physiological and psychosocial moderators in addition to time-related moderators.

Conclusions: Although the measurement of participant engagement in MRTs of mHealth interventions is prevalent, there is a need for future trials to diversify the measurement of engagement. There is also a need for researchers to address the lack of attention to how engagement is determined and moderated. We hope that by mapping the state of engagement measurement in existing MRTs of mHealth interventions, this review will encourage researchers to pay more attention to these issues when planning for engagement measurement in future trials.

Introduction

Background

In the past decade, digital solutions that leverage mobile technologies to improve health and well-being have become increasingly popular and have emerged as promising adjuncts to traditional health care provision [1]. These so-called mobile health (mHealth) interventions generally involve the use of mobile technologies such as mobile apps, SMS text messaging, and wearable devices to improve patient health outcomes by delivering health-related intervention content. Mounting evidence suggests that mHealth interventions are largely effective for treating chronic health conditions [2,3] and for preventing unhealthy behaviors [4]. Effectiveness aside, it is not difficult to see why mHealth interventions are so popular; mHealth interventions are highly scalable and cost-efficient [1]. High rates of mobile ownership worldwide also signal the potential for mHealth interventions to reach a diverse audience, including the underserved; however, we must acknowledge that there are barriers to access (such as the lack of internet access) that prevent mHealth interventions from being truly equitable [5].

Recently, more sophisticated mHealth interventions have been proposed to take advantage of the technological advances in mobile technology. These novel interventions (such as just-in-time adaptive interventions) tend to be multicomponent, that is, they tend to involve the manipulation of ≥2 components hypothesized to have a treatment effect. They also tend to be adaptive, in the sense that components of the intervention (eg, its content and timing of delivery) can change in response to some input data provided by the user (tailoring data collected from surveys or sensors). To make this concrete, let us consider a hypothetical mHealth intervention designed to reduce the severity of depression symptoms by sending daily motivational messages via SMS text messaging. The intervention is said to be multicomponent if both message content and timing of SMS delivery are thought to be *active* ingredients that can influence depression symptom severity. Such an intervention could be made adaptive if daily message content is tailored to the participant's mood the night before such that if a given participant had high negative mood the night before, a more strongly worded motivational message would be sent the next day. Unfortunately, conventional randomized controlled trials (RCTs) cannot be used to develop and optimize these interventions because they do not allow researchers to separate the treatment effect of individual treatment components from the overall treatment effect. In addition, RCTs do not allow researchers to investigate time-varying effects, which is of interest when the goal is to identify the optimal time to administer an intervention component [6]. Therefore, if the RCT design is used to study the aforementioned hypothetical mHealth intervention, we will only be able to estimate the *overall* treatment effect of sending motivational messages on depression symptom severity and not the specific treatment effect of message content and timing of SMS delivery on the severity of depressive symptoms.

To address these limitations of the RCT design, several cutting-edge trial designs have been proposed in recent years. The microrandomized trial (MRT) design in particular has gained considerable traction as a way to optimize multicomponent and adaptive mHealth interventions (including but not limited to just-in-time adaptive interventions) [6-9]. Essentially, the MRT design involves the repeated random assignment of participants to different intervention options of a single or multiple intervention components; therefore, an MRT of our hypothetical multicomponent motivational SMS text messaging intervention would entail repeatedly randomizing participants to receive *different types of motivational messages* at *different times daily*. This repeated random assignment then facilitates the estimation of the time-varying causal effects of each specific treatment component [6], that is, we can estimate the treatment effect of message content and timing of SMS text message delivery on the severity of depressive symptoms. Therefore, unlike RCTs, MRTs allow researchers to investigate the effectiveness of specific components of mHealth interventions, which could be informative for theory, future research, and intervention optimization. Notably, RCTs and MRTs are not mutually exclusive. One additional benefit of the MRT design is that it can be easily embedded within the treatment arm of a conventional RCT; therefore, the overall treatment effect and the effect of specific intervention components can be tested simultaneously.

Regardless of the trial design used, the measurement of participant engagement is integral to understanding the feasibility of mHealth interventions. This is because engagement with the constituent digital or nondigital intervention stimuli and tasks of an mHealth intervention is necessary for the individual to experience the intended distal health outcomes of the intervention [10,11]. The measurement of engagement, however, is not straightforward. Engagement, like many other psychological constructs, is an abstract and fuzzy concept that is not directly measurable (unlike, for example, the measurement of height). To measure engagement, researchers must first operationalize engagement, that is, define engagement in measurable terms [12]. To unpack how exactly engagement with mHealth interventions can be operationalized, it is instructive to consider *how* engagement can be measured, *which* kinds of engagement can be measured, and *what* levels of engagement can be measured.

Measures of Engagement

According to Yardley et al [13] and then Short et al [14], there are 7 methods of engagement measurement that researchers can use to obtain a sense of participant engagement in their digital interventions: self-report questionnaires, ecological momentary assessments (EMAs), qualitative methods, system usage data, sensor data, social media data, and psychophysiological measures. The measurement of engagement via self-report questionnaires and EMAs involves directly asking participants to report (via single items or questionnaires) their subjective experience of using the digital intervention or their use of the intervention. Qualitative methods of engagement, by contrast, involve the inference of engagement from qualitative sources (such as written responses and semistructured interviews). Measuring engagement via system usage data involves the quantification of how the digital intervention is used through metrics including, but not limited to, the number of log-ins, time spent on the intervention, and number of modules viewed. Engagement can also be measured by analyzing passively collected social media and sensor data if social media and sensors (eg, pedometers and heart rate sensors) are a feature of the intervention. Finally, psychophysiological measures of engagement involve the use of measures such as electroencephalography, eye tracking, or functional magnetic resonance imaging to infer engagement from neural and physiological activity.

Facets of Engagement

Engagement is thought to be a multifaceted construct composed of 3 distinct facets—physical, affective, and cognitive [11,14]. The physical facet of engagement refers to the "actual performance of an activity or task" [11]. The affective facet by contrast is thought to capture "a wide range of positive affective reactions to a task or activity, from feeling pride, enthusiasm, and satisfaction, to affective states that may underlie more enduring experiences of attachment, identification, and commitment" [11]. Finally, the cognitive facet of engagement is thought to refer to "selective attention and processing of information related to a task or activity" [11]. These facets represent distinct *kinds* of engagement that can be measured in mHealth interventions.

Levels of Engagement

When discussing the measurement of engagement in digital interventions, it is crucial to ask the question, "engagement with what?" [11]. This is because engagement measures can either be measures of engagement with the features and the active ingredients of the intervention or engagement with the health behavior of interest. Formally, Cole-Lewis et al [15] termed engagement with the mHealth intervention as "Little e" and engagement with the health behavior of interest as "Big E"; elsewhere, the terms microengagement and macroengagement are used instead [13]. In essence, Little e and Big E represent 2 distinct levels of engagement, where the 7 methods of engagement outlined in the *Measures of Engagement* section can be applied to measure participant engagement in the mHealth intervention context.

This Study

Given the importance of engagement to mHealth interventions, researchers have endeavored to understand how engagement has been conceptualized and operationalized in studies evaluating mHealth interventions. For instance, Pham et al [16] recently reviewed how engagement has been defined and measured in mHealth apps for chronic conditions. Perski et al [10], by contrast, reviewed how engagement was conceptualized in digital behavior change interventions (their review was not limited to mHealth interventions; it included other digital interventions). Other recent reviews evaluated the measurement of engagement in mHealth interventions designed for specific health conditions [17,18]. However, none of these reviews examined mHealth interventions evaluated by MRTs, perhaps owing to the relative infancy of the trial design. Thus, not much is known about the state of participant engagement measurement in MRTs of mHealth interventions. Furthermore, it is not yet known what kinds of factors have been studied as determinants of engagement in these MRTs.

Therefore, we conducted a scoping review to map this relatively new research area. We chose to conduct a scoping review as we expected that only a handful of mHealth intervention MRTs have been conducted to date—too few to be meaningfully synthesized with a systematic review. This scoping review aimed to address 3 review questions:

1. What proportion of existing (or planned) MRTs of mHealth interventions to date have assessed (or have planned to assess) engagement?
2. How has engagement been operationalized in existing (or planned) MRTs of mHealth interventions that have assessed (or have planned to assess) engagement?
3. In existing (or planned) MRTs of mHealth interventions that have assessed (or have planned to assess) engagement, what kind of factors have been studied as determinants of engagement?

Methods

Protocol and Registration

The protocol for this scoping review was developed using the Joanna Briggs Institute Manual for Evidence Synthesis [19] and was designed to ensure adherence to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analysis extension for Scoping Reviews) guidelines [20]. The protocol and its appendices were prospectively registered with the Open Science Framework (OSF) on June 30, 2022 [21].

Eligibility Criteria

We prioritized the inclusion of papers published in peer-reviewed journals. We included preprints, trial protocols, and dissertations (this was mistakenly left out of the "Types of Sources" section of our protocol [21]) only if no corresponding peer-reviewed journal articles were available. Conference abstracts were excluded from this scoping review.

All papers fulfilling these criteria to date were considered for inclusion if they were written in English and if they reported MRTs of mHealth interventions. We also included any secondary analyses of mHealth intervention engagement data collected from an MRT if the primary analysis (if available) did not report the assessment of engagement in detail. We defined mHealth interventions as any intervention designed to improve health outcomes through (though not limited to) the modification of health behavior (such as physical activity or treatment adherence), the improvement of patient knowledge, health monitoring, and the reduction of psychological distress via mobile technology such as SMS text messaging; mobile phone apps; or devices (including but not limited to smartwatches, wearables, and sensors) [1].

As the review's objectives concerned the assessment of engagement in MRTs of mHealth interventions, we included all studies in which authors *explicitly* attempted or claimed to quantitatively or qualitatively measure the participation in or use of mHealth interventions directly (by measuring participation in or performance of mHealth intervention activities or components) or indirectly (using measurements derived from non–intervention-related activities or components as a proxy), regardless of how they actually defined and measured engagement (eg, if they use alternative terms like adherence).

Information Sources and Search Strategy

We conducted a broad search for all published MRTs of mHealth interventions to date (the search was initially conducted on July 13, 2022, and again on September 28, 2022) by searching the following 5 bibliographic databases: MEDLINE (via PubMed), Embase, PsycINFO, CINAHL, and Cochrane Library. The search strategy was originally developed for MEDLINE, and we consulted an academic librarian from the National University of Singapore to ensure that the search strategy was comprehensive and sound. This search strategy was then translated for the 4 other databases (only syntax was changed to accommodate differences in search engines; keywords remained the same). Although only 1 broad search was eventually performed, it must be noted that we registered 2 separate searches in our protocol—1 for all published MRTs of mHealth interventions to date and 1 fine-grained search for MRTs of mHealth interventions that have assessed (or have planned to assess) engagement. During our search process, we realized that the latter search was redundant as it was nested within the former (because we used the Boolean operator AND between the mHealth intervention search terms and the engagement-related search terms). Therefore, we condensed the 2 planned searches into 1 by using the Boolean operator OR instead, such that our database searches indexed any MRTs that mentioned mHealth interventions or engagement-related terms. The comprehensive search strategies for all 5 databases (and their respective previous iterations) can be found on OSF [21].

To search for gray literature and unpublished studies, we searched the reference lists of included studies for any additional sources not indexed by our database search. We also posted an open call for unpublished MRTs of mHealth interventions on Twitter and contacted known experts of the MRT design to request unpublished and file-drawered studies. Finally, we performed a search (similarly, this search was initially conducted on July 13, 2022, and again on September 28, 2022) of MRTs of mHealth intervention on 2 preprint servers (PsyArXiv and medRxiv; we added this search during our search process to ensure the comprehensiveness of our gray literature search) and on 2 clinical trial registries, ClinicalTrials.gov (as detailed in our protocol) and the International Clinical Trials Registry Platform (this was added during the search process as well). The following search terms were used: "microrandomised," "microrandomized," "micro-randomised," and "micro-randomized."

Selection of Sources of Evidence

The results of the searches described in the previous section were imported into EndNote (version 20; Clarivate; we did not use Zotero as planned because of technical difficulties) for source selection and screening. The titles and abstracts of all potential evidence sources were first screened for eligibility. Eligible sources were then subjected to a full-text screening. Before the 2 screening stages, both authors discussed a subset of the search results (5 titles and abstracts and 4 full-text articles) to calibrate the selection of evidence sources. UL performed the screening using the eligibility criteria, and BC verified the screening at both stages. Any disagreements were resolved by consensus.

Data Charting Process and Data Items

As described in our protocol [21], we developed an initial data extraction form (a Microsoft Excel [Microsoft Corporation] spreadsheet) to chart the data from eligible evidence sources to obtain the information necessary to answer our review questions. Both authors (UL and BC) piloted this initial data extraction form with 4 included articles to calibrate the charting process and to ensure that relevant data items were captured by the form. This form was continuously updated during the charting process through the discussion of the extracted results. UL performed data charting, and BC verified the charted data for all eligible evidence sources. Any disagreements were resolved by consensus.

The initial data collection form was designed to abstract the following information from each paper: whether the paper described a primary or secondary analysis of MRT data, type of paper, sample size of the MRT, sample characteristics, purpose of the study, type of mHealth intervention assessed, mode of delivery for the mHealth intervention, if engagement was or will be assessed, how engagement was operationalized (if assessed), if determinants of engagement were or will be assessed, and (if any) what determinants of engagement were or will be assessed; for comprehensiveness, we also charted any moderating variables and control variables (covariates) assessed.

After piloting the form and during the charting process, we included additional data items to capture the following information: primary and secondary (if any) outcomes of the study, randomization design of the MRT, frequency of microrandomization, and the overall duration of the MRT. The final version of the data extraction form is available on OSF [21].

Synthesis of Results

To quantify the proportion of existing and planned MRTs of mHealth interventions to date that have assessed (or have planned to assess) engagement, we tabulated the number of evidence sources charted to have assessed or planned to assess engagement. The included evidence sources were grouped by their purpose and presented in a tabular format. The mHealth interventions of each included evidence source were categorized based on their target. We used the following categories: mental health promotion, smoking cessation, physical activity promotion, sleep improvement, dietary lapse prevention or weight management behavior promotion, gambling reduction, and alcohol use reduction.

To understand how engagement has been operationalized in MRTs of mHealth interventions, we sought to determine *how* included evidence sources measured engagement, *which* kinds of engagement they measured, and *what* levels of engagement they measured. To determine *how* engagement has been measured, we classified *explicit* measures of engagement from each included source according to the methods of engagement measurement outlined by Short et al [14] described in the *Introduction* section. We combined the self-report questionnaires and EMA categories for parsimony, as they are largely similar methods of measuring engagement. To determine *which* kinds of engagement have been measured, we classified *explicit* measures of engagement by the facets (physical, affective, or cognitive) of engagement they appear to measure [11]. Finally, to determine *what* levels of engagement have been measured, we classified the *explicit* measures of engagement from each included source as Little e or Big E measures [15].

To identify the factors that have been studied as determinants of engagement in MRTs of mHealth interventions, we extracted the variables of interest, moderators, and covariates from each model (with a measure of engagement as the dependent variable) tested in each included source. We then organized these variables into the following categories: notification related (eg, type of prompt sent), time related (eg, days since the start of the intervention or day of the week), psychological, societal, health behavior related (eg, alcohol use), contextual (eg, location data), physiological (heart rate), demographic, anthropometric (eg, weight change), or task related (eg, intervention-related activities).

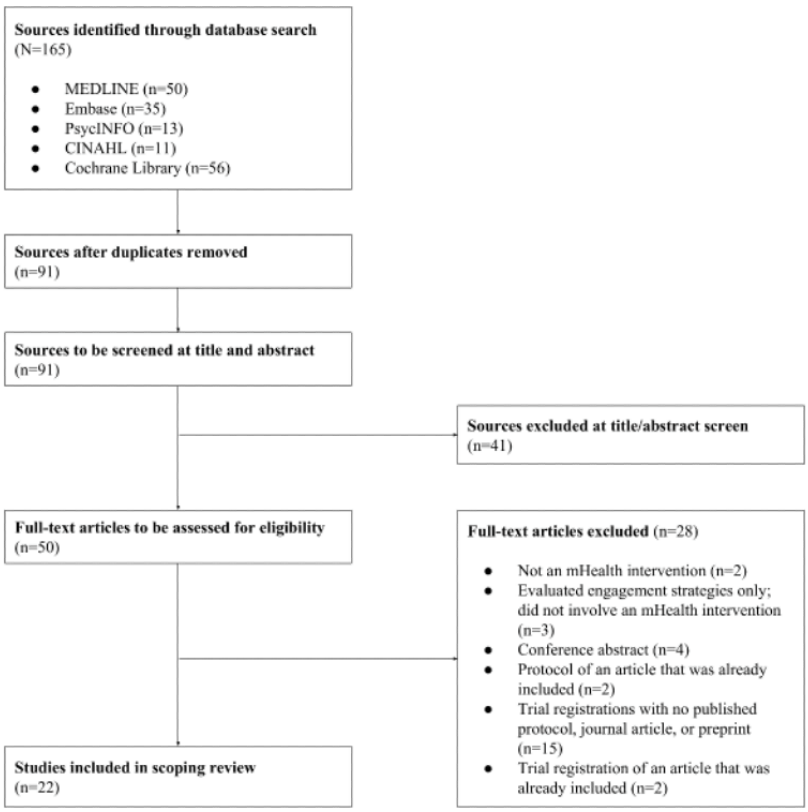
Results

Selection of Sources of Evidence

A total of 165 evidence sources were retrieved by our database search. After removing duplicates, 91 evidence sources were retained for further screening. During the title and abstract screening, 41 sources were excluded. Of the remaining 50 evidence sources, 28 were excluded at the full-text screening (Figure 1).

Notably, 17 of these sources excluded at full-text screening were trial registrations (a total of 19 trial registrations were retrieved by our database search of the Cochrane Library). A total of 15 (88%) of these 17 sources had no published protocol, journal article, or preprint; we performed a manual Google search of their respective trial identification numbers to confirm this. In total, 2 (12%) of these 17 sources were duplicate trial registrations, that is, a corresponding protocol, journal, article, or preprint for each registration was already indexed by our database search. Therefore, only 22 evidence sources identified by our database search were considered eligible for this scoping review. No additional studies were identified and included from our planned searches of gray literature and unpublished studies.

Figure 1. Evidence source selection flow diagram.



Characteristics of Sources of Evidence

All charted data described in the preceding section are available on OSF [21] and Multimedia Appendix 1 [22-43]. We present a subset of the charted data that are pertinent to our review questions.

Table 1 details the characteristics of each included evidence source. Of the 22 included sources, 12 (54%) were published journal articles, 8 (36%) were trial protocols, 1 (5%) was a preprint, and 1 (5%) was a dissertation. Only 1 evidence source was a secondary analysis of MRT data [22]. All included sources were published between 2018 and 2022. More than half of the included sources (14/22, 64%) were designed to evaluate the effect of intervention components. Physical activity promotion was the most common target of the mHealth interventions (8/22, 36%). Interventions were largely delivered via smartphone apps. The median sample size of the included MRTs was 110.5.

[b]SMS text messages were delivered as smartphone and smartwatch notifications.

Synthesis of Results

Operationalization of Engagement

Overview

Of the 22 included sources, 20 (91%) explicitly included at least 1 measure of engagement; 2 (9%) studies did not claim to measure engagement at all [25,32]; NeCamp et al [32] did not do so because of technical limitations. Though we did not chart the different terms used to refer to participant engagement, we noticed during our full-text screening that some studies did indeed use alternative terms in place of the term "engagement," such as adherence [27] and investment [30].

Measures of Engagement

Table 2 summarizes the measures of engagement used in each study. Across all included studies, system usage data were by far the most frequently used measure of engagement. Sixteen (80%) out of the 20 studies that explicitly measured engagement included at least 1 measure of this category. Generally, researchers used 2 types of system usage data: (1) responsiveness to self-reports, logs, or EMAs [23,24,26,27,29,30,33,35-37,41,42] and (2) access or use of interventions [22,26,33,35,36,39-41,43].

[e]PP: psychophysiological data.

[f]This study was also designed to evaluate the feasibility and acceptability of its mHealth intervention.

Sensor data were the second most common measure of engagement. Overall, 35% (7/20) of the studies that explicitly measured engagement included at least 1 measure of this category [24,27,28,31,33,34,41]. Wang et al [34], for example, measured the proportion of days in a week that participants wore the study's FitBit smartwatch to track their step counts and sleep duration.

Engagement was measured via self-reports or EMAs in 20% (4/20) of the studies that explicitly measured engagement [30,38-40]. Latham [30] evaluated a sleep intervention designed to improve the regularity of wake times in college students via prompts. One measure of engagement in this study was participants' self-reported adherence to the sleep-related suggestions included in the prompt. Nahum-Shani et al [38] proposed to study how prompts to engage in self-regulatory strategies increased engagement in self-regulatory activities; researchers planned to measure engagement as self-reported engagement in self-regulatory activities during the hour after receiving a prompt. In their evaluation of a web-based intervention delivered via SMS text messaging, Nordby et al [39] measured engagement as the self-reported frequency of practicing the coping strategies taught in the web-based intervention. Militello et al [40] assessed the feasibility and acceptability of intervention prompts to encourage engagement in mindfulness activities guided by a mindfulness mobile app. Here, engagement was measured as self-reported performance of a mindfulness activity or exercise in the 24 hours after receiving an intervention prompt.

Only 1 study measured engagement with qualitative methods. In this study, researchers sought to describe engagement with an Acceptance and Commitment Therapy (ACT)–based mobile app in a clinical and a nonclinical sample [42]. The researchers inferred participant engagement by assessing whether participant responses reflected an understanding of the ACT intervention content. The following 3 indicators were used: the identification of the function of behavior, process alignment (whether the content of a given participant's response is congruent with the core ACT process underlying the intervention prompt received), and the qualitative content of responses.

Only 8 (40%) out of the 20 studies that explicitly measured engagement used >1 method to measure engagement. Interestingly, no study used >2 methods. No studies measured engagement with social media data or psychophysiological measures.

Facets of Engagement

Table 3 summarizes the facets of engagement measured by each included study. The physical facet of engagement was the most frequently measured facet of engagement; all 20 studies that explicitly measured engagement included at least 1 measure of this facet [22-24,26-31,33-43]. Multimedia Appendix 2 [22-24,26-31,33-43] provides examples of how this facet of engagement was measured in each included study.

Only 1 study included a measure of the affective facet of engagement [30]. Recall that the affective facet of engagement "captures a wide range of positive affective reactions to a task or activity," including the "the affective states that may underlie more enduring experiences of attachment, identification, and commitment" [11]. By asking participants how likely they were to complete the intervention (ie, their commitment to the intervention), it could be argued that Latham [30] measured this facet of engagement.

Similarly, only 1 study assessed the cognitive facet of engagement—recall that this involves the "selective attention and processing of information related to a task or activity" [11]. This processing of information related to a task was comprehensively measured by Hoel et al [42] using the qualitative measures described in *Measures of Engagement* section.

Levels of Engagement

Table 4 summarizes the levels of engagement measured in each included study. Of the 20 studies that explicitly measured engagement, 14 (70%) studies measured Little e only, 2 (10%) studies measured Big E only, and 4 (20%) studies measured both Little e and Big E. Clearly, measures of engagement in MRTs of mHealth interventions are most often Little e measures.

Determinants of Engagement

Table 5 presents the determinants, moderators, and covariates of engagement studied (if any) in MRTs that assessed or planned to assess engagement. Of the 20 included studies that measured engagement explicitly, 6 (30%) investigated the determinants of participant engagement. Of the 6 studies, 4 (67%) studies were designed to evaluate strategies to improve engagement and investigated the influence of notification-related variables on participant engagement as variables of interest [22,37-39]. The remaining 2 (33%) of the 6 studies were designed to evaluate the effect of intervention components on health outcomes or to describe engagement. The former study assessed a time-based variable as its variable of interest—the causal effect of being in an intervention week on participant engagement [34]. The latter study assessed task-related variables (lapses in self-monitoring and behavioral goal attainment) and an anthropometric variable (weight change) as determinants of participant engagement [43].

Of the 6 studies, only 3 (50%) studies designed to evaluate strategies to improve engagement investigated how the determinants of engagement were moderated. Two of these studies exclusively examined the moderating effect of time-related variables [22,37]. Concretely, Bell et al [22] investigated how the causal effect of sending a push notification (vs not sending it) on engagement was moderated by the number of days in the study. Bidargaddi et al [37], by contrast, investigated if the causal effect of sending (vs not sending) a push notification on engagement was moderated by the number of weeks in the study or by the day of the week (sent on a weekday or a weekend). The third study of this trio planned to study the moderating effect of a comprehensive set of physiological and psychosocial moderators representing vulnerability and receptivity, in addition to time-related moderators [38].

Discussion

Principal Findings

In this scoping review, we aimed to better understand the state of participant engagement measurement in MRTs of mHealth interventions. To do so, we quantified the proportion of existing and planned studies that have explicitly assessed engagement and investigated how engagement has been operationalized in these MRTs. Of the 22 eligible studies indexed by our search, 20 (91%) studies included at least 1 explicit measure of engagement. Overall, our findings suggest that MRTs of mHealth interventions have operationalized engagement in overly narrow terms. We also sought to identify the factors that have been studied as determinants of engagement in MRTs of mHealth interventions. We found that out of the 20 studies that measured engagement explicitly, only 6 (30%) studies investigated the determinants of engagement. Even fewer attempts had been made to investigate the moderators of engagement.

Operationalization of Engagement

Measures of Engagement

Objective measures of engagement—in particular, system usage data (16/20, 80%) and sensor data (7/20, 35%)—were the most common methods of measuring engagement in MRTs of mHealth interventions. The relative popularity of measuring engagement with objective measures, especially system usage data, in MRTs of mHealth interventions is not surprising. System usage has been a central focus in the extant mHealth intervention literature [16]. In fact, it is one of the most common measures of engagement in mHealth interventions [10,44,45]. Subjective measures of engagement, by contrast, were far less common: self-report or EMA (4/20, 20%) and qualitative methods (1/20, 5%). Unfortunately, the lack of attention to the subjective experiences of participants in engagement measurement is not unique to MRTs of mHealth interventions [14,17]. Surprisingly, only 8 (40%) out of the 20 studies measured engagement using >1 method (no study used >2 methods). Of these 8 studies, only half (4/8, 50%) used both subjective and objective measures of engagement.

Taken together, these findings highlight a pressing need for future MRTs of mHealth interventions to diversify the methods of engagement used; the aforementioned lack of diversity does not seem limited to mHealth interventions evaluated using MRTs [14]. Researchers should keep in mind that subjective and objective methods are complementary, not competing, methods to measure engagement—subjective methods provide unique information about participant engagement that objective methods do not capture and vice versa [13,14]. Let us consider the distinction between qualitative and sensor data measures of engagement. Using qualitative methods, we may glean interesting insights about how a participant feels about an intervention or how cognitively invested they are in the intervention. This is certainly not possible for sensor data extracted from a pedometer. However, with said sensor data, it is possible to obtain detailed information (unobtrusively) about health behavior participation and how it fluctuates over time. We recommend that future MRTs of mHealth interventions adopt a multimethod approach to engagement measurement [13] such that engagement data from several subjective and objective measures are collected and interpreted.

Facets of Engagement

In this review, we found that the physical facet of engagement was the dominant kind of engagement measured in MRTs of mHealth interventions. Indeed, all 20 studies included at least 1 explicit measure of this facet. Surprisingly, the affective and cognitive facets of engagement were only measured by 1 study each. Clearly, our findings suggest an imbalance in the *kinds* of engagement measured and that researchers' conceptualizations of engagement, and consequently their operationalizations of engagement, are largely constrained to intervention-related task or activity performance. Given that self-report and qualitative measures of engagement are best suited to measure the affective and cognitive facets of engagement, we cannot rule out that this imbalance is a product of the lack of diversity in methods of measuring engagement described in *Measures of Engagement* subsection in the *Discussion* section.

From the theoretical position that engagement is a multidimensional latent construct composed of physical, affective, and cognitive facets, this imbalance is particularly worrying because it signals that the construct of engagement is not being adequately measured in MRTs of mHealth interventions. Scholars who adopt this position generally agree that no facet of engagement alone can constitute engagement. Instead, they concur that engagement involves the physical, emotional, and cognitive energies of a person working in concert [11]. Therefore, without measuring all 3 facets of engagement, it is not possible to accurately identify how engaged participants are with a task. We hope that this review will draw attention to this gap in engagement measurement and encourage future MRTs of mHealth interventions to incorporate more measures of the affective and cognitive facets of engagement.

On a related note, although an assessment of the quality of engagement measurement in MRTs of mHealth interventions is beyond the scope of this review, we did observe that many included studies relied on single items to measure engagement. Estimates of reliability were also rarely (if ever) reported. As single items have a bad reputation for being unreliable measures of psychological constructs [46], we encourage researchers to clearly report estimates of reliability (such as test-retest reliability) so that readers can evaluate for themselves how much variation in "engagement scores" can be attributed to measurement error.

Levels of Engagement

The distinction between Little e and Big E is an important consideration when studying engagement in digital health interventions. Recall that Little e and Big E can be construed as 2 distinct answers to the question "Engagement with what?" [11]. Our findings suggest that most explicit measures of engagement in MRTs of mHealth interventions are Little e measures (measures of engagement with the mHealth intervention) and that only a handful of studies have measured engagement with the health behavior of interest (or Big E).

Although this review focuses on explicit claims of engagement measurement, a careful analysis of the outcome measures used in all 22 studies makes it clear that many of these outcomes qualify as Big E measures, even though they were not explicitly conceptualized as such [15]. This was observed in 12 studies [24-29,31-36]. All 12 studies were designed to evaluate the effects of intervention components. Most of these studies measured the physical aspect of engagement using sensor data. If we account for such studies, we may conclude that all 22 studies of mHealth interventions included in this review included at least one measure of engagement and that out of the 22 MRTs of mHealth interventions included here, 4 (18%) studies measured Little e only, 4 (18%) studies measured Big E only, and 14 (64%) studies measured both Little e and Big E (Multimedia Appendix 3 [22-43]). It was difficult for us to decide whether the outcome measures of these 12 studies should be deemed measures of engagement in this review. Our concern stems from the fact that the inclusion of these outcomes as measures of engagement hinges on our use of the Little e and Big E distinction to understand how engagement has been operationalized. If this distinction was not invoked, there would be no clear evidence from these 12 studies to suggest that these outcome measures are measures of engagement or that the authors themselves considered them to be measures of engagement. Let us consider the engagement-related information extracted from Goldstein et al [26], which is one of the 12 studies. The outcome measure of this study, whether a dietary lapse was experienced since the last EMA, is a clear-cut measure of Big E. However, it was not included in the authors' own list of engagement measures stated in the paper. If the authors themselves do not conceptualize these outcomes as measures of engagement, would it be appropriate to include these outcomes as measures of engagement in this scoping review? Even if we were to include this outcome as a measure of engagement, can we assume that the underlying motivations of Goldstein et al [26]—in terms of modeling decisions and decisions about the study design—are similar to those of researchers who explicitly frame health behavior outcomes as measures of engagement? This is important because we cannot rule out the possibility that researchers' choice of causal effects, moderators, and control variables are at least partly influenced by how they conceptualize outcome measures. On the basis of these considerations, we decided not to consider the outcome measures of these 12 studies as measures of engagement in this scoping review.

Nevertheless, our findings clearly suggest the need for future MRTs of mHealth interventions to strike a balance between Little e and Big E measurement or at least be more intentional and explicit with Big E measurement (especially when using sensor data as an outcome measure). As the field begins to recognize that sustained engagement is not always required for participants to experience the intended health outcomes of an intervention [13], we encourage researchers to find this balance so that they can gain a sense of effective engagement in the interventions they develop—the sufficient amount of engagement needed to attain the intended outcome of the intervention [11,14].

Determinants of Engagement

We found that very few studies investigated the determinants of engagement (6/20, 30% of the studies that measured engagement). In studies that did assess the determinants of engagement, notification-related causal effects were most common. This is likely attributable to the fact that most of these studies were designed to evaluate strategies to improve engagement [22,37-39]. Even fewer studies (3/6, 50%) assessed the moderators of engagement. Although all 3 studies assessed time-related (time-variant) moderators such as the number of days in the study or the day of the week, only 1 study [38] planned to investigate time-invariant moderators (such as psychological or social variables) in addition to the time-related moderators. These findings suggest that there is a striking lack of attention to how engagement is determined and to the effect of time-invariant psychosocial moderators on engagement in existing MRTs of mHealth interventions. To advance our understanding of engagement in the multicomponent and adaptive mHealth interventions tested by MRTs, it is necessary for future MRTs to address this research gap.

To begin addressing this research gap, we recommend that researchers adopt existing theoretical frameworks to guide their selection of the determinants and moderators of participant engagement in MRTs of mHealth interventions. If widely adopted, this approach should ensure some semblance of parity in the kinds of determinants and moderators of engagement studied across MRTs and provide researchers with a common taxonomy (or at least a common language) to guide their inquiry. With this, researchers can compare and synthesize results from different MRTs to better understand how engagement is modulated across mHealth interventions tested with MRTs.

Researchers can consider studying the determinants and moderators of engagement through the lens of participant engagement frameworks. Recently, Nahum-Shani et al [11] proposed the affect-integration-motivation and attention-context-translation framework for participant engagement. In this paper, they outlined 3 areas, namely, attention, contextual influences, and the translation of motivation to behavior (attention-context-translation), that might influence the neural-based process (affect-integration-motivation) of how engagement with a task (eg, walking) is realized through engagement with a stimulus (eg, a prompt to take a walk). It would be interesting for future MRTs to examine how constructs from each of these 3 areas contribute to participant engagement. Alternatively, researchers can consider selecting theoretically relevant determinants and moderators from the Big Five Personality trait framework [47], which is composed of trait openness, conscientiousness, extraversion, agreeableness, and neuroticism. This approach might be a good first step toward clarifying the role of individual differences in participant engagement, considering the lack of attention given to the psychological characteristics of participants in the extant MRT literature and the relevance of personality to health behaviors and outcomes [48]. Researchers should pay particular attention to the role of conscientiousness as it seems to be the most relevant to mHealth engagement [49] and it has been consistently linked to positive health behaviors [50,51]. These 2 frameworks are by no means exhaustive. We encourage researchers interested in understanding the determinants and moderators of engagement to seek out other appropriate frameworks to advance this line of research.

Limitations

There are 3 notable limitations of this scoping review. First, at the time of conducting our database searches, there was no available Medical Subject Heading in PubMed for MRTs (or equivalent controlled vocabularies for other databases). Therefore, our database searches might not have picked up papers and protocols that did not use the phrase "micro-randomised trial" or "micro-randomized trial" as a keyword or in their title and abstract. Nevertheless, we believe that the main findings of this scoping review still hold true, as our database and manual searches would have indexed most mHealth intervention MRTs planned and conducted to date. Second, we did not use existing frameworks such as the Frequency, Intensity, Time, and Type principle [14] to further categorize engagement measured using system usage data. This has been done in previous scoping reviews [17] and is necessary to obtain a nuanced understanding of engagement measurement in mHealth interventions. Unfortunately, we were not able to do so, as some studies and protocols did not clearly operationalize their measurement of engagement in exact terms. Finally, it must be noted that because of the inclusion and exclusion criteria, we were not able to include several well-designed MRTs in this review because they were not strictly evaluations of mHealth interventions—they were designed either to evaluate digital but not mHealth interventions [52,53] or to evaluate engagement strategies only [54-56]. To fully understand the extent of engagement measurement in digital health interventions evaluated by MRTs, we encourage future reviews to broaden their inclusion and exclusion criteria to include these 2 types of evidence sources.

Conclusions

In this scoping review, we demonstrate that although most MRTs of mHealth interventions have measured engagement explicitly, they have operationalized engagement in overly narrow terms; there is an overemphasis on using objective measurements of engagement, measuring the physical facet of engagement, and measuring engagement with the mHealth intervention (as opposed to engagement with the health behavior of interest). There is also a lack of attention to how engagement is determined and moderated in these existing trials. We hope that by mapping the state of engagement measurement, this review will encourage researchers to pay more attention to these issues when planning engagement measurement in future MRTs. Although these issues are by no means unique to mHealth interventions evaluated with MRTs, the relative infancy of the MRT design suggests that there is still time and opportunity for the field to course correct and establish best practices for the measurement of engagement in MRTs of mHealth interventions.

Acknowledgments

The authors would like to thank Loh Mee Lan from the National University of Singapore Libraries for her guidance in formulating the database search strategies used in this review. This scoping review was supported by the Khoo Bridge Funding Award, the Academic Research Fund Tier 2 grant (Ministry of Education T2EP20122-0013) from the Ministry of Education, Singapore, and the start-up funding from Duke-NUS Medical School awarded to author BC.

Abstract

Background: In recent years, there has been a rise in the use of conversational agents for lifestyle medicine, in particular for weight-related behaviors and cardiometabolic risk factors. Little is known about the effectiveness and acceptability of and engagement with conversational and virtual agents as well as the applicability of these agents for metabolic syndrome risk factors such as an unhealthy dietary intake, physical inactivity, diabetes, and hypertension.

Objective: This review aimed to get a greater understanding of the virtual agents that have been developed for cardiometabolic risk factors and to review their effectiveness.

Methods: A systematic review of PubMed and MEDLINE was conducted to review conversational agents for cardiometabolic risk factors, including chatbots and embodied avatars.

Results: A total of 50 studies were identified. Overall, chatbots and avatars appear to have the potential to improve weight-related behaviors such as dietary intake and physical activity. There were limited studies on hypertension and diabetes. Patients seemed interested in using chatbots and avatars for modifying cardiometabolic risk factors, and adherence was acceptable across the studies, except for studies of virtual agents for diabetes. However, there is a need for randomized controlled trials to confirm this finding. As there were only a few clinical trials, more research is needed to confirm whether conversational coaches may assist with cardiovascular disease and diabetes, and physical activity.

Conclusions: Conversational coaches may regulate cardiometabolic risk factors; however, quality trials are needed to expand the evidence base. A future chatbot could be tailored to metabolic syndrome specifically, targeting all the areas covered in the literature, which would be novel.

Introduction

Background

Metabolic syndrome (MetS) is a highly prevalent condition that affects up to approximately 30% of adults aged >65 years worldwide [1]. It consists of multiple symptoms, namely abdominal obesity, glucose intolerance, hypertension, and high cholesterol as well as low high-density lipoprotein [2]. It is associated with a substantially increased risk of premature morbidity and mortality from diabetes and cardiovascular disease (CVD) [2]. Low levels of physical activity (PA) are strongly associated with MetS, including obesity and overweight [3], high blood pressure [4], and insulin intolerance [5]. Furthermore, low levels of activity are significantly associated with increased risk of complications of MetS, including diabetes and CVD [5,6]. In addition, research has found that losing weight by approximately 5% to 10% results in significantly reduced MetS-associated markers [1] in patients with existing disease, highlighting that MetS may be modifiable through lifestyle-related weight interventions. Dietary modifications, including reduced sodium, sugar, and fat intake, are also highly beneficial for reducing the risk of the syndrome and its complications [7].

In recent years, mobile health (mHealth) has increasingly been used to support behavior changes related to weight loss, including improving dietary intake and physical activity [8]. Research on the use of mHealth interventions has found support for a moderate effect size for assisting with weight loss [8]. This includes the use of SMS text messaging for behavior change and mHealth apps that target weight loss using a range of behavior change techniques (BCTs) [9], including self-monitoring, feedback, goal setting, education, tips, personal tailoring, reminders, encouragement, and social and professional support [8]. mHealth is a form of health care that enables timely accessibility, portability, and personalized medicine tailored to the needs of the user [10,11]. It includes smartphones, PDAs, MP3 players, iPads (Apple Inc), smart clothing, and smart watches [10,11].

Emerging research in the mHealth field has focused on developing conversational agents that can simulate human professional interactions for managing different health problems [12], including weight issues [13]. Furthermore, avatars have also been developed to display a conversational coach in addition to written conversational text, simulating real-life interactions with a professional, such as a live fitness coach [14,15]. Having a conversational coach complement or replace metabolic-related health advice from professionals may increase accessibility and enable more timely health monitoring and diagnosis of health conditions [15] such as MetS if physicians also gain access to patient data. Given that technology in the field is advancing, it is time to determine whether these conversational agents are effective for assisting with MetS-associated risk factors, including overweight, obesity, physical inactivity, and unhealthy dietary intake. There is also a need to better understand what types of weight-related and MetS-related studies have been undertaken using conversational agents and to identify challenges with the technology and future areas of research.

Aims

This review aimed to better understand the evidence surrounding the use of conversational coaches for metabolic-related risk factors and biomarkers. Furthermore, this review aimed to determine whether conversational coaches are effective for improving weight-related behaviors and metabolic indicators and whether conversational agents are acceptable for consumers as agents of behavior change.

Research Questions

- Research question (RQ) 1: How effective are conversational agents (chatbots and avatars) for weight-related behaviors, including diet and exercise?
- RQ 2: How effective are conversational agents for improving metabolic risk factors, including blood pressure, cholesterol, abdominal obesity, and glucose (diabetes management)?
- RQ 3: What are consumers' perspectives on the use of chatbots?

Methods

A systematic review of PubMed and MEDLINE was conducted in December 2021 for all relevant studies on conversational coaches for metabolic risk factors published over the last 10 years. Google Scholar was also searched for any additional papers along with manual hand searching.

Inclusion and Exclusion Criteria

This review included studies on chatbots or avatar conservational agents that acted as coaches for improving metabolic health behaviors, including dietary intake (sodium and sugar intake), PA, and weight (including abdominal obesity). Studies that evaluated one or more physiological indicators of metabolic health or risk factors for MetS, such as diabetes, glucose intolerance, hypertension, cholesterol, and serum triglycerides, were also included. Studies must have been published in the English language to be included. Chatbots that were used for survey reasons but not primarily for targeting weight-related or metabolic risk factors were excluded. Studies whose primary focus was not on conversational coaches were excluded (including those that had an avatar element but did not primarily focus on evaluating it). Studies on wearables that did not include avatars or chatbots were excluded. Studies in pregnant women were excluded.

Search

The keywords included word variations for "chatbot," "virtual assistant," "virtual coach," or "avatar"; weight-related behaviors, including "diet," "exercise," or "weight"; and metabolic risk factors, including "hypertension," "cholesterol," or "diabetes." The search strategy is shown in Textbox 1.

1 AND 2

Screening and Data Extraction

Titles were screened for relevance to the RQs, followed by abstract and full-text retrieval of eligible studies that met the inclusion criteria. A second reviewer (LL) screened the abstracts and full texts against the inclusion and exclusion criteria to ensure agreement. Quantitative and qualitative data were extracted and summarized in a tabular format, including study characteristics, measures, outcomes, and intervention details.

Results

General Description

LL and ME screened the final selected papers individually. A total of 52 full texts were selected [13,14,16-65]; however, after double peer screening, 1 protocol and 1 dated technology were removed. The final number included 50 papers [13,14,16-59,61-63,66]. Details of the search process and reasons for exclusion are illustrated in Figure 1 [67].

Most of the studies were feasibility and usability studies. A few studies were qualitative and explored consumer perspectives on conversational agents for weight-related behaviors [14,19]. The countries where the studies were conducted included Australia, the United States, Italy, Spain, and Taiwan [13,14,16-29]. Most of the studies explored virtual agents for diet and exercise, with only 2 (4%) exploring chatbots for hypertension management [17,19]. The majority were conducted among adults, but 3 (6%) were conducted among teenagers and preteens [14,26,29]. The study characteristics and results are summarized in Table 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the search and screening process. MetS: metabolic syndrome.

Study and year	Location, N, and design	Sex (%)	Age (years)	Health targets and measures	Technology and procedures	Outcomes
Echeazarra et al [17], 2021	• Location: Spain • N=112 • Design: 2-year RCT[a]	Female: 42	Mean 52.1	BP[b]	• Tensiobot (telegram app) • Reminders to check BP • Education on how to properly check BP using videos • Warnings and graphic feedback on BP • GPs[c] can connect with the app to access patient data • Advice offered 24/7	• No significant differences in adherence between groups • Bot group had higher levels of knowledge on good practice skills for BP (t=2.11; *df*=82.3; 95% CI 0.39-12.6; *P*<.05) • Measurements (*P*<.05) • Bot found to be acceptable/likable • Adherence after intervention: 85%
Griffin et al [19], 2021	• Location: United States • N=15 • Design: mixed methods questionnaires with semistructured interviews qualitative	Female: 53	Mean 59 (SD 11)	BP	• Theoretical discussion around chatbots for hypertension medication management	• Most patients were interested in and open to trying a chatbot for hypertension medication management and reminders • Privacy concerns and usability with mobile phones
Larbi et al [20], 2021	• Location: Switzerland • N=30 • Design: feasibility study	Female: 50	Range 18-69	PA[d]	• MYA social media chatbot	• Perceptions of usefulness and informativeness: 53% • User friendly: 83% • Failed to understand user input: 63.3% • Potential confusion with using the technology 43.3%
Lin et al [27], 2021	• Location: Taiwan • N=96 • Design: factorial experimental study with 4 arms	Female: 53	Mean 21.5; range 18-42	PA (core muscle exercise)	• VR[e] avatar	• Increase in PA (vector movement) of 986.7 (SD 1.03) points in in normal realistic avatar relative to muscular avatar • Higher self-efficacy for core muscle exercise in normal avatars vs muscular avatars in female participants (+0.66, SD 0.1 points) and higher levels than in male participants (+0.9, SD 0.2 points) • *P*<.05
Dol et al [37], 2021	• Location: The Netherlands • N=71 • Design: qualitative study	Female: 100	Mean 44.4 (SD 12.86); range 19-70	Emotional eating	• Conversational coach for emotional eating	• The design of the conversational coach should integrated dialectal behavioral coaching strategies, as preferred by participants with emotional eating behavior

Study and year	Location, N, and design	Sex (%)	Age (years)	Health targets and measures	Technology and procedures	Outcomes
Lin et al [27], 2021	• Location: Taiwan • N=104 • Design: experimental design study	Female: 50	Mean 70.39 (SD 6.51); range 60-88	PA perceived exertion Self-efficacy	• Assigned to either age-matched or young avatars for PA Theory: Proteus effect of avatar embodiment • Watched videos in a digital gym where they exercised • Wore a head-mounted display	• Older male participants assigned to young avatars had higher perceived exertion than counterparts assigned to older ones (+1.56, SD 0.31 points; male participants only) • Female participants assigned to young avatars had higher self-efficacy for future exercise than counterparts (+0.45 points) and male participants • $P<.05$
Maher et al [13], 2021	• Location: Australia • N=31 • Design: proof-of-concept study	Female: 67	Range 45-75	PA, Mediterranean diet, and weight	• AI[f] Paola chatbot teaches users about exercise and uses BCTs[g], including goal setting, self-monitoring, and feedback	• Mean increase in diet score: 5.7 (95% CI 4.2-7.3) • Mean PA increase: 109.8 min (95% CI 1.9-217.9; $P<.01$) • Mean weight loss: 1.3 kg (95% CI −2.5 to −0.7; $P<.05$) • $P<.01$ • No significant changes in blood pressure
Hickman et al [40], 2021	• Location: United States • N=109 • Design: 2-arm RCT	Female: 59	Mean 52 (SD 11)	Hypertension, quality of the physician-patient interaction	• Avatar intervention or video on hypertension management	• Scores for the quality of the patient-provider interaction were better over time (F_3=5.25; $P<.01$) in the within-subjects analysis along with a time by experimental condition interaction (F_3=2.91; $P<.05$) • Between-subject effects per treatment were insignificant • No significant changes in blood pressure
Napolitano et al [49], 2021	• Location: United States • N=136 • Design: feasibility study (12 weeks)	Female: 100	Mean 27.8 (SD 5.4)	Weight, diet, and PA; exercise self-efficacy	• Conversational coach gave lessons on health behaviors	• No significant results were found for differences in weight, PA, or consumption of fast food between the intervention arm and control groups • High attrition 44% • Goal achievement for nutrition <10%
Santini et al [55], 2021	• Location: Austria, Italy, and Netherlands • N=60 (2 waves) • Design: qualitative study with focus groups and phone interviews	Female: 53.3% wave 1; 51.6% wave 2	Mean 61.9	Health behaviors, diet, and PA	• Embodied coach for diet and PA	• Desire for the avatar to motivate older adults to exercise • Supportive tone and language that is not authoritarian or patronizing
Krishnakumar et al [44], 2021	• Location: India • N=102 • Design: pre-post intervention (1 arm) • 16 weeks	Female: 31.4	Mean 50.8	Diabetes (blood sugar), diet, PA, and weight (logged)	• Wellthy CARE mobile app	

Study and year	Location, N, and design	Sex (%)	Age (years)	Health targets and measures	Technology and procedures	Outcomes
						• The use of the Wellthy CARE digital therapeutic for patients with T2D[h] showed a significant reduction in the mean levels of HbA_{1c}[i] −1.16% (95% CI −1.40 to −0.92; *P*<.01); FBG[j] (−11 mg/dL), and PPBG[k] (−22 mg/dL); *P*<.05 • Weight decreased by 1.32 kg (95% CI −0.63 to −2.01 kg) after 16 weeks
Dhinagaran et al [36], 2021	• Location: Singapore • N=60 • Design: one arm web-based feasibility stud	Female: 62	Mean 33.7	Diet, PA, sleep, and stress	• Chatbot for diabetes prevention, diet, exercise delivered over Facebook Messenger (Meta Platforms Inc)	• Engagement: 50% • Retention: 93% • Satisfaction: high at 92% • 50% agreed that the chatbot was acceptable and usable • No significant changes in health behaviors including PA • Minimal improvement in diet: increase in fruit intake (3 portions) by 4% and vegetables once per day by 2%
To et al [61], 2021	• Location: Australia • N=116 • Design: quasi-experimental study (6 weeks)	Female: 81.9	Mean 49.1 (SD 9.3)	PA	• Fitbit plus a chatbot in the Messenger app	• Usability score: 89.4% • Desire to continue using: 35.4% • Helped them: 53% • Mean PA increase: 154.2 min/week (95% CI 2.28-5.63) • OR for meeting PA guidelines: 6.37 (95% CI 3.31 to 12.27) • Mean steps/day increase: 627 (95% CI 219 to 1035)
Mitchell et al [48], 2021	• Location: United States • N=158 • Design: mixed methods survey with qualitative interviews study	Female: 100	Mean 56 (SD 11) intervention; 57 (SD 11) control	Diabetes	• Avatar for diabetes self-management	• Avatars provide support for diabetes self-management via 3 areas (self, social, and physical) that are linked with engagement
Strombotne et al [58], 2021	• Location: United States • N=590 • Design: quasi-experimental study	Female: 11	Mean treatment=58.1; control=57.7	Diabetes and risk factors	• Conversational coach and ketogenic diet	• BP decrease (systolic): 1.4 mm Hg (95% CI −2.72 to 0.14) • Diastolic BP levels decreased: −1.43 (95% CI −2.72 to −0.14) mm Hg • HbA_{1c} decreased: −0.69 (95% CI −1.02 to 0.36) • Diabetes medication fills: −0.38 (95% CI −0.49 to −0.26) • BMI: −1.07 (95% CI −1.95 to −0.19) kg/m^2
Alves Da Cruz [31], 2020		Female 48.1	Mean 63.4 (SD 12.7)	HR[l], BP, and RR[m]		

Study and year	Location, N, and design	Sex (%)	Age (years)	Health targets and measures	Technology and procedures	Outcomes
	• Location: Brazil • N=27 • Design: cluster randomized crossover trial				• Avatars with exergames for PA in patients undergoing cardiovascular rehabilitation	• Increase in HR (z=82.8; *P*<.01) and RR (z=12.9; *P*<.01) during and (5 min) after exergame • Changes in systolic BP but not diastolic with differences within moments z=11.26 (*P*<.01) • With no statistical significance between groups
Kowalska et al [43], 2020	• Location: Poland • N=249 • Design: cross-sectional study	Female: 36.5	Mean 65.3 (SD 13.8)	CVD[n]	• Telehealth voice technology with health professionals and voice conversational agent	• High desirability for telehealth consultations with a cardiologist combined with a conversational agent • Desirability for telemonitoring of vitals: 67.5% • 70.7% wanted a consultation with a cardiologist remotely
Piao et al [51], 2020	• Location: South Korea • N=106 • Design: Exploratory Randomized Controlled Trial • 12 weeks	Female: 56 intervention; 57 control	Range 20-59	Health behaviors (diet and exercise); SRHI[o]	• Lifestyle coaching chatbot • Informed by habit formation • Cues and goals	• Significant improvement in health behavior • The intervention group had higher scores on the SRHI of 7.12 (SD 5.57) with *P*<.05 at 4 weeks; no significant differences between groups at 12 weeks, PA remained higher after 12 weeks (*P*<.05)
Naylor et al [50], 2020	• Location: United States • N=20 • Design: pilot study	N/A[p]	Mean 8.4 (SD 1.3)	VO_2 (mL × kg^{-1} × min^{-1}) using indirect calorimetry questionnaire on liking and motivation	• Children played tennis with their friend and an avatar	• Increased VO2 during game play in both cooperative (3.8 + 1.8 mL × kg^{-1} × min^{-1}) and competitive play (4.4 +1.8 mL × kg^{-1} × min^{-1}) compared with resting condition (*P*<.01) • Children liked exercising more in cooperative games than in competitive games (*P*<.01) • No differences between game styles in motivation for PA (*P*>.05)
Hahn et al [39], 2020	• Location: United States • N=42 (child and parent dyads [n=40 completed baseline and follow-up measures]) • Design: pilot intervention	Female (children): 55.2	Treatment: mean 8.06 (SD 1.10); control: mean 7.5 (SD 1.38)	PA using Fitbit and self-report on motivation for PA	Children wore Fitbit with a personalized dog avatar for socializing and support (digital fitness kiosk); theory informed (social cognitive theory)	• Completion rate: 81.63% • Mean number of PA goals reached: 3.28 • Mean time playing with pets: 20.35 min • Mean number of active min: 66 min (no statistical significance was found)
Navarro et al [24], 2020	• Location: United States • N=305 • Design: 3-arm RCT	Female: N/A	Mean 20.0 (SD 2.2); range 18-37	Cardiac frequency, step counts, accelerometer, and HR monitor	• Randomly assigned to avatars embodying them (same face) or different from them (strangers) • Avatars wore normal clothes or gym clothes	

Study and year	Location, N, and design	Sex (%)	Age (years)	Health targets and measures	Technology and procedures	Outcomes
						• Higher cardiac output (frequency) from 6 to 12 min in users of avatars that had a similar appearance (face) • Higher output in users with avatars that additionally wore sports clothing at 6-7 and 10-minute periods • Support for the Proteus effect hypothesis • No changes in step count
Davis et al [16], 2020	• Location: Australia • N=28 • Design: pilot single-arm study	Female: 68	Mean 56.2 (SD 8); range 45-75	Diet: Mediterranean diet adherence tool. Weekly log for diet and step count; activity tracked using a wrist worn tracker (Garmin) that syncs with Paola. Minutes of moderate to vigorous PA assessed with Active Australia Survey	• Conversational assistant Paola for diet and PA consisted of educational modules, weekly check-ins, and 24/7 availability for PA and diet questions • 12-week pilot	• Assisted with increasing PA (step goal achieved 59% of the time) • Adherence to diet: 91%
Navarro et al [23], 2020	• Location: Spain • N=42 • Design: 3 arms—2 avatars vs control	Female: 100	Mean 31.9 (SD 11.7); range 19-61	PA, IPAQ[q], self-efficacy to regulate exercise, and PA enjoyment scale (PACES[r])	• Avatar: ideal (perfect body) or normal (matching the participant) and web-based intervention without the avatar	• Increased PA in all groups ($F_{1,39}$=15.8; P<.01; web-based intervention effects) • No effects of time by avatar assignment, ie, interaction
Balsa et al [32], 2020	• Location: Portugal • N=20 • Design: usability study with qualitative interviews	Female: experts 88.9%; end users 27.3%	Mean 62.62; mean end users 70.9; mean experts 54.3	Usability of the app for diabetes medication adherence and improving lifestyle behaviors, diet, and PA	• The conversational coach resembles a human • Integrated BCTs: goal setting, self-monitoring, feedback, and social support/counseling	• Usability score: 73.75 (SD 13.31) (indicates high usability of the coach)
Chin et al [35], 2020	• Location: United States • N=15 • Design: feasibility study	Female: 60%	Mean 67 (SD 5.84)	PA	• Health coach for PA • As part of a PA program using a Google Home device (Google LLC)	• Usability was high • 80% of the participants did not experience challenges when interacting with the conversational coach
Fadhil et al [18], 2019	• Location: Italy • N=19 • Design: validation study (4 weeks)	Female: 42	Mean 28.5; range 19-53	Diet and PA questionnaires via chatbot and motivation (HAPA[s])	• CoachAI text based conversational agent • Tailored coaching for habits	• Participants were satisfied with the agent • High trust to share personal information to the coach
Ahn et al [30], 2019	• Location: United States • N=67 • Design: field study (3 days)	Female: 61.19	Mean 11.24 (SD 0.85); range 9-13	PA and basic psychological needs	• Use of a digital dog, with and without a points-based reward system	• Higher levels of PA in the rewards points group briefly versus control ($F_{1,58}$=5.32; P<.05) • No significant effects on PA over time
Stephens et al [26], 2019	• Location: United States • N=23 • Design: feasibility study	Female: 57	Mean 15.2; range 9.7-18.5	Weight management; pre-diabetes		• Usefulness rate: 96% • Progress toward goals frequency: 81%

Study and year	Location, N, and design	Sex (%)	Age (years)	Health targets and measures	Technology and procedures	Outcomes
					• Tess text-based chatbot counsellor for healthy behavior change usability assessed with progress toward goals and engagement	
Srivastana et al [57], 2019	• Location: United States • N=10 • Design: usability study	Female: 70	Range 44-67	Prediabetes	• The web-based module used to support diabetes prevention education and a mobile app that is an electronic diary and a coach	• Success of modules 60% as they meet weight loss of 5% • Compliance with dietary recommendations: 59%-87% • Compliance with PA: 52%-93%
Thompson et al [59], 2019	• Location: United States • N=27 • Design: pilot feasibility study	Female: 73 (teens)	Range 10-15	Diabetes	• Conversational agent with human features • Conversations around diabetes education	• Attrition: low (<10%) • High satisfaction: >80% • Technical issues<10% • Teens and families had a positive experience
Thompson et al [29], 2018	• Location: United States • N=48 • Design: laboratory-based study	Female: 50	Range 12-14	PA	• PA exergame with an avatar coach	• Completion: 87.5%; teens enjoyed the game (mean enjoyment score 68%) • Vigorous PA during 74.9% of the game
Duncan-Carnesciali et al [38], 2018	• Location: United States • N=198 • Design: cross-sectional, survey-based design using quantitative and qualitative paradigms	Female: 97.5	Range 26-76	Diabetes	• Avatar for diabetes management	• Ethnicity including Arab or Middle Eastern, Asian, and White or European descents as well as age were significantly associated with an excellent rating of the video with *P*<.05
Klaassen et al [42], 2018	• Location: N/A • N=21 • Design: usability study	Female: 52	Mean 13.9	Diabetes	• Conversational coach game with feedback • Integrates BCTs including information on consequences	• Usability index of 44.18 (SD 21.18; low)
Sinoo et al [56], 2018	• Location: Netherlands • N=21 • Design: experimental study	Female: 37	Mean 9.2 (SD 1.1)	Diabetes self-management	• Avatar for gameplay and diabetes self-management vs robot	• Preference for the robot (mean friendship score 4.0, SD 0.6) over the avatar (mean friendship score 2.9, SD 0.7) as a companion • Usability moderate: 58.7 (SD 24.5) • Similarity of avatar to robot led to greater friendship (*P*<.01)
Tongpeth et al [62], 2018	• Location: Australia • N=22 (development of the application) • N=10 (feasibility testing) • Design: pilot feasibility	Female: 10	Mean 52.2 (SD 10.4)	Cardiovascular: acute coronary syndrome management	• An interactive, avatar-based education application for improving patients' knowledge of, and response to, acute coronary syndrome symptoms	• Symptom recognition increased: 24% • Satisfaction: 87.3% • Knowledge increase: 15.7%

Study and year	Location, N, and design	Sex (%)	Age (years)	Health targets and measures	Technology and procedures	Outcomes
Friedrichs et al [63], 2014	• Location: Netherlands • N=958 • Design: 3-arm RCT	Female: 60.4	Mean 42.9 (SD 14.5)	PA; Dutch Short questionnaire	• Avatar with a web intervention or a digital web-based text condition versus control	• Significant increases in PA in the intervention arms versus control with B=0.39 in the avatar arm and B=0.44 in the text arms (*P*<.05) • No differences between the text arm or the avatar arm for PA
Stein et al [25], 2017	• Location: United States • N=70 • Design: longitudinal observational study	Female: 74.5	Mean 47 (SD 1.8); range 18-76	Weight and dietary intake	• Lark Weight Loss Health Coach (participants were a part of a diabetes prevention weight loss program) • Advice on dietary intake and PA • BCTs used include motivation, encouragement, reminders, and education	• 31% increase in healthy eating • Mean weight change: −2.4 kg (SE 0.82; 95% CI −4.03 to −0.77)
Thompson [66], 2016	• Location: United States • N=48 (round 1) • N=43 (round 2) • Design: mixed methods survey with qualitative interviews	Female: 50	Range 12-14	Preferences for a PA intervention	• Exergame with a self-representation avatar	• Desired gameplay with the avatar that could be controlled by eliciting the desired action: 62.5% male and 58.3% female • Personalized avatar: 41.7% • Most common avatar features to be customized: • Body: 95.8% • Clothing: 93.8% • Hair color: 87.5%
Behm-Morawitz et al [33], 2016	• Location: United States • N=90, female=100% (the 2 male participants were excluded) • Design: qualitative research and RCT	Female: 100	Range 18-61	Weight and PA self-efficacy	• Avatar (embodied) and video game to promote PA	• Findings support the use of the avatar for weight management t_{18}=2.15 (*P*<.05) with the intervention losing 1.75 lbs versus 0.91 lbs in the control • No effects on dietary self-efficacy • Strong correlation with avatar sense of self-presence and confidence in meeting health goals (r=0.95; *P*<.01) • Themes: avatar benefits include motivation and assisting with self-efficacy for PA • Barrier: games are not for everyone
Kuo et al [45], 2016	• Location: Taiwan • N=76 • Design: 2-arm intervention in laboratory	Female: 63.15	Mean 21.2	Eating behavior observed in laboratory	• Avatar that embodied the participants or was a weight-reduced (thinner) version of them	• Avatars that embodied a thinner version of the participants shaped eating behaviors more compared with identical self-avatars; including selecting less ice cream (Cohen d=0.35; F1,73=7.8; *P*<.01) and opted for sugar free drinks (Cohen d=0.29; F1,73=6.0; *P*<.01)

Study and year	Location, N, and design	Sex (%)	Age (years)	Health targets and measures	Technology and procedures	Outcomes
Ruiz et al [54], 2016	• Location: United States • N=41 • Design: laboratory study	Female: 0	Mean 64 (SD 7)	Cardiovascular behavioral risk factors (diet and exercise)	• Avatar vs a voice (nonanimated) for behavior change linked with CVD	• Avatar increased intentions (+1.56 points) to improve lifestyle behaviors relative to controls (Cohen d=0.77 $P<.01$; $t_{36}=2.48$) • Differences in confidence to change risk of heart disease was nonsignificant
LeRouge et al [14], 2015	• Location: United States • N=41 • Design: user-centered design, 3 phases with focus group and interviews	N/A	Teenagers: 12-17	Perceptions of the avatar for diet and exercise	• Interactive avatar coach	• Desire for a fun human-like interaction • Desire for a lifestyle coach and personal embodiment avatar and an authoritarian one • Desire for customization of the avatar • Advice on activity on the go and meals when eating at home • Goal setting • Technical issues could be a barrier including the internet
Thomas et al [28], 2015	• Location: United States • N=37 • Design: feasibility and usability study with pre-post test	Female: 100	Mean 55.0 (SD 8.2)	Weight-related eating behaviors	• Conversational coach for weight (focuses on dietary intake and managing eating behaviors)	• The coach assisted with perceptions of increased self-control over eating (confidence to control eating: +1 point (SD 0.2; $P<.01$) and skills for controlling eating +0.7 points (SD 0.1; $P<.01$)
Ruiz et al [53], 2014	• Location: United States • N=150 • Design: RCT	Male: 100	Mean 62 (SD 7.9)	Diabetes (knowledge)	• Computer program with an avatar to increase diabetes knowledge and medication (adherence)	• There were no significant differences between the intervention group and control group in terms of knowledge, with $P=.95$ • Satisfaction levels were higher in the digital intervention group (F4=3.11; $P<.01$)
Li et al [46], 2014	• Location: Singapore • N=140 • Design: factorial design experiment	Female: 41	Range 9-12	PA attitudes, motivation, and game performance	• Assigned to varying avatars (normal and overweight)	• Healthy weight avatars linked with greater scores in motivation for Nintendo exercise ($F_{1,134}=5.49$; $P<.05$ [boys]) attitude, and performance ($F_{1,134}=2.27$; $P<.05$ [girls])
Napolitano et al [22], 2013	• Location: United States • N=128 (phase I) N=8 (phase 2) • Design: mixed methods (pilot usability testing) study with interviews	Female: 100	Mean 34.1 (SD 13.0); range 18-60 (phase 1)	Weight, PA [14], and weight self-efficacy; satisfaction; preferences survey and interviews	• Avatar for diet and exercise • Informed by social cognitive theory • Behavioral modeling • Targeted self-efficacy • 4 weeks	• The avatar helpful: 87.5% • Mean weight loss after 4 weeks: 1.6 (SD 1.7) kg • All women found that it helped with their diet and exercise • Most were interested in the avatar
Bickmore et al [34], 2013	• Location: United States • N=122 • Design: 4-arm RCT (2 months)	Female: 61	Mean 33.0 (SD 12.6); range 21-69	Diet (NIH[t]/NCI[u] fruit and vegetable scan) and PA (IPAQ)	• Animated counselor • for diet and PA (separate and combined)	

Study and year	Location, N, and design	Sex (%)	Age (years)	Health targets and measures	Technology and procedures	Outcomes
						• No significant differences between groups in PA after adjustment • Fruit and vegetable servings significantly increased in the diet arm (F3,103=4.52; *P*<.01) • No significant differences in weight or PA between groups • Likability: Karen was perceived as nice by 35% of the participants • 50% of the participants found Karen helpful
Johnoson-Glenberg et al [41], 2013	• Location: United States • N=19 • Design: pilot feasibility study (pre-post study)	N/A	Grades 4-12 (ages 9-18)	Diet (nutrition and food choice test and knowledge)	• Diet and exercise game (exergame) with an alien interactive coach	• Differences in dietary knowledge of nutrition pre and post intervention (t=4.13; *P*<.01) and knowledge of the My Plate content in the study (t=3.29; *P*<.01)
Ruiz et al [52], 2012	• Location: United States • N=30 • Design: comparative pilot with three arms (with randomization) intervention	N/A	N/A	PA	• 3D avatar-based VR intervention	• Participants completing a 3D VR intervention mediated by avatars resembling the participants showed significant improvement in PA (*P*<.05) • No significant effects of the intervention on obese or overweight participants
Mestre et al [47], 2011	• Location: France • N=6 • Design: laboratory experimental study	N/A	Range 19-25	PA enjoyment	• Digital coach paced participants in a VR bicycling setting	• The VR coach and VR cycling were associated with higher levels of PA enjoyment (F2,10=13.24; *P*<.001) in the feedback group

Weight

A few studies evaluated the effects of conversational assistants for weight loss [13,22-24,44]. The study by Maher et al [13] in Australia found that the conversational assistant (chatbot) Paola assisted with a weight loss of 1.3 kg at 12 weeks follow-up (95% CI –0.1 to –2.5). In addition, there was a mean waist circumference reduction of 2.5 cm at follow-up compared with baseline (95% CI –3.5 to –0.7). The chatbot used a range of BCTs, including goal setting, self-monitoring, education, social support, and feedback to users on PA and the Mediterranean diet [13]. A study in the United States found that the Lark Weight Loss Coach, an artificial intelligence–powered bot, assisted participants with a weight loss of 2.38% (95% CI –3.75 to 1.0) with a mean use of 15 weeks [25]. The conversational agent was informed by cognitive behavioral therapy and used a range of BCTs, including education, encouragement, and reminders surrounding dietary and PA targets [25]. The determinants of weight loss included the duration of using the artificial intelligence program and engaging with it, logging meals, and the number of counseling sessions completed [25]. A large study in the United States examining the use of an avatar coach that targeted self-efficacy and modelled vicarious experiences for diet and PA (4 weeks) found that women lost an average of 1.6 (SD 1.7) kg at follow-up [22]. A study in India found that an avatar coaching app with calls from health professionals assisted with a weight loss of 1.39 kg (95% CI –0.63 to –2.01; P<.01) at 16 weeks [44]. A randomized controlled trial (RCT) with a qualitative component found that avatars increase motivation and PA self-efficacy linked with weight loss [33]. However, some studies did not report any significant weight loss [34,49].

Diet

A few studies evaluated the effects of conversational coaches (chatbots and avatars) on dietary intake and found that overall, the coaches assisted with ameliorating dietary habits and goals [13,16,25,28,34,45,49]. A study in the United States found that healthy dietary intake improved in 30% of participants who were using a conversational weight loss coach [25]. Another study found that eating behaviors improved in users of a conversational eating coach, which included increases in the mean scores for the perceptions of skills to eat healthily and self-control over their eating habits (0.7 increase in points) as well as confidence to control food consumption in social situations (1.0 increase in points; P<.01) [28]. The Paola chatbot study found a mean increase in the Mediterranean diet score [68] of 5.8 points at 12 weeks follow-up [13]. Similarly, a study of Karen, an animated counselor, found significant increases ($F_{3,103}$=4.5; P<.01) in fruit and vegetable intake in the diet intervention arm relative to the control group [34]. A further study found that eating behaviors were shaped by the appearance of the avatar, with healthier eating behavioral patterns in participants who had thinner avatars including reduced portions of ice cream and opting for healthier sugar-free drink alternatives [45].

Physical Activity

A few conversational assistant PA coaches, including chatbots and avatars, were evaluated, and overall, they assisted with increasing PA [13,16,21,23,24,27,55,63]. Most of them involved exergames with the avatar. However, one of the studies did not find any improvements in PA among the 2 avatars, attributing improvements only to the web-based part of the intervention [23], and another study did not find a difference between the web-based intervention and the chatbot (only when considering a standard control) [63]. A preliminary usability study in Australia found that step count goals increased 59% of the time in users of the chatbot that targeted PA and that participants had a preference for personalization and greater knowledge-based content [16]. Another pilot study of Paola, the chatbot in Australia, found that it assisted with increasing mean step count by 109 minutes per week at 12 weeks follow-up (95% CI 1.9-217.7) [13]. A study involving an exergame that used a PA avatar coach in teens found that 75% of the time, participants engaged in 15.88 (SD 5.8) minutes of vigorous PA throughout the game [29]. Participants also wanted the avatar to have a supportive and nonpatronizing or nondisparaging tone in interactions regarding PA and found that it could motivate older adults when adequately personalized [55]. Similarly, a study in children also found that they desired the option to personalize the avatar, including controlling and customizing its physical appearance during game play when exercising [66].

Proteus Effect

The Proteus effect is a phenomenon wherein individuals embody and emulate the behaviors of their virtual characters such as avatars [69,70]. A few studies demonstrated support for the Proteus effect when it came to PA behaviors, although the type of avatar varied. A study in Taiwan found that younger looking avatars were associated with higher levels of PA than older looking avatars but only in women. Male participants had higher levels of PA than female participants who used an older looking avatar, highlighting differences between sexes [27]. A further study found a higher cardiac output resulting from increased intensity of PA in adult users of an avatar that resembled them and wore gym clothes when compared with avatars that appeared unfamiliar like strangers in regular clothing, which reduced heart rate [24]. Similarly, a study in Taiwan found increases in physical activity assessed in movements (986.7 points higher) in users of a “normal avatar”, more closely resembling them than the most muscular avatar [21]. They also found that self-efficacy was higher (0.66 points) for core muscle exercises in female participants assigned to normal avatars relative to their muscular counterparts and male participants assigned to the same standard avatar (0.9 points higher), with P<.05 [21]. Similarly, dietary behavior was also shaped by thinner embodied avatars in another study [45].

Diabetes

Most diabetes studies were feasibility studies. The results of diabetes conversational coaches were mixed. A few studies did not have positive findings concerning the applications with avatars for diabetes [42,53]. However, one study reported a usability score of 73, which is relatively high. Notably, the study integrated a range of BCTs, including goal setting, feedback, self-monitoring, social support, and counseling [32]. Low usability scores were reported in a few studies, including one that reported an overall score of 44.58 (SD 21.18) [42].

Similarly, an RCT of a diabetes coaching avatar did not find that knowledge increased relative to controls, but intervention participants in the computer-based programmed dynamic avatar had higher satisfaction levels (F_4=3.11; P=.01) [53]. Another study in the United States in participants with prediabetes found that 60% of patients had successfully completed the modules and met weight targets during 6 months of use (60% success rate) [57]. Engagement was also moderately high (50%) in a study in Singapore involving a chatbot, although usability was high along with retention (93%) [36]. In a study in teenagers, attrition was also low, and 80% of the participants were satisfied with the conversational diabetes coach [59]. A study that evaluated a coaching application for diabetes found an improvement of –11 mg/dL in fasting blood glucose levels [44]. However, the intervention also involved phone calls from health professionals [44]. Similarly, an avatar application with a ketogenic diet program assisted with a reduction in hemoglobin A_{1c} levels of 0.69% (SE 0.168%) [58]. Qualitative research found that avatars created an environment of social presence that facilitated social support and coherence for patients with diabetes [48]. In another study of avatars combined with robots, children preferred robots over avatars, but their friendship increased if the two had a greater similarity, which impacted usability [56].

CVD and Associated Risk Factors

A few studies evaluated the use of conversational coaches for CVD. One of them was a pilot study of the Tensiobot chatbot [17], a coaching application that teaches users how to properly check their blood pressure using recommended practice guidelines and provides users with graphic feedback and reminders. The study found that the chatbot group did not differ from the control group in terms of adhering to blood pressure measurement recommendations. However, there were significantly higher levels of knowledge (+6.53 points) with regard to checking blood pressure in the chatbot group than in the control group (P<.05) [17]. Blood pressure (diastolic) was significantly reduced, that is, by 1.43 mm Hg (SE 0.65; 95% CI –2.72 to –0.14; P<.01), in users of an avatar application that also involved a ketogenic diet [58]. In addition, a mixed methods study with a qualitative component found that users in general were interested in trying a hypertension chatbot for medication management as well as for health communication and self-care [19]. In addition to these studies, a general diet and PA chatbot study evaluated changes in blood pressure, but these changes were nonsignificant [13]. A study in Poland found high desirability for a CVD voice technology coach, in addition to accessing phone-based telemedical services by health professionals [43]. A further study in Brazil evaluated avatars for cardiovascular rehabilitation and found that an avatar with an exergame influenced heart rate, systolic blood pressure, and respiratory rate during the intervention and up to 5 minutes after its completion [31]. Furthermore, a study found that the avatar intervention increased the intent to improve lifestyle behavioral risk factors in patients relative to controls (P=.01), although confidence did not change [54]. Finally, a study evaluated a cardiovascular educational avatar application and found that it increased symptom recognition by 24% and knowledge of CVD by 15%, with a high satisfaction rate of 87% among patients [62].

User Perceptions

Several studies found that users were interested in using conversational coaches for lifestyle behaviors [14,19,22]. Overall, participants enjoyed using the chatbots and avatars or found them helpful for diet, exercise, and hypertension management [17,22,25,26,29]. User-friendliness was reported by 83% of the participants in a study that evaluated a PA social media chatbot [20]. Similarly, 87.5% of women in a weight loss avatar intervention found it helpful [22]. With the exception of studies on diabetes conversational coaches, adherence or completion of tasks was high across studies on lifestyle (diet and PA) conversational coaches, ranging from 85% to 90% [13,16,17,29]. The qualitative study themes were related to the desirability for a conversational coach for hypertension and weight-related behaviors, especially for one that simulates human interaction closely, provides advice and goals for meals when cooking, and provides educational support [14] including for hypertension management [14,19].

Technological Challenges

A few tech challenges were brought up across the studies. Although users found that the conversational coach answered basic questions correctly, failure to understand and respond to more complex or spontaneous questions was reported in the studies. The percentage of failure for spontaneous or complex questions was 79% in one study [16], and participants in another study gave a high ranking for the chatbot's failure to recognize their input [20]. Paola chatbot correctly answered spontaneous questions on diet in 4 out of 20 attempts, with a success of 20%, while the percentage of correctly answered simple and predetermined questions and responses was 96% and 97% [16].

Discussion

Principal Findings

This review aimed to better understand the effectiveness of virtual coaches for managing metabolic health and weight-related risk factors. It appears that virtual coaches hold potential for assisting patients with improving their dietary intake and PA behaviors, leading to subsequent weight loss. However, more studies that are larger and sufficiently powered RCTs are needed to establish a stronger evidence base. RCTs are the gold standard of evidence but are often costly and time-consuming [71,72]. Most of the studies were limited, as they were pilot studies. Ideally, it would be of interest to research long-term weight changes and cardiometabolic risk factor modifications over longer periods.

It appears that PA interventions may benefit from using avatars that embody the participant. The Proteus effect is based on the hypothesis that users adjust their behavior by modeling the virtual character with which they interact [73]. Thus, it seems that incorporating an avatar may enhance mHealth chatbot interventions, as it adds the element of user interaction and promotes the modeling of behavior through embodiment [73]. However, 1 (2%) study did not find that the avatars enhanced the effects of the web-based intervention [23].

We also found that consumers seemed to be interested in and enthusiastic about trying virtual coaches for managing their weight-related behaviors and blood pressure. Adherence to the intervention was also high throughout the studies, which indicates that this technology is acceptable and usable for patients. However, there is a need to undertake qualitative research on developing a MetS coach to further understand consumer perspectives. The main barrier to consider when developing future virtual agents is that the virtual agents did not always answer correctly to spontaneous responses. As consumers want personalized and tailored mHealth for weight-related behaviors [74], future applications should ensure that the virtual agents are sufficiently advanced to be able to interact with users in a natural and personalized manner.

It appears that diabetes virtual coaches should be improved to maximize engagement and adherence, as not all studies found that they were helpful. Although outside the scope of this review, we note that some studies used BCTs, which could suggest that future applications may benefit from integrating BCTs [13,20,22,25,32,42,51]. In addition, we identified some studies on blood pressure and CVD management, which demonstrated preliminary improvement in patients with hypertension as well as knowledge of CVD. However, we did not identify any virtual coaches for managing MetS. Therefore, there is a need to develop virtual coaches specifically tailored to this syndrome and its associated risk factors. Such virtual coaches could be integrated into a combined synchronized application that involves diabetes and CVD education and monitoring.

MetS is linked with high blood pressure, which is one of the main hallmarks of the disease. The theoretical mechanisms underpinning the development of hypertension in patients with MetS have included a combination of endothelial dysfunction, systemic inflammation, adiposity, and oxidative stress [75]. Dysfunction in the renin-angiotensin system has also been theorized to be a determinant [75]. Obesity itself has also been identified as a risk factor for high blood pressure in MetS [76]. Blood pressure is modifiable to some extent through lifestyle changes previously described, including dietary sodium restriction, PA, stress reduction [77], and medication [78]. Future virtual coaches may target hypertension as part of a MetS intervention, and this review found that patients are willing to try chatbots for managing their blood pressure.

MetS is also associated with high glucose levels of at least 100 mg/dL when patients are fasting [78], which indicates that they are in the prediabetes stage, as diabetes begins at fasting glucose levels of 126 mg/dL [79]. In a recent longitudinal study, patients who reduced their fasting blood glucose levels decreased their overall risk of diabetes by 54% when compared with their counterparts who did not improve their blood sugar levels (95% CIs exclude 1) [80]. A recent study found that individuals who consumed high amounts of sugar were 32% more likely to have MetS than their counterparts [81]. Thus, a future MetS virtual coach could target blood glucose monitoring and offer personalized advice on optimum sugar intake.

In addition to targeting dietary intake, PA is integral to managing this syndrome. A meta-analysis found that the risk of cardiovascular events was reduced by 30% in physically active individuals compared with those who were inactive [6]. A longitudinal study in middle-aged women found that increasing step counts significantly reduced, by 30%, the risk of MetS in this population and that they had clinically improved levels of the protective cholesterol high-density lipoprotein, whereas their serum triglycerides had significantly decreased [82]. A review found that walking on a daily basis reduced the risk of type 2 diabetes by nearly half [5]. Furthermore, recent research suggests that sedentary behavior, including sitting time, is an independent and significant risk factor for MetS syndrome [83]. Thus, PA chatbots and avatars, which were found to increase PA time, steps, and self-efficacy in this review, could be integrated into a comprehensive future MetS interventions.

Given that chatbots and avatars hold potential for increasing PA and reducing sedentary behavior, as well as improving dietary intake, studies are needed to evaluate their effectiveness for managing the symptoms and risk factors associated with MetS specifically.

In addition, stress is often an underlying determinant of maladaptive weight-related behaviors, including binge eating, emotional eating, and an unhealthy dietary intake as well as weight gain [84-88]. Future avatar and chatbot interventions for cardiometabolic factors could also consider integrating psychological supportive interventions such as mindfulness-based stress reduction, which assists with weight and stress [89-93], as an element.

Conclusions

In summary, we found that virtual coaches hold promise for regulating diet, PA, weight, and possibly hypertension. However, studies on virtual coaches are few in number; therefore, more research, including RCTs, is needed to confirm the effectiveness of virtual coaches. Overall, most participants in the reviewed studies were interested in using virtual coaches, including chatbots and avatars, for regulating their weight-related behaviors, and study adherence was good. Future interventions could be ameliorated to reduce technical challenges associated with these conversational agents and ensure that they respond correctly to complex and spontaneous questions. Furthermore, future research could involve developing a comprehensive conversational agent for MetS, such as a health coach that simultaneously targets diet (sodium, sugar, and fat intake), exercise, weight (including abdominal obesity), blood pressure, and diabetes, and evaluating it. This would include a health coach that simultaneously targets diet (sodium, sugar, and fat intake), exercise, weight (including abdominal obesity), blood pressure, and diabetes.

Abstract

Background: A total of 75% of people with mental health disorders have an onset of illness between the ages of 12 and 24 years. Many in this age group report substantial obstacles to receiving quality youth-centered mental health care services. With the rapid development of technology and the recent COVID-19 pandemic, mobile health (mHealth) has presented new opportunities for youth mental health research, practice, and policy.

Objective: The research objectives were to (1) synthesize the current evidence supporting mHealth interventions for youths who experience mental health challenges and (2) identify current gaps in the mHealth field related to youth's access to mental health services and health outcomes.

Methods: Guided by the methods of Arksey and O'Malley, we conducted a scoping review of peer-reviewed studies that used mHealth tools to improve youth mental health (January 2016-February 2022). We searched MEDLINE, PubMed, PsycINFO, and Embase databases using the following key terms: (1) mHealth; (2) youth and young adults; and (3) mental health. The current gaps were analyzed using content analysis.

Results: The search produced 4270 records, of which 151 met inclusion criteria. Included articles highlight the comprehensive aspects of youth mHealth intervention resource allocation for targeted conditions, mHealth delivery methods, measurement tools, evaluation of mHealth intervention, and youth engagement. The median age for participants in all studies is 17 (IQR 14-21) years. Only 3 (2%) studies involved participants who reported their sex or gender outside of the binary option. Many studies (68/151, 45%) were published after the onset of the COVID-19 outbreak. Study types and designs varied, with 60 (40%) identified as randomized controlled trials. Notably, 143 out of 151 (95%) studies came from developed countries, suggesting an evidence shortfall on the feasibility of implementing mHealth services in lower-resourced settings. Additionally, the results highlight concerns related to inadequate resources devoted to self-harm and substance uses, weak study design, expert engagement, and the variety of outcome measures selected to capture impact or changes over time. There is also a lack of standardized regulations and guidelines for researching mHealth technologies for youths and the use of non–youth-centered approaches to implementing results.

Conclusions: This study may be used to inform future work as well as the development of youth-centered mHealth tools that can be implemented and sustained over time for diverse types of youths. Implementation science research that prioritizes youths' engagement is needed to advance the current understanding of mHealth implementation. Moreover, core outcome sets may support a youth-centered measurement strategy to capture outcomes in a systematic way that prioritizes equity, diversity, inclusion, and robust measurement science. Finally, this study suggests that future practice and policy research are needed to ensure the risk of mHealth is minimized and that this innovative health care service is meeting the emerging needs of youths over time.

Introduction

Mental Illness

Mental health disorders are the leading cause of disability worldwide and are considered a global public health challenge [1,2]. Globally, 1 in 4 people are affected by mental health disorders each year; up to 50% of people experience mental health challenges in their lifetime [3]. The global burden of disease (GBD) is compounded by the "mental health treatment gap," referring to those people in need of mental health treatment but who have not received it. People with mental health challenges experience different levels of barriers to accessing specialized care when needed [4]. Such barriers are multifaceted and may include poor mental health literacy, social stigma, trust and confidentiality issues with health professionals, and systemic difficulties such as financial hardship [5].

A total of 75% of people with mental health disorders have an onset of illness between the ages of 12 and 24 years [6]. This is a peak period of development for youths (defined here as ages 12-24 years); it is often the life stage to pursue education or begin a career, to build social relationships, and to explore new interests [7]. Yet, youths experience the worst levels of access to mental health care from poorly designed, grossly underresourced, and typically unfriendly health care services [8]. Current research indicates the need for a full range of interventions for youths [9], including health promotion [10,11], early intervention [12], and long-term supports such as integrated self-management [13], community outreach [14], and hospital care [15]. With existing barriers compounded by the COVID-19 pandemic, in-person mental health care is more challenging than ever to navigate and access for youths [16]. In response, mobile health (mHealth), a term used to describe the collective set of digital mental health interventions, has been proposed as a solution to meet the needs of youths across the world.

mHealth

In 2022, mobile phone users reached 6.5 billion worldwide, accounting for approximately 80% of the global population. In developed countries such as Canada and the United States, 97% of people own a mobile phone and 85% use a smart phone [17,18]. Such mass usage is motivating the rapid growth of medical software and apps for diverse populations, including youths [19]. These mobile device–based apps cover multiple domains of technologies used to assess, capture, or support areas of health, including physical activity and fitness, diet, emotional and mental health, and health services. mHealth technologies have been used to track vital body signs, such as blood pressure, heart rate, exercise, sleep activity, nutritional values in meals, mental health and wellness, anxiety, and mood [20]. A total of 54,603 health care and medical apps were available on the Google Play Store in August 2022, up by almost 4% compared to the previous quarter [21].

While the pace of new mHealth technologies is growing rapidly, the regulations and standards for their use have not yet followed. In a recent study of nearly 300 apps for mental health, less than one-third received input from a mental health expert [22]. There is also little consensus regarding standards for mHealth tools, not to mention the effectiveness of mHealth interventions on diverse populations, including youths experiencing mental health challenges.

In summary, the field of mHealth often presents a dichotomy of opportunity and risk. On the one hand, the lack of standards and regulation for mHealth apps presents global concerns for the safety of youths, notably personal security and the uptake of misinformation [23-25]. On the other hand, mHealth may have an increasingly important role in health promotion, education, and interventions to bridge the gap for those who cannot access in-person services [26]. A greater understanding is needed to learn about how youths use mHealth technologies in their daily lives, with specific emphasis on understanding how they navigate safety risks and use these technologies to improve health and wellness outcomes.

The purpose of this scoping review is to synthesize the current evidence supporting mHealth interventions for youths accessing support for mental health challenges. This will facilitate understanding of what is missing in the field of mHealth and support recommendations for research, practice, and policy. The specific objectives are to (1) synthesize the current evidence supporting mHealth interventions for youths who experience mental health challenges and (2) identify current gaps in the mHealth field, with an overarching goal of improving youths' mental health service access, outcomes, and experiences.

Methods

Overview

We conducted a scoping review to examine the extent, range, and nature of mHealth and to identify gaps in the existing literature on this emerging topic. This scoping study followed the 5 stages of Arksey and O'Malley's scoping study framework [27] to (1) identify the research question; (2) identify relevant studies; (3) select studies; (4) chart the data; and (5) collate, summarize, and report the results.

Step 1: Identify the Research Question

What is known in the existing literature about the feasibility and effectiveness of mHealth intervention for youths, aged 12-24 years, facing mental health challenges?

Step 2: Identify Relevant Studies

Under the guidance of a medical librarian, a comprehensive search of the following electronic databases was conducted: MEDLINE (Ovid), Embase (Ovid), PsycINFO (EBSCO), and PubMed (see Multimedia Appendix 1 for example search). We consulted with mHealth stakeholders and youths to decide on the range of dates to search. Our expert team highlighted rapid changes in the field, notably the influence of TikTok after its launch in 2016. To ensure relevance and reference value, we decided to only review articles published during the past 6 years (January 1, 2016, to February 7, 2022) to manage the scope, breadth, and rapidly changing information available. Key terms derived from the research question were selected and expanded to create a comprehensive list of search terms, including "telemedicine," "telerehabilitation," "mobile applications," "mHealth (mobile health)," "eHealth (electronic/digital health)," and "telehealth," as well as a combination of the following mental health condition-related terms: "mental disorders," "anxiety," "depression," "eating disorder," "schizophrenia," "bipolar," "obsessive compulsive disorder," and "posttraumatic stress disorder," along with a list of key terms to define the age group of this review: "adolescent," "teen," "youth," and "young adult." Combinations of these terms, along with Medical Subject Heading (MeSH) terms, were tested iteratively in each of the databases selected to inform the new combination of different terms leading to relevant literature. All searches included at least one identifier for mHealth (eg, telehealth and eHealth), 1 identifier for mental health condition (eg, depression and anxiety), and 1 identifier for age range (eg, youth and young adult). The lead author reviewed the title and abstract of each study to determine eligibility based on predetermined inclusion and exclusion criteria (described below) after duplicates were removed. After the completion of the initial review, the articles were thoroughly reviewed by the lead author based on the research topic.

Step 3: Select Studies

The following inclusion criteria were considered: (1) published in English; (2) published between January 1, 2016, and February 7, 2022; (3) included human subjects, whose ages fall between 12 and 24 years; (4) included at least one mHealth intervention tool targeting 1 or more mental health conditions for youths; and (5) referenced literature from peer-reviewed journals and book chapters. Exclusion criteria were as follows: (1) editorial comments, commentaries, book reviews, and opinion articles; (2) incomplete studies (eg, description of intervention, protocols, ideas from symposia, and conference summaries); (3) articles without full text available. Relevant systematic reviews were included in the study to serve as background literature but were excluded from the data extraction and analysis process to focus on intervention studies.

Step 4: Chart the Data

Through careful review of the literature, the researchers (XD and SB) identified the key components and issues discussed in all relevant studies. This information was recorded in a data extraction sheet, along with information on each study (author, publication year, population demographics, location, study design, level of evidence, characteristics of the intervention, targeted health condition, and outcomes).

Step 5: Collate, Summarize, and Report Results

The information was synthesized and used to map out the scope and breadth of included literature on the topic of mHealth intervention for youths' mental health challenges.

Results

Overview

As noted in Figure 1, the search identified 4270 citations for initial screening. As noted in Figure 1, a total of 1411 duplicates were removed, resulting in 2859 citations for title and abstract reviews. A further 2413 articles were excluded because their title or abstract did not address mHealth interventions for youths' mental health, leaving 446 citations. After full text review, a total of 151 articles met the inclusion criteria for this study. Table 1 summarizes the countries of origin of the included studies.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram describing the search process and the number of articles meeting inclusion criteria for this study (N=151).

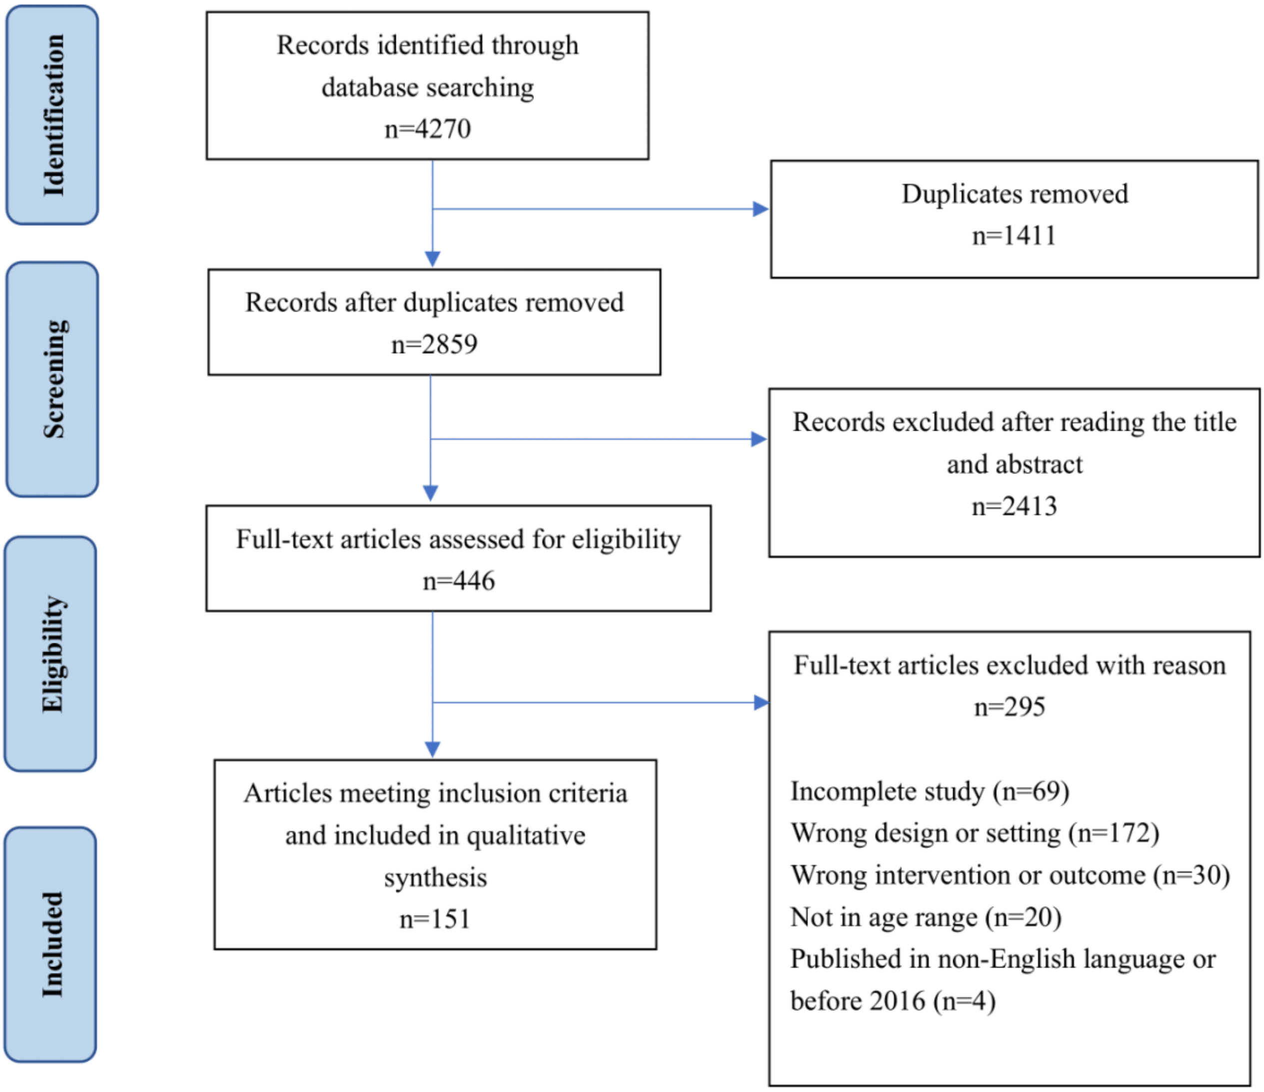

Table 1. Countries of origin of papers included in the scoping review.

Country	Articles (N=151), n %
United States	61 (40)
Australia	28 (19)
Canada	10 (7)
Sweden	10 (7)
United Kingdom	8 (6)
New Zealand	7 (5)
China	4 (3)
Nigeria	3 (2)
Finland	3 (2)
The Netherlands	3 (2)
Japan	2 (1)
Germany	2 (1)
Korea	1 (1)
India	1 (1)
Spain	1 (1)
Iceland	1 (1)
Denmark	1 (1)
Belgium	1 (1)
Italy	1 (1)
Norway	1 (1)
Israel	1 (1)
France	1 (1)

Level of Evidence

As shown in Table 2, four levels of evidence were adopted to show the power of evidence among included youths' mHealth interventions for mental health research [28,29].

Table 2. Design of studies included in the scoping review.

Level of evidence	Study design	Articles, n
I	Randomized controlled trials	60
II	Nonrandomized experimental studies (quasi-experimental, pre-post, and cohort)	34
III	Cross-sectional, longitudinal surveys, and mixed method study with nonexperimental quantitative part	27
IV	Descriptive, case studies, and qualitative studies	30

As shown in Table 2, study types and designs varied. The highest level of evidence included experimental studies identified as randomized controlled trials (60/151, 40%). The second highest level of evidence included studies that were nonrandomized trials, such as quasi-experimental design (usually with 2 groups) or 1-group pre-post design (34/151, 23%). The third level of evidence included studies that only conducted feedback surveys to their participants once after the intervention, longitudinal observational studies, and mixed methods design with these mentioned quantitative parts (27/151, 18%). Last, some of the included studies had lower levels of evidence, including descriptive studies, case studies, and qualitative studies describing the outcome of mHealth interventions (30/151, 20%).

Age

All included studies have a general targeted age group of "young people," "adolescent," or "youth." The median age for participants in all studies was 17 (IQR 14-21) years, with 2 outliers (with participants aged 61 years [30] and 62 years [31]) coming from the studies targeting "university students."

Sex and Gender

A total of 20 (13%) papers did not provide any statistics on sex or gender. Only 3 (2%) studies involved participants who reported their sex or gender beyond binary options. One study focused on eating disorders and had 1 intersex participant [32]. The other 2 studies prioritized mental health in 2-spirited, lesbian, gay, bisexual, transgender, queer/questioning, intersex, and agender (2SLGBTQIA+) groups: 1 included 108 sexual minority young adults [33] and the other included 565 participants with a combination of transgender, genderqueer, gender expansive, intersex, agender, 2-spirited, and third gender identities [34]. The remaining 148 (98%) studies had a total of 6478 (34.2%) men and 12,480 (65.8%) women as participants.

Organizational Affiliation

The included studies took place in various settings. They were coded into the following 4 different categories, inspired by Marshall et al [22]: (1) research developed under clinic or hospital-related setting (97/151, 64%); (2) research developed in a university (28/151, 19%); (3) research developed in other nonuniversity schools and institutions (9/151, 6%); and (4) insufficient information to tell (17/151, 11%).

Modes of Delivery of mHealth Interventions

As noted in Table 3, a variety of modes are used to deliver services. These included web pages (54/151, 36%), smartphone apps (51/151, 34%), phone calls and SMS text messages (10/151, 9%), and innovative virtual reality (VR) tools (3/151, 2%).

Table 3. Delivery modes among studies included in the review.

Delivery modes	Studies, n (%)	Randomized controlled trials, n/N (%)	Positive[a] results, n/N (%)
Web pages	54 (36)	33/54 (61)	48/54 (89)
Smartphone apps	51 (34)	13/51 (26)	40/51 (78)
Video conferencing	20 (13)	3/20 (15)	15/20 (75)
SMS text messages	10 (7)	5/10 (50)	7/10 (70)
Chatbox	4 (3)	2/4 (50)	4/4 (100)
Phone calls	3 (2)	1/3 (33)	2/3 (67)
Virtual reality	3 (2)	0/3 (0)	3/3 (100)
Mixed modes	6 (4)	3/6 (50)	4/6 (67)
Total	151 (100)	60/151 (N/A[b])	123/151 (N/A)

[a]Positive results: researchers stated overall positive effect of intervention or received positive feedback from users to show promising practical usage of the intervention. Negative results: researchers see no changes in mental health symptoms before and after the intervention or receive negative feedback from users.

[b]N/A: Not applicable.

Targeted Conditions

The number and percentage of health conditions targeted using mHealth interventions are summarized in Table 4.

Table 4. Health conditions and measurement tools among included studies.

Health condition	Studies, n (%)	Measurement tools (scales) used, n
General health	26 (15)	66
Anxiety	35 (20)	52
Depression	32 (19)	68
Suicide, self-harm, or violence	11 (6)	15
Substance use	10 (6)	22
Eating disorder	10 (6)	10
Stress or mood related	9 (5)	20
Sleep disorder	6 (4)	9
ASD[a]	5 (3)	4
STD or STI[b]	5 (3)	10
Psychosis	4 (2)	5
ADHD[c]	4 (2)	8
PTSD[d]	4 (2)	3
OCD[e]	3 (2)	1
FASD[f]	2 (1)	N/A[g]
Others	6 (4)	N/A
Total	172[h] (N/A)	N/A

[a]ASD: autism spectrum disorder.
[b]STD or STI: sexually transmitted disease or sexually transmitted infection.
[c]ADHD: attention-deficit/hyperactivity disorder.
[d]PTSD: posttraumatic stress disorder.
[e]OCD: obsessive-compulsive disorder.
[f]FASD: fetal alcohol spectrum disorder.
[g]N/A: not applicable.
[h]The total number of conditions exceeds the total number of studies because there are articles targeting more than 1 condition.

Measurement Approaches Used in the Studies

A wide range of tools were employed to measure outcomes in mHealth intervention research (Table 4). A detailed table listing the outcome measures and the references to the studies using them can be found in Multimedia Appendix 2.

COVID-19

Of the 151 studies included within the given time period, 68 (45%) were published after the COVID-19 outbreak, with most (44/151, 65%) published in 2020. The numbers of studies published each year are as follows: 11 studies in 2016; 21 studies in 2017; 19 studies in 2018; 32 studies in 2019; 44 studies in 2020; 23 studies in 2021; and 1 study in February 2022.

The following 8 studies directly addressed health conditions or service delivery modalities influenced by the pandemic: (1) treatment of eating disorders in adolescents [35]; (2) group-based psychiatric care using telehealth [36]; (3) a web-based art therapy group for learning disabled young adults using WhatsApp [37]; (4) telehealth versus in‐person intensive outpatient program (IOP) for eating disorders during versus before COVID‐19 [32]; (5) a well-being app to support young people living in New Zealand [38]; (6) peer-to-peer live-streaming intervention to promote physical activity and reduce anxiety during homeschooling [39]; (7) a mindfulness-based mHealth intervention among psychologically distressed university students in quarantine [40]; and (8) smartphone application for adolescents with anorexia nervosa [41].

Discussion

Overview

This scoping review provides a comprehensive synthesis of mobile mental health intervention research for youths. The study identified that the number of interventions is proliferating over time, with limited emphasis on study quality, youths' engagement, youth-centered outcome assessment, implementation standards, or consideration for equity, diversity, and inclusion in research. Youths' engagement was rarely mentioned as a part of any research study method, and most studies focused primarily on youths who identified within the gender binary. Few studies discussed the implementation and scale of interventions in diverse settings (Table 3) and even fewer studies showed an impact of mHealth interventions over time for diverse types of youths. With significant growth and investment in the area, this review may inform direction for future research and advance practices within mHealth intervention approaches for youths who experience mental health challenges or illnesses.

Among the studies that met the inclusion criteria, depression (32/151, 19%), anxiety (35/151, 20%), and general mental health concerns (26/151, 15%) accounted for over half of the studies, and the remaining addressed 17 other mental health concern categories. According to a GBD systematic analysis of mental health conditions relevant to this study, the top concerns for all youths are self-harm, depressive disorders, interpersonal violence, anxiety disorders, HIV/AIDS, conduct disorder, and drug use disorder [42]. The point estimate of alcohol and drug use disorders combined is very close to the prevalence of depression, serving as 2 of the most concerning mental health disorders worldwide [43]. The high prevalence of depressive and anxiety disorders corresponds with the allocation of research priorities in studies included in this review, suggesting the current focus for youths' mental health care services. Nevertheless, while self-harm and interpersonal violence ranked high on the GBD mental health conditions list, there were comparatively limited research studies for these categories. Substance use disorders are also underrepresented in existing mHealth studies for youths. More attention and resources should be given to the development of mHealth intervention tools targeting self-harm, interpersonal violence, and substances use among diverse youths.

From a global health perspective, 95% (143/151) of studies came from developed countries. This result is not surprising, as mHealth resources are almost exclusively concentrated in high-income countries, although the prevalence of depression and anxiety in high-income countries is not significantly higher than in the rest of the world [44]. Therefore, more future mHealth research needs to be conducted in low- and middle-income countries, especially when one of the advantages of remote health care access is cost-effectiveness. Previous studies have demonstrated adapting interventions developed in high-income countries for use in low- and middle-income countries, such as India, Sierra Leone, Romania, Malaysia, and South Africa [45,46]; these lessons could be adapted for mHealth interventions for youths' mental health.

Delivery Modes

With respect to delivering mHealth interventions, most studies employed web pages (54/151, 36%) and smartphone apps (51/151, 34%), and these modes also had the largest number of randomized controlled trials conducted. The results show web-based mHealth tools have the strongest evidence for improving mental health conditions in youths, but the effectiveness of other intervention modes cannot be ruled out. Web-based intervention tools require youths to have internet access, and the use of computers may not be convenient in home and school settings, so the development of mHealth interventions has gradually evolved to include smartphones, smart devices, wearables, and newer technologies, including VR and augmented reality [47]. However, with the rising number of options available for mHealth intervention delivery, youths' intention to use has become a more complicated question. Currently, many studies contributing to the adoption research of mHealth for youths are based on the technology acceptance model, an information systems theory that models user's acceptance of technology mainly based on perceived usefulness and perceived ease of use [48-50]. Yet, it is essential to realize that participants in research studies are provided with a predetermined type of intervention by the researchers, often with limited youths' engagement. That is, unlike in a real-world environment where diverse users who need support must seek it themselves, participants in the research settings did not actively choose which kind of mHealth intervention to use. Therefore, future studies need to consider the youth-intended delivery modes during mHealth intervention development from a user perspective, especially when considering innovative technologies, such as VR, artificial intelligence chat, and gaming. Future research should also consider implementation research, not only to understand the efficacy and effectiveness of the interventions but also their capacity to be sustained over time in diverse settings.

Measurement

The measurement tools used in the studies (Multimedia Appendix 2) can be broadly defined as either (1) measuring the outcome of a patient's condition or (2) measuring the subject usability of a product or service. As displayed in Table 4, depression, anxiety, and general mental health categories each adopted more than 50 measurement tools. The review also identified numerous measurement scales used for each health condition. For example, 7 sleep-relevant measurements were used in 6 sleep-related studies [51-56], but the researchers did not provide a rationale as to why they chose the scale used among all available sleep-related measurements, nor was evidence provided about the fitness of the tools for youths in the varying contexts. Similar complications were presented in other included studies with varying health conditions. Future research should focus on developing a guideline for researchers to follow when selecting the most appropriate measurement scales in both research and clinical settings and on validating measurement scales designed for use with youths with consideration for equity, diversity, inclusion, and psychometric rigor.

Evaluation of mHealth Products

The percentage of positive results is considerably high among all included studies (123/151, 81%). Study aims included "feasibility," "effect," "acceptability," "efficacy," "fidelity," "effectiveness," and "cost-effectiveness," with research designs including experiments, surveys, and interviews. Questions remain as to whether positive results translate to real-world applications or which types of outcomes possess high level of evidence in the knowledge translation process for health care services. In a Canadian study where participants were asked to rate mHealth apps objectively, results were highly variable, and 28% of reviewers were not even sure about the overall quality of the health product [57]. The same characteristics in different studies also vary within a wide range. For instance, the intervention durations ranged from as short as 7 days [58] or 2 sessions [59] to as long as 24 weeks [60] or 24 months [61]. The number of participants among all studies ranges from 2 [62] to 2532 [63]. Intervention types also varied significantly. Such variations raise concerns about the lack of a standardized evaluation strategy. To address the complex uncertainty in evaluating mHealth tools, a multifaceted evaluation framework needs to be adopted to assess the different perspectives, elements, and features of an intervention that leads to a final mHealth product. Using non–youth-centered frameworks to evaluate mHealth products can consequently produce ambiguous or incorrect information on their effectiveness, leading to misuse, misdiagnosis, wasted time, and, worst of all, negative health impacts and experiences [64].

Remote Care Transition

Several included studies discuss how to support youths during the COVID-19 pandemic [65,66]. With many people transitioning to work-from-home or hybrid arrangements during and after the pandemic, there arose an imminent need for a mental health technology revolution, and web-based health service delivery has emerged as a preferred tool [67].

Childs and colleagues [36] illustrated the feasibility of a rapid transition to telemedicine services during the pandemic. Yale New Haven Psychiatric Hospital decided to discontinue in-person IOP services within 3 business days of the World Health Organization's pandemic declaration [36]. The first mobile service was available within a week, and subsequent treatment plans and adolescent ambulatory services were developed to reach IOP level. The study demonstrated that it took a comprehensive program 2 months to transition from 100% in-person service prepandemic (March) to 100% telehealth service after the start of the pandemic (May 2020), showing the feasibility of the deployment of mHealth tools in clinical settings and the smooth transition from physical to virtual health care access. One notable limitation of this study is that the clinicians focused on the transition process rather than the effectiveness of the intervention tool.

Another youths' mHealth intervention study showed the transition to virtual services was not always desired by clients. The authors presented a case where a participant refused to cooperate, and the telemedicine service increased the tension between the participant and family members [35]. When developing mHealth interventions targeting youths' mental health, it is important to consider how to achieve optimal patient engagement when physical contact with a service provider is not an option. Last, it is still unknown whether these transitioned services will continue to be provided virtually on an ongoing basis. Future research is needed to investigate the long-term influence of such transitions and determine the feasibility of normalizing mHealth services.

Youths' and Stakeholder Engagement

Engagement with mHealth interventions is thought to be important for intervention effectiveness by increasing acceptability, satisfaction, intervention adherence, and levels of attention and enjoyment [68]. This can be extended to engaging youths in mHealth research to provide comprehensive, ongoing, tailored, and interactive support to improve health [69].

Current youth mHealth research often engages youths by asking for feedback in a survey or interview to test usability, feasibility, and acceptability [31,70,71], or by including young users as participants in experiments to evaluate the effectiveness and efficiency of an intervention. However, few studies mentioned how they engaged youths in the development phase and followed design thinking with the priority population. Youths and other stakeholders (eg, family and caregivers, service providers, and graphic designers) can contribute more than just feedback on the provided services; they can be offered opportunities to participate in the product and service design stages to make sure the end product is tailored to their needs and preferences. A previous conceptual model indicated that, during the optimization phase of an intervention [72], participants need to understand how the provided materials can inspire them and facilitate their thoughts to improve self-efficacy, which increases capability for self-monitoring and self-regulation and can lead to improved health outcomes and behavioral changes [72,73]. Researchers proposed a supportive accountability model that emphasized the importance of human support in mHealth interventions to increase adherence to trustworthy, benevolent, and professional information [74]. To summarize, it is crucial to apply such theoretical models to interventions targeting youths' mental health as well. mHealth researchers and developers ought to involve youths in every stage of design, development, and implementation. Our team is currently studying youths' engagement in the mHealth development phase to understand youths' information preferences and make sure mHealth interventions are designed to convey the benefits of human support, similar to in-person services.

Policy

More than two-thirds of the studies took place in a clinical setting, yet none of the studies reviewed provided systematic frameworks or models to help translate, scale, and sustain available mHealth tools to clinical practice. If health care stakeholders and policy makers aim to scale up and normalize mHealth services in the near future, it is essential to understand the feasibility and impact of implementing new mHealth tools in current models of care (eg, health care and schools). Guidelines and standards may be critical to ensuring that mHealth interventions are trustworthy and can be value added to health services that are delivered to youths and their families.

Strengths and Limitations

This review has a broad scope of attempting to draw a picture of existing mHealth intervention tools specifically designed for younger populations and how their effectiveness is being assessed. This scoping review addressed a broad term list and a large number of parameters. Inclusion and exclusion criteria were strictly set from the beginning and determined by experts in the field and a medical librarian, and diversity is presented for all included studies. There are unlimited possibilities for future work, particularly with the uncertainty of the COVID-19 pandemic and the ongoing response of the health care system to remote health access. Regarding weaknesses, the lack of critical appraisal is a widely recognized limitation for scoping reviews [75]. The scope of this review may be broad, but the depth and the quality of all included papers were not systematically critiqued. We also acknowledge that our search strategy may have missed key terms (eg, internet-based interventions) and intervention descriptions (eg, asynchronous vs synchronous) that may have limited our ability to completely summarize all relevant articles. In addition, the COVID-19 pandemic has not come to an end, and there is still ongoing research about long-term COVID-19 symptoms. Thus, the results relevant to remote care transition and COVID-19 should be interpreted with some caution.

Conclusions

As the need for mental health services continues to accelerate [76], mHealth technologies provide a solution to support diverse youths who may not be able to access in-person services. The impact of mHealth interventions on youths' mental health has been increasingly recognized by researchers, service providers, and policy makers. Results of our scoping review demonstrate a range of studies that capture the exponential growth of mHealth interventions for youths, with significant potential to be value-added for youths who are seeking support for mental health challenges. However, the review also highlighted notable gaps in research that include youths' voice throughout the research process, notably diverse youths in both developing and developed countries. Future research is needed that adopts an equity, diversity, and inclusion lens, prioritizes understanding how current mHealth technologies can be adopted into existing models of care, and develops guidelines, standards, and evaluation frameworks to support future mHealth development and implementation. As the field continues to expand rapidly, more global resources are needed to monitor technological advancements to provide quality mHealth services to every youth where and when they need them.

Abstract

Background: The advancements and abundance of mobile phones and portable health devices have created an opportunity to use mobile health (mHealth) for population health systems. There is increasing evidence for the feasibility and acceptance of mHealth with Indigenous populations. Providing a synthesis of qualitative findings of mHealth with Indigenous populations will gain insights into the strengths and challenges to mHealth use in Indigenous populations.

Objective: This review aimed to identify and synthesize qualitative data pertaining to the experiences and perceptions of mHealth from the perspectives of end users (patients and service providers) living in the colonial settler democracies of Canada, Australia, New Zealand, the United States, the Pacific Islands, and the Sápmi region of northern Europe.

Methods: In May 2021, systematic searches of peer-reviewed, scientific papers were conducted across the 5 databases of PubMed, CINAHL, Embase, PsycINFO, and Web of Science. Qualitative or mixed method studies were included where a mHealth intervention was the primary focus for responding to health challenges with Indigenous populations. Two authors independently screened papers for eligibility and assessed the risk of bias using a modified version of the Critical Appraisal Skills Programme. A meta-aggregative approach was used to analyze the findings of included studies.

Results: Seventeen papers met the eligibility criteria, 8 studies with patients, 7 studies with service providers, and 2 studies that included both patients and service providers. Studies were conducted in Australia (n=10), Canada (n=2), New Zealand (n=2), Papua New Guinea (n=1), the United States (n=1), and Samoa (n=1). Our interpretation of these qualitative findings shows commonalities between Indigenous patients' and service providers' perceptions of mHealth. We summarize our findings in six themes: (1) mHealth literacy, (2) mHealth as a facilitator for connection and support, (3) mHealth content needed to be culturally relevant, (4) mHealth security and confidentiality, (5) mHealth supporting rather than replacing service providers, and (6) workplace and organizational capacity.

Conclusions: This research suggests that mHealth can meet the needs of both patients and service providers when the mHealth intervention is culturally relevant, accounts for digital and health literacy, incorporates interactive components, is supported by workplaces, fits into health provider workflows, and meets security and confidentiality standards. Future mHealth research with Indigenous populations should partner with key representatives (eg, patients, service providers, and executive leaders) in the mHealth design appropriate to the purpose, people, setting, and delivery.

Introduction

The technological advancements and abundance of mobile phones and portable health devices have created a plethora of mobile health (mHealth) tools. mHealth is defined as "the use of mobile devices—such as mobile phones, patient monitoring devices, personal digital assistants and wireless devices—for medical and public health practice" [1]. These include mobile phone apps, text messages, portable monitoring devices and electronic patient information.

Systematic reviews globally have suggested mHealth is a broadly feasible and effective resource for a range of health conditions including; behavior change [2,3], noncommunicable disease management [4-9], perinatal care [10,11] medication adherence [12], and mental health well-being [13,14]. Likewise, health care workers suggest mHealth improves patient health outcomes and increases peer communication and care coordination [15,16].

There is a growing number of qualitative studies exploring the views and perceptions of mHealth from 2005 onward, resulting in a number of qualitative systematic reviews [16-21]. Findings from these reviews provide a collective insight into user perceptions and experience of mHealth to influence future research and implementation. These systematic reviews predominantly focus on non-Indigenous populations and fail to explore the user experiences of Indigenous people and their service providers. We need to ensure a space is kept privileging Indigenous worldviews as it pertains to mHealth. mHealth interventions are being explored with Indigenous populations with increasing interest [22-24]. Reviews examining the applicability of mHealth for Indigenous populations exist, and these indicate it is an acceptable health resource [23,24]. Yet, these reviews include qualitative data as only a peripheral focus and are inconsistent with the intervention type [23], and outcomes [24].

Providing a synthesis of qualitative findings of mHealth with Indigenous populations will gain insights to the strengths and challenges to mHealth use in Indigenous populations. This review aimed to identify and synthesize qualitative data pertaining to the experiences and perceptions of mHealth with Indigenous populations and the service providers that work with Indigenous populations.

Methods

Overview

A systematic search was conducted of peer-reviewed literature for this qualitative synthesis. A protocol of this qualitative synthesis was registered with the International Prospective Register of Systematic Reviews (PROSPERO; registration number CRD42021251861). We extracted qualitative data pertaining to the experiences and perceptions of both patients (Indigenous peoples) and service providers (either Indigenous or non-Indigenous health policy makers, health care professionals, and researchers) who work with Indigenous peoples from Canada, Australia, New Zealand, the United States, the Pacific Islands, and the Sápmi region of northern Europe. We define Indigenous Peoples as "distinct social and cultural groups that share collective ancestral ties to the lands and natural resources where they live, occupy or from which they have been displaced" [25].

Search Strategy and Selection Criteria

A comprehensive list of search terms and strings were developed with the assistance of a librarian with expertise in systematic reviews. Systematic searches of peer-reviewed, scientific papers in English were conducted across 5 databases in May 2021: PubMed, CINAHL, Embase, PsycINFO, and Web of Science. Qualitative or mixed method studies were included where a mHealth intervention was the primary focus for responding to health challenges with Indigenous populations. As such, experimental and quasi-experimental studies were considered, as long as they met the following inclusion criteria:

- Participants: Indigenous people of all ages from Canada, Australia, New Zealand, United States, the Pacific Islands, the Sápmi region of northern Europe; OR are service providers (either Indigenous or non-Indigenous) who work with Indigenous persons from Canada, Australia, New Zealand, the United States, the Pacific Islands, the Sápmi region of northern Europe; OR where participants are multicultural, outcomes for Indigenous persons are reported specifically.
- Interventions: primary focus was a mHealth intervention delivered using a wireless device (eg, mobile or tablet app, website designed for mobile, messaging [SMS, voice, multimedia messaging system, etc]). The mHealth intervention aims to address a health challenge (eg, diagnosis of disease, substance use, health behaviors, quality of life, health knowledge, self-efficacy, caregiver support, etc).
- Outcomes: studies reported on one or more outcomes including user; experiences, perceptions, barriers, and enablers via qualitative research methods (eg, interviews and focus groups).

A sample of the search strings using text words and subject heading keywords for PubMed can be found in Multimedia Appendix 1. The use of proximity operators, truncation, and phrase searching was used to widen the search to capture all iterations of both the mHealth and Indigenous themes. The 2 search strings were then combined to narrow the results—enabling discovery of all possible scientific papers, which capture mHealth interventions with Indigenous populations from Canada, Australia, New Zealand, the United States, the Pacific Islands, and the Sápmi region of northern Europe. The qualitative papers were then identified via screening by 2 researchers (AG and SL).

Data Extraction and Quality Appraisal

Initial database searches and duplicate removal were conducted by 1 author (AG). Screening, review, and extraction were assisted by the web-based systematic review program Covidence (Veritas Health Innovation) [26]. Two authors (AG and SL) independently screened titles and abstracts against the inclusion criteria, and papers clearly not meeting the inclusion criteria were excluded.

Subsequently, 2 authors (AG and SL) screened the full-text papers independently and then discussed for comparison. Any differing views were resolved through discussion. Manual searches of reference lists were conducted on full-text papers included in the review. A final list of full-text papers and their citations which met inclusion criteria were downloaded and saved using Covidence software.

The quality of the included studies was appraised using a modified version of the Critical Appraisal Skills Programme (CASP) qualitative checklist [27]. An additional question from the Joanna Briggs Institute (JBI) was added that related to locating the researchers cultural or theoretical standpoint [28], improving the cultural rigor of this critical appraisal tool.

Data Analysis and Synthesis

The data included in the analysis were all text included in the "Results" or "Findings" sections of the papers (excluding purely quantitative findings) and was extracted from the papers into NVivo 12 Plus software (QSR International) [29]. Characteristics of each study to be extracted for descriptive purposes included: Indigenous identification, study location (country), year, sample size, participant demographic characteristics (age, gender), data collection, and analysis methods.

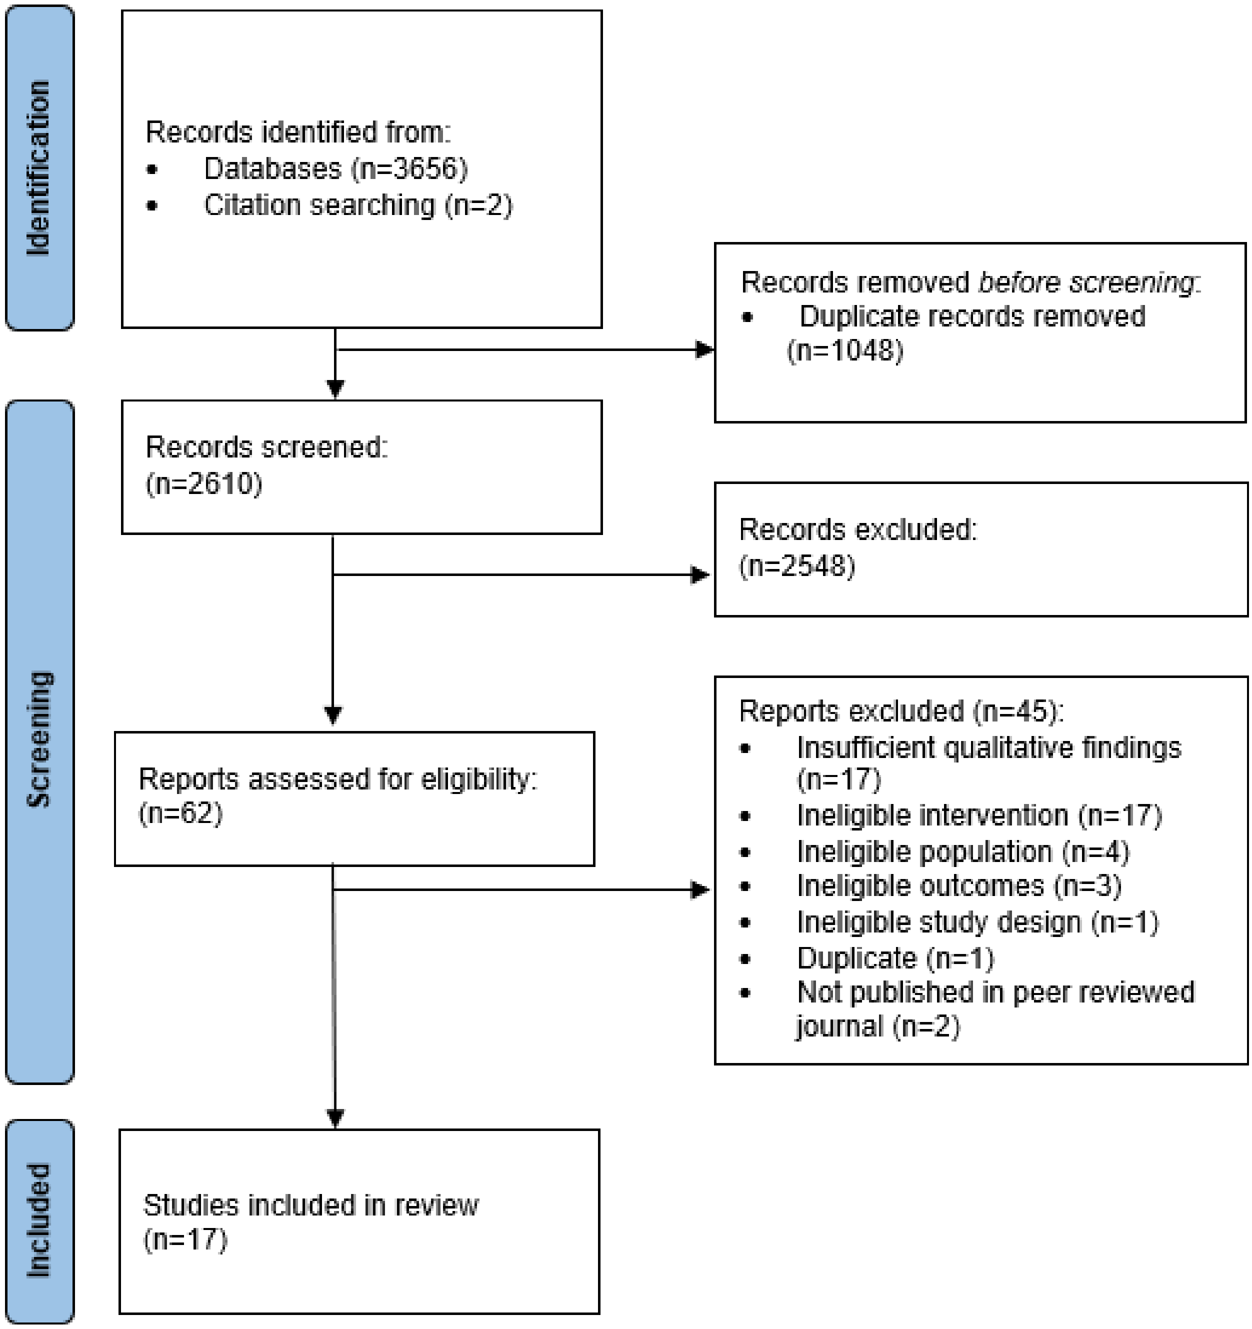
A meta-aggregative approach was used to analyze the findings [30]. This analysis approach privileges the findings, presented as "themes" or "constructs" in qualitative research, as identified by the researchers (not the reviewer). This method helps ensure the expanse and breadth of cultural learnings identified by researchers conducting the original studies are not lost by the reviewers.

Results

Overview

From database searches, 2608 unique papers were identified; 2 additional papers were located by manual searches. In total, 2610 titles and abstracts were reviewed against the inclusion criteria, of which 2548 were excluded, leaving 62 papers for full-text review. Following the full-text review, 45 papers were excluded, leaving 17 studies included in this qualitative systematic review (Figure 1).

Figure 1. Preferred reporting items for systematic reviews and meta-analyses flow diagram of study selection.



Description of Included Studies

All 17 studies included in this review were published between 2013 and 2021. Eight were studies specifically with Indigenous patients [31-38]. Seven studies were with service providers (either Indigenous or non-Indigenous) who work with Indigenous peoples [39-45]. Two studies involved both patients and service providers in data collection [46,47], so findings were considered for both.

Characteristics of the 17 studies are shown in Table 1. Ten papers involved Aboriginal and Torres Strait Islander peoples of Australia [31,36-38,40,42,44-47], 2 with the First Nations, Inuit, or Métis peoples of Canada [34,39], 2 with the Māori peoples of Aotearoa, New Zealand [33,35], 1 paper with the Indigenous peoples of Papua New Guinea [43], 1 paper with the Native Hawaiian and Pacific Islander peoples of Hawaii, the United States [41], and 1 paper with the Indigenous peoples of Samoa [48]. We were unable to identify any papers with Indigenous people of the Sápmi region of northern Europe that met the review criteria.

Table 1. Characteristics of included studies.

Studies	Indigenous peoples (country)	Focus area of intervention	Type of mHealth[a] delivery	Participants (roles)	Method	CAT[b] [27,28]
Indigenous patients

Both Indigenous patients and service providers						

Studies	Indigenous peoples (country)	Focus area of intervention	Type of mHealth[a] delivery	Participants (roles)	Method	CAT[b] [27,28]
Brown et al [46]	Aboriginal and Torres Strait Islander (Australia)	Mental health well-being	mHealth broad concept	12 (8 Indigenous health workers, 4 Indigenous patients).	Focus group[h,k]	11
Houston et al [47]	Aboriginal and Torres Strait Islander (Australia)	Perinatal health care or parenting	App[e] and website	31 (21 administration staff, pediatricians, child health nurses, general practitioners, and Indigenous health workers; 10 Indigenous patients)	Interviews and focus group[d]	8

[a]mHealth: mobile health.

[b]CAT: critical appraisal tool, maximum score is 11.

[c]mHealth interactive: integrated app used for access to health information or personal monitoring of health determinates that allows for information exchange (eg, peers and service providers).

[d]Thematic analysis.

[e]mHealth personal: autonomous app used for access to health information or personal monitoring of health determinates with no interactive capabilities.

[f]Inductive analysis.

[g]Rapid qualitative analysis.

[h]Hybrid approach to qualitative analysis.

[i]Kaupapa Maori approach.

[j]Narrative approach to qualitative analysis.

[k]Yarning approach.

Thematic Synthesis

Overview

Our interpretation of these qualitative findings shows commonalities between Indigenous patients and service providers perceptions of mHealth. We have collectively termed both as “end users” hereafter unless explicitly stated otherwise. Common themes across end users were: the importance of mHealth or digital literacy, mHealth as a facilitator for connection and support, mHealth content that needed to be culturally relevant, and data security and confidentiality. Two themes emerged that were unique to service providers including the importance of mHealth supporting rather than replacing service providers, and the role of workplace champions and organizational capacity for influencing uptake and sustainability of mHealth.

mHealth Literacy

Access to the required hardware (mobile or smartphones and touch screen tablets) and systems (network coverage and IT) was identified as an important influence to mHealth uptake by end users. Service providers noted barriers to accessing the mHealth hardware and systems with reasons including regionality and workplace restrictions [40,42,43,45,46]. Service providers held a perception that mobile phones were not prevalent or accessible to patients due to cost [46] and remote location [42]. However, Indigenous patients saw themselves as competent and confident users of technology and mobile phones for everyday life [31,33-38,46,47]. Yet, technology difficulties and lack of device access were still raised in several studies [31,34-36,46,47]. Some studies noted concerns end users had relating to the digital literacy required for mHealth [40,42,44].

> *Low levels of IT literacy pose a challenge to electronic mental health adoption. Unfamiliarity with different ways of using technologies impedes the utilization of the approach by both service providers and community members. Poor IT literacy within communities was attributed to limited access to technology…* [42]

Limited confidence in using new technology such as mHealth initiatives was identified as a barrier to uptake for service providers [40,44]. The investment of time and effort into appropriate mHealth training and ongoing support was suggested as a mitigation strategy for technical difficulties for end users [36,40].

Age and generational implications were raised as influential factors to the uptake of mHealth. Whether implicitly or explicitly, end users perceived mHealth would be more applicable and accepted by younger people [31,33,40-42,44,46]. Service providers perceived that older people have limited or no access to mobile phones and thus would have lower digital literacy [40,41,46]. Interestingly, these age-related barriers were not reflected by Indigenous patients in this Australian study.

> *Most older interviewees did not appear to have any major issues with knowledge on how to access phone features.* [36]

End users noted the importance of mHealth resources easy to understand and use for a confident user experience. A notable motivation for service providers to use a mHealth resource was for it to be uncomplicated and easy to use [39,40,45-47]. Likewise, Indigenous patients advised that if mHealth platforms were complex, slow, or used too much data, uptake and sustained use was less likely [31,33,35,38,46]. The importance of clear and concise language and the avoidance of jargon in mHealth messaging was noted to encourage comprehension for end users [31,37,38,41,43,47,48]. Service providers stated the importance of mHealth content being appropriate to the learning styles, health knowledge, and communication styles of their patients [39-41,43,44,46,47]. Indigenous patients were enthusiastic about the potential benefits mHealth provided in accessing relevant information for their health journey [33-35,37,38,46-48].

> *Participants spoke of parents being technologically savvy, and parents referred to accessing apps, YouTube clips, social media and the internet from their mobile phones for infant feeding information and support prior to the Growing healthy program.* [47]

The incorporation of visual and audio capabilities was suggested by end users to create a better understanding of the content [31,35-41,44,46-48]. mHealth may provide an appropriate tool to bridge health knowledge gaps [42] and enable education and empowerment for health care.

> *Several interviewees described how the iECG device provided unique opportunities to engage patients in education around AF and their heart, and to empower patients to find out more about their heart health.* [45]

mHealth as a Facilitator for Connection and Support

End users found mHealth an appropriate resource to facilitate engagement, connection, and support within health care systems. Indigenous patients appreciate that mHealth facilitated connection to support people, along with health care providers [31,33-38,47,48]. Likewise, service providers viewed mHealth as important for connection to patients with the added facility to connect with professional colleagues [40-42,46].

mHealth was found to provide a sense of reassurance and encouragement across a range of health journeys for Indigenous patients, including perinatal health [35,47], patients living with mental health challenges [34,37], and people on a smoking cessation journey [36,48]. Indigenous patients suggested mHealth could enable a web-based community to connect with others on similar health journeys [31,33-38,46]. Moreover, Indigenous patients appreciated the capability of mHealth to share health knowledge with family and support people in their lives [33,35,47,48].

> *Participants valued sharing advice and experience-based information with their families, partners or wider virtual communities, such as Facebook groups.* [35]

Service providers found that mHealth encouraged trust with patients while creating a collaborative environment with other health staff [40-42,46]. mHealth was found to provide professional peer support [40,46] while streamlining clinical communication and encouraging service provider collaborations [42].

> *Communication across services working with the same client may help to ensure nonoverlapping of interventions and resources.* [42]

Australian service providers noted mHealth broke down the barriers of patient engagement, "equalising the power imbalance often present in their relationships with clients" [40]. Service providers attributed this to the app acting as an impartial entity, encouraging person-centered care [40]. First Nations, Inuit, and Métis youth in Canada explained that having a mobile phone would enable them to connect with health professionals as well as on behalf of peers in emergency situations [34]. Youth in Australia found that mHealth provided connection to service providers while adding anonymity and privacy to the navigation of their mental health journey.

> *Some may have felt known in a small community or simply hesitant to engage a service because they felt uncomfortable. The app allowed them a choice in health care that was previously unavailable.* [37]

mHealth Content Needed to Be Culturally Relevant

End users stated the importance of mHealth including culturally relevant imagery and language to enable engagement, trust, and relatable connection. The inclusion of culturally relevant language and imagery was important for Indigenous patients to encourage engagement and build trust in mHealth content [31-33,37,38,46,47]. Likewise, service providers suggested the need for culturally applicable imagery and language in mHealth content in several studies [39-41,43,44,46,47]. End users suggested the translation of mHealth content to traditional language would enable comprehension of content as well as increase uptake [31,33,40,43,46].

> *…participants were keen to engage with apps that included Māori language, tikanga and knowledge.* [33]

> *Culturally relevant graphics, voices, animation, and optional short video clips may assist in engagement with the content, improve understanding, and overcome literacy issues.* [31]

> *Recommended features of a technology resource included a look and feel that was user-friendly, aesthetically pleasing (e.g., more visuals, Indigenous artwork and potentially Indigenous language for more remote communities), easy to read, quick to navigate, and interactive (e.g., notifications, touch screen, user online status shown).* [46]

Yet, the acknowledgment of diversity in cultural relevance was an important implication noted by Indigenous patients [31,33,38], namely, the tailoring of dialect [31,38] and that content be appropriate to the local cultural peoples [33], to ensure mHealth is not dismissive of cultural diversity.

Findings suggest mHealth can assist in developing cultural competence through gaining a better understanding of cultural diversity, histories, and traditional languages. In Australia, Indigenous patients advised the importance of including cultural determinants such as colonization, intergenerational trauma, and identity within mHealth content [31,38]. In Aotearoa, New Zealand, Māori patients chose to use traditional terminology in the thematic findings of mHealth exploration, acknowledging the importance of the cultural determinants of health [33,35]. mHealth was found to be an important resource to support culturally competent health care delivery for locum service providers in Canada.

> *Respondents expressed gratitude that the app now exists as an important tool for use in training and orienting new hires to Nunavut's cultural and language context.* [39]

mHealth Security and Confidentiality

Security and privacy consistently emerged with Indigenous patients across several studies with differing views and implications [31,34,35,37,46]. Povey et al [31] found Indigenous patients were largely dismissive of privacy issues with regard to mHealth, noting that personal information held on phones such as photos, or emails being seen would worry them more. There were, however, concerns raised about the privacy and confidentiality of information being shared during group discussions embedded in mHealth [46]. In addition, Māori women felt a sense of intrusion when using their mobile phone to seek health advice [35]. This intrusion was due to third-party systems, not necessarily a mHealth resource.

> *…emphasised privacy concerns whereby they encountered personalised advertising on Google and Facebook that was based on previous searches done on the device.* [35]

Importantly, mHealth offered the opportunity of anonymous support for patients wishing not to engage with health services face to face [31,34,37]. Access to their own phone provided a sense of privacy and a safety net for Indigenous patients in Canada [34]. Likewise, Indigenous patients in Australia appreciated the facility of remote support seeking with the avoidance of unwanted in-person contact.

> *The ability to interact with the app privately, without anyone else needing to be present, meant that youth who may have been reluctant or afraid to speak to family members or health care professionals in a face-to-face setting could still access support.* [37]

mHealth Supporting Rather Than Replacing Service Providers

Service providers stated the importance of mHealth needing to support established workloads and practices rather than being an onerous addition to established workloads. Service providers raised uncertainties about the sustainability of mHealth, and how their roles and responsibilities may change with the implementation of mHealth [40-42,44,46]. The perceived "lack of fit" with established work practices was a professional barrier identified [40,42,44]. Service providers suggested that mHealth should be considered as a complementary resource in addition to "in person" and physical resources [40,41,46]. Service providers in Australia found mHealth may be more useful for staff lacking experience and confidence in health practice.

> *Gatekeepers less experienced in suicide prevention may find a resource more useful than more experienced or confident gatekeepers.* [46]

Service providers saw the benefit of mHealth as an educational tool to develop skills and knowledge. Service providers in Australia liked the health promotion opportunity a smartphone-enabled electrocardiogram (ECG) provided [45]. Service providers in Papua New Guinea valued the guidance capabilities mHealth provided them for clinical malaria treatment procedures [43]. Service providers in Australia identified mHealth as an appropriate resource to gain professional skills and knowledge in interviewing and counseling [40,44]. A smartphone-enabled ECG (ie, iECG) was found to have an indirect educational effect on service providers in Australia.

> *Some staff also spoke of how using the device for screening led them to want to learn more about AF and cardiovascular disease themselves in their professional role.* [45]

Workplace and Organizational Capacity

Workplace leadership, capacity, and strategic direction emerged as influencing factors to the uptake and sustainability of mHealth for service providers working with Indigenous populations [39,40,42,44,45].

Workplaces that have leaders and champions to drive and support mHealth were a central factor in enabling mHealth uptake. The presence of enthusiastic managers and eager IT champions had a positive effect on the workforce's interest in mHealth resources with service providers in Australia [42,44]. Workplace leaders that did not perceive the need for or effectiveness of mHealth were often a barrier to the uptake by service providers [42,44]. The advocacy of mHealth from leadership was an influencing factor to acceptance:

> *Having leaders within the organization showing interest and providing direct support was perceived to facilitate uptake. It created incentives and provided opportunities for service providers to reflect and evaluate the utility of the electronic mental health approach.* [42]

Workplace staff capacity and retention contributed to the opportunities service providers had to commit to mHealth implementation [40,42,44]. High turnover of staff contributed to a lack of sustained mHealth knowledge and skill within the workplace [40,42,44]. The significance of investment into continued staff training and development was seen as important for mHealth success [40,42,45]. Limited workload capacity due to underresourcing impeded mHealth delivery [40,42,44] and restricted service providers' capacity to engage in mHealth.

> *…in many services, demanding workloads left the workers with little or no opportunity to incorporate new skills into their existing work practices…* [44]

A workplace culture that supports and drives the use of health innovations was shown to positively impact service providers' perception of mHealth. The absence of health innovation priorities in workplace strategies caused a sense of ambivalence and ineptness toward the need for mHealth among service providers [39,42,44]. Workplaces that invested in systems, valued innovation, and had supportive leadership, positively influenced service providers' perception and engagement with mHealth tools [40,42,44]. Alignment of the health innovation with organizational principles was found to influence uptake.

Uptake of electronic mental health approaches was dependent upon the perceived fit of the innovation to the organization's priorities. [42]

Discussion

Principal Results

This review found that both Indigenous patients and service providers are enthusiastic about the role that mHealth can play in health service delivery.

Common themes across end users were: importance of mHealth or digital literacy, mHealth as a facilitator for connection and support, mHealth content needed to be culturally relevant, and data security and confidentiality are a priority. Two themes emerged that were unique to service providers: the importance of mHealth supporting rather than replacing service providers and the role of workplace champions and organizational capacity for influencing the uptake and sustainability of mHealth.

In this review, most included studies stated the importance of relevant cultural imagery and language, which enabled greater comprehension of mHealth messaging and increased engagement by end users [31-33,37-41,43,44,46,47]. Cultural content needs to account for the heterogeneity of Indigenous peoples, appropriate to location, language, people, and knowledge systems. This creates a challenge for mHealth developers and researchers alike in having 1 product with the capability to be distributed to a culturally diverse audience. Regarding language, Varnfield et al [49] increased their scope of patient engagement with their mHealth app being "available in several different selected languages." This demonstrates that mHealth has the potential to be adaptive with its content.

Similar to the included study findings of this review, mHealth has been shown to enable patients to engage with their health care providers more effectively as well as connect with peers on similar health care journeys [21]. Moreover, our findings support other reviews reporting health care providers who found mHealth improved communication between their patients and colleagues [15,16].

Our findings showed the importance of workplaces and their leadership in influencing the uptake of mHealth [39,40,42,44,45]. Likewise, Palacholla et al [50] found leadership and organizations that were supportive and facilitated digital health adoption in clinical settings. An important factor when implementing health service innovation is localized agenda setting being led by need, want, and appropriateness [51]. Within a mHealth context, Gagnon et al [52] found health professionals considered their workplace environment as one of the top contributing factors to adoption. Engaging health care organizations as a partner to support mHealth may offer the greatest opportunity for sustained uptake.

Other systematic reviews conducted to understand the influencing factors to mHealth uptake show a strong correlation with the findings presented here. Namely, the principal influencers for adoption are the mHealth design, personal perceptions of mHealth, and the workplace environment [16,21,52], which suggest that co-design may offer an effective methodology for sustained mHealth uptake with Indigenous populations and service providers that work with Indigenous populations.

Early engagement with the Indigenous community within eHealth research and implementation has shown to offer the greatest opportunity for acceptability, and local advocacy [22,23,53,54]. Moreover, this model of prioritizing community partnership and co-design is recommended by governing ethical guidelines on research with Indigenous peoples internationally to achieve beneficial research outcomes [55-58]. Despite this, Eyles et al [59] found a lack of co-design methods for minority and Indigenous groups internationally in the development of mHealth interventions. With the novelty of mHealth along with the cultural considerations involved in the study population, it would be practical to enter a colearning and cocreation relationship to achieve mutually beneficial outcomes.

In conclusion, there has been considerable growth in qualitative research exploring contextual factors in relation to mHealth uptake in non-Indigenous populations, yet less so for Indigenous populations. To our knowledge, this is the first review of qualitative studies that provides an understanding of the influential factors for both patients and service providers for Indigenous populations in relation to mHealth.

Strengths, Limitations, and Future Directions

Having 2 reviewers from diverse cultural backgrounds and gender orientations independently screening improved the quality of this meta-synthesis. The authors are a multidisciplinary team with a breadth of expertise in this review focus (psychology, digital health, qualitative research, and Indigenous health). Using a meta-aggregative approach to analyze the findings ensured cultural learnings identified by researchers' conducting the original studies were not lost by the reviewers. The quality appraisal tool used a modified version of the CASP qualitative checklist, with the additional question locating the researchers' cultural or theoretical standpoint, improving the cultural rigor of this critical appraisal tool. Most studies were of medium to high quality, and the quality appraisal tool can be found in Multimedia Appendix 2.

Our review has some limitations; first, the searches were restricted to peer-reviewed literature published in 5 databases (PubMed, CINAHL, Embase, PsycINFO, and Web of Science). Second, publication bias may have occurred due to the subjective quantifying of studies reporting on one or more outcomes via qualitative research methods. Finally, the results of this study are based on the meta-synthesis of qualitative data, which is inherently subjective. There are studies included from all countries (except the Sápmi region), but there are still only a few studies in each country, and so more work is needed. Papers need to report not only on patients' perspective but other end users to gain a full understanding of the perceptions of mHealth in supporting health care with Indigenous populations.

Conclusions

This review used meta-aggregation to summarize the findings of 17 qualitative studies on the experiences and perceptions of mHealth with Indigenous populations and the service providers that work with Indigenous populations. mHealth end users are enthusiastic about the role that mHealth can play in Indigenous health service delivery. There is a need for mHealth design to center end users within a co-designed approach with Indigenous people. There is recent work driving this agenda in an Australian context [60]. Allowing end users to suggest localized agenda setting through co-design may provide an opportunity for ownership, championship, and mitigation of barriers in mHealth implementation. Future research should partner with key representatives (eg, patients, health care professionals, and executive leaders) in the mHealth design appropriate to the purpose, people, setting, and delivery.

Acknowledgments

To ensure a culturally inclusive lens, our authorship reflects a diversity of the background, career stage, gender, and race. Specific to the focus of the manuscript AG and RM are Indigenous, and GS and SL are non-Indigenous. AG is an Aboriginal PhD candidate from Iningai country in Central West Queensland, Australia. AG has spent more than 13 years as an Indigenous health worker in Queensland alongside rural and remote Aboriginal and Torres Strait Islander people in the discipline of cardiac and health care services. RM is Aboriginal, a descendant of the Bidjara people of Central Western Queensland, Australia. RM is an Aboriginal health leader and researcher and has worked extensively to implement best practice cardiovascular care, particularly for Aboriginal and Torres Strait Islander peoples. GS is a General Practitioner at the Inala Indigenous Health Service in Brisbane, Queensland, and a General Practice academic at The University of Queensland. SL is a public health academic, with research interests in broad reach interventions to improve health outcomes in priority populations. We thank The University of Queensland for the support of this review via an Indigenous higher degree by research Development Grant. The funder of the study had no role in study design, data collection, data analysis, data interpretation, or writing of the report. All authors had full access to the full data in the study and accept responsibility to submit for publication.

Data Availability

The search strategy is available in Multimedia Appendix 1. Any additional data are available upon request from the corresponding author.

Authors' Contributions

AG and SL conceptualized the study design, retrieved, analyzed, and interpreted the research data on which the scholarly work is based. AG and SL prepared the manuscript with significant input and critical review from RM and GS. All authors have read and approved the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Over the past few decades, there has been a rapid increase in the number of wearable sleep trackers and mobile apps in the consumer market. Consumer sleep tracking technologies allow users to track sleep quality in naturalistic environments. In addition to tracking sleep per se, some sleep tracking technologies also support users in collecting information on their daily habits and sleep environments and reflecting on how those factors may contribute to sleep quality. However, the relationship between sleep and contextual factors may be too complex to be identified through visual inspection and reflection. Advanced analytical methods are needed to discover new insights into the rapidly growing volume of personal sleep tracking data.

Objective: This review aimed to summarize and analyze the existing literature that applies formal analytical methods to discover insights in the context of personal informatics. Guided by the problem-constraints-system framework for literature review in computer science, we framed 4 main questions regarding general research trends, sleep quality metrics, contextual factors considered, knowledge discovery methods, significant findings, challenges, and opportunities of the interested topic.

Methods: Web of Science, Scopus, ACM Digital Library, IEEE Xplore, ScienceDirect, Springer, Fitbit Research Library, and Fitabase were searched to identify publications that met the inclusion criteria. After full-text screening, 14 publications were included.

Results: The research on knowledge discovery in sleep tracking is limited. More than half of the studies (8/14, 57%) were conducted in the United States, followed by Japan (3/14, 21%). Only a few of the publications (5/14, 36%) were journal articles, whereas the remaining were conference proceeding papers. The most used sleep metrics were subjective sleep quality (4/14, 29%), sleep efficiency (4/14, 29%), sleep onset latency (4/14, 29%), and time at lights off (3/14, 21%). Ratio parameters such as deep sleep ratio and rapid eye movement ratio were not used in any of the reviewed studies. A dominant number of the studies applied simple correlation analysis (3/14, 21%), regression analysis (3/14, 21%), and statistical tests or inferences (3/14, 21%) to discover the links between sleep and other aspects of life. Only a few studies used machine learning and data mining for sleep quality prediction (1/14, 7%) or anomaly detection (2/14, 14%). Exercise, digital device use, caffeine and alcohol consumption, places visited before sleep, and sleep environments were important contextual factors *substantially* correlated to various dimensions of sleep quality.

Conclusions: This scoping review shows that knowledge discovery methods have great potential for extracting hidden insights from a flux of self-tracking data and are considered more effective than simple visual inspection. Future research should address the challenges related to collecting high-quality data, extracting hidden knowledge from data while accommodating within-individual and between-individual variations, and translating the discovered knowledge into actionable insights.

Introduction

In tandem with the advent of consumer wearable technologies, there has been a growing interest in using consumer sleep tracking technologies for personal health management. Being aware of the importance of having a good night's sleep, many individual users are routinely monitoring their sleep [1-3], and sleep tracking has been a popular topic, especially in the quantified-self community. Consumer sleep tracking technologies are largely divided into 2 types: smartphone dependent and smartphone independent. Smartphone-dependent sleep tracking technologies leverage the integrated sensors of a smartphone (eg, accelerometer, gyroscope, and microphone) to measure body movements and ambient sound, based on which a user's sleep states can be estimated. Smartphone-independent sleep tracking technologies use independent hardware with multiple sensing modalities, such as accelerometers and photoplethysmography. These devices often come in the form of a wristband (eg, Fitbit [Fitbit Inc] and Apple Watch [Apple]), headband (eg, SleepSheperd [Sleep Shepherd] and Neuroon [Vandrico Inc]), or finger ring (eg, Oura [Oura Health Oy]), and they rely on proprietary sleep staging algorithms to calculate sleep metrics based on measurable physiological signals [4]. The accuracy of these consumer technologies has been significantly improved over the years. Recent models have proven to be reasonably accurate, especially in measuring the time of sleep onset and offset, total sleep duration, and sleep efficiency (SE) [5-7]. A recent study comparing 7 consumer sleep tracking devices with polysomnography (the gold standard of sleep measurement) demonstrated that their validity could outperform medical-grade actigraphy [6]. In the past decade, sleep tracking has become one of the most studied topics in the research field of personal informatics. At the intersection of ubiquitous computing, human-computer interaction, and sleep science, researchers from multiple disciplines have made joint efforts to investigate the validity of existing consumer sleep tracking devices [5-10], develop accurate sleep staging algorithms tailored to consumer sleep tracking devices [11-15], develop smartphone apps for visualizing personal sleep data [16-19], develop artificial intelligence–based sleep coaching systems that help people improve sleep hygiene [20], and understand the challenges for sleep tracking technologies to eventually improve sleep health [3,21-23]. At a higher level, sleep tracking studies have mostly been guided by general self-tracking frameworks, such as the lived informatics model [24] and the Prevetiver Health care on Individual Level framework [25]. Both frameworks emphasize the iterative exploration and analysis of the self-tracking data to gain insight and drive behavioral changes.

One of the known challenges in sleep tracking is how to empower layperson users to make sense of their sleep data and to identify lifestyle or environmental factors that they can modify for better sleep [22]. In the field of health informatics, health data analytics could be divided into multiple levels according to their analytical capabilities [26]. Depending on its outcomes, health analytics can be descriptive, diagnostic, predictive, or prescriptive in nature [27]. At the lowest level lies *descriptive analytics*, which answers the question, *what has happened?* This level of analytics describes data *as is* without applying complex calculations and exploration. Common techniques at this level, such as standard reports and alerts, focus on categorizing, characterizing, aggregating, and classifying data to understand the past and current states. Existing sleep tracking analytics is mostly centered on this level, which aims to help users gain a *nice-to-know* validation of their subjective perception of sleep. At the second level is *diagnostic analytics*, which focuses on possible antecedents and answers the question, *why did it happen?* This level of analytics requires extensive exploration and directed analysis and inference based on existing data to identify the potential problems and their probable causes. At the third level lies the *predictive analytics*, which focuses on the possible consequences and answers the question, *what is likely to happen next?* Sleep tracking technologies at this level should be able to predict users' sleep quality in the near or far future by examining their historical self-tracking data, detecting patterns, and then leveraging the patterns to forecast. The highest level of analytics is *prescriptive analytics*, which answers the question, *what should be done about it?* It uses domain knowledge in medicine and health science in addition to data to generate recommendations for health interventions (eg, recommendations for better sleep).

Table 1 provides a mapping of the 4 levels of the analytics framework by Burke [26] for sleep tracking. The descriptive analytics would focus on answering questions such as "How many hours did I sleep last night?" "How many awakenings did I have last night?" and "What is the average deep sleep ratio during the past one month?" So far, sleep tracking has predominantly centered on such descriptive analytics, typically by visualizing data with charts and tables on a dashboard. This type of application could be meaningful in understanding users' current sleep patterns. However, with a flux of multiple models of sensor data, simple data visualization may miss important patterns that are not easily observable through visual inspection. As the complexity of sleep tracking data increases, it becomes necessary to examine the data in a more structured manner using advanced analytics. For example, diagnostic analytics could help answer questions such as "Was my sleep normal?" or "Why did I have so many awakenings last night?" Predictive and prescriptive analytics could answer questions such as "How will my sleep quality be in five years if I keep going to bed at 2:00 am?" or "Will I sleep better tonight if I work out 10 minutes longer in the morning?" To achieve advanced analytics, it is necessary to combine different streams of contextual information into a sleep analysis. Although many consumers' sleep tracking systems support the simultaneous collection of multiple streams of contextual information, these data are often visualized separately and rarely integrated with sleep analysis. Currently, there is a paucity of advanced analytics in sleep tracking research.

Knowledge discovery is the process of finding meaningful patterns from data, and data mining is a central step within a knowledge discovery process. Popular data mining techniques, such as association rules mining and anomaly detection, are widely used in many application domains to detect hidden patterns in large data sets [26]. In this paper, we present a scoping review on the application of knowledge discovery methods in sleep tracking. Such a review is useful for technical researchers interested in applying a wide range of machine learning and data mining techniques to the personal health domain as well as for sleep scientists who want to leverage the latest wearable technology combined with a data-driven approach for personalized and nonpharmaceutical interventions. Previous reviews on consumer sleep tracking technologies have dominantly focused on the utility and validity of these devices, especially in terms of their strengths and limitations relative to more widely accepted devices [4,28,29]. To the best of our knowledge, this scoping review is the first to focus on the advanced data analytics related to sleep tracking. An advanced data-driven approach has the potential to discover meaningful patterns or hidden correlations that could be used to guide behavioral change for better sleep. On the basis of the scoping review, we highlight the research opportunities for data-driven sleep computing.

Table 1. Level of analytics and its mapping to sleep tracking.

Analytics level	Questions answered	Mapping to sleep tracking
Descriptive	What has happened?	"How many hours did I sleep last night?"
Diagnostic	Why did it happen?	"Why did I have so many awakenings last night?"
Predictive	What is likely to happen next?	"How will my sleep quality be in five years if I keep going to bed at 2:00 am?"
Prescriptive	What should be done about it?	"Will I sleep better tonight if I work out 10 minutes longer in the morning?"

Methods

Research Questions

This scoping review was guided by the problem-constraints-system framework, which is widely used for conducting a literature review in computer science. The problem-constraints-system framework focuses on 3 different aspects of a research topic in computing research: a specific problem of interest (P); systems, applications, or algorithms (S) for tackling the problem; and constraints (C). After iterative brainstorming, we proposed the following 4 research questions (RQs) to anchor the entire review process:

- RQ1: What is the general research trend of knowledge discovery in sleep tracking?
- RQ2: What sleep quality metrics and contextual factors were considered, and how were they measured?
- RQ3: What knowledge discovery methods or algorithms were applied? What knowledge was discovered?
- RQ4: What challenges exist? What are the opportunities for future research?

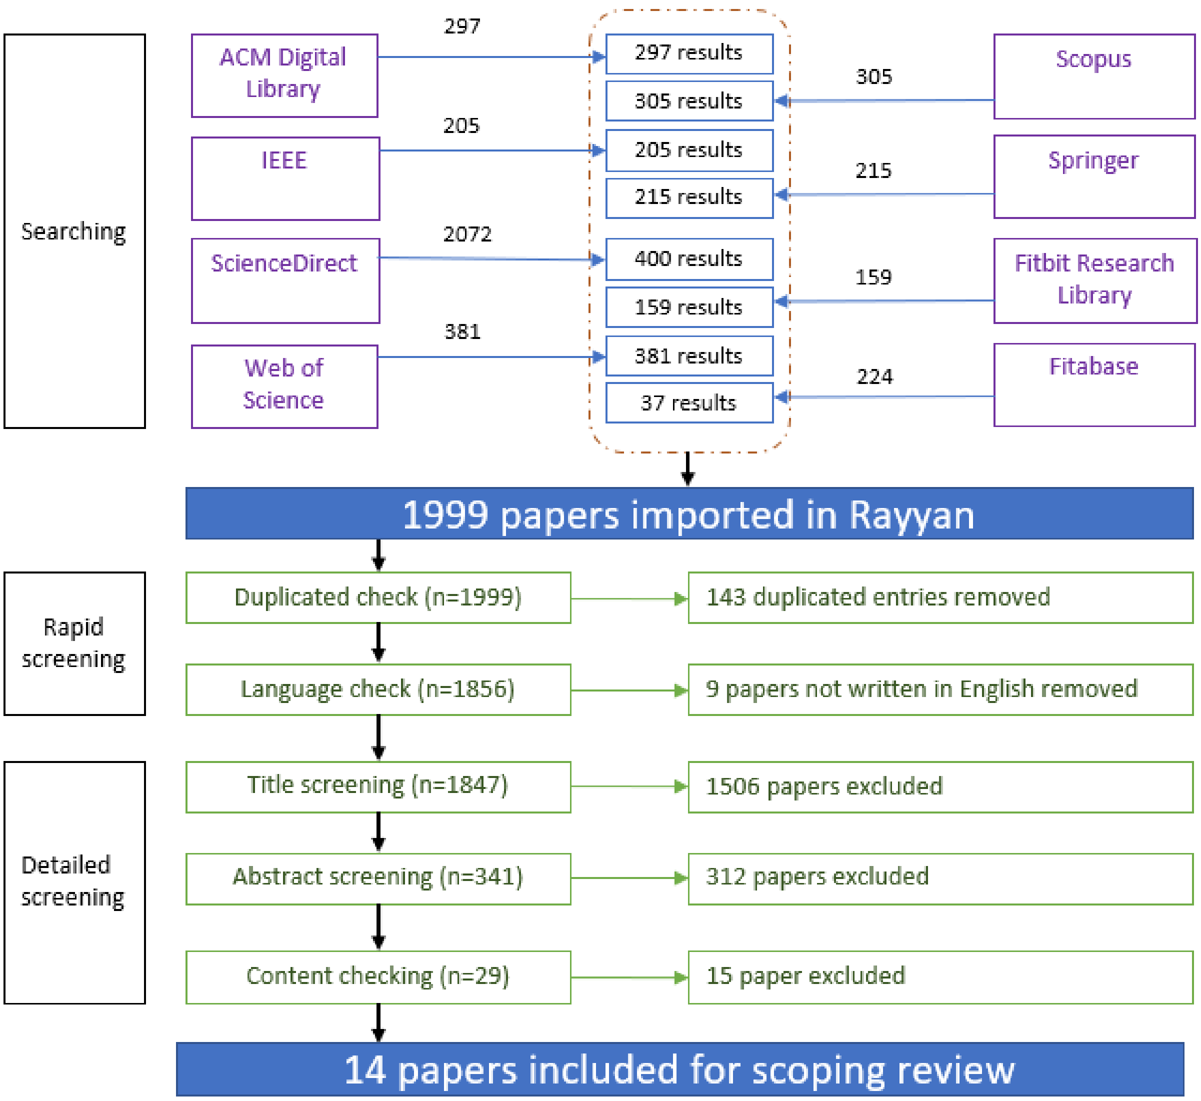
Search Strategy and Query String

In this review, we focused on the application of data mining to identify the relationships between sleep and contextual factors with consumer wearable devices. Therefore, search results must contain all 4 pertinent aspects: sleep metrics, contextual factors, wearable devices, and knowledge discovery. Automated searches were conducted in a number of databases, including the Web of Science, Scopus, ACM Digital Library, IEEE Xplore, ScienceDirect, Springer, Fitbit Research Library, and Fitabase. As our review was centered on the computing aspect rather than the clinical aspect of sleep tracking, we used databases that focus more on engineering and computer science publications, including the ACM Digital Library, IEEE Xplore, ScienceDirect, and Springer. PubMed was not used because we were not interested in cohort studies or medical assessments. We also included gray literature such as the Fitbit Research Library and Fitabase because of their relevance to our topics of interest. The query strings were slightly different for each database but always contained 4 main keyword combinations: "sleep," "lifestyle" AND "contextual," "data mining" OR "knowledge discovery," and "wearable device." Synonyms words and words of related concepts (eg, "self-tracking," "sensors," "machine learning," "correlation," and "statistics") were also listed to avoid missing out on related publications. The search strategy varied for each search engine, as each of them had different rules and options. The query string was truncated in some databases (eg, Web of Science, ScienceDirect, and IEEE Xplore) either because long query strings resulted in many irrelevant entries or because of word limit. We included several types of publications, including journal articles, conference proceeding papers, workshop presentations, patents, and gray literature, to gain a broad scope of the research topic. Editorial articles, theses, and dissertations were also excluded.

Study Selection

The study selection process is shown in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart in Figure 1. We applied the following exclusion criteria to filter out irrelevant papers retrieved from the databases: (1) studies not related to human sleep (eg, animal studies and sleep mode of sensor system), (2) clinical studies aiming at treating sleep disorders, (3) hypothesis-driven laboratory-based studies using invasive sleep tests (eg, polysomnography), (4) validation studies focusing on comparing wearable devices with medical devices, (5) studies focusing on estimating sleep architecture based on concurrent physiological signals, and (6) papers not written in English. We retrieved the returned entries from each database and imported them into the web-based review management software Rayyan (Rayyan). All databases provided tools to export the returned entries in a single file, except for the Fitbit Research Library and Fitabase. We exported only 400 of the 2072 papers from the ScienceDirect because the rest of the papers were not relevant to our review topic. For the ScienceDirect database, the returned items were first listed using the "relevant order" tool provided by the database. We used an a prior condition to include the first 400 items. For the remaining items, we separated them into groups of 200 items and randomly checked 50 items in each group. We found that from the 400th item onward, the studies were off the topic according to our exclusion criteria. Thus, we eliminated these items because they did not help address our central RQs. For example, the keyword "contextual" led to the retrieval of papers in civil engineering on checking bedroom quality with air condition, ambient light, and noise exposure. Those were excluded based on the exclusion criterion 1. The keyword "wearable device" led to the retrieval of papers in electrical and mechanical engineering on hardware design for sensors, batteries, and ergonomic design. Those were excluded based on the exclusion criterion 4. For the Fitbit Research Library, 2 papers were missing because they were either retracted or no longer available. Entries in Fitabase were screened for duplicity before manually adding to Rayyan because Fitabase does not support automatic export. As many of the Fitabase entries were duplicates of publications from other databases, only 37 papers were added to Rayyan.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of article screening process.



In total, 1999 papers were imported to Rayyan. Screening for duplication and written language was performed automatically in Rayyan. After the rapid screening step, the first author performed title and abstract screening and suggested the inclusion of 341 papers. The second author repeated the title and abstract screening of the 341 papers while paying special attention to the exclusion criteria 3 and 5. Any conflicts were resolved through discussion with the first author. After the screening and eligibility checks, 29 papers remained. Both authors read the full text of the 29 papers in detail and finally selected 14 papers for the scoping review.

Results

General Research Trend (RQ1)

Ubiquitous and personal sleep tracking has become an active research area since approximately 2011, when a few pioneer studies were published in the human-computer interaction community [17,18,30]. Since then, a large number of studies on sleep tracking have been published, but most of them are dominantly centered on the validation of existing sleep tracking devices or systems [5-10], on the development of new sleep staging algorithms [11-15], or on the investigation into users' experience with the technologies [3,21-23]. In contrast, studies that focus on knowledge discovery in sleep tracking data are scarce and ad hoc. The screening process identified only 14 relevant studies, of which more than half (8/14, 57%) were conducted in the United States, followed by Japan (3/14, 21%). The other publications were from China, Korea, Finland, and Australia. Only 5 (36%) of the 14 publications were journal articles, and the rest were conference proceeding papers. Chronologically, studies by Jayarajah et al [31] and Gelman and Hill [32] were one of the earliest studies in this field. The authors developed a binary tree model to predict good and poor sleep based on app use activity and social time during the day. Since 2015, the topic of knowledge discovery in sleep tracking has begun to attract more attention along with the advances in consumer sleep tracking technologies. As a result, the number of publications has increased slightly in the subsequent years, but the total amount is still limited.

A common objective of these studies was to help users gain insights into how their sleep quality was associated with other aspects of their daily lives. Some of the specific motivations are as follows:

- Identify aspects of daily life that demonstrate significant associations with personal sleep quality from self-tracking data [16,20,33]
- Highlight the potential for sleep metrics from wearable devices to provide novel insights into data generated from a large cohort [34-36]
- Detect aberrant sleep patterns or typical events during sleep by considering individuals' sleep baselines [37,38]
- Guide users in designing self-experiments to identify personal modifiable lifestyle factors for better sleep health [20]
- Develop a recommender system that provides both general and personalized recommendations for better sleep health [20]

The studies reviewed in this paper demonstrated a tendency to analyze sleep tracking data along with a flux of contextual factors. These factors were used as independent variables for predicting sleep quality and, to a lesser degree, for identifying antecedent events that affect sleep quality. In the scheme of traditional sleep science studies, only a limited number of independent variables were considered, and the confounding effect of noninterested factors needed to be controlled through a rigid experiment design. In comparison, data collection experiments in ubiquitous sleep tracking studies are often conducted in a naturalistic environment, making it challenging to control for confounding factors. Therefore, advanced data analysis techniques are required to control the effects of confounding factors during the analysis. Another line of research effort is the personalized detection of aberrant sleep. Although sleep quality assessment may sound straightforward using clinical standards [39], it remains challenging if personal differences in sleep needs should be taken into consideration. Studies in this direction are limited, and we identified only 2 relevant studies [37,40].

Quantification and Measurement of Sleep and Contextual Factors (RQ2)

Human sleep can be quantified along multiple dimensions, such as sleep duration, sleep continuity, sleep timing, and subjective perception of the sleep event [41]. We found that not all studies used the same set of metrics to characterize sleep quality. Even the same sleep metric may be capsulated in different terminologies across studies. To facilitate cross-study comparisons, we mapped the sleep metrics in each study to standard clinical terms, whenever possible. Original sleep metrics that have no corresponding clinical terms were simply left as they were. As presented in Table 2, the most used sleep metrics among the reviewed studies were subjective sleep quality (4 studies), sleep efficiency (SE, 4 studies), sleep onset latency (SOL; 4 studies), and time at lights off (3 studies). Ratio parameters such as deep sleep ratio and rapid eye movement ratio were not used in any of the studies. Moreover, the cutoff between good and poor sleep varied from study to study. A few studies have adopted clinical cutoffs, particularly for the Pittsburgh Sleep Quality Index (5) [31], SE (85%) [42], wake after sleep onset (30 minutes) [16], and total sleep time (7-9 hours) [16]. The rest chose to use heuristic cutoffs that did not comply with the clinical guidelines.

Table 2. Sleep quality metrics, measurement methods, and cutoff of good or poor sleep.

Clinical term, original term, and measurement method	Cutoff
Subjective sleep quality	
Pittsburgh Sleep Quality Index [31,38]	Good: ≤5 and poor: >5 [31]; good: ≤7 and poor: >7 [38]
Sleep rating (SleepAsAndroid app) [20]	N/A[a]
Leeds Sleep Evaluation Questionnaire [19]	N/A
Sleep rating (SleepApp) [19]	N/A
SE[b]	
SE (Fitbit) [33]	Good: ≥95% and poor: <95%
Efficiency (MS Band) [43]	N/A
SE (Polar) [40]	Good: >mean (SD) and poor: <mean (SD)
SE (Garmin) [42]	Good: ≥85% and poor: <85%
SOL[c] (minutes)	
Minutes to fall asleep (Fitbit) [16]	N/A
SOL (SleepAsAndroid app) [20]	N/A
Sleep latency (Garmin) [42]	Good: ≤15, average: 15-30, and poor: >30
Time to fall asleep (MS Band) [43]	N/A
Time at lights off	
Bedtime (Fitbit) [35]	Normal bedtime: median of a participant's bedtimes; deviation categories were 1-30 minutes, 30-60 minutes, 1-2 hours, 2-3 hours, and ≥3 hours
Bedtime (Fitbit) [37]	N/A
Bedtime as estimated by the time of the last network signal [36]	N/A
Wake after sleep onset (minutes)	
Awake minutes (Garmin) [42]	Good: ≤20 and poor: >20
Minutes awake (Fitbit) [16]	Good: ≤30 and poor: >30
Number of awakenings >5 minutes	
Awakenings >5 minutes (Garmin) [42]	Good: ≤1 and poor: >1
Number of wakeups (MS Band) [43]	N/A
Time in bed (minutes)	
Time in bed (MS Band) [34]	N/A
Total sleep time (minutes)	
Minutes asleep (Fitbit) [16]	Good: 420-540 and poor: <420 or >540
Original metrics (no corresponding medical term)	
Sleep ratio=the ratio of the sleep minutes with normal heart rate versus total sleep time (Fitbit) [44]	Good: >90%, normal: 60%-90%, and bad: <60%
Number of awakenings per hour [20]	N/A
Awakening count including restlessness (Fitbit) [16]	N/A
Permutation entropy of Fitbit measured sleep state time series [37]	N/A

[a]N/A: not applicable.

[b]SE: sleep efficiency.

[c]SOL: sleep onset latency.

Sleep quality metrics were measured using 3 methods: questionnaire based, app based, and wearable based. The Pittsburgh Sleep Quality Index was the most widely used questionnaire to measure the subjective perception of sleep duration, continuity, efficiency, and satisfaction [31,38]. The SleepAsAndroid app was used to collect sleep data based on user movement patterns in the study by Daskalova et al [20], and the SleepApp was used to collect users' subjective sleep quality ratings in the study by Ravichandran et al [19]. Although sleep tracking apps such as SleepAsAndroid were widely downloaded and used by millions of users, their ability to distinguish between quiet awakenings, deep sleep, or empty beds was still limited [20]. In a related vein, studies by Jayarajah et al [31] and Faust et al [36] have defined sleep time as the longest period during which there was no activity on users' smartphones. However, the authors acknowledged that this method was not reliable because not everyone had the habit of using smartphones until they fell asleep. Most studies (9/14, 64%) used commercial wearable devices such as Fitbit [16,33,35,37,44], Microsoft Band (MS Band) [34,43], Garmin [42], and Polar [40]. Although all 3 methods are noninvasive, easy to use, and allow longitudinal collection of sleep data, each method has some limitations. The questionnaire-based method is subject to memory recall bias. Sleep data collected by sleep tracking apps and wearable sleep trackers provide an objective description of sleep quality and sleep structure. However, they may also be prone to measurement errors because of hardware and software limitations [7,28]. They also require users to place the smartphone nearby or to wear the device continuously, which may cause discomfort during long-term use. Moreover, despite being small and convenient, consumer wearable trackers cannot provide hypnogram information that is as detailed as medical devices.

Along with sleep quality metrics, researchers have considered a wide range of contextual factors in their studies. As presented in Table 3, the contextual factors of interest include the sleep environment [16,20,42], daily activities [16,19,20,31,36,37,40,42,43], physiological states [16,35,36,43,44], and mental states [16,19]. It was a common practice to collect demographic information (eg, age, gender, and BMI) and medical history using questionnaires at the beginning of a sleep tracking study [16,35,36,43,44]. Other contextual factors were recorded during the data collection experiments. Researchers have been curious about how web activities of university students could be coupled with their sleep quality [31,34,36]. These studies developed their own tools to track users' web-based behavior and linked them to sleep quality metrics. Using consumer wearable trackers such as Fitbit, MS Band, and Garmin, researchers were able to expand their list of factors to include, for example, bedtime, steps, distance, hours of exercise, and calories burned [16,19,20,31,36,37,40,42,43]. Biosignals such as heart rate during sleep and daytime activities were included in the studies by Faust et al [35], Farajtabar et al [43], and Choi et al [44]. Several studies have also manually collected input features such as coffee, alcohol, mood, and stress [16,19,20]. These factors may have a significant effect on the circadian cycle of hormone secretion and thus may provide useful information for sleep quality prediction. However, collecting these data are nontrivial, as users tend to forget to log the data on a daily basis. How to collect these data more efficiently and how to reduce the risk of missing data remain challenging.

Table 3. Contextual factors and measurement methods.

Category and contextual factor	Data collection method
Physiological factors	
Age	Self-report [43,44]
Sex	Self-report [36,43]
Body weight	Fitbit [16] and self-report [43]
BMI	Self-report [44]
Body temperature	Diary [16]
Heart rate	Fitbit [35,44] and MS Band [43]
Menstrual cycle	Diary [16]
Calorie in and out	Fitbit [16] and MS Band [43]
Activity calorie	Fitbit [16]
Psychological factors	
Stress	Diary [16]
Mood	Diary [16] and SleepApp [19]
Tiredness	Diary [16]
Dream	Diary [16]
Sleep quality the previous night	SleepAsAndroid [20] and MS Band [43]
Cognitive performance	Keystroke time [34] and click time [34]
Behavioral factors	
Steps	Fitbit [16,37] and MS Band [43]
Distance walked	Fitbit [37]
Active time	Fitbit [16,37]
Exercise	SleepAsAndroid [20], MS Band [43], Polar [40], Garmin [42], and SleepApp [19]
Coffee	Diary [16], SleepAsAndroid [20], and SleepApp [19]
Alcohol	Diary [16], SleepAsAndroid [20], and SleepApp [19]
Tobacco	Self-report [44] and SleepApp [19]
Electronic device use	App use time (total and different app categories) [31], diary [16], Bing search logs [43], SleepApp [19], and campus network [36]
Nap	Diary [16], SleepAsAndroid [20], and SleepApp [19]
Location	Campus Wi-Fi [31] and Cortana [43]
Social activity	GruMon (location estimation based on Wi-Fi signals) [31], diary [16], and Twitter [43]
Mealtime	Diary [16], smartphone camera [42], SleepApp [19], and campus smart card [36]
Waketime	SleepAsAndroid [20]
Bedtime	Fitbit [37], IoT[a] sensor [42], and SleepApp [19]
Environmental factors	
Ambient temperature	Diary [16] and IoT sensor [42]
Ambient humidity	Diary [16] and IoT sensor [42]
Ambient light	Diary [16] and SleepAsAndroid [20]
Ambient noise	SleepAsAndroid [20]
Day of week	MS Band [43]

[a]IoT: internet of things.

We found that 13 (93%) of the 14 reviewed studies conducted their own data collection experiments [16,31,33,37,38,43,44] in free-living conditions. In these studies, sleep data were recorded in participants' usual sleep environments (eg, homes and caregiving facilities), whereas contextual factors were recorded while participants were at schools, universities, workplaces, or sports centers. In contrast, only 1 study used an existing data set [35], which can be accessed over the web [45]. Data sharing is not yet a common practice in the field, and the number of public data sets is limited.

Knowledge Discovery in Sleep Tracking (RQ3)

Data Preprocessing

All the reviewed studies used data sets that were collected in free-living environments. Data collection "in the wild" increases the ecological validity of the studies but at the sacrifice of data quality. The first step in the knowledge discovery process is to deal with missing, wrong, and duplicate data. Although there are many methods for data cleaning in the literature, the methods adopted in the reviewed publications are extremely simple and straightforward. Most of the studies (5/14, 36%) simply excluded records that contain missing values (eg, sleep logs with missing fields or sleep duration of 0 minutes) [16,19,37] or excluded users who do not contribute sufficient data (eg, fewer than 30 sleep records) [35,36]. One study excluded a certain data source (eg, search engine interactions originating from mobile devices) to avoid causing distortion to the data distribution [34].

Similarly, data out of logical ranges were removed. Users aged <10 years or >100 years, with weight <22.7 kg or >112.5 kg, or with height <127 cm or >457.2 cm were excluded in the study by Farajtabar et al [43]. Extremely short (<0.5 or 4 hours) and long (>12 hours) sleep records were removed in the studies by Althoff et al [34] and Farajtabar et al [43]. Sleep entries with bedtime between 7:00 AM and 7:00 PM were removed in the study by Liang et al [33]. Exercise time is another criterion for filtering out potentially erroneous data records. For example, exercise events <5 or >180 minutes were removed in the study by Farajtabar et al [43]. Exercises with calorie consumption per hour <50 or >2000 calories or with a duration of <10 minutes were excluded in the study by Liu et al [40]. In addition, data records with steps <1000 and those with a sedentary time of 0 minute were removed in the study by Liang et al [16].

Time stamps are another focus in data preprocessing. The data collection in the study by Ravichandran et al [19] primarily relied on users' manual input in SleepApp and thus had a higher risk of human errors. Consequently, all logs with aberrant timestamps were removed. In addition, 12 hours were added to or subtracted from the recorded bedtime or wake-up time where the users might have forgotten to toggle the AM and PM switch on the app. Dealing with timestamps involves not only data cleaning but also temporal matching among multiple data sources [42] as well as data type conversion (eg, 18:30 to 1830) [16,37].

Other types of data preprocessing included selecting users with larger variations in sleep and exercise [38], removing redundant entries [19], and resampling the raw data (eg, the photoplethysmography-derived heart rate time series was aggregated every 3 minutes to achieve a constant sampling rate [38]).

Some knowledge discovery processes that rely on machine learning or data mining techniques may require a feature engineering process instead of directly using the cleaned data as input. For example, several studies have involved the construction of secondary features from the cleaned data [37,38,40]. Features were normalized to have a mean and SD equal to 0 and 1 [42] or normalized over another feature (eg, exercise intensity features were normalized by dividing the basal metabolic rate [38]). Dimension reduction (eg, principal component analysis) was applied to reduce the number of input features to avoid the adverse effect of the "curse of dimension" [31].

Data Mining

The selection of the data mining method depends on the purpose of the studies and, to a lesser degree, on the size of the available data set. Table 4 provides a summary of the data mining methods and the specific techniques or algorithms used in the reviewed studies. We also listed the independent variables (or input) and dependent variables (or output) of the constructed models. Correlation analysis, regression analysis, and rule induction are the most used methods for finding meaningful associations between contextual factors and sleep quality metrics. In total, 3 correlation analysis techniques, Pearson correlation, Spearman correlation, and repeated measure correlation, were applied to examine the strength of the pairwise linear relationships between sleep and contextual factors [16,19,20]. Similarly, various regression analysis methods have been used, ranging from simple linear regression to linear mixed effects regression to piecewise fixed effects regression [34,35,43]. Least square estimation was the most popular technique for parameter estimation in regression analysis and was used in the studies by Althoff et al [34] and Farajtabar et al [43]. The study by Faust et al [35] provided no information but is highly likely to use the same technique. It is worth noting that the Pearson correlation coefficient is equivalent to the standardized slope of a simple linear regression line.

Table 4. Summary of the data mining methods used in the reviewed studies.

Data mining method and techniques or algorithms	Data size	Independent variable	Dependent variable
Correlation analysis			
Pearson correlation [20]	Preliminary study: 24 users over 20 days; final study: 19 users over 21 days	TST[a] and contextual factors	SOL[b], NAWK[c], and sleep rating
Spearman correlation [16]	12 users over 2 weeks	Contextual factors	TST, WASO[d], NAWK, SOL, and SE[e]
Repeated measure correlation [19]	10 users over 2 weeks	Bedtime, TIB[f], and contextual factors	SE, SOL, NAWK, restlessness, TIB, and LSEQ[g]
Regression analysis			
Piecewise fixed effects regression [34]	31,793 users over 18 months; all American users	Time of day, time after waking up, and sleep duration	Cognitive performance
Simple linear regression [43]	Approximately 20,000 users over 4 months	Contextual factors	SOL, NAWK, and SE
Linear mixed effects model [35]	557 users over 1 year	Bedtime regularity	Resting heart rate
Rule induction			
A priori algorithm [33]	1 user over 180 days; 4 users over 2 weeks	Contextual factors	SE
Learn from Examples using Rough Sets [44]	280 users over 1 month; only the data of males were used	Contextual factors	Sleep ratio
Event mining (+causal inference) [42]	1 user over 800 days	Contextual factors	SOL, WASO, NAWK, and SE
Causal inference			
Stratified propensity score analysis [43]	Approximately 20,000 users over 4 months	Contextual factors	SOL, NAWK, and SE
Bayesian network analysis [36]	5200 users over 6 months	Contextual factors and bedtime	Contextual factors and bedtime
Time series analysis			
Anomaly detection [37]	1 user over 35 days	Fitbit measured intraday time series, TST, WASO, NAWK, and bedtime	Permutation entropy of sleep time series
SAX[h]-based motif matching and principle optimization [38]	100 users over 10 weeks	Heart rate time series data	PSQI[i]
Statistical test			
Unpaired 2-samples Wilcoxon test [40]	271 users over 8 months	Contextual factors	Statistical differences between good and poor sleep
Decision tree			
J4.8 Classifier [31]	400 users over 15 months	Contextual factors	PSQI

[a]TST: total sleep time.

[b]SOL: sleep onset latency.

[c]NAWK: number of awakenings.

[d]WASO: wake after sleep onset.

[e]SE: sleep efficiency.

[f]TIB: time in bed.

[g]LSEQ: Leeds Sleep Evaluation Questionnaire.

[h]SAX: Symbolic Aggregate Approximation.

[i]PSQI: Pittsburgh Sleep Quality Index.

Although correlation analysis and regression analysis (except piecewise constant approximation) capture the relationships between sleep and contextual factors in the entire sampling range, the piecewise regression in the study by Althoff et al [34] shared some resemblance with rule induction methods that capture the relationship between sleep and contextual factors within a constrained range. However, in contrast to piecewise regression, which quantifies the covariance between 2 variables in each partitioned segment, rule induction methods focus on extracting frequent patterns in the data sets that characterize the co-occurrence of 2 variables when their values fall into the corresponding ranges specified in a rule. Moreover, rule induction methods are usually robust to missing data. As the rule induction methods were originally developed to analyze categorical data, numerical data need to be converted to categorical data through a discretization step before rule induction methods can be applied. There are 4 discretization methods used in the reviewed studies: equal size discretization [33,44], equal frequency discretization [33], k-means clustering discretization [33], and discretization with heuristically defined cutoffs [42]. Association rules mining is a popular rule induction method that has been widely used in traditional medical and health informatics applications; however, it has only been used in 1 study among all the studies we reviewed [33]. In that study, the a priori algorithm was applied for rule induction. The quality of the induced association rules was validated by higher local correlation coefficients (ie, the Pearson correlation coefficient when the variables fall into the ranges specified in a rule) than the global correlation coefficients (ie, the Pearson correlation coefficient between 2 variables within the entire sampling range). To better handle the potential inconsistency (eg, conflicting records) in the data set, Rock-Hyun et al [44] applied another rule induction algorithm named learning from examples using rough sets. The global covering algorithm computes the lower and upper approximations of all the target sleep quality metrics (eg, sleep ratio="good") if the input data set contains conflicting records. The quality of the induced rules was assessed based on the predictive accuracy of the target sleep metrics. Although association rules mining and learning from examples using rough sets capture only the parallel co-occurrence of 2 items (ie, when the values of 2 variables fall into the corresponding ranges specified by a rule), event mining can also capture the co-occurrence of 2 items with a time lag (ie, the temporal sequence when the 2 items occur) [46]. To a certain degree, event mining resembles sequential pattern mining [47]; however, this characteristic was not used in the study by Upadhyay et al [42].

Causal inference is a powerful approach to reduce potential bias in the identified relationships between sleep and contextual factors because of observed confounding factors. This method is likely to outperform simple correlation analysis or rule induction–based methods. In the study by Farajtabar et al [43], stratified propensity score analysis was performed to isolate the effects of potential confounding factors. A similar technique was used in the study by Upadhyay [42] to enhance the quality of the induced rules by accommodating confounding factors. In addition, the Bayesian network was applied to explore the relationship between sleep schedules and behavioral factors [36].

Statistical tests and decision trees were also used in the existing literature, but only in 1 study each. The unpaired 2-samples Wilcoxon test was applied to identify significant differences in a set of selected contextual factors between good and poor sleepers [40]. Despite its simplicity, this method does not generate quantitative relationships between the contextual factors and sleep quality. In contrast, decision trees were used in the study by Jayarajah et al [31] to predict sleep quality using contextual factors as input features.

In addition to the abovementioned methods, time series analysis was also used but only in 2 studies [37,38]. Dimension reduction and anomaly detection were combined to identify aberrant sleep recordings while counting in personal sleep baseline in the study by Liang et al [37]. Feng and Narayanan [38] introduced a method to discover motifs in heart rate time series, which were signal patterns that appeared most frequently during sleep [38]. They then used these motifs as features to predict sleep quality. In contrast, although the study by Upadhyay et al [42] adopted a streaming data perspective, it did not incorporate any formal time series analysis technique [39].

Knowledge Discovered

The knowledge discovery process in the reviewed studies identified interesting associations both at the cohort level and the individual level. First, significant associations were found among the sleep quality metrics. Late bedtime was associated with a higher permutation entropy of the Fitbit measured sleep time series (indicating a higher chance of aberrancy) [37]. Bedtime deviation was correlated to longer SOL [19]. In addition, sleep duration was positively associated with subjective sleep satisfaction [19,20].

Regarding the relationship between sleep quality and contextual factors, exercise was the most identified association factor [33,40], but the relationship between exercise and sleep was complex [40,43]. First, not all exercise features have a predictive power of sleep quality. For example, Liu et al [40] found that exercise duration, relative calories consumption, and exercise timing could be used as predictors of sleep quality, but exercise intensity was not significantly associated with sleep quality. Second, exercise may be positively associated with some sleep quality metrics but negatively associated with others. For example, exercise before bed may be linked to shorter SOL and higher SE [43], and exercise seems to improve SOL the most among all the sleep quality metrics [42]. However, the results diverged as different types of exercises were considered. Taking more steps meant fewer awakenings, whereas running and burning more calories were correlated with more awakenings [43]. Moreover, longer exercise duration (eg, >100 minutes) may be associated with good sleep for some users but poor sleep for others [40]. Furthermore, confounding factors may modulate the relationship between sleep and exercise. With causal inference, it was found that pleasant ambient temperature at bedtime significantly strengthened the relationship between exercise and sleep, whereas having a poor sleep the previous night detracted from the beneficial effects of exercise [42].

Digital device use is another important factor that correlates with sleep quality and sleep schedule. No web searches before bed correlated with shorter SOL and higher SE, whereas web searches before bed correlated with more awakenings [43]. The association between app use and sleep quality was modulated by the frequency and timing of use [31]. In particular, low social app use was associated with good sleep, and more app use correlated with good sleep if used for >4 hours before sleep. Reading and gaming app use within 1 hour before bedtime correlated with poor sleep. A strong connection between internet surfing habits and bedtime was identified by Guo et al [36]. Video lovers tended to go to bed later than game fans. Going to bed late, in turn, has negative consequences. Deviations from usual bedtime may result in a higher resting heart rate during sleep [35]. Students who went to bed late were more likely to have a poor academic performance [36]. Late bedtime (in relation to one's circadian cycle) reduced cognitive performance the next day, whereas early bedtime did not have the same negative effect [34]. In contrast, having a sufficient sleep was important for maintaining normal cognitive performance [34].

As expected, caffeine and alcohol consumption were significant association factors. Consuming caffeine late in the day was a universal negative factor in subjective sleep ratings [20]. Alcohol consumption was positively correlated with SE and wake-up freshness and was negatively correlated with wake after sleep onset and number of awakenings for some users but not all users [16].

Not just personal activities or substance consumption associated with sleep, but places visited before bedtime and social life also play a role. One study found that students who spent more time with friends had better sleep quality than those who stayed alone on campus most of the time [31]. In addition, if students spent most of their time outside campus, good quality sleep was found for those who spent <15% of their time being alone. Another study tracked users' location during the day and stated that users took longer to fall asleep if they visited food-related or bank-related locations close to bedtime [43]. In addition, sleep quality may vary depending on the environment in which sleep takes place. The most common relationship identified for many users by Daskalova et al [20] was the pair of noisiness and number of awakenings [16]. Temperature was positively associated with all sleep metrics except for SOL [42].

Challenges and Opportunities (RQ4)

Knowledge discovery in sleep tracking is the process of extracting nonobvious hidden knowledge from self-tracking sleep data and other available contextual information. Preparing a data set of a sufficient size is the first step in this process. Almost all the reviewed studies (13/14, 93%) conducted original data collection experiments using noninvasive wearable and mobile sensors. The existing literature highlighted several challenges of data collection in sleep tracking. First, the absence of an objective, quantifiable, and universal definition of good sleep places a big challenge in annotating the collected sleep data [16,19]. Without a well-annotated data set, it is not feasible to apply supervised data mining techniques, and the absence of ground truth impedes the unbiased evaluation of the knowledge discovery process. Second, some contextual factors are considered difficult to quantify. These factors include digital device use, caffeine and alcohol consumption, and social interaction [16], to name but a few. The timing of data logging may also influence the results [20]. For example, users were advised to avoid using digital devices 2 hours before bedtime but had to log on to their smartphones to submit daily data at the end of the day. Third, existing passive sensing methods may have strong limitations [34]. For example, some studies (2/14, 14%) assume that users check their smartphone right before bedtime and immediately after waking up [31,36] and thus may miss out on users who have no such habits. Consumer wearables may have limited accuracy in measuring sleep stages and other factors [7], but the issue of data quality was not considered in the reviewed studies [35].

Moreover, interpreting the knowledge discovery outcome is not always straightforward. Correlation analysis essentially captures the covariance of 2 variables. Users with regular sleep and daily life routines may end up with no significant correlations found because of the lack of variability in their data. However, users may misinterpret this as having no relationship [16]. Rule induction methods usually generate a large number of rules, but not all of them are useful. Long rules with too many factors in the antecedent, despite of being explainable, provide no actionable insights because of their complexity (eg, "IF 17.85 < BMI < 25.21 AND Smoking is Yes AND 61.81 < Normal_Avg_HR < 79.0 AND 0 < Normal_Awake <19.0 AND 1.5 < Normal_Really_Awake < 24.0 AND 1.5 < High_Asleep < 606.5 AND 1.5 < High_Awake < 155.0 AND 0.5 < High_Really_Awake < 175.5 THEN Sleep Quality Status is 'Bad' with support 8") [44]. In contrast, short association rules may be more comprehensible (eg, "minutes very active={33; 38}=> good sleep or steps={18,658; 20,263}=> good sleep" [33]). However, heuristic discretization without a semantic meaning may impede understandability [20].

Despite the challenges, the reviewed studies highlighted several opportunities for future research. In total, 3 studies suggested considering more contextual factors in addition to the ones already studied, such as emotion, diet, productivity, and chronotypes [31,34,36,42]. Acknowledging that the correlations at a cohort level may be weak [31], argues for an individual-centric approach to identifying the most important contextual factors for each user. Along the same line [43], it was pointed out that building predictive models within similar user groups is more practical. They proposed a hierarchical modeling scheme with a top layer containing population parameters and lower layers personalized to individual users. Similar user profiling and segmented modeling proposals were presented in the studies by Liang et al [33] and Farajtabar et al [43].

Discussion

Principal Findings

Sleep tracking using consumer wearable devices and mobile apps has attracted remarkable attention from the research community. However, sleep tracking studies have focused on developing sleep tracking technologies for accurately measuring sleep per se, and little attention has been directed to the extraction of patterns and insights from these data. To the best of our knowledge, this scoping review is the first to map the existing literature from a knowledge discovery perspective in sleep tracking.

Our analysis results showed that the number of publications on the topic of interest has slightly increased over the years but is still low, probably because the data-driven scheme has not been fully embraced in personal informatics. Nonetheless, we found that the existing literature covered all 4 levels of analytics, as presented in Table 1. Most of the 14 studies that we reviewed applied simple correlation analysis, regression analysis, and rule induction methods to discover the associations between sleep and other aspects of life. Although most consumer sleep tracking technologies allow users to visually inspect their sleep data (which is descriptive in nature), the reviewed studies demonstrated the feasibility of diagnostic analysis with a flux of sleep and contextual data. Although correlation does not necessarily indicate causality, a combination of association analysis and causal inference—as was done in the study by Upadhyay et al [42]—may help users narrow down the scope of possible modifiable factors that are likely to affect their sleep quality. Machine learning and data mining techniques were only used in a few studies for anomaly detection (which is diagnostic) [37] or sleep quality prediction (which is predictive) [31,43]. In total, 2 studies developed computational models to generate personalized recommendations for better sleep and showed promise in prescriptive analysis of sleep tracking [20,42]. The most used sleep metrics among the reviewed studies were subjective sleep quality, SE, SOL, and time at lights off. Exercise, digital device use, places visited during the day and before bedtime, and sleep environment are the major factors that significantly correlate with various dimensions of sleep quality.

Taken together, there are a few key challenges that are relevant to the findings. On the one hand, it is nontrivial to collect high-quality data in naturalistic settings. Challenges include how to motivate users to overcome tracking fatigue, how to enhance the reliability of consumer wearables and apps, and how to quantify and automate the collection of contextual information to represent the current challenges surrounding the collection of sleep tracking data sets. On the other hand, how to extract hidden knowledge from data, how to accommodate commonness and individuality, and how to interpret data mining results are topics for future studies.

Nuance in Handling Within-Individual Variation

The selection of appropriate data mining methods relies on a correct understanding of the nature of the sleep tracking data set. Researchers often conduct longitudinal data collection experiments that involve the collection of multiple measurements of the same variables (eg, sleep quality, exercise, and ambient light) from each individual user. The data form a hierarchical or clustered structure when aggregated at the cohort level. Caution must be exercised when applying traditional analytic and modeling techniques developed for single-level data, as hierarchical data are likely to violate the assumption of independent errors of those techniques. In particular, although a hierarchical data set offers the benefit of a larger amount of data, the within-individual variation at the individual level needs to be addressed carefully through multilevel analysis and modeling.

In a multilevel analysis framework, the repeated measures are clustered within the level of an individual, and each individual is treated as a cluster unit. Depending on whether the analysis of one cluster involves pooling the data of other clusters, there are 3 approaches to analyzing a hierarchical data set: complete pooling, no pooling, and partial pooling. Complete pooling completely ignores the variation between individual users and treats all samples as being drawn from the same population. A dominant portion of the studies reviewed in this work [16,31,33,34,36,38,40,43,44] adopted this approach. Nonetheless, this approach is undesirable, as it violates the assumption of independence. The results could have been distorted when the between-individual variation was high. At the other end of the spectrum lies the no pooling approach, where the analysis of the relationship between sleep and contextual factors was performed only on the data of each individual user without considering data from other users. Daskalova et al [20] Upadhyay et al [42] embraced an N-of-1 design and correspondingly adopted the no pooling approach to analyze the collected data. At the surface, this approach is plausible for fully handling the within-individual variation. However, it bears the risk of overstating the variation between individual users because of potential overfitting when the number of samples from individual users is small. Partial pooling or multilevel modeling compromises between pooled and unpooled estimates, with the relative weights of pooling determined by the sample size of each individual user and the variation within and between individuals. Multilevel modeling automatically adjusts the degree of pooling with a "soft constraint," which ensures strong pooling for users with fewer records and weak pooling for users with abundant records in the data set [32]. We found that only Ravichandran et al [19] and Faust et al [35] used the multilevel modeling approach and explicitly considered the within-individual variation.

Most reviewed studies (8/14, 57%) seem to have relied on the undue assumption of an independent and identically distributed data set. As a result, some studies (2/14, 14%) found mixed or even conflicting results on the relationships between sleep and contextual factors at the cohort level [40,44] and, consequently, generated no valuable insights. Studies using an N-of-1 design are interesting exceptions. In these studies, analysis was conducted on each user's data, thus eliminating the effect at the cohort level. However, the robustness and generalizability of the findings are questionable. Even in studies with an N-of-1 design, it may still be helpful to partially pool some samples from the population to increase the reliability of the model parameter estimates. As such, Gelman et al [48] suggested always using multilevel modeling (ie, "random effects") as a rule of thumb, for example, linear mixed effect model over simple linear regression model and generalized linear mixed model trees [49] over the J4.8 classifier.

Limitations of the Study

There is room for improvement in several aspects of this study. First, because of the limitations inherent in scoping reviews, this study is exploratory and primarily qualitative in nature.

Limited by the review methodology, we were unable to generate a quantitative "summary of findings, " as required for systematic reviews or meta-analyses. Second, our method is nonstandard in a sense that we performed prescreening on the items identified in the ScienceDirect database before importing all entries into Rayyan. Although we made an effort to ensure that the removed items were not relevant, we cannot rule out the possibility of missing publications that should have been included. Third, we did not conduct critical appraisal on the quality of the selected papers or perform a risk of bias assessment, which may have led to potential bias in the selection and interpretation of the papers. Despite these limitations, this review provides a well-scoped summary of existing research and could lay the groundwork for future systematic reviews. The research gaps that we identified can be used to inform future research agendas.

Conclusions

This scoping review built an understanding of the scope and nature of existing literature on knowledge discovery in ubiquitous and personal sleep tracking. To the best of our knowledge, this is the first review that exclusively focused on the knowledge discovery aspect of self-tracking in the realm of sleep health. In total, 14 studies were included in the review based on the exclusion criteria. We found that the existing literature covered all 4 levels of the analytics framework in health informatics. However, half (7/14, 50%) of the studies have only applied simple correlation analysis and regression analysis, aiming to discover significant associations between sleep and available contextual information. Machine learning and data mining techniques have not yet been widely used, probably because of the lack of large and quality data sets. Exercise, digital device use, places visited during the day and before bedtime, and sleep environment were the most identified factors associated with sleep quality. We identified key challenges surrounding the collection of high-quality sleep tracking data sets with consumer-grade sensors and in naturalistic settings as well as the extraction of hidden knowledge that could be translated into actionable insights and personalized behavior interventions. We highlight that future research should develop data analytics techniques and prediction models that properly handle the within-individual variation and between-individual variation in sleep tracking data sets. We hope that this scoping review could lay the groundwork for future research on ubiquitous and personal sleep tracking.

Acknowledgments

This study was sponsored by a Japan Society for the Promotion of Science (JSPS) KAKENHI Grant-in-Aid for Early-Career Scientists (grant 21K17670). The funder had no role in the study design, data collection and analysis, or manuscript preparation.

Authors' Contributions

ZL contributed to study conception. ZL and NHH contributed to study design, analysis and interpretation of results, and manuscript drafting and revision. NHH collected the data. All authors have reviewed the results and approved the final version of the manuscript.

Abstract

Background: Women with urinary incontinence (UI) may consider using digital technologies (DTs) to guide pelvic floor muscle training (PFMT) to help manage their symptoms. DTs that deliver PFMT programs are readily available, yet uncertainty exists regarding whether they are scientifically valid, appropriate, and culturally relevant and meet the needs of women at specific life stages.

Objective: This scoping review aims to provide a narrative synthesis of DTs used for PFMT to manage UI in women across their life course.

Methods: This scoping review was conducted in accordance with the Joanna Briggs Institute methodological framework. A systematic search of 7 electronic databases was conducted, and primary quantitative and qualitative research and gray literature publications were considered. Studies were eligible if they focused on women with or without UI who had engaged with DTs for PFMT, reported on outcomes related to the use of PFMT DTs for managing UI, or explored users' experiences of DTs for PFMT. The identified studies were screened for eligibility. Data on the evidence base for and features of PFMT DTs using the Consensus on Exercise Reporting Template for PFMT, PFMT DT outcomes (eg, UI symptoms, quality of life, adherence, and satisfaction), life stage and culture, and the experiences of women and health care providers (facilitators and barriers) were extracted and synthesized by ≥2 independent reviewers.

Results: In total, 89 papers were included (n=45, 51% primary and n=44, 49% supplementary) involving studies from 14 countries. A total of 28 types of DTs were used in 41 primary studies, including mobile apps with or without a portable vaginal biofeedback or accelerometer-based device, a smartphone messaging system, internet-based programs, and videoconferencing. Approximately half (22/41, 54%) of the studies provided evidence for or testing of the DTs, and a similar proportion of PFMT programs were drawn from or adapted from a known evidence base. Although PFMT parameters and program compliance varied, most studies that reported on UI symptoms showed improved outcomes, and women were generally satisfied with this treatment approach. With respect to life stage, pregnancy and the postpartum period were the most common focus, with more evidence needed for women of various age ranges (eg, adolescent and older women), including their cultural context, which is a factor that is rarely considered. Women's perceptions and experiences are often considered in the development of DTs, with qualitative data highlighting factors that are usually both facilitators and barriers.

Conclusions: DTs are a growing mechanism for delivering PFMT, as evidenced by the recent increase in publications. This review highlighted the heterogeneity in types of DTs, PFMT protocols, the lack of cultural adaptations of most of the DTs reviewed, and a paucity in the consideration of the changing needs of women across their life course.

Introduction

Background

Pelvic floor muscle (PFM) dysfunction, which most commonly manifests as urinary incontinence (UI), pelvic organ prolapse, and pain, is a major and often unreported problem for women. UI, defined as "any involuntary leakage of urine" [1], affects between 25% and 45% of women worldwide, yet the true prevalence is likely to be higher, with women underreporting UI because of the associated shame and embarrassment [1]. UI substantially affects quality of life (QoL) in relation to both women's physical and mental health and well-being and also represents a major economic burden (eg, costs associated with routine care and treatment) [2].

PFM training (PFMT), which includes exercises to increase PFM strength and endurance, is recommended as the first choice for managing UI, especially stress UI [1]. PFMT can be undertaken by women to maintain pelvic health by preventing the onset of UI or can cure or improve symptoms and enhance QoL in adult and older women, including during pregnancy and the postpartum period [3,4]. However, despite its effectiveness, approaches to PFMT vary across communities and countries, and maintaining exercise programs, which are often undertaken at home, is difficult [5]. In addition, many women avoid seeking treatment for UI based on the belief that UI is an inevitable consequence of aging or childbirth, or the perception that little can be done to improve symptoms or QoL, or because of limited access to health services [6].

Digital technologies (DTs; such as the World Wide Web; eHealth; and mobile health [mHealth], including SMS text messaging and apps) provide an avenue for women with UI to seek guidance with PFMT and potentially improve their symptoms and QoL [5-8]. To elicit health benefits, women require access to DTs based on the best scientific evidence. However, although the market appears to be flooded with PFMT apps, few have been scientifically validated in terms of content, quality, or appropriateness [9,10]. In addition, knowing whether PFMT delivered via DTs is sound from a clinical perspective is equally important, but there is a lack of information as to whether PFMT in this context is based on contemporary evidence [11]. This is potentially compounded by the notion that few mHealth apps have been developed in collaboration with key stakeholders, such as women experiencing UI or health care professionals [12].

Factors such as age and culture may influence how women engage with PFMT DTs. For example, there is evidence that women are more vulnerable to developing UI at certain stages in life, including (1) young athletic women, particularly those participating in high-impact sports [13]; (2) during and after pregnancy, when one-third of women giving birth for the first time have UI, which may persist for at least 3 months post partum; (3) menopause, where a peak in UI occurs; and (4) older women (UI prevalence ranges from 43% to 77%), particularly those in residential care, where UI is a substantial risk factor for falls [1]. On the basis of this evidence, age-appropriate and specific PFMT programs seem imperative to best cater to women, yet there appears to be a distinct lack of information related to the uptake of DTs to manage UI at different stages in life [11]. Culture, which encompasses particular spiritual, intellectual, and emotional features, including lifestyle, value systems, traditions, and beliefs [14], not only affects how women interact with DTs [15,16] but also shapes their experiences and attitudes toward UI [15-17]. Although it is essential to understand how culture may affect the use of and engagement with PFMT DTs, with reference to UI, it is unclear whether the experiences and needs of women from different cultures or ethnic groups are considered when developing these types of DTs.

Objectives

Several systematic reviews have recently been published in this field, mostly focusing on the effectiveness of PFMT DTs in terms of improving symptoms of UI and QoL along with adherence to the prescribed PFMT program [7,8,18-21]. In this context, knowledge of the quality and content of PFMT DTs is also important, as is an understanding of whether such DTs are designed for women across their life course and take into account the cultural contexts and experiences of women and other relevant stakeholders. The main aim of this scoping review was to provide a narrative synthesis of digital health technologies used for women's PFMT to manage UI. The key objectives of this review were to (1) explore whether PFMT DTs follow best-practice guidelines and describe outcomes related to their use, (2) establish whether DTs have been designed for PFMT at specific stages in life or consider culture, and (3) describe users' experiences of DTs for PFMT.

Methods

This scoping review was conducted in accordance with the Joanna Briggs Institute methodological framework [22] and the

PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [23]. A protocol was prospectively registered with the Open Science Framework [24].

Search Strategy

Following an initial search in PubMed, a systematic search of 7 electronic databases (AMED, CINAHL, Embase, MEDLINE, SPORTDiscus, Scopus, and PsycINFO) was conducted to identify relevant literature (from inception to December 2021). Key search concepts related to (1) DTs (eg, smartphones, cell phones, apps, telemedicine, and mHealth), (2) UI, (3) PFMT or exercise, and (4) key life stages (eg, pregnancy and menopause). Hand searching of reference lists of included articles, as well as citation tracking (eg, Web of Science for the last 5 years), was used to identify additional articles that may have been eligible for screening and inclusion (Multimedia Appendix 1).

Study Selection Criteria

Population

Studies were included if they (1) focused on women aged ≥14 years with or without UI who were using or had used some form of DT to engage in PFMT, (2) evaluated outcomes related to the use of PFMT DTs for managing UI, or (3) explored users' experiences of DTs for PFMT. Studies were excluded if the research focus was on women with overactive bladder or enuresis or neurological conditions, they reported collective data for men and women unless the data specific to women could be extracted separately, they used biofeedback devices that were not connected to an app or any other form of eHealth, and they were published in a language other than English for which a translation could not be acquired (eg, through Google Translate).

Concept

This review considered studies that explored PFMT delivered via DTs for the management of UI—with a focus on the evidence base for DTs and PFMT—the life course, culture, and users' experiences. The use of DTs for health (PFMT) is defined as "a broad umbrella term encompassing eHealth (which includes mHealth), as well as emerging areas, such as the use of advanced computing sciences in 'big data,' genomics, and artificial intelligence" [25]. In addition to eHealth, other applications such as wearable devices with a digital component (eg, a vaginal biofeedback probe connected to a mobile app), telehealth, and personalized medicine are encompassed within the scope of DTs.

Context

Studies that met the previously defined criteria were included to establish the widest coverage of information related to PFMT delivered via DTs for managing UI. This encompassed a large and heterogeneous group of women with or without UI, health care providers (HCPs) or researchers, and other disciplines (eg, IT experts). Any type of health care setting (eg, primary care and community) or discipline (eg, physiotherapy and general practitioners) was considered.

Study Design

Research involving quantitative and qualitative study designs and other forms of gray publications, such as opinion pieces, editorials, conference abstracts, theses, and case studies or series, were considered [26].

Study Selection

Titles and abstracts were independently screened by 5 authors (AC, BS, JK, MB, and SW) using web-based software (Covidence systematic review software; Veritas Health Innovation). The full texts were read and assessed by 2 of the 3 authors (BM, BS, and SW), with discrepancies resolved through consensus or discussion with another member of the team.

Data Extraction and Verification

A customized template was developed in Microsoft Word (Microsoft Corp) and piloted on 5 of the included studies. Data were independently extracted into the template by 5 authors (MB, AC, JK, BM, BS, and SW), transferred to a Microsoft Excel (Microsoft Corp) spreadsheet, and cross-checked by 2 authors (BS and SW). Any disagreements were resolved through consensus or consultation with a third reviewer when necessary.

The data extracted related to general study and participant characteristics included authors; year of publication; country; study aims; sample size; inclusion and exclusion criteria (intervention and comparator groups if relevant); age, gender, and level of education of participants; type of UI; and duration of symptoms.

To address the key objectives of this review, the data outlined in Textbox 1 were extracted.

Textbox 1. Data extracted from the included studies.

- Data related to the digital technologies (DTs)
  - Evidence base for or validation through previous testing
  - Type and features of DTs—capacity to extract, educational features, gamification, reminders and reinforcements, social media and self-monitoring, and technical support [7,27]
- Data specific to pelvic floor muscle training (PFMT)
  - Evidence base for the PFMT program
  - Descriptions of PFMT, which were charted according to the 16 key elements in the PFMT variation of the Consensus on Exercise Reporting Template (CERT-PFMT) [28]. In the context of this review, there was overlap between some CERT-PFMT items and DT features. Item 1 (exercise equipment) in the CERT-PFMT refers to the DT of interest, which incorporates descriptions of the device and related features (eg, biofeedback and mobility requirements) [7]. Item 5 (adherence) is covered by "self-monitoring," item 6 (motivation) relates to "reminders and reinforcements," and item 10 (nonexercise components) equates to "educational features." In the case of overlap, the data were extracted and synthesized under the umbrella of DT.
- Outcomes related to the use of PFMT DTs for managing urinary incontinence (UI), including UI symptoms, quality of life, and adherence to and satisfaction with the program
- Information related to key life stages and the culture of the women engaging with the PFMT DTs
- Experiences (facilitators and barriers) of women and health care providers with PFMT DTs for managing UI

Data Synthesis

The included studies that shared common author teams or apps were grouped accordingly. Descriptive statistics were used to summarize the data (BM, BS, and SW). With the exception of the study protocols, the methodological quality of the included studies was independently appraised using the relevant Joanna Briggs Institute critical appraisal tools [29] by pairs of reviewers, with a third reviewer consulted to reach a consensus if required.

For qualitative studies or the qualitative components of mixed methods studies, thematic synthesis, with the development of analytical themes driven by our review questions (ie, deductive analysis), was used for data synthesis [30] (MP and SW). The analysis occurred over 3 steps, with the last step designed to present clear implications for HCPs and policy makers. First, coding of text segments from the results and discussion specific to the review objectives was performed from sections of the included articles. Next, the raw codes were grouped and named in an iterative manner to form descriptive themes (grouped by the study's reported main themes and women's or clinician's perceptions of facilitators of and barriers to the use of DTs). Finally, analytical themes were generated from descriptive themes, and these analytical themes extended the synthesis beyond the conclusions of the included articles. Data were grouped for both barriers and facilitators under the headings of interactions between users and eHealth, interactions between users and PFMT exercises, and interactions between PFMT exercises and eHealth [31,32]. Although other tangential themes were generated, we presented the themes that were most coherently related to the study objectives.

Deviations From the Protocol

Owing to the large number of papers retrieved, a decision was made to exclude systematic reviews, meta-analyses, and scoping reviews from the analysis, which represents a deviation from the study protocol. Similarly, because of the number of DTs included in this review, we did not classify the types of DTs using the World Health Organization (WHO) classification [33] or rate the apps using the Mobile App Rating Scale [34].

Results

Search Results and Characteristics of the Included Studies

From the 7444 records screened for titles and abstracts, and after the removal of duplicates, 288 (3.87%) full-text reports were reviewed (Figure 1). A total of 89 papers met the inclusion criteria, of which 45 (51%) were classified as primary papers, with the other 44 (49%) considered supplementary papers (Table S1 in Multimedia Appendix 2 [5,6,11,12,31,35-118]; Table S2 in Multimedia Appendix 2 presents the inclusion and exclusion criteria for the included studies [5,6,11,12,31,35-118]). Of the 45 primary studies, many were randomized controlled trials (RCTs; n=13, 29%), with various other designs including cross-sectional studies (n=7, 16%); qualitative studies (n=6, 13%); mixed methods studies combining either RCTs or quasi-experimental trials with qualitative research (n=4, 9%); quasi-experimental studies (n=4, 9%); cohort studies (n=4, 9%); case series (n=4, 9%); and a case report, case-control, and validation study; of these 45 studies, 6 (13%) were study protocols and 2 (4%) were published in a language other than English (Dutch [35] and Portuguese [36]). The supplementary articles consisted of follow-up studies, secondary analyses, associated abstracts reporting a subset of data from the primary article, and author comments and letters to the editor (eg, [89,90,92-99,102-106,108-118]). Publications in this area have increased rapidly since the 2010s, with most protocols registered since 2019 (Figure 2). The methodological quality was rated for 84% (38/45) of the primary studies and was predominantly high (15/38, 39%) or fair (14/38, 37%), with 24% (9/38) considered poor (Multimedia Appendix 3 [5,6,36-41,43-46,48-51,53,57-59,61-77,80]). Key methodological areas for consideration included blinding of participants, therapists, and outcome assessors; measuring outcomes in a valid and reliable way and identifying confounding factors (cross-sectional studies); and consecutive recruitment of participants (case series), although aspects such as double-blinding are recognized as problematic in pragmatic and clinical trials.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) study flow diagram—search for papers related to digital technologies (DTs) and pelvic floor muscle training (PFMT) for women.

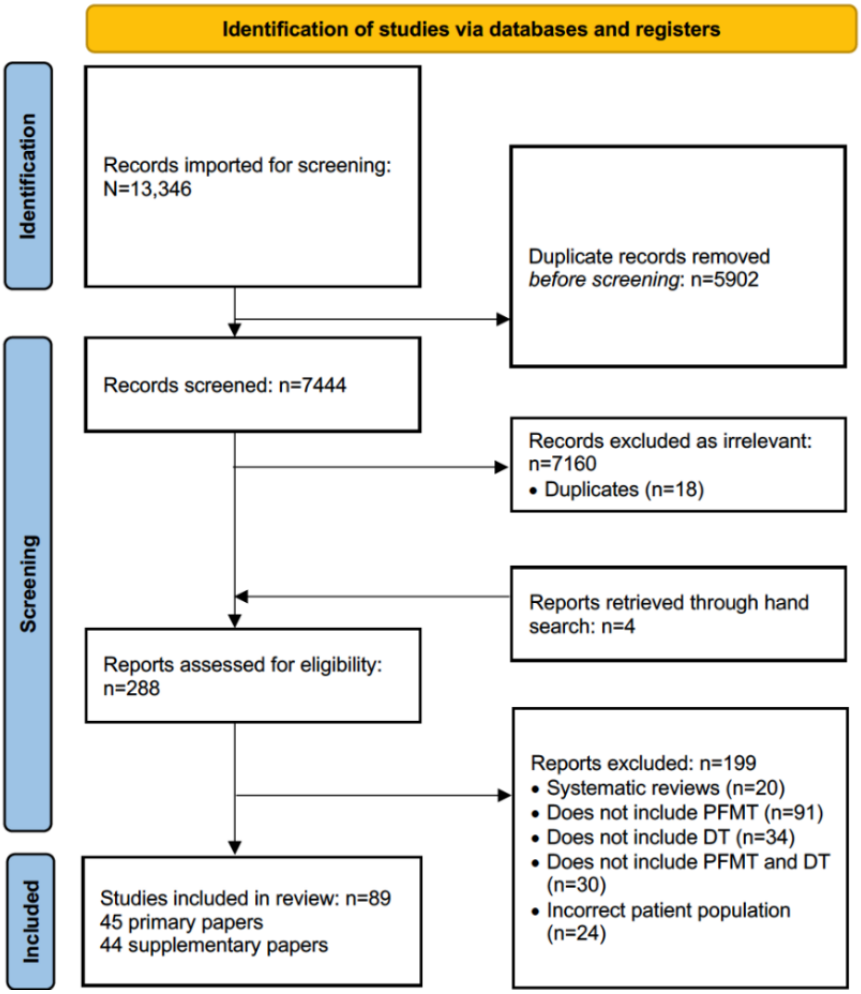

Figure 2. Publications included in this review presented by year of publication. RCT: randomized controlled trial.

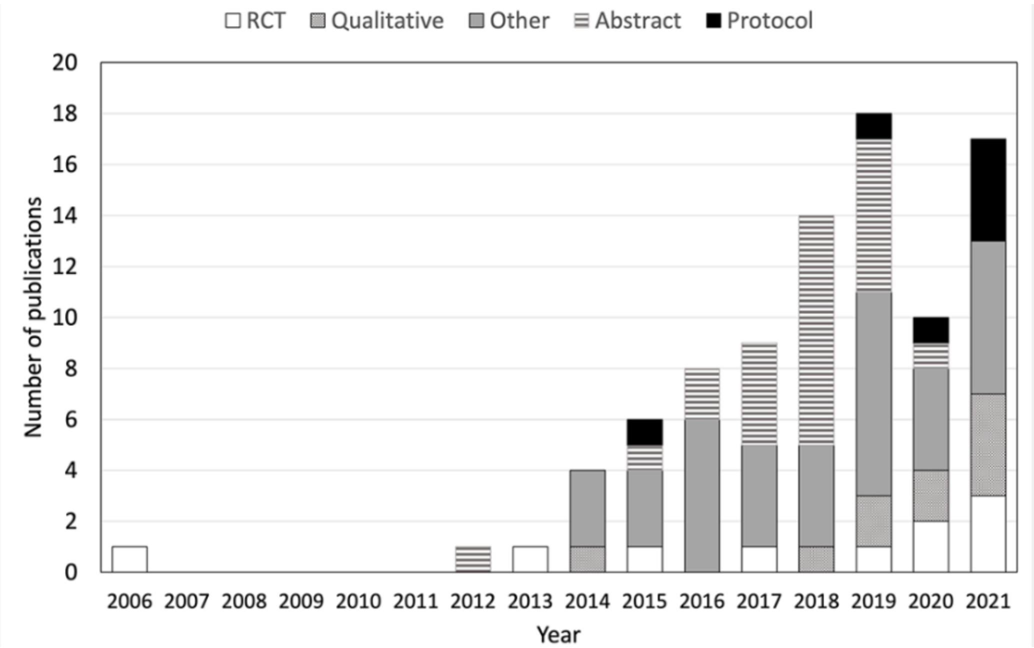

The studies originated in 14 countries, primarily from Europe (9/45, 20% from Sweden; 7/45, 16% from the Netherlands; 3/45, 7% from Spain; and 1/45, 2% from Germany), as well as the United States (6/45, 13%), the United Kingdom (4/45, 9%), Brazil (4/45, 9%), China (4/45, 9%, including Hong Kong), Australasia (4/45, 9%), Canada (1/45, 2%), Japan (1/45, 2%), and Malaysia (1/45, 2%). A total of 47% (21/45) of the studies had a total sample size of <50, 9% (4/45) recruited between 50 and 100 participants, and 44% (20/45) of the studies sampled >100 participants (2/20, 10% of which analyzed data from a sample of >10,000 women; Multimedia Appendix 3).

Participant Characteristics

Age

The age of the participants ranged from 18 to 98 years, with approximately 35% of studies (16/45, 36%) including women in their 40s or 50s as the average age. The level of education of the recruited participants was stated for just over half (24/45, 53%) of the primary studies. Among these, most women in each study were shown to be educated at the university level.

UI in the Included Studies

Studies mostly recruited women with stress UI only (17/45, 38%) [5,6,37-51], whereas 7% (3/45) of the studies included those with stress and mixed UI if stress symptoms were predominant [52-54], and 24% (11/45) included a mixture of stress, urge, and mixed UI types [55-65]. In total, 11% (5/45) of the studies included healthy (continent) and incontinent participants [66-70], and 11% (5/45) did not clearly specify the UI type [71-75], and this was irrelevant in 7% (3/45) [36,70,80]. Only 2% (1/45) of the studies [76], a case study, looked at urge UI only. A total of 20% (9/45) of the studies documented the duration of women's UI symptoms before their inclusion in the study. Of these, Asklund et al [5] required participants to have had symptoms for at least 6 months as part of their inclusion criteria. The remaining 18% (8/45) of the studies [38,40,43,46,51,61,64,65] showed variable durations, ranging from <3 months to 26 years (Multimedia Appendix 3).

Stage in Life

A total of 17 (38%) of the 45 studies reported life stage parameters: 29% (5/17) recruited women in the postpartum period [67-69,75,77]; 18% (3/17) recruited pregnant women [47,51,60]; 12% (2/17) included both pregnant and postpartum women [52,66]; 6% (1/17) included postmenopausal women [59]; and 24% (4/17) reported including a mixture of premenopausal, perimenopausal, postmenopausal, lactating, and postpartum participants [45,46,58,62]. A case study [76] included women reported as parous and Campbell et al [42] recruited athletic women for their RCT.

Cultural Context

Some studies developed the DTs for use by women in their specific countries (eg, Sweden [5], Japan [68], and Germany [70]), and the Tät has been translated into a number of different languages [56,63,78].

One group conducted a systematic review to explore variables that may influence adherence to PFMT DTs, which led to the development of the iPelvis app [11,57]. The authors emphasized the importance of considering ethnicity as part of a woman's individuality, and as such, the avatar character within the iPelvis app can be ethnically matched to the woman by altering features such as skin color, the flag of the country, and cultural costumes, as well as age and stage in life (eg, pregnant or older adult). This concept was supported by Han et al [72], who stated that the information in apps needs to be formatted in a culturally relevant way to ensure that it is effective. The importance of ongoing research to evaluate apps in different and diverse cultural contexts was acknowledged in 7% (3/45) of the studies [72,73,79].

DTs in the Included Studies

Overview

Among the 45 primary studies, data related to DTs and PFMT were not extracted from 4 (9%)—1 (25%) [55] analyzed data collected from 3 previous RCTs [5,6,64], and 3 (75%) qualitative studies [46,77,80] took a broad approach without focusing on a specific technology for the delivery of PFMT. Therefore, the data and information in the following sections were derived from 91% (41/45) of the studies, some of which used the same DTs (eg, Tät, Leva, and Pen Yi Kang; Table 1).

Table 1. Summary of digital technologies (DTs) and their features.

[a]Studies are ordered alphabetically but grouped by app where relevant.
[b]BF: biofeedback.
[c]EB: evidence base (provide some evidence base or previous testing of the DTs).
[d]DE: data extraction (capacity to extract data).
[e]EF: educational features.
[f]R and R: reinforcements and reminders.
[g]NI: not indicated.
[h]With the exception of the study by Asklund and Samuelsson [66], in which women had the choice to use the statistics function.
[i]KEPT: Kegel Exercise Pregnancy Training.
[j]UIW: Urinary Incontinence for Women.
[k]Not indicated in the study by Wessels et al [65].

Types of DTs (Consensus on Exercise Reporting Template for PFMT Item 1)

A total of 28 types of DTs were used across the 41 studies. Just over 40% (12/28, 43%) of these were solely mobile apps, 4% (1/28) trialed a smartphone-based messaging system, 11% (3/28) were internet-based programs, and 7% (2/28) were dedicated to videoconferencing. A total of 32% (9/28) of the technologies involved the use of a portable vaginal biofeedback or accelerometer-based device [36-38,43,44,48,49,53,54,62,67,71,76] that provided real-time feedback transmitted via Bluetooth to a mobile app or, in one instance, to a computer application [43]. In addition to the vaginal device, electromyographic data were integrated from surface electrodes attached to the abdominal muscles [37,38] or PFMs [36].

Evidence Base or Previous Testing of DTs

A total of 54% (22/41) of the studies provided some evidence base for or testing of the DTs [5,41,50,51,56,58,61,63-66,69,73,74], which had been either undertaken in the development stage or as an iterative process (eg, Tät) or was one of the specific purposes of the study [11,36-38,47,48,60,75]. Some studies (4/41, 10%) implemented a design framework (eg, the Reach, Effectiveness, Adoption, Implementation, and Maintenance framework [47] or the Fit Between Individuals, Task, and Technology framework [56]) in their trials. The development of the technologies generally involved collaboration, testing, and input from IT experts (such as hardware or software engineers) and HCPs or researchers with relevant clinical expertise (eg, obstetricians, women's health physiotherapists, and nurses) and feedback from women, the end users of the product. One app (1/12, 8%) was developed based on 12 key variables identified through a systematic review of the literature [57].

Capacity to Extract Data

Approximately 60% of the studies (25/41, 61%) reported the capacity to extract data to monitor women's progress; approximately 30% did not (12/41, 29%), and this was not indicated in 10% (4/41) of the studies. Data were extracted directly from the DTs in 20% (5/25) [39,43,49,61,65], and in 1 (4%) of the 25 studies, data could be emailed to the researchers via the app [36]. In other studies (19/25, 76%), data were transmitted from an app and stored or accessed on an associated web platform or server [37,38,42,44,47,56-58,68-71,75,76] or uploaded from the app to a cloud-based storage system [51,54,60,62,67]. Of the suite of studies that used Tät, 11% (1/9) indicated the collection of user statistics from the internet-based program [56], and 22% (2/9) reported that women could voluntarily choose to use the statistics function and submit their user statistics at follow-up [5,64].

Educational Features (Consensus on Exercise Reporting Template for PFMT Item 10)

Educational information was incorporated into 61% (25/41) of the studies, with most including a combination of topics such as education about the anatomy and function of the PFMs, PFMT, stress UI, and related lifestyle advice (eg, weight management, physical activity, and fluid management). A total of 2% (1/41) of the studies provided holistic advice on breathing, posture, and movement [40] and used videos to deliver this information, an approach also adopted by another 7% (3/41) of the studies [57,72,81], with another incorporating audio fragments [56]. In a videoconferencing study, education was provided by a nurse specialist across a series of talks rather than being integrated into the technology itself [59]. Of the studies that did not incorporate education, 6% (1/16) involved telerehabilitation [43], and 12% (2/16) were mobile apps [39,68], with 6% (1/16) solely using a smartphone reminder system [68].

Reinforcements, Reminders, and Self-monitoring (Consensus on Exercise Reporting Template for PFMT Items 5 and 6)

A variety of reinforcements were used across 59% (24/41) of the studies, but the most common was the provision of visual (eg, graphics) or audiovisual feedback to guide women on the performance of PFMT, with the inclusion of voice [52,57] or sound [47] commands or accompanying music [39]. Goode et al [58] included storytelling; another study had an exercise module with a timer and score board [60].

In just over 50% (21/41, 51%) of the studies, reminder systems were incorporated into or complemented the DTs. In most cases (13/21, 62%), the reminders were customizable and were set by the women; in 24% (5/21) of the studies, push notifications were sent by the researcher or HCPs [21,47,52,60,68], and in 14% (3/21) of the studies, women were emailed a reminder (internet-based programs) [6,56,58].

Self-monitoring was a feature in 61% (25/41) of the studies. Apps commonly enabled tracking of exercise progress by women, including a statistical function (eg, Tät) or graphs or the capacity to record exercise adherence over time (eg, number and level of exercises). This function was also available through a web portal [37,38,76], or training diaries were completed and sent via email [6]. Some technologies also included a bladder diary [58,60,71] to monitor urinary symptoms.

Social Media and Gamification

In total, 7% (2/28) of the DTs had the capacity for social media forums: the iPelvis, which included a website and Facebook page [11,57], and the iBall [67], which enabled women to connect with others in a web-based community (but it was disabled for the purpose of the study, as it was only available in Chinese).

A total of 21% (6/28) of the DTs incorporated gamification [36-38,48,57,67], which, with 1 exception [57], was used in conjunction with biofeedback. Descriptions of gamification included "serious games" [37,38], games or activities (eg, weight lifting room and flying arena) [67], and gaming and virtual reality mediated by a comic character [11,57] or a cyclist [36] with built-in scoring systems.

Technical Support

A total of 32% (13/41) of the studies offered instructions (eg, handouts and instructions via email) on how to download and install the app or use and effectively care for the equipment (eg, vaginal probes) [5,47,49,51,53,54,57,60,61,64,67-69].

Follow-up technical support was offered in 15% (6/41) of the studies by a research assistant [6,47,51,54,56,60] using encrypted email or via the app. A total of 10% (4/41) of the studies included in-person sessions with supervision or testing of the technology [36,43,62,76] by physiotherapists [36,43,76] or an unspecified individual [62].

PFMT in the Included Studies

Evidence Base

Just over half (21/41, 51%) of the studies provided some evidence base for the PFMT program that was being delivered via the DTs; in the remaining studies, this was not indicated or was unclear. Evidence for PFMT varied, ranging from existing programs tested in RCTs, including the seminal publication by Bø et al [119] and others later (eg, the *Group Rehabilitation Or IndividUal Physiotherapy for Urinary Incontinence in Aging*

Women [GROUP] trial [120]), to expert opinion [121], guidelines (eg, the National Institute for Health and Care Excellence) [122], and the Dutch clinical practice guidelines for the physiotherapy management of stress UI [123], with enhancements made based on feedback from clinicians, women, and researchers (eg, Tät).

Delivery of PFMT (Consensus on Exercise Reporting Template for PFMT Items 1, 2, 3, 4, and 12)

On the whole, women engaged with the DTs at home on an individual basis, with 22% (9/41) of the studies including exercise both at home and in a clinical setting [39,42,43,51,52,57,62,76] or community center [59] (Table 2; please note that, in some cases, the same DT was used across multiple studies). In 10% (4/41) of the studies, women also attended supervised group sessions once a week to undertake PFMT via teleconferencing [59], in person [52,57] with a maximum of 4 women per group [52], or specific to one of the study arms (app plus physiotherapy group) [57]. In the study by Pla et al [49], Skype was the medium for supervision of group-based hypopressive abdominal exercises 3 times per week (5-9 women per group), with women also receiving monthly individual videoconferencing sessions to check progress.

In addition to the 10% (4/41) of studies that provided supervision for women in a group setting [49,52,57,59], 34% (14/41) supported women on an individual basis. Examples included confirming a PFM contraction or PFMT practice [39,51] and checking women's adherence to the program [39]; providing a set number of supervised sessions over the duration of the program (which ranged between 1 and 12) either in person [42,76] or remotely via email [6,41], phone call [54], or videoconferencing [45]; and more intense supervision, such as five 30-minute sessions over 2 weeks [43] and daily sessions 5 days per week [62]. If women required extra support with PFMT-related content, this was offered through email [45,49,56] or the chat function on an app [54], with Anglès-Acedo et al [37,38] noting that their web platform enabled "personalised supervision."

Details of the personnel providing supervision or support for PFMT were reported in 18 studies, with 8 (44%) referring to a physiotherapist [49,57] who was specialized in women's or pelvic health [39,42,43,45,52,76]. In others, a nurse specialist [59], therapist [37,38], urogynecologist [61], urotherapist [6,41], general practitioner [56], trained researcher [51], trained research assistant [62], or trained study staff member [54] provided supervision or support.

Table 2. Summary of pelvic floor muscle training (PFMT) delivery and content.

Study[a]	DT[b]	PFMT evidence base	Individual or group PFMT and setting	Supervision of PFMT and qualifications	Confirmation of voluntary PFM[c] contraction	PFMT parameters	Duration of program
Anglès-Acedo et al [37,38]	Mobile app—WOMEN UP	NI[d]	Individual; home	Web platform; therapist	Biofeedback	NI	3 months
Araujo et al [39]	Mobile app—Diário Saúde	NI	Individual; home and clinic	In person, monthly; specialist women's health physiotherapist	Digital assessment; specialist physiotherapist	8-second hold, 8-second relaxation followed by 3 phasic contractions 8 times, 2 times per day (sitting, lying down, or standing)	3 months
Asklund et al [5]; Asklund and Samuelsson[e] [66]; Nyström et al[f] [73]; Rygh et al[f] [63]; Samuelsson et al[f] [50]	Mobile app—Tät	Yes	Individual; home	No; —[g]	No	Progressive PFMT (6 basic and 6 advanced levels), different combinations and repetitions of PFM contractions (strength and endurance, quick contractions, and the "knack"); advanced phase incorporates different positions (standing, lifting, and walking); strengthening: from a 5-second hold, 5-second relaxation 2 times (basic) to a 7-second hold, 7-second relaxation 40 times (advanced); endurance: from a 14-second hold once (basic) to a 59-second hold, 59-second relaxation 2 times (advanced); quick: from a 3-second hold, 3-second relaxation 5 times (end of the basic phase) to a 3-second hold, 3-second relaxation 20 times (advanced) 3 times daily	3 months
Wadensten et al [64]	Mobile app—Tät II	Yes	Individual; home	No; —	No	Progressive, 4 different PFM exercises are included across 8 modules based on the Tät [5], from 3 times per day for 2 minutes (module 1) to 3 times per day for 3-4 minutes (module 4) and 3 times per day for 12 minutes (module 8)	15 weeks
Bokne et al [41]; Sjöström et al [6]	Internet-based program—Tät	Yes	Individual; home	Email once per week plus support as needed; urotherapist	No	Progressive, tailored (in part) program with 8 levels, including the "knack"; strength: hold maximal contractions for 8 seconds, 8-10 repetitions, 3 times per day; endurance: hold submaximal contractions for 15-90 seconds, 1 repetition, 3 times per day; quick contractions: hold for 3 seconds, 8-10 repetitions, 2-3 times per day	3 months
Firet et al [56]	Internet-based program—Tät	Yes	Individual; home	Email support as needed; GP[h] in training or researcher	No	Progressive, 4 different PFM exercises are included across 8 modules based on the Tät [5], from 3 times per day for 2 minutes (module 1) to 3 times per day for 3-4 minutes (module 4) and 3 times per day for 12 minutes (module 8)	3 months
Barbato et al [40]	Internet-based program	NI	Individual; home	No; —	No	"Self-paced" PFMT, 10-15 minutes daily	3 weeks

Study[a]	DT[b]	PFMT evidence base	Individual or group PFMT and setting	Supervision of PFMT and qualifications	Confirmation of voluntary PFM[c] contraction	PFMT parameters	Duration of program
Campbell et al [42]	Mobile app—Squeezy App	NI	Individual; home and clinic	In person, ≤7 appointments (45-60 minutes) over 6 months depending on women's needs; specialist pelvic health physiotherapist	Digital assessment (crook lying) and specialist physiotherapist; biofeedback (standing)	Progressive, tailored PFMT (in different functional positions) for strength, power, endurance, and relaxation, and the "knack"; no specific details of the PFMT program	Phase 2: 6 months[i]
Robson [74]	Mobile app—Squeezy App	NI	Individual; home	—	—	NI	Survey, open for 3 months
Carrión Pérez et al [43]	Telerehabilitation device and vaginal probe	NI	Individual; home and clinic	In person, 5 times for 30 minutes over 2 weeks plus monthly follow-up; pelvic floor expert physiotherapist	Biofeedback	PFMT: five 30-minute sessions in the clinic (over 2 weeks) plus home exercise program; daily	3 months
Coggins et al [44]	Mobile app and vaginal device—Elvie	NI	Individual; home	No	Biofeedback	NI	NI
Conlan et al [45]	Telehealth	NI	Individual; home	In person, initial 1-hour session plus email support over 6 weeks[j]; continence physiotherapist	NI	Individualized PFMT	6 weeks
Cornelius [71]	Mobile app and vaginal probe—PeriCoach	NI	Individual; home	NI; pelvic floor clinicians (for some participants)	Digital palpation[k]; biofeedback	Dosage[k]: contraction, relaxation 5 times for 5 seconds, 10 repetitions, 4 times per day, 5 times per week	8 weeks
Shelly [76]	Mobile app and vaginal probe—PeriCoach	NI	Individual; home and clinic	In person, 6 sessions over 8 weeks; pelvic floor physiotherapy specialist	Digital assessment and specialist physiotherapist; biofeedback	Progressive, tailored, starting with contraction, relaxation 3 times for 8 seconds, 8 repetitions (20-25 repetitions per day; week 1); 5 times for 7 seconds, 8 repetitions (40-50 repetitions per day; week 2); 6 times for 3 seconds, 15 repetitions (week 5); 10 times for 3 seconds, 15 repetitions (week 8); supine, then standing; functional training with forward bending and during ADLs[l] 2 times per day, 5 times per week	8 weeks
Smith [53]	Mobile app and vaginal probe—PeriCoach	NI	Individual; NI	NI; NI	NI	NI	20 weeks
Dufour et al [67]	Mobile app and vaginal device—iBall	Yes	Individual; home	No; —	Digital palpation; specialist pelvic health practitioner	3 times, 10 sets of 10 exercises 3-4 times per week	16 weeks
Goode et al [58]	Web-based—My-HealtheBladder	Yes	Individual; home	No; —	No	Progressive, from contraction, relaxation 2 times for 4 seconds (week 1) to 5 times for 5 seconds (week 4), 9 times for 9 seconds, and 10 times for 10 seconds (week 8) plus bladder control strategies	8 weeks

Study[a]	DT[b]	PFMT evidence base	Individual or group PFMT and setting	Supervision of PFMT and qualifications	Confirmation of voluntary PFM[c] contraction	PFMT parameters	Duration of program
Han et al [72]	Mobile app—Bwom	NI	Individual; home	No; N/A[m]	No	Progressive, "personalized" exercise plans, each with 6-12 exercises, with a new exercise each week	2 weeks
Hui et al [59]	Videoconferencing	NI	Individual and group; home and community center	Weekly videoconferencing; nurse specialist assisted by a research assistant (registered nurse)	Digital assessment and nurse specialist; biofeedback	1 videoconferencing session per week	8 weeks
Jaffar et al [60]	Mobile app—KEPT[n]-app	Yes	Individual; home and clinic	No; —	No	Progressive, 3 training skills and modes (different positions): beginner (2-second hold), intermediate (6-second hold), and advanced (10-second hold); 10 repetitions, 3 times per day; adherence phase: once they can perform PFMT confidently, maintain 10 cycles, 3 times per day	At least 16 weeks[o]
Kinouchi and Ohashi [68]	Smartphone-based messaging system	Yes	Individual; home	No; —	No	Hold 3-6 seconds, 3 sets of 6 contractions per day; different positions (standing, bent-knee lying, and 4-point kneeling)	8 weeks
Fischer Blosfield et al [57]	Mobile app—iPelvis	Yes	Individual and group; home and clinic (depending on study group allocation)[p]	12 sessions once a week, in person, in a group; physiotherapist	All participants had "physical examination"; women who had difficulty contracting PFM had a vaginal examination, with instruction	App+physiotherapy: PFMT in a group once per week plus app at home App only: PFMT at home. Progressive and tailored, including strength, explosive strength, endurance, timing, precontraction, exhaustibility, coordination, and functional exercises (eg, sneezing and coughing); PFM contraction and relaxation in different positions, situations, and activities, 6 phases, each with a 15-day duration	3 months[p]
Mooss-dorff-Steinhauser et al [52]	Mobile app—iPelvis (in conjunction with the Motherfit program)	Yes	Individual and group; home and clinic	8 sessions in person (60 minutes) in a group (maximum of 4 women); specialist pelvic physiotherapist	Observation and digital assessment, supine; pelvic specialist physiotherapist	Progressive group program, including strength and endurance, speed, and functional exercises, and the "knack"; NI if the home program was the same; build up to 8-12 contractions, 6-8–second hold plus 3-4 fast contractions; strength and endurance: 3 times per day, daily (minimum of 3-4 times week); different positions (lying down, sitting, kneeling, and standing); after 6 months of training: maintenance 2 times per week; speed: fast repetitions, build up to 10 sets of 3 quick contractions and 10 sets of 5 quick contractions 3 times per day	8 weeks, continuing past 6 months of home training
Li et al [69]	Mobile app and audio guidance—Pen Yi Kang	NI	Individual; home	No; —	Digital assessment; experienced physiotherapist	NI	6 weeks

Study[a]	DT[b]	PFMT evidence base	Individual or group PFMT and setting	Supervision of PFMT and qualifications	Confirmation of voluntary PFM[c] contraction	PFMT parameters	Duration of program
Wang et al [51]	Mobile app and audio guidance—Pen Yi Kang	NI	Individual; home	In-person initial 45-minute session plus phone contact once a month; trained researcher	Digital palpation; surface EMG[q], supine, and hips and knees bent	Progressive, different positions (sitting, standing, and lying down); 3-second hold, 2-6–second relaxation for 15 minutes, 2 times per day or 150 contractions per day	3 months
Li et al [47]	Mobile app—UIW[r]	Yes	Individual; home	No; —	Perineum palpation, supine, and surface EMG in lithotomy position; experienced obstetrician	Adapted from Tät [5]; progressive, 2 basic and 4 advanced levels, including different combinations and repetitions of 4 commonly used contraction types: test contraction, strength contraction, endurance contraction, and quick contraction; up to each woman to determine use (frequency and duration)	8 weeks
Loohuis et al [61]	Mobile app—URinControl	Yes	Individual; home	No; —	Assessed according to the ICS[s]; urogynecologist	Progressive program, directed to appropriate part of the app to start training; no further information provided	4 months
Wessels et al [65]	Mobile app—URinControl	Yes	Individual; home	No; —	No	Progressive program, directed to appropriate part of the app to start training; no further information provided	—
Moretti [36]	Mobile app, vaginal probe, and surface electrodes—MyoPelvic	Yes	—	—	Biofeedback, maximal voluntary contraction, and supine; researcher	Phasic fibers: contract <4 seconds, relax for twice the duration of the contraction, 12 repetitions maximum (as dictated by the game); tonic (slow) fibers: contract 4-10 seconds, relax for the same duration, 12 repetitions maximum (as dictated by the game); 1-2–minute rest between games recommended but not enforced; muscle coordination training (not specified)	—
Pedofsky et al [48]	Mobile app and intravaginal pressure sensor array—FemFit	Yes	—	—	—	Progressive, graduated exercise; no further information provided	12 weeks
Pla et al [49]	Mobile app and vaginal device—Birdi	NI	Individual and group; home	Videoconferencing, 2 initial individual sessions 3 times per week in a group and monthly individual session plus email or phone support; physiotherapist	Measured by the device	Daily PFMT, tailored	2 months
Pulliam et al [62]	Mobile app and vaginal insert—Leva Pelvic Digital Health System	NI	Individual; home and clinic	In person, once a day, 5 times per week over 6 weeks; trained research assistant	Accelerometer-based system	15-second PFM contraction 5 times, 15-second relaxation, 2 times per day in standing position	6 weeks
Weinstein et al [54]	Mobile app and vaginal insert—Leva Pelvic Digital Health System	NI	Individual; home	3 phone calls in first 2 weeks plus support via the chat function; trained study staff	No	5 cycles of squeeze and lift, and 15 seconds of rest for 15 seconds each, 2.5 minutes 3 times per day	8 weeks

Study[a]	DT[b]	PFMT evidence base	Individual or group PFMT and setting	Supervision of PFMT and qualifications	Confirmation of voluntary PFM[c] contraction	PFMT parameters	Duration of program
Saboia et al [75]	Mobile app—Continence App	Yes	—	—	—	NI	12 weeks
von Au et al [70]	Mobile app—Pelvina	NI	Individual; home	NI; NI	No	NI	Survey, open for approximately 1 year

[a]Studies are ordered alphabetically by first author but grouped by app where relevant.
[b]DT: digital technology.
[c]PFM: pelvic floor muscle.
[d]NI: not indicated.
[e]Survey, open for 10 months.
[f]3 months of app use.
[g]No information provided.
[h]GP: general practitioner.
[i]3 phases to this study.
[j]None of the participants used the email option.
[k]As reported in the study by Starr et al [83].
[l]ADL: activities of daily living.
[m]N/A: not applicable.
[n]KEPT: Kegel Exercise Pregnancy Training.
[o]Start at 28-week gestation until delivery at 36 weeks and continue PFMT until 8 weeks post partum.
[p]6-month program=12 phases as per Latorre et al [11].
[q]EMG: electromyography.
[r]UIW: Urinary Incontinence for Women.
[s]ICS: International Continence Society.

Content of PFMT (Consensus on Exercise Reporting Template for PFMT Items 7, 8, 9, 13, 14, and 15)

Confirmation of a voluntary PFM contraction was undertaken in just under half (19/41, 46%) of the studies and was either not included in the study design in 41% (17/41) of the studies or not indicated or appropriate (5/41, 12%). Confirmation was obtained through digital assessment [39,57,61,69], which was also used to teach a correct contraction or relaxation of the PFM [52,67]; biofeedback or the digital device [36-38,43,44,49,62]; or a combination of both [42,47,51,59,71,76]. Digital assessment was undertaken by a specialized HCP, although it was not indicated who performed this procedure in 7% (3/41) of the studies [51,57,71]. In the RCTs that used digital assessment, this was provided to all women across all the study groups.

A total of 49% (20/41) of the studies offered PFMT programs that were progressive in terms of content or position. Although most programs were generic, 10% (2/20) were tailored to the individual by provision of supervision [49,76], and another 15% (3/20) provided some indication or tailoring of the starting level for PFMT [61,64,72].

The details of the PFMT content were not indicated in 34% (14/41) of the studies, whereas the rest used a combination of strength, endurance, and power exercises; relaxation; or a combination of these. Direct PFMT, together with functional PFMT (eg, the "knack"), was included in 29% (12/41) of the studies [5,6,41,42,50,52,57,63,64,73,76,78], and it is likely to have been integrated into another 5% (2/41) of the studies that were based on the Tät [47,56].

Of the 19 studies that provided details about the prescribed dose, 14 (74%) recommended PFMT 3 times a day [5,6,41,47,50,52,54,56,60,63,64,68,73,78], 4 (21%) recommended PFMT twice a day [39,51,62,76], and 1 (5%) recommended it 4 times a day [71]. The most common program duration was 3 months (17/41, 41% of the studies) [5,6,37-39,41,43,50,51,56,57,63,66,73-75,84], followed by 2 months [47,49,52,54,58,59,68,71,76], with others spanning 2 to 6 weeks [40,45,62,69,72] or >15 weeks up to 6 months [42,53,60,61,64,67] to 1 year [70]. It should be noted that women in the study by Moossdorff-Steinhauser et al [52] continued exercising at home for at least 6 months after the end of the 8-week group exercise PFMT, and the 16 weeks specified by Jaffar et al [60] were the minimum program duration.

Adverse Events (Consensus on Exercise Reporting Template for PFMT Item 11)

A total of 20% (8/41) of the studies documented adverse events [6,36,37,43,52,54,62,64]. Adverse effects were reported in 12% (5/41) of the studies, none of which were deemed serious. Some examples include vaginal discomfort, infection, or allergic reactions related to the use of the vaginal device [37,43]; lower abdominal pain related to PFMT [6]; and increased spontaneous urine leakage [64].

Treatment Fidelity (Consensus on Exercise Reporting Template for PFMT Item 16)

A total of 5% (2/41) of the studies, both of which were protocols [47,60], assessed the implementation of the intervention. The methods used included monitoring participant activity and training time through the app [60], tracking technical support provided, consultation support, and reminders sent to women who had not used the app over the previous week [47].

UI Outcomes

UI outcomes following DTs were presented in 56% (23/41) of the studies (Table S1 in Multimedia Appendix 4 [5,6,39-41,43-45,49-51,53,57-59,61-64,67,68,73,76]), with improvements reported across measures in all but 1 study (within groups; 22/23, 96% [68]). All studies (23/23, 100%) analyzed changes in UI symptoms and severity or general or UI-specific QoL as measured through self-reported questionnaires, UI episode frequency, pad weight tests, or UI aid use.

Adherence to the Program

A total of 61% (25/41) of the studies indicated methods for evaluating adherence, with some (9/25, 36%) using more than one approach (Table S2 in Multimedia Appendix 4 [5,6,37,39,41-44,47,50-52,54,56,58,60,61,63,64,67-69,71,73,74]). In total, 72% (18/25) of the studies gathered data from the DTs themselves [5,37,39,42,43,47,51,52,54,56,58,60,61,64,67-69,79], 48% (12/25) used self-report via email [6] or a web- or app-based questionnaire [5,41,44,50-52,61,63,64,74,79], and 4% (1/26) included in-person appointments [42].

A total of 68% (17/25) of the studies provided data following completion of the program. Women in 76.4% (13/17, 50%) of these studies provided a self-report of adherence to the prescribed PFMT, which was measured and reported in a variety of ways—visual analogue scale [39], validated questionnaire to assess efficacy [51], number of exercises completed over specified time points (eg, in the last month or last week, daily, weekly, or monthly) [5,41,44,50,58,63,74,79], or percentage of women who performed PFMT [37,68] or adhered to the program [58] or some of the program [85]. Self-reported daily PFMT for women using DTs ranged from 23.4% to 41% over 3 months [5,63].

Performance of PFMT was also captured via the DTs in some studies (9/25, 36%), including measures of how often the app was used (eg, never, once a week, and >3 times per week) [50,61,63,64,69], mean number of exercises performed per day (1.6 [5]), median number of days PFMT was performed per week (4.9 [43]), and percentage of women who completed at least 75% of the study requirements for the program (14.4% [85]).

Two studies compared adherence to the DTs with a control group. Adherence was significantly higher (P<.001) in the group using the DTs at 1, 2, and 3 months [39], but there was no difference (P=.40) reported between the groups in the study by Carrión Pérez et al [43].

Satisfaction With DTs and Outcomes

A total of 63% (17/41) of the studies considered satisfaction with the DTs, including reporting on experiences with specific aspects (eg, PFMT, exercise logs, reminder features, and ease of accessing videos or instructions) [5,36,37,39,40,44,45,52,54,59,60,62,64,67,72,74,75] (Table S2 in Multimedia Appendix 4). Although a range of different outcome measures was used, it appears that most participants were satisfied with the DTs and would recommend them to others. An exception was the study by Dufour et al [67], in which only 18.2% (2/11) of the women would recommend the mHealth device or consider using it again; however, this response increased to 63.6% (7/11) if the device were to be modified.

Satisfaction with the program as a whole, or self-reported improvement, was reported in 27% (11/41) of the studies [5,6,40,43,44,49,52,54,58,64,71]. Responses varied with respect to overall satisfaction, ranging from not satisfied (6% in the study by Goode et al [58] and 33% in the study by Wadensten et al [64]) to somewhat satisfied (75% in the study by Goode et al [58]) and completely satisfied and symptom-free (7% in the study by Wadensten et al [64]). Although satisfaction in the study by Sjöström et al [6] was higher in the intervention (app) group at 4 months, there was no significant difference at the 1- and 2-year follow-ups; no difference between groups was reported by Carrión Pérez et al [43]. Self-reported improvement in symptoms was variable, with <25% of the women in 18% (2/11) of the studies [40,44] reporting that they were much or very much better (10.3%-23.5%) with respect to symptoms, but more women (55.7%) reported the same for self-perceived improvement in PFM strength [5].

Qualitative Synthesis: Experiences of Women and HCPs

The summary data from the completed qualitative or mixed methods studies (11/45, 24%) are presented in Multimedia Appendix 5 [31,38,42,46-48,65,67,77,78,80,86,87]. In almost all the studies, the same factors were presented as both facilitators and barriers. This demonstrates that preference for or against any given DT may be related to the individual and that personal preferences can change over time.

The results demonstrated some overarching facilitators. Participants liked the anonymity that DTs provide for the treatment of UI symptoms [31,38,46,65,86,87]. Several studies (6/11, 55%) discussed that UI is still considered a socially “taboo subject,” a topic that women can find difficult to acknowledge to themselves, let alone discuss with an HCP [31,65,77,80,86,87]. Being judged or feeling embarrassed to discuss UI was a common finding, and the opportunity to access DTs provided women with a viable, accessible, and potentially less time-consuming alternative means of seeking support [31,38,46,48,65,77,78,80,86,87]. Furthermore, the ability to use an app in the convenience of their own environment facilitated empowerment, confidence, and self-efficacy regarding the ability to manage their UI symptoms with PFMT exercises [31,38,46,48,65,77,78,86,87].

All studies (11/11, 100%) demonstrated that the knowledge content across the various apps was helpful. Knowledge included gaining a better understanding of the causes of UI, where PFMs are and what is their function, and the fact that UI is a common problem. In total, 18% (2/11) of the studies [65,87] reported that women felt less isolated after learning about the prevalence of UI.

DTs were considered successful by participants if an improvement in UI symptoms was observed [31,67,78,86,87]. Participants were reported to be more adherent when UI symptoms were more severe [31,86,87] and less adherent to PFMT as UI symptoms improved [31,65,78,86,87]. However, other personal and technological factors also influenced adherence to the various PFMT programs and, thus, UI symptom outcomes. These included the needs of other family members, especially for new mothers; concomitant health issues; and other life events [31,65,78,80,86,87].

Establishing a routine; the use of reminders, journals, and diaries; and family support went some way toward mitigating these barriers [31,46,77,78,86,87]. Although some HCPs expressed concerns about the ability of older women to use DTs [80], the studies in this review suggest that the competing time pressures experienced by women with young families, especially if they were working, were more of a barrier [31,65,67,87]. Culture was not discussed in any of the studies, so it is unclear whether the same facilitators and barriers apply across all cultures and ethnic groups.

Another common finding across the studies was concern about the ability to "correctly" contract the PFMs. Although the concept of an internal exam to determine a "correct" contraction was not always appealing [65], being unsure of whether the exercises were being performed correctly was a barrier to adherence [31,46,65,77,78,80,86,87]. Consequently, several studies (8/11, 73%) [31,46,48,65,77,78,80,87] suggested that engagement with HCPs, perhaps for an initial assessment and then for progression at a later point in time, was an important facilitator. Other studies found that HCP consultations were required to support adherence and provide encouragement and progression of PFMT in addition to the benefits of DTs [31,86]. Both consultations with HCPs and DTs (if from a recognized institution, such as a university) reassured participants that the information they received and the PFMT program they were trying were from a credible source [31,77].

As per the results in Multimedia Appendix 5, technology that was easy to set up, insert (if applicable), comfortable, and portable was more acceptable to participants [31,38,46,48,67,77,78,87].

Discussion

Principal Findings

This systematic scoping review was undertaken to explore the range and features of DTs available for managing UI. Specifically, we sought to determine whether the PFMT embedded in DTs follows best-practice guidelines, is designed for women at specific stages in life, and considers cultural contexts and the experiences of women and other relevant stakeholders.

It is evident that the medium of DT for the conservative management of UI is prevalent and continually expanding, with rapid growth apparent particularly over the last 10 years. In total, 89 studies were included in this scoping review—51% (45/89) were primary studies and 49% (44/89) supplementary papers—which is larger than the number (between 3 and 10 papers) included in several recent narrative and systematic reviews in this field [7,8,18-21,124,125]. This difference likely reflects variations in inclusion and exclusion criteria, which in this study were intentionally broad so as to encompass a range of sources, including qualitative research.

The WHO global strategy on digital health stipulates that DTs should be "people-centred, trust-based, evidence-based, effective, efficient, sustainable, inclusive, equitable and contextualised" [126]. In terms of the evidence-based dimension, it is encouraging that over half of the DTs (22/41, 54%) were developed based on evidential research or testing. The means of achieving this varied across the studies, but most adopted an iterative process of continuous testing, implementation, and refinement. IT input is obviously integral to the development of DTs, but importantly, a number of studies in this review took a user-centered approach by seeking the opinions of women with or without UI and, in some cases, HCPs who may be involved in a woman's care. Considering users' opinions, needs, and expectations at all stages of DT design is not only endorsed by the WHO [126] but is also vital in optimizing the usability and acceptability of the DTs and their adaptation to ensure effectiveness in outcomes [127]. Some studies (4/41, 10%) adopted a theoretical user-centered framework to guide the design of the DTs [47,48,56,60], and standardization and use of such frameworks by future developers will assist in continued improvements in the quality of DT apps specifically for PFMT, which could ultimately enhance the conservative management of UI.

Free and commercial PFMT apps are readily available for download from app stores, but only some are clinically sound from a PFMT perspective [128], with many lacking in terms of accuracy, content, quality, and functionality [10,128-130]. Just over half (21/41, 51%) of studies documented that the PFMT programs were drawn or adapted from a known evidence base, which suggests that they are in line with the recommendations of PFM exercise theory that lead to improvements in UI symptoms [122,131]. However, there was a large variation in the PFMT reported, including the type of exercise, dose, frequency, progression, and supervision, and some PFMT details were often incompletely reported (particularly in abstracts, which is to be expected). In addition to details about PFMT, other items in the Consensus on Exercise Reporting Template for PFMT guidelines [28] were also inconsistently adopted across the studies—less than half incorporated confirmation of a voluntary PFM contraction (19/41, 46%) or reported on adverse events (8/41, 20%) or treatment fidelity (2/41, 5%), whereas just over half used reminder systems available with the DTs (21/41, 51%). From a technological perspective, some of these items, such as reminders (eg, individualized push notifications), and other features, such as social media and gamification (used in 2/28, 7% and 6/28, 21% of the studies, respectively), are suggested to be important in supporting adherence to mHealth [11,132] and are worth considering for future DTs.

As shown across a range of studies, using DTs to deliver PFMT can be effective in improving UI symptoms and QoL. In the 56% (23/41) of the studies that reported outcome measures, improvements were seen across most outcome measures for women using DTs and, in the case of comparison groups, often for those who were receiving PFMT via an alternative method (eg, pamphlet or usual care). Many of the outcome measures were self-reported, which is appropriate, as the lived experience of women is of interest. As the qualitative data show, aspects such as convenience and reduction in symptoms were of most relevance, which reinforces the need for future studies to include qualitative components to determine relevance to the primary end user. Women's satisfaction with the program as a whole, as documented in 27% (11/41) of the studies, was variable in terms of outcome measures and data but was likely closely connected with UI outcomes. For example, in an RCT [6], the satisfaction of the women using the app was higher than that in the control group (printed PFMT) at 4 months, aligning with a significant improvement in UI symptoms; however, there was no difference between the groups at the 1- and 2-year follow-ups [88], when the effectiveness of the intervention had also waned, as had adherence to the prescribed intervention program. These findings suggest that PFMT delivered via DTs is promising as a first-line conservative management for UI, but more high-quality research, which includes long-term follow-up, is required.

There was heterogeneity in the definitions of adherence used by the studies included in this review and the methods (eg, DTs and web-based questionnaires) and measurements used to monitor this. In addition, reporting of adherence data was variable with little standardization, making comparison difficult. Among the 2 RCTs that measured adherence, in 1 (50%; 21 women), adherence was significantly better in those who used an app in the short term (up to 3 months) [39]. However, no difference was found in UI symptoms between groups, consistent with the findings of the other RCT that compared telerehabilitation and control [43]. A known problem with app use is attrition after they have been downloaded. Examples from other areas of health research suggest that approximately 20% to 25% of apps are used only once or infrequently, with use dramatically reducing to <5% over a short period (eg, 8 sessions or 15 days) [132,133]. The self-reported daily PFMT for women using DTs ranged from 24.3% to 41% over 3 months [63,79], but no long-term data were available to determine whether this followed a downward trend. There is a plethora of research that demonstrates that managing a long-term condition with regular commitment to exercise is difficult irrespective of the condition [134,135]. Therefore, factoring this typical type of human behavior into PFMT programs delivered via DT, providing reassuring statements regarding the fact that this is typical, being kind to oneself, and knowing how to start again, would be beneficial.

Other suggested benefits of using remote or app-based technologies to deliver PFMT include helping women overcome their embarrassment about seeking help for UI, improving access to health services in remote or underdeveloped areas, and enhancing cost-effectiveness [46,61,82,136]. Although using DTs in isolation may be beneficial, personal or HCP support is also recommended [11,132]. This approach aligns with best-practice guidelines for effective PFMT [122], with supervision provided to support the behavioral aspect of exercise. In this review, many studies (18/41, 44%) incorporated HCP or researcher support either synchronously (eg, in person or remotely) or asynchronously (eg, email contact), ranging from confirmation of a PFM contraction to constant monitoring of progress across the course of the program. A notable feature from the synthesis of findings from the included qualitative studies was that engagement with an HCP was an important facilitator, not only to support adherence and progression of exercises but also because women valued knowing that they were performing the PFM exercises correctly and expressed concern if they were unsure about their technique [31,46,48,65,77,78,80,86,87]. This concern is valid as inadvertently performing an incorrect PFM contraction, such as the Valsalva maneuver, could result in an increase in intra-abdominal pressure, leading to depression of the levator ani muscle and weakening of the surrounding connective tissues, which may inadvertently increase UI [137].

Interestingly, group-based supervised PFMT (either in person or remotely) was offered in 10% (4/41) of the studies [49,52,57,59]. Although results related to improvements in UI outcomes in these studies were mixed, a recent large RCT has shown that group-based PFMT is not inferior to individually supervised PFMT in older women in the treatment of UI, with both groups also undertaking a home exercise program [138]. It is known that peer support is a key strategy to help with long-term self-management as it can facilitate individual problem-solving and goal setting, which can aid with self-efficacy [139,140]. This indicates that a group-based approach to exercise likely offers further advantages to women, such as enhanced motivation to perform PFMT and reduced stigma and feelings of isolation [141]. Given the large variation in the types and levels of support and supervision currently provided for PFMT delivered via DTs, further information is needed to establish what represents best practice in terms of integrating supervision to optimize women-centered care and UI outcomes.

Culture plays a role in how women interact with DTs [15,16], perceive UI [17,142,143], and engage with PFMT and should be taken into account when designing mHealth interventions to encourage use and enhance motivation [16]. Incorporating cultural characteristics into DTs includes considering not only the user's needs and preferences related to functionality (eg, color, typeface, and layout) but also more implicit aspects such as values, health beliefs, religion, social practices, and language [144,145]. In this scoping review, most DTs originated in high-income countries such as the United Kingdom and the United States and most likely targeted the dominant culture. This is also exemplified by the finding that only 4% (2/45) of the primary papers were written in a language other than English [35,36]. However, some apps (the Tät in particular) have been translated into a number of different languages, and research teams have also sought user input to refine them further [56,63,78], processes that are some of several different methods to enable cultural relevance [144]. The iPelvis app [11,57] explicitly incorporates culturally relevant elements, and although these may be features of other DTs included in this scoping review, they were not described. It cannot be assumed that PFMT DTs developed in one culture and translated for use in another will be successful without consulting the cultural context of the women who will use it [146], meaning that user engagement is successful in its success. Therefore, to meet the remit of inclusive and equitable DTs [126] and reach women in low- and middle-income and remote countries, more understanding is needed of what culturally related insights are required to increase the acceptability of and engagement with these technologies [146].

Many studies (28/45, 62%) did not explicitly document information related to the delivery of PFMT via DTs for women at a specific stage in life. Of those that did, most focused on pregnancy or the postpartum period, a time when UI is highly prevalent, with a risk that it could persist and become a long-term condition in some women [1]. During the childbearing years, women experience competing interests for their energy and time, such as preparing for or caring for their new baby, which means that it is vital that they receive sufficient support to adopt and maintain PFMT [67,147]. Engaging with an HCP in conjunction with using DTs was identified as an important facilitator to support PFM exercise (physical and behavioral aspects) [31,46,48,65,77,78,80,87], and there is evidence demonstrating that starting PFMT in early pregnancy may reduce the risk of UI later in pregnancy or up to 6 months post partum [4]. However, pregnant or postpartum women might not seek help from an HCP as they may feel embarrassed about their UI symptoms [148] or think that UI is a “normal” occurrence before and soon after childbirth [149]. In these instances, DTs provide a convenient tool that can support and motivate women to exercise [11,132] in the comfort of their own environment, facilitating empowerment, confidence, and self-efficacy with PFMT [31,38,46,48,65,77,78,86,87]. An additional avenue for support could be further developing and integrating social media into DTs, enabling pregnant and postpartum women to connect with each other as well as with HCPs. In general, more evidence is required to establish the acceptability, design, development, and effectiveness of PFMT DTs across various age ranges, including both adolescent and older women, to ensure that the programs meet women’s needs and circumstances. However, HCPs should have some confidence integrating DTs for PFMT into their practice as, in partnership with a clinician, this may offer women another tool in the management of UI symptoms.

Limitations

As this scoping review included a wide range of studies and a variety of DTs, heterogeneity was evident across many study parameters, including the PFMT programs and UI outcomes, and the duration of the trials was relatively short, demonstrating the need for longer follow-up and high-quality data in this developing field of research. Biofeedback is broadly considered a DT; however, we only included studies that provided feedback to women via an app, meaning that we did not capture valuable data from trials of biofeedback that did not have this feature [150,151]. Many studies were from high-middle–income urban settings, which restricts the diversity of the target populations despite one of the benefits of mHealth being its ability to reach a range of people, including those in remote areas [61,82,136]. This review considered women with stress UI and, therefore, did not explore the impacts of PFMT DTs on other conditions or populations, such as urge UI or pelvic organ prolapse or men. As described previously, owing to the large volume of data, we were unable to implement some elements of our a priori protocol, such as synthesizing data from systematic reviews and rating the quality of the apps used in the included studies. Owing to space limitations, we were only able to present the themes most coherently relevant to the scoping review objectives, and in our synthesis, we did not consider how the quality ratings (high, fair, and poor) influenced the data.

Conclusions

Evidence related to PFMT delivered via DTs for the conservative management of UI continues to grow exponentially. The development of DTs specifically for this purpose is increasingly based on evidential research or testing, including the exploration of the perspectives and experiences of women and HCPs. Although large variation exists in the reported PFMT parameters, PFMT delivered via DTs is promising in terms of improving UI symptoms and QoL. To further optimize UI outcomes and promote long-term adaptation of PFMT, incorporating technological features such as reminders, social media, and gamification, together with other facilitators such as support from HCPs, could be beneficial for women with UI. A greater understanding is required of how women from different cultures and stages in life regard the acceptability, design, development, and effectiveness of PFMT DTs. This is essential to ensure that the quality and content are appropriate and inclusive so that all women and clinicians can have confidence in using these technologies.

Acknowledgments

The authors wish to sincerely thank Mrs Thelma Fisher for her assistance in developing the systematic search strategy and the Health Research Council of New Zealand (Health Delivery Research Activation Grant; reference 20/1325) for its support in funding this project.

Authors' Contributions

SJW, MDB, ARC, and JK were responsible for the conceptualization and design of this study. BS developed the search strategy and performed the database searches. Literature screening, data extraction, and quality ratings were completed by MDB, ARC, JK, BM, BS, and SJW; data synthesis and analyses were performed by BM, BS, MAP, and SJW. SJW drafted the manuscript with contributions from BM and MAP. All authors critically revised and approved the final manuscript.

Conflicts of Interest

JK is the chief executive officer of Junofem, which has developed FemFit, one of the apps reviewed in this study. She had no role in the data extraction or analyses of data related to FemFit. The authors have no other conflicts of interest to declare.

Abstract

Background: The use of physical activity (PA) electronic devices offers a unique opportunity to engage children and adolescents in PA. For this age group (2-17 years), parents play a key role in promoting healthy lifestyles and regulating the use of electronic devices. Therefore, parents' perceptions of the use of electronic devices for PA in children and adolescents are critical for efficient intervention.

Objective: The aim of this qualitative systematic review was to improve the understanding of parents' perceptions of the use of electronic devices for PA in children and adolescents.

Methods: A systematic search of electronic databases (Medline/PubMed, SPORTDiscus, Web of Science, Scopus, OpenGrey, and Deep Blue) was conducted. Studies from inception (2010) to May 2022 were identified. Qualitative studies on the perceptions of healthy children's and adolescents' (aged 2-17 years) parents regarding PA interventions performed on electronic devices were included according to the Cochrane Qualitative and Implementation Methods Group Guidance Series and the Enhancing Transparency in Reporting the Synthesis of Qualitative Research (ENTREQ) statement. The Joanna Briggs Institute Qualitative Assessment and Review Instrument was used for methodological validity.

Results: In total, 18 studies with 410 parents, mostly mothers, were included. Parents' perceptions were grouped into 4 categories: usefulness, advantages, general perceptions (electronic devices for health promotion, preferences for real-life PA, and concerns), and acceptability (barriers and facilitators) of electronic devices for PA. Parents perceived electronic devices as useful for increasing PA, learning new skills, and increasing motivation for PA and valued those devices that promoted socialization and family and peer bonding. In terms of general perceptions, parents had positive attitudes toward PA electronic devices; however, they preferred outdoor and real-life PA, especially for preschoolers and children. Concerns, such as physical and psychological harm, addiction, conflicts, and compliance difficulties, were found. Facilitators were identified as ease of use, appropriate feedback, promotion of socialization, and motivational strategies, such as rewards, challenges, and attractiveness. Barriers, such as discomfort, price, and difficulties in using or understanding electronic devices, were also identified. For older children and adolescents, parents were more concerned about high levels of screen time and setting limits on electronic devices and therefore preferred PA electronic devices rather than traditional ones.

Conclusions: Overall, the participants had positive attitudes toward electronic devices for PA and perceived them as an effective way to promote PA in children and adolescents. They also perceived several benefits of using electronic devices, such as health promotion, increased awareness and motivation, and socialization, as well as barriers, facilitators, and age differences. The results of this study could provide researchers with insights into designing more effective, age-appropriate PA electronic devices for children and adolescents and improving adherence to their use.

Introduction

Currently, smartphones, tablets, computers, and apps that run on electronic devices have become part of the everyday life of children and adolescents [1]. Most parents allow their children to use their smartphones to play games or watch videos, and almost all children start handling electronic devices before the age of 1 year [2]. In addition, 73% of parents with children aged 9-11 years say that their children use a computer, 68% say that they use gaming devices, 67% say that they use a smartphone, and 78% say that they use a tablet [1]. There are substantial age differences in the use of electronic devices, and usage increases with age, being higher in adolescents, with most of them reporting using electronic devices daily or almost all the time [3]. Traditionally, research on the use of electronic devices has focused on its association with sleep problems, sedentarism, and overweight/obesity [4]. However, with the growth in technology, the use of eHealth (ie, electronic devices with health-related purposes [5], including physical activity [PA] and fitness apps), has increased [6].

Some advantages of using electronic devices to implement PA interventions are that these programs are more flexible, can be tailored to individual needs, and can be delivered anywhere at any time compared to traditional PA interventions [7]. Moreover, electronic devices might make PA more attractive to children and adolescents [8], as well as having other advantages, such as low cost, empowerment of participants, exposure to new information, increased opportunities for social contact, and new opportunities to access health promotion programs [9]. The potential role of apps in improving PA across children and adolescents has been suggested [10], but evidence of the efficacy of PA apps for this age group is still scarce [10,11]. Thus, more research on electronic devices to promote PA in children and adolescents is needed.

Furthermore, early habits track from childhood through adolescence to adulthood [12], making early childhood a crucial period for the acquisition of habits, such as PA. In addition, parents' behaviors related to PA have been shown to be associated with their children's health behaviors [13]. Previous research indicates that PA programs that include families are more effective in increasing PA in children [14,15]. Moreover, a meta-analysis by Hammersley et al [16] suggested that eHealth interventions might be more successful when parents are involved as agents of change. Not only health-related behaviors but also screen time and electronic device access and use depend on the individual's family [17]. Additionally, parents' attitudes toward electronic devices are associated with different regulation practices, depending on age and the time spent using electronic devices from childhood through adolescence [18]. All these results recommend parents' involvement in eHealth interventions [19], with the family being a key intervention target [20]. Finally, from a qualitative perspective, Burrows et al [21] found that most parents are interested in an online eHealth family program and that they feel that important features of the program should be easy to use, engaging, and endorsed by a reputable source and should involve their children directly.

To examine the feasibility of PA interventions delivered through electronic devices, before implementing the interventions, it is critical to understand parents' perceptions of the interventions because parents' engagement in these activities is a key factor for their success in children [21] and in the regulation and mediation practices that control electronic device use in adolescents [22]. However, to date, no reviews have focused on parents' opinions and perceptions of eHealth to promote PA in children and adolescents, although this knowledge might be relevant for the design of both PA electronic devices and effective interventions. The aim of this systematic review of qualitative evidence is to increase the understanding of parents' perceptions of electronic device–based PA interventions in children and adolescents.

Methods

Overview

This review was conducted according to the Cochrane Qualitative and Implementation Methods Group Guidance Series [23] and the Enhancing Transparency in Reporting the Synthesis of Qualitative Research (ENTREQ) statement [24]. The review protocol was registered in PROSPERO (CRD42021292340).

Eligibility Criteria

Studies were eligible for inclusion if they reported qualitative research analyses of the use of electronic devices for PA in healthy children and adolescents. In this study, electronic devices were defined as tools that can receive, store, process, or send digital information, including computers, tablets, smartphones, smart or electronic watches, and virtual reality devices [25]. Studies using qualitative designs with any of the following data collection procedures were eligible for inclusion: interviews, focus groups, or other qualitative data collection procedures, such as observation. Mixed methods studies were included when quantitative and qualitative data were separately reported; however, only data on qualitative analyses were considered. There are different types of electronic devices (ie, activity trackers, video games, smartphone apps) for direct use by children, for use by parents to enhance their children's PA, or for use by both together.

Studies were excluded if (1) parents were not directly asked; (2) PA interventions referred participants to rehabilitation programs or facilities; (3) populations had developmental disabilities, developmental delays, or cognitive impairment; (4) the electronic device was not designed for use by children or adolescents or for interactive use by parents and children (eg, electronic devices for parents' use only); and (5) the study was a protocol, review, or meta-synthesis.

Search Strategy

Two authors (MVA and ARH) independently identified qualitative studies published from the beginning (in 2010) up to May 2022, reporting parents' perceptions of PA electronic devices. The research objective was addressed with the question framework PerSPecTIF proposed by Booth et al [26]. Both authors systematically searched Medline/PubMed, SPORTDiscus, Web of Science, and Scopus using a search strategy that combined 5 different concepts: "electronic devices," "physical activity," "parents," "qualitative research," and "children and adolescents." The free-text terms and Medical Subject Headings (MeSH) terms used to search were restricted to titles/abstracts. Searches for gray literature (eg, unpublished studies) were conducted using OpenGrey and Deep Blue. In addition, the 2 authors screened the reference lists of the papers included. The complete search strategy is presented in Multimedia Appendix 1.

Study Selection

Search terms were entered into each database, and duplicates were removed. The titles and abstracts retrieved were independently assessed for eligibility for inclusion in the review by 2 authors (MVA and ARH) and coded as "yes," "no," or "maybe." The 2 authors were trained regarding study inclusion/exclusion criteria before completing the coding of abstracts. Any disagreements between the 2 authors were resolved through discussion, and if disagreement persisted, a third author (MSL) was consulted.

Assessment of Methodological Quality

Papers selected for inclusion were assessed by 2 authors (MVA and MSL) using the 10-item checklist of the Johanna Briggs Institute Qualitative Assessment and Review Instrument (JBI-QARI) [27] for methodological validity prior to inclusion in the review. All items in the checklist were ranked as "yes," "no," or "unclear." Finally, each study was rated overall as "included," "excluded," or "seeking further info" [27]. Studies meeting more than 7 items were rated as "included," studies with items rated as "no" or "unclear" were rated as "seeking further info" and protocols, and corresponding authors were consulted. Studies meeting less than 5 items were rated as "excluded" and removed from the study. Any disagreements between the 2 authors were resolved through discussion, and a third author (BRM) was consulted if disagreement persisted.

Data Abstraction

Qualitative data were extracted by 2 independent authors (MVA and MSL). Both authors read the papers and extracted key themes and concepts. These were compared, and any differences were resolved through discussion. The following data were extracted from all eligible papers: authors and context, year of publication, location, paradigmatic approach, method of data collection and analysis, data analysis software, participants' background, sample size and age, recruitment location and method, study aims, intervention or exposure, and main results.

Data Analysis and Synthesis

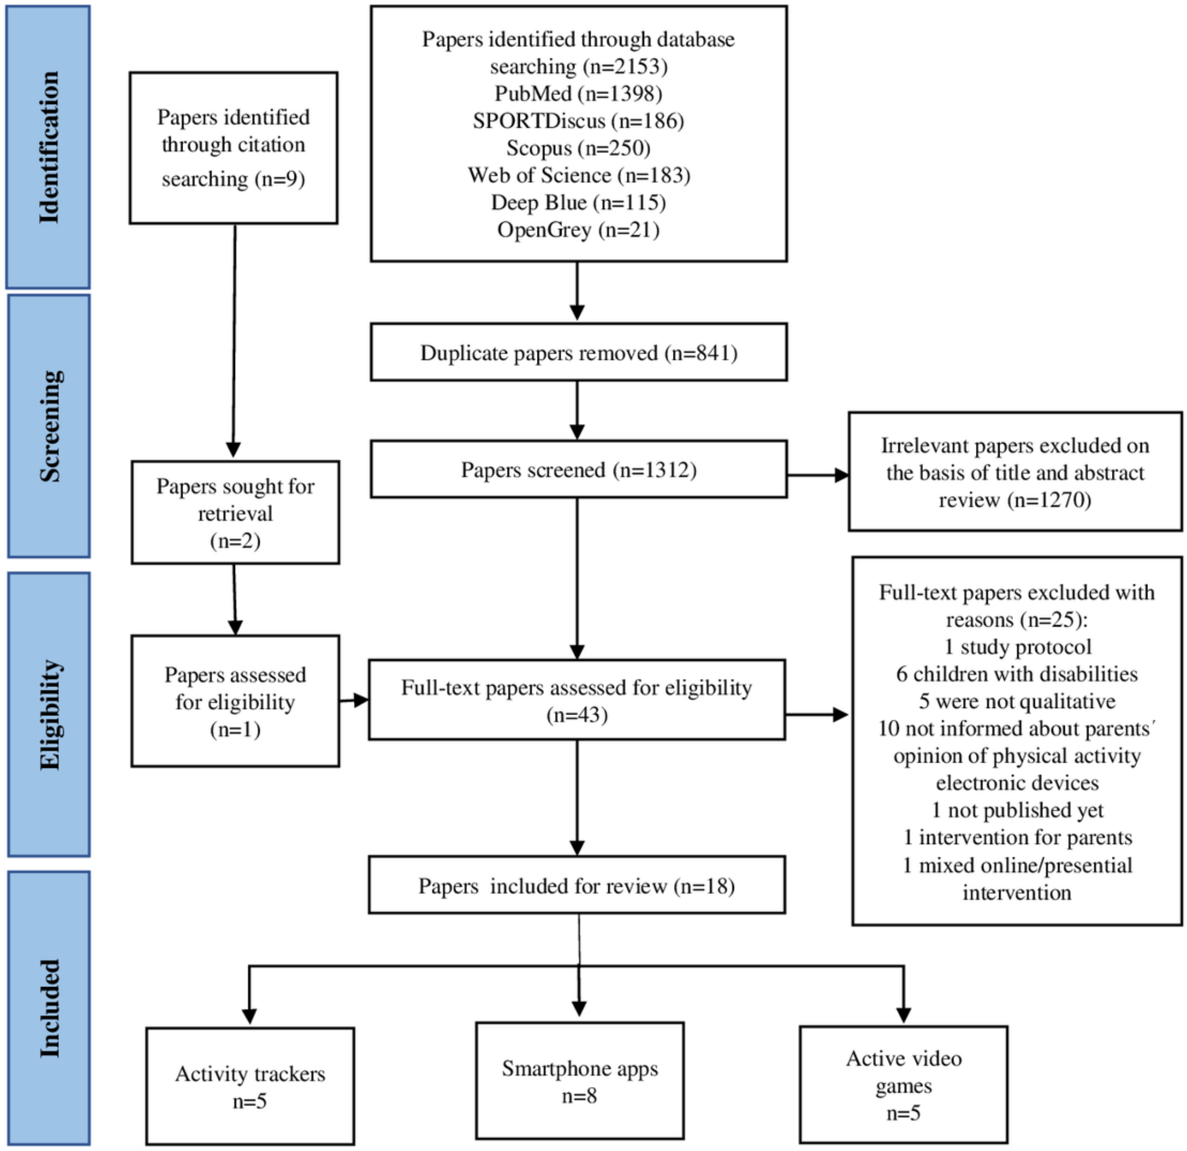
First, 2 authors (MVA and MSL) read the papers, extracted key themes and proofs (transcriptions of parents' verbalizations), and generated categories. A third author (BRM) was consulted if discrepancies arose. Differences were solved through discussion until agreement was reached. To identify common themes and analyze meanings, the meta-aggregation approach [28] was used. This process identifies meanings and common themes in qualitative studies using different methodologies and further extracts those meanings into categories that are then synthesized [29]. Next, MVA synthesized the key themes, meanings, and proofs (transcriptions of parents' verbalizations) into tables.

Results

Study Selection and Characteristics

The electronic search retrieved 2153 records. After the removal of duplicate studies, 1312 (60.9%) papers were reviewed based on the title and abstract. Following this, the full texts of 43 (3.3%) studies were reviewed; 1 (0.1%) additional study was identified after screening the reference lists of eligible papers. Finally, 18 (41%) eligible papers were included using the selection process shown in Figure 1.

Figure 1. Flowchart of search and selection process.



The 18 studies selected were published between 2010 and May 2022 and included 410 parents, mostly mothers, of 2-17-year-old children and adolescents (Tables 1-3). Of the 18 studies, 5 (28%) analyzed preschool children, 7 (39%) analyzed school children, 3 (17%) analyzed adolescents, and 3 (17%) did not provide separate results for children and adolescents. For data collection, 12 (67%) studies [30-41] used focus groups with semistructured interviews, 7 (39%) [20,30,42-46] used individual interviews, and 1 (6%) [41] used nonparticipant observation. Regarding the electronic devices analyzed, 5 (28%) studies [20,30,38,41,42] used smartphone apps, 2 (11%) [37,40] used the *Pokémon GO* mobile game, 1 (6%) [45] used mobile text messages, 5 (28%) [31-33,39,44] used activity trackers, 4 (22%) [34-36,43] used active video games, and 1 (6%) [46] used virtual reality.

Table 1. Characteristics of included studies (preschoolers).

Author, country	Method of data collection	Method of analysis (software); paradigmatic approach	Participants' details (background, age, parents' details)	Place and methods of recruitment
McCloskey et al [20], United States	Individual semistructured telephonic and face-to-face interviews	Thematic analysis, inductive approach (NVivo v.11, QSR International); N/I[a]	• Background: low-income families in rural areas • Age=3-5 years • Parents (telephonic interviews): n=29, mean age N/I, 93% (27/29) mothers • Parents (face-to-face interviews): n=31, mean age N/I, 77% (24/31) mothers	Purposive sampling (preschool centers, letters)
Alexandrou et al [30], Sweden	Focus groups, individual interviews	Thematic analysis, inductive approach; N/I	• Background: socioeconomically diverse district • Age=2.5-3 years • Somali parents: n=5, mean age 34 (SD 6.6) years; 100% (5/5) mothers • Arabic parents: n=4, mean age 31.2 (SD 2) years, 100% (4/4) mothers • Swedish parents: n=6, mean age 35.8 (SD 4.7) years, 83% (5/6) mothers	Purposive sampling (health care centers)
Costa et al [31], United Kingdom	Focus groups, semistructured interviews	Thematic analysis (NVivo v.9); N/I	• Background: low socioeconomic status • Age=2-3 years • Asian and White European parents: n=17, mean age 30.36 SD (6.9) years, 100% (17/17) mothers	Purposive sampling (children's centers)
Phillips et al [32], United Kingdom	Focus groups, semistructured interviews	Thematic analysis, inductive approach; N/I	• Background: highly deprived areas • Age=3-4 years • Parents: n=11, mean age 29 (SD N/I) years, 100% (11/11) mothers	Purposive sampling (children's centers, nurseries, preschools)
Ek et al [42], United States	Individual semistructured interviews	Thematic analysis, inductive approach; N/I	• Background: urban preschools • Age=3-4 years • Parents: n=10, mean age 38.9 (SD 5.2) years, 91% (9/10) mothers	Purposive selection of schools (posters)

[a]N/I: not informed.

Table 2. Characteristics of included studies (children).

Author, country	Method of data collection	Method of analysis (software); paradigmatic approach	Participants' details (background, age, parents' details)	Place and methods of recruitment
Creaser et al [33], United Kingdom	Focus groups, semistructured interviews	Thematic analysis, inductive approach (NVivo, QSR International); N/I[a]	• Background: families from different ethnicities • Age=5-9 years • Parents: n=36, mean age 38 (SD 7.7) years, 67% (24/36) mothers	Purposive sampling (social media)
Coknaz et al [34], Germany	Focus groups, semistructured interviews	Thematic analysis, inductive approach (NVivo v.10); N/I	• Background: public primary schools • Age=8-13 years • Parents: n=N/I, mean age N/I	Purposive sampling (from a clinical trial)
De Vet et al [35], the Netherlands	Focus groups, semistructured interviews	Content analysis (ATLAS.ti v 5.2); N/I	• Background: primary schools • Age=8-12 years • Parents: n=19, mean age 42.3 (SD 4.1) years, 95% (18/19) mothers	Purposive sampling (letter)
Dixon et al [36], New Zealand	Focus groups	Inductive approach; N/I	• Background: different ethnicity and socioeconomic groups in urban communities • Age=10-14 years • Maori parents: n=8, mean age N/I • Pacific parents: n=24, mean age N/I • Others: n=7, mean age N/I	Purposive sampling (community and church)
Lindqvist et al [37], United States	Focus groups, semistructured interviews	Latent content analysis; N/I	• Background: families • Age=7-12 years • Parents: n=9, mean age 38.7 (SD N/I), 78% (7/9) mothers	Purposive sampling
Rossi et al [38], Italy	Focus groups, semistructured interview	Content analysis (NVivo), community-based participatory action research	• Background: mothers • Age=0-14 years[b] • Parents: n=5, mean age N/I, 100% (5/5) mothers	Purposive sampling (public health local program)
Sharaievska et al [39], United States	Semistructured group interviews	Open, axial, selective coding techniques, grounded theory	• Background: families in rural communities • Age=7-13 years • Parents: n=N/I, mean age N/I	Purposive sampling
Sobel et al [40], United States	Nonparticipant observations and semistructured interviews	Inductive-deductive approach; N/I	• Background: families playing *Pokémon GO* in public locations • Age=2-17 years[b] • Parents: n=87, mean age 42 (SD 7.2) years, 70% (61/87) mothers	Purposive sampling (parks, shopping centers, events, online platforms)
Barnett et al [43], Australia	In-depth semistructured telephonic interviews	Thematic analysis (NVivo), descriptive qualitative approach	• Background: N/I • Age=9-10 years • Parents: n=29, mean age N/I	Purposive sampling (from a clinical trial)
Mackintosh et al [44], Australia	Web-based and face-to-face semistructured interviews	Thematic analysis, inductive approach (NVivo v.12); N/I	• Background: families • Age=7-12 years • Parents (web interview): n=25, mean age N/I, 84% (21/25) mothers • Parents (face-to-face interviews): n=10, mean age N/I, 100% (10/10) mothers	Purposive sampling (email)

[a]N/I: not informed.

[b]Some studies mixed ages in the sample and did not provide a separate analysis by age.

Table 3. Characteristics of included studies (adolescents).

Author, country	Method of data collection	Method of analysis (software); paradigmatic approach	Participants' details (background, age, parents' details)	Place and methods of recruitment
Carrion et al [41], Spain	Focus groups	Content analysis, phenomenological approach	• Background: parents from public or charter schools • Age=13-15 years • Parents: n=10, mean age N/I, 50% (5/10) mothers	Purposive sampling (schools)
Lindqvist [45], Sweden	Individual semistructured interview	Latent content analysis (NVivo, QSR International), empowerment	• Background: families of a municipality of North Sweden • Age=13-15 years • Parents: n=10, mean age N/I, 60% (6/10) mothers	Purposive sampling (from an intervention)
McMichael et al [46], United Kingdom	Semistructured interview	Framework analysis, Medical Research Council *(*MRC) framework	• Background: families • Age=13-17 years • Parents: n=18, mean age 53 (SD 3) years, 72% (13/18) mothers	Purposive sampling (social media, schools, university, emails, and posters)

Study Quality

The assessment of the 18 studies included in this systematic review is presented in Multimedia Appendix 2. Only 1 (6%) study [31] met all 10 items in the JBI-QARI checklist, 8 (44%) studies [20,30,32,33,40-42,46] met 9 items, 8 (44%) [35-39,43-45] met 8 items, and 1 (6%) [34] met 5 items. No studies were rated as "excluded"; thus, none was excluded based on methodological quality. The main weaknesses were a lack of clarity and a lack of reporting on the researcher's influence on the study and vice versa [20,30,34,35,39,40,43-45]. Other limitations were that participants and their voices were not adequately represented in 3 (17%) studies [34,36,38] and that there was no congruity between the stated philosophical perspectives and the research questions or methodology [34,35].

Synthesized Findings

We identified 4 main themes (Textbox 1) in terms of parents' perceptions of PA electronic devices: usefulness, advantages, general perceptions, and acceptability (barriers and facilitators). The main results are shown in Table 4, and proofs are shown in Multimedia Appendix 3.

Textbox 1. Themes and subthemes describing parents’ perceptions of physical activity (PA) electronic devices.

Usefulness of PA electronic devices

- PA promotion and PA in special moments
- Learning of skills and transferability to real life

Advantages of PA electronic devices

- Increase in motivation
- Awareness of behaviors
- Family bonding
- Socialization with peers

General perceptions

- Electronic devices for health promotion
- Preferences for real-life activities or active screen time
- Concerns: content, addiction, negative emotions, isolation, conflicts, limits

Acceptability (barriers and facilitators)

- Lack of time and stress
- Price
- Lack of space at home
- Discomfort/discomfort
- Difficulties with electronic devices or understanding feedback given by the app
- No new activities/suggestions
- Lack of use/interest after novelty
- Attractiveness (high technology, good graphs, good quality, videos)
- Gamification (competition, challenges, goals, and rewards) and fun
- Teacher and school support
- Ease of use
- Durability
- Integrated into daily routines

Table 4. Summary of findings.

Participants included, author, country	Area of inquiry/aims	Intervention/exposure	Main results
Preschoolers			
McCloskey et al [20], United States	To explore parents' beliefs about preschoolers' use of mobile devices and the acceptability and perceptions of a PA[a] intervention	Jungle Gym: a mobile app to encourage PA, focused on movement, motor skills (running, jumping, leaping, etc), and interactions with parents/children	Parents supported the use of mobile apps for PA and reported that they were useful in various situations (eg, on bad-weather days). Parents also expressed concerns about the apps.
Alexandrou et al [30], Sweden	To explore needs and concerns among Somali, Arabic, and Swedish parents regarding a PA app	MINISTOP 1.0 mobile app: a 6-month program to support parents in promoting PA	Parents found the app useful. Insights into their needs and important features were obtained.
Costa et al [31], United Kingdom	To assess mothers' opinions about the feasibility and acceptability of using an activity tracker	ActiGraph GT3Xþ, Actiheart (CamNtech Ltd), ActivPAL3 (PAL Technologies Ltd): 3 activity trackers	Children were most comfortable with ActiGraph and least comfortable with Actiheart. Problems with the devices were the possibility of children taking them off, allergic skin reactions, or discomfort.
Phillips et al [32], United Kingdom	To examine parents' acceptability and feasibility of measurement tools to assess PA	ActiGraph GT3X+, ActivPAL4 micro, Actical (Philips Respironics Inc): 3 accelerometers	Parents reported that ActivPAL was the least preferred electronic device (children's opposition to wearing it on their chest, skin irritation). ActiGraph was the most accepted.
Ek et al [42], United States	To explore parents' needs and perceptions of a PA app in a school setting	Mobile phone app to promote PA in a school setting	Parents reported the need for interactive features, problem-solving tasks, creativity, and music and dance activities and had a positive attitude toward the app. Children found activities more fun when adults participated.
Children			
Creaser et al [33], United Kingdom	To examine parents' acceptability of using wearables in a family setting	Fitbit Alta HR for 4 weeks, ActiGraph GT3X+	Fitbit was considered easy and enjoyable to use, but its perceived impact on PA was mixed. Most parents were willing to purchase a wearable.
Coknaz et al [34], Germany	To analyze the feelings and perspectives of parents about active video games	Nintendo Wii® sports (boxing, tennis, golf, baseball, bowling, skiing, aerobics, running, water skiing, etc) for 50-60 minutes, 3 days/week, 12 weeks	Parents believed that active video games might help in physical changes, socializing, and intellectual and personal development of children.
De Vet et al [35], the Netherlands	To explore parents' perceptions and opinions about active video games	Active video games	Parents had a positive attitude toward active and interactive video games. Some parents were less restrictive with them.
Dixon et al [36], New Zealand	To explore parents' perceptions of active video games and the probability of sustained engagement	Active video games (eg, EyeToy™, Dance Mat)	Parents supported active video games. They preferred nonviolent and sporty video games. Benefits, such as increased PA, improved fitness, and increased socializing, were reported.
Lindqvist et al [37], United States	To explore parents' perceptions of playing *Pokémon GO*	A gamification-inspired program using the *Pokémon GO* mobile game	Parents found that the game promotes PA. They were less likely to limit the time spent on this game. They suggested new features and concerns about safety.
Rossi et al [38], Italy	To explore parents' perceptions of a mobile app	Multimodal app for parents' mobile phones to promote children's health, including PA	Mothers had a positive attitude toward the app and made suggestions (feedback, geolocalization, and attractive features).
Sharaievska et al [39], United States	To explore the perception of a PA tracker	PA-tracking electronic device (Fitbit Zip), which each family member was asked to wear for 2 weeks	Parents reported minimal changes in PA because of a lack of interest or an already active lifestyle. The electronic device provided more awareness.

Participants included, author, country	Area of inquiry/aims	Intervention/exposure	Main results
Sobel et al [40], United States	To explore parents' perceptions of an app that promotes outdoor PA and to explore how they play with children	*Pokémon GO*	Parents reported an increased level of PA and valued how play led to family bonding. Concerns about safety and limits of game-play emerged.
Barnett et al [43], Australia	To identify parents' perceptions of active video games for development of movement skills	Active video games	Parents were skeptical of the capacity of video games to contribute to skill development and preferred real sports.
Mackintosh et al [44], Australia	To explore parents' perceptions of the acceptability and usability of wearable activity trackers to monitor PA	KidFit (X-Doria International) worn by each child for 4 weeks	Parents reported that the activity tracker is easy and useful. Barriers (lack of real-time feedback and difficulties in interpreting information) and suggestions (visual display, self-monitor activity, goal setting, and challenges) were identified.
Adolescents			
Carrion et al [41], Spain	To explore parents' perceptions, values, and preferences regarding mobile apps to promote PA	PEGASO Fit for Future: a mobile app to promote a healthy lifestyle, including PA, through gamification and family connections	Parents valued mobile apps for health promotion. They preferred apps that promote activity and interactions and include gamification and rewards.
Lindqvist [45], Sweden	To describe parents' perceptions of an empowerment-inspired PA intervention via mobile phones	Empowerment-based intervention via Short Messaging Service (SMS)	Parents found that children felt involved in the process and reported that social support and encouragement had an impact on PA. Goals and rewards could be motivating for PA.
McMichael et al [46], United Kingdom	To understand parents' views of PA, gaming, and virtual reality in PA interventions	vEngage project active virtual reality	Parents had a negative perception of gaming and preferred real-world PA. They reported the benefits of active games (socializing, motor skills, moving) and concerns (eg, addiction).

[a]PA: physical activity.

Parents' Perceptions of the Usefulness of PA Electronic Devices

The first theme reported was the main usefulness that eHealth technologies might have. The core concepts that support this theme included PA promotion and the learning of skills.

Parents perceived electronic devices as useful for increasing PA levels [34,35,37,39,40,44,45]; for example, parents reported that the *Pokémon GO* mobile game encourages children to be more active and promotes taking long walks through the neighborhood [37,40]. Alternatively, PA is not possible in specific moments when outdoors, for example, on bad-weather days [20]. Regarding activity trackers, parents reported that wearing the electronic device makes the children more motivated to accomplish daily step recommendations or take walks [33,39,44]. However, some parents said that their children, especially younger children, were physically active enough and so did not benefit much from the apps [43].

Regarding motor skills, such as balance or hand-eye coordination, some studies [20,35,40,43] reported that children show improvement and that those skills can be transferable to real sports [43]. In addition, they could learn how to score and follow the rules of some sports [43]. Furthermore, some parents found that eHealth might improve other skills, such as logical thinking and cognitive development [34,35]. In contrast, other parents were skeptical of the transferability of skills learned in video games to a real-life context, and they felt that it is unlikely that their children would benefit from learning skills from virtual apps [43].

Parents' Perceptions of the Advantages of PA Electronic Devices

The advantages of PA electronic devices that parents reported included an increase in motivation for engaging in real-life sports [39,41,43], more awareness, family bonding, and socialization with peers. For example, playing video games motivated children to engage in real-life sports [33,35,37,40,43,44]. Moreover, eHealth apps were useful for parents to become aware of their own levels of PA [39,44], and this, in turn, promoted changes in their attitude toward PA and increased their own PA levels [39]. In addition, parents said that using activity trackers made them aware of other interesting habits of their children, such as sleep or heart rate [30,33,44].

Another advantage of some electronic devices that parents highlighted is that they promote socialization [34,35,37,40,46] and cooperation and competition [37,40,45] with peers and family [20,35,37,39,40,44]. Parents also reported that active video games are suitable for playing with the family and an enjoyable activity to do together, reinforcing their bonds [20,35,37,39,40,44]. Other games promoted social interactions by providing users with something in common to talk about [39,40,44-46] or by enabling them to play interactively with others [35,40,46]; these features were particularly important for adolescents. Thus, parents reported how cooperation and social interaction were important factors in continuing to use the apps, since they found the apps fun and motivating [37,39].

Parents' General Perceptions of PA Electronic Devices

The general perceptions of parents about PA electronic devices were grouped into 3 key concepts: attitudes about electronic devices for health promotion, preference for real-life sports or active electronic devices, and concerns about the use of electronic devices.

Generally, parents were prone to using technology for health and educational purposes [20,42,46]. Furthermore, parents reported the desirability of apps being targeted not only at children but also at parents [30]. They suggested tracking their health lifestyles to be important, such as having an agenda or a reminder and the inclusion of health information [30]. Additionally, parents reported a preference for active and social video games or the active use of screens over passive screen time [35,36,46]. For example, active video games, such as Nintendo Wii, were perceived as a healthier alternative to passive screen time [35]. However, parents distinguished between real-life sports and virtual worlds, showing preferences toward playing outside rather than virtual PA [17,36,40,43,47].

In contrast, they also highlighted several concerns and dangers. Many of the parents were worried about violent content in video games, the appropriateness of content for different ages [35,46], concerns about children playing with strangers, safety [40,46], and physical accidents resulting from walking with the phone in hand [37]. In addition, psychological effects, such as anger, frustration, isolation, or addiction, were also reported [35,37,40,46]. Other common issues highlighted were conflicts when playing video games [37] and difficulties in establishing time limits, which increased with age. In that respect, although parents were more positive toward active video games and active screen use, setting limits and supervising screen use were important issues [20,35,37,40,46].

Parents' Perceptions of the Acceptability of PA Electronic Devices

Barriers

Some barriers to using PA electronic devices were found. Commonly, parents reported a lack of time to engage in eHealth activities because of their work or children's schedules [33,39,45]. Others found difficulties in managing extensive health information and reported feeling stressed by trying to follow all the recommendations [30]. Still, others highlighted the high prices of video games and electronic devices [35,36], and some were annoyed by the noise and space the devices occupy at home while playing [36,42,46].

Regarding the physical characteristics of activity trackers, the main issues raised included unsuitability, discomfort caused by a large size, drawbacks of wearable devices, children trying to remove electronic devices [31,32,44], and difficulties with batteries and syncing [44]. The size of the electronic device was especially important for younger children [31,32]. Other issues were difficulties in using activity trackers or understanding the information provided [33]. Several other factors impacted the use and wearability of activity trackers, including forgetting to wear them, having to remove them for certain sports, the lack of real-time feedback [44], and the lack of interest by parents [33,39]. In this sense, some parents said that activity trackers did not promote any new activity [39]. They also highlighted concerns about the lack of use of the electronic devices once they lost their novelty [33,36] and a lack of long-term wear compliance [44].

Facilitators

Parents reported several facilitators of the use of PA electronic devices. For example, they showed a preference for cheaper games that they could afford [35]. Other factors that facilitated engagement were the attractiveness of the game or electronic device, whether it uses high-level technology or appealing graphics [33,46], or the inclusion of videos [30,32,35].

Parents also reported that 2 important facilitators that ensure long-term engagement are gamification and fun [32,33,35,37,42,44]. Teacher support was found to be an important factor in engagement [44,45]. Parents said that goals [31,45] and rewards and new challenges [38,39,43,47] are important features—for example, different levels and new challenges to accomplish [47]. In that sense, many of the parents reported that an important feature is for an app to be fun [39,42,43]. To make apps appealing to children, parents recommended including reinforcement, such as treasure hunts or challenges, which might make the apps motivating. Regarding goal setting, the possibility of establishing goals with others, such as family members, peers, or classmates, was also recommended [31,45]. Furthermore, parents suggested that apps provide interaction with professionals, such as online forums [30,38], and be linked to the school curriculum [44], and teacher support was found to be an important factor in engagement [44,45]. Other ideas were links with sports associations and outdoor activities, such as events, active commuting, and geolocalization [38].

For activity trackers, parents reported some important characteristics that facilitate engagement. Most of them highlighted the importance of comfort [31-33,44], considering that an activity tracker should be worn all the time [32], and ease of use so that the children can understand and handle the device on their own [33,44] with an easy-to-use app [33]. Parents also reported the importance of considering the durability and damage resistance of electronic devices, since younger children might break them [32], and the integration of eHealth with their daily routines [33]. Other suggestions for activity trackers were real-time feedback and a complete dashboard showing information about scores, steps with good graphs, and demonstrations [32]. Features such as competition with others, options for new activities, and high-level technology were perceived as important.

Age Group Differences

Of the 18 studies, 5 (28%) [20,30-32,42] analyzed the opinions of the parents of preschoolers' (<5 years old). Generally, parents were less worried about their children's PA [30] because they perceived them as spontaneously active and preferred outside PA [20,42]. For preschoolers, most parents tried to limit technology as much as they could [20,42] and used PA apps when real PA was not possible [20,30]. Regarding activity trackers, the problems of wearability due to the size of the devices were highlighted [32].

Furthermore, 10 (55%) studies [33-40,43,44] analyzed schoolchildren between 7 and 12 years old. Parents of children in this age group also showed preferences for real PA [43], although they preferred PA apps over passive screen use [35,36]. Parents were worried about content and addiction and the necessity to set limits on screen time [35-37], and they more frequently reported interactive uses of PA electronic devices with peers and family [35,37]. Regarding activity trackers, parents highlighted the requirement of usefulness for children [44] and the importance of PA electronic devices and activity trackers to be designed specifically for children's use [33].

In addition, 3 (17%) studies [41,45,46] analyzed samples of parents of adolescents and showed that technology could be an effective strategy to connect with adolescents and help them acquire healthier habits [41]. Regarding this age group, parents were more worried about screen time, the time spent in gaming, and the time spent in sedentary pursuits and preferred technology uses that promote health, education, or socializing [45,46]. They perceived technology as unavoidable and reported difficulties in limiting screen time [46].

Discussion

Principal Findings

To the best of our knowledge, this is the first study that systematically reviews qualitative research that explores parents' perceptions of electronic devices that promote PA in children and adolescents. Overall, parents perceived electronic devices as useful for PA promotion. Moreover, they found other advantages, such as health promotion, awareness of health behaviors, learning of motor and cognitive skills, increased motivation for PA, and promotion of family and social interactions. Parents also valued some of the features of electronic devices, such as being comfortable, easy to use, active, challenging, and fun. However, some barriers and concerns, such as the risk of addiction, safety issues, or difficulties in setting limits, emerged. Preschoolers' parents found it less necessary to promote PA and preferred that their children spend time in outdoor activities. In contrast, in the case of older children and adolescents, when screen time increased, parents reported more advantages of using active electronic devices that promote PA.

A previous qualitative study that asked parents about their attitudes toward the use of electronic devices and media reported that parents are concerned about the total amount of time that children engage with electronic devices; specifically, they said that engaging with electronic devices prevents children from being physically active [47]. Additionally, other studies have reported positive attitudes of parents toward the use of electronic devices in children, as parents perceive them as a reality in children's and adolescents' lives [48], especially for educational and health purposes [49,50]. Similarly, in our study, parents had positive attitudes toward the use of technology for health purposes, such as promoting PA, and they preferred active electronic devices and dance- or sports-based video games rather than traditional sedentary screens [35] because parents perceive active electronic devices as a healthier alternative to passive screen time. Nevertheless, they preferred real PA or outdoor PA over PA on an electronic device [20,35,46]; thus, PA apps do not substitute but complement traditional forms of PA.

Other concerns that parents had, in addition to the high amount of time spent on electronic devices by children and adolescents, were the risk of addiction; the lack of skills; the emergence of negative emotions, such as anger; and violent or sexual content. These concerns are similar to those shown by previous studies, where parents reported being worried about access to inappropriate content, addiction, and negative emotions [9,47,51,52]. In this study, as in previous studies [47,52], parents perceived difficulties in setting limits on the time spent on electronic devices. Their concerns led them to implement different mediation strategies, such as couse, supervision, active mediation, restrictive mediation, and monitoring, depending on positive or negative attitudes toward media [53]. Along this line, parents reported being less restrictive in the case of active electronic devices, rather than passive ones, that promoted social interactions. Regarding social bonds, strong social and family bonds play a large role in controlling the overuse of electronic devices [52]. In this study, parents liked electronic devices that promoted family interactions to play together or that promoted peer interactions, as they believed that games that promote interactions might mitigate the lack of skills and isolation arising from the overuse of electronic devices.

Regarding age, as in a previous study [54], some differences were found, since electronic device usage and social, cultural, and cognitive experiences are vastly different between a 3-year-old child, an older child, and a teenager. In this study, parents of preschool children found no necessity for PA promotion since they perceived that their children were naturally active and used as few electronic devices as possible. In contrast, a study that analyzed general attitudes toward the use of electronic devices and media exposure in young children found that most parents have positive attitudes toward electronic devices, not only for educational purposes but also for entertainment [48]. This difference might be because our study analyzed only PA electronic devices and parents showed a general tendency to overestimate their children's PA [55], and thus, they perceived a low necessity of electronic devices to increase PA in their children. As children grow older, parents show increasing concerns about the amount of time spent using electronic devices, due to a substantial increase in hours using electronic devices with age [56]. In older children and adolescents, parents report more conflicts and difficulties in limiting electronic device use, consistent with previous studies [18] in which parents of adolescents have reported that setting limits on electronic device use is often confrontational and frequently escalates into arguments and shouting [57]. Therefore, parents implement different mediation practices [58] to regulate the use of electronic devices according to age, as the needs of children and adolescents change with development. Regarding gender differences, only 1 study showed that girls might engage in different challenges and games than boys [46]; congruently, a previous study found limited evidence of children's gender differences that precluded us from drawing conclusions [54], suggesting that differences in electronic device use and preferences might be considered in further studies.

Finally, parents reported some barriers that need to be considered in further studies, such as lack of time, stress, and high prices of electronic devices. Specifically for activity trackers, comfort, ease of use, difficulties in understanding the apps, or difficulties in understanding the feedback provided were the most common barriers. Conversely, facilitating factors for engagement included the attractiveness of the app, comfort, and children's self-efficacy in using the electronic device, similar to a previous study of eHealth programs [21]. Some suggestions provided by parents for new PA electronic devices included goal setting and rewards, usability, comfort, real-time feedback, and activities that promote interactions with friends and family, similar to a previous study [8]. In addition, parents had a favorable attitude toward the promotion of technology-based PA strategies in school contexts, and some also considered the involvement of schools and teachers in interventions and connection with the community [42,44,59].

Strengths

To the best of our knowledge, this is the first systematic review to synthesize findings from qualitative studies examining parents' perceptions of PA electronic devices. To ensure that the search process was systematic, an exhaustive search was carried out in specialized databases and gray literature by multiple researchers. This search was reported accurately according to the ENTREQ statement [24]. The meta-aggregation approach [29] was used to extract key themes and proofs, which enhanced the reliability of the data. In addition, data were meticulously documented in a matrix, and an assessment of the methodological strength of the analyzed papers was performed.

Limitations

This review has some limitations that should be acknowledged. First, there was high heterogeneity in the studies regarding the type of electronic device (mobile phones, activity trackers, exergames, virtual reality), data collection methods, location, duration of interventions, sample recruitment strategies, and the age of users. Along this line, studies considering differences between preschoolers, children, and adolescents are needed because these 3 age groups have different lifestyles, interests, and needs. Furthermore, gender differences between boys and girls were considered only in 1 study [46], which might be a source of bias since girls and boys have different levels of PA and different uses and preferences of technology. Second, most participants in the included studies were mothers, which might be due to mothers still parenting more than fathers; however, further studies considering fathers' opinions are recommended. Finally, some studies did not include an adequate description of the theoretical paradigm and did not provide information about how the researchers' background was managed.

Conclusion

This review explored the perceptions of children's and adolescents' parents regarding the use of electronic devices for PA enhancement. Parents reported that PA electronic devices could be an effective way to promote PA in children and adolescents and to overcome barriers, such as bad weather, lack of motivation, or the high rate of sedentarism in this population. In addition, parents prefer games and apps that require PA over traditionally passive games and apps. Parents also reported negative attitudes toward the use of technology in terms of addiction, safety problems, and difficulties in establishing limits, which should be considered in future interventions. These insights might provide researchers with more knowledge of how parents manage, promote, and regulate the use their children make of PA eHealth, the acceptability of interventions, and how they use PA eHealth at home. Some important features to consider in the development of new PA apps and technology-based interventions are the developmental stage, ease of use, appropriate feedback, promotion of socialization, and motivating strategies, such as rewards, challenges, and an appealing appearance.

Authors' Contributions

MVA contributed to writing the original draft, project administration, and visualization; VMV contributed to conceptualization and supervision; MSL and MVA performed investigation and formal analysis; ARH contributed to validation and data curation; BRM and RBG conducted supervision, methodology, and review and editing; and ISD contributed to data curation and review and editing.

Conflicts of Interest

None declared.

Abstract

Background: As a global medical problem, tinnitus can seriously harm human health and is difficult to alleviate, ranking among the top 3 complex diseases in the otolaryngology field. Traditional cognitive behavioral therapy and sound therapy require offline face-to-face treatment with medical staff and have limited effectiveness. Mobile health (mHealth), which, in recent decades, has been greatly applied in the field of rehabilitation health care, improving access to health care resources and the quality of services, has potential research value in the adjunctive treatment of tinnitus.

Objective: This study aimed to understand the research trends, product characteristics, problems, and research transformation of tinnitus treatment software by analyzing the research progress of mHealth for tinnitus treatment based on the literature and related marketed apps.

Methods: Bibliometric methods were used to describe the characteristics of the relevant literature in terms of the number and topics of publications, authors, and institutions. We further compared the features and limitations of the currently available tinnitus treatment software.

Results: Data published until February 28, 2022, were collected. Following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) standardized screening process, 75 papers were included. The country with the highest number of publications was Germany, followed by the United Kingdom and the United States, whereas China had only a single relevant study. The most frequently found journals were the *American Journal of Audiology* and the *Journal of the American Academy of Audiology* (18/75, 24%). With regard to publication topics, cognitive behavioral therapy started to become a hot topic in 2017, and research on mHealth apps has increased. In this study, 28 tinnitus treatment apps were obtained (n=24, 86% from product data and n=4, 14% from literature data); these apps were developed mainly in the United States (10/28, 36%) or China (9/28, 32%). The main treatment methods were sound therapy (10/28, 36%) and cognitive behavioral therapy (2/28, 7%). Of the 75 publications, 7 (9%) described apps in the market stage. Of the 28 apps, 22 (79%) lacked literature studies or evidence from professional bodies.

Conclusions: We found that, as a whole, the use of mHealth for treatment and intervention in tinnitus was showing a rapid development, in which good progress had been made in studies around sound therapy and cognitive behavioral therapy, although most of the studies (50/75, 67%) focused on treatment effects. However, the field is poorly accepted in top medical journals, and the majority are in the research design phase, with a lack of translation of the literature results and clinical validation of the marketed apps. Furthermore, in the future, novel artificial intelligence techniques should be used to address the issue of staged monitoring of tinnitus.

Introduction

Background

The American Academy of Otolaryngology-Head and Neck Surgery defines tinnitus as "a sound perceived by the patient in the absence of an external sound source" [1]. Several studies have shown that the worldwide prevalence rate of tinnitus ranges from 5.1% to 42.7% [2]. Xu et al [3] showed that 9.6% of the global adult population has experienced tinnitus in the past 12 months. Of these, 36% had persistent tinnitus, and 27% had tinnitus for >15 years. Persistent tinnitus can lead to severe psychological disorders, such as depression, anxiety, mania, and other affective disorders. Suicide and personal injury rates are significantly increased in patients with tinnitus [4]. As a matter of concern, the decreased availability of effective treatments for tinnitus greatly increases the socioeconomic burden of this disease in medical care [5].

Tinnitus lacks effective standardized and individualized treatments. Drugs, surgery, electrical stimulation, and psychophysiological integrative therapy are traditional treatment modalities that have serious adverse effects. Moreover, their long-term safety is unknown. Mobile health (mHealth) apps are a novel tool expected to be effective in alleviating tinnitus. The popularity of smartphones and the inherent immediacy, accuracy, and low costs of the mobile internet have contributed to the unique advantages of mHealth apps in providing health interventions and other outcomes. As of 2020, there were >300,000 (this number is rapidly growing) mHealth apps available in mobile app stores [6]. These apps help users to monitor multiple physiological indicators and provide relevant health knowledge and services to address a range of health issues [7], including tinnitus. Several studies have found that mHealth apps can provide continuous and remote monitoring of tinnitus as well as diagnostic and intervention services for patients with the condition. This can, in turn, be effective in alleviating or resolving this disorder. Most Chinese researchers provide sound therapy for patients with tinnitus through software. There are also attempts to use herbal medicine, acupuncture, and electrical stimulation for the same purpose. He et al [8] used audition software for sound therapy. Cai et al [9] integrated personalized music into tinnitus software, in combination with cognitive behavioral therapy, to innovate a tinnitus treatment intervention with substantial results.

Objectives

Nevertheless, most studies have focused only on monotherapeutic interventions for tinnitus. As such, there is a lack of a systematic analysis of tinnitus treatment software studies and marketed apps [10]. Therefore, using bibliometric and comparative product analysis methods, this study provides a complete and detailed description of the field of tinnitus monitoring, diagnosis, and intervention with the help of mHealth apps. Our work is the first bibliometric study to comprehensively analyze trends in publication, national and institutional distribution, core journals and highly productive authors, and research topic hot spots in this area. This study aimed to understand the research trends in tinnitus treatment software, including the characteristics and limitations of the apps available in the market. The outputs of our research can help patients to choose the right tinnitus treatment software and provide suggestions to manufacturers regarding potential ways to improve the quality and use of tinnitus treatment software.

Methods

Data Retrieval and Filtering

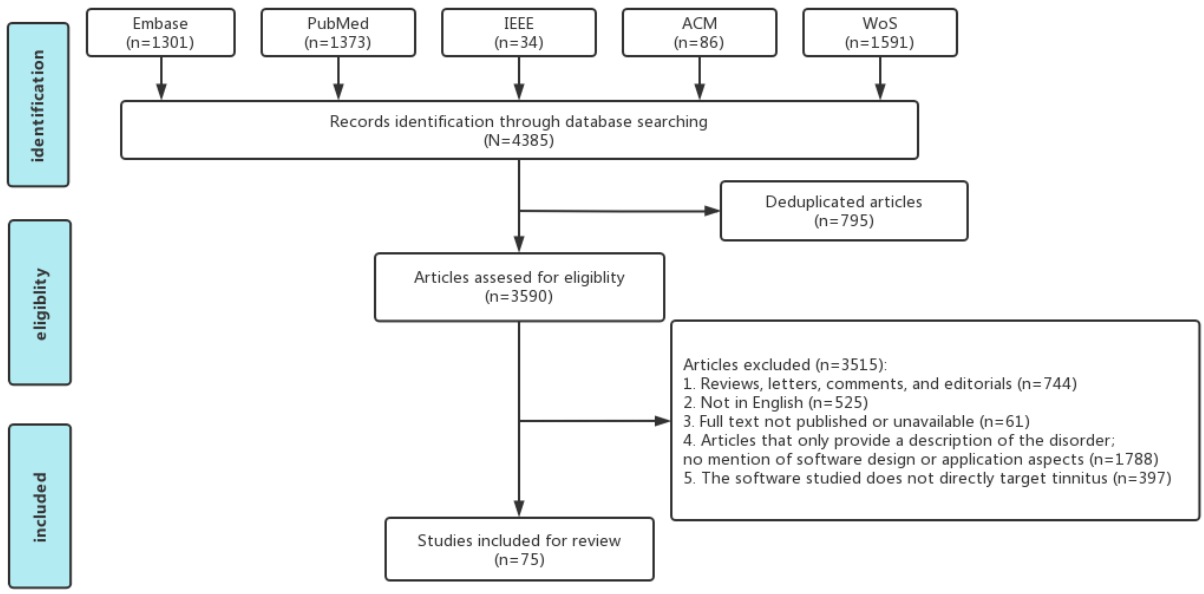
Regarding the research literature, to ensure completeness, our study followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) principle and searched databases in 5 different fields [11,12]. In the medical field, the PubMed and Embase databases were used. In the general science field, the Web of Science core collection was chosen. In the computer field, the IEEE and ACM databases were chosen. The search queries and strategies used for the different databases are listed in Multimedia Appendix 1. The inclusion and exclusion criteria for this study are shown in Multimedia Appendix 2.

A total of 4385 papers were retrieved from 5 databases (n=1301, 29.67% from Embase; n=34, 0.78% from IEEE; n=1373, 31.31% from PubMed; n=1591, 36.28% from Web of Science; and n=86, 1.96% from ACM). After literature deduplication, of the 4385 papers, 3590 (81.87%) remained. Two trained postgraduate students screened the retrieved papers according to the established inclusion and exclusion criteria (Cohen κ=0.91), and, of the 3590 papers, 75 (2.09%) were included in the final literature pool, as illustrated in Figure 1.

After a preliminary market survey, we identified 2 sources of information in which to search for product data: the Android platform and the Apple App Store (China and the United States), for a total of 7 official mobile software marketplaces, with the Android platform accounting for 5 (71%) mobile software marketplaces (Google Play Store as well as the mobile software marketplaces operated by Huawei, Vivo, Oppo, and Xiaomi). To obtain relevant search results for mHealth apps on the Qimai app data analysis platform [13] (accessed in March 2021), we used the following search terms: "tinnitus diagnosis," "tinnitus intervention," and "tinnitus treatment" A total of 2384 mHealth apps were retrieved, with 1812 (76%) stand-alone mHealth apps remaining after data deduplication.

In this study, mHealth apps related to tinnitus treatment were screened from 75 literature reports and 1812 independent software reports, using established inclusion and exclusion criteria. A total of 28 tinnitus treatment apps were obtained (n=24, 86% from product data and n=4, 14% from literature data). The specific inclusion and exclusion criteria applied to select the target apps are listed in Textbox 1. A screening flowchart of the mHealth apps is shown in Figure 2.

Figure 1. Flowchart of literature data screening. WoS: Web of Science.



Textbox 1. Inclusion and exclusion criteria applied to select the target apps.

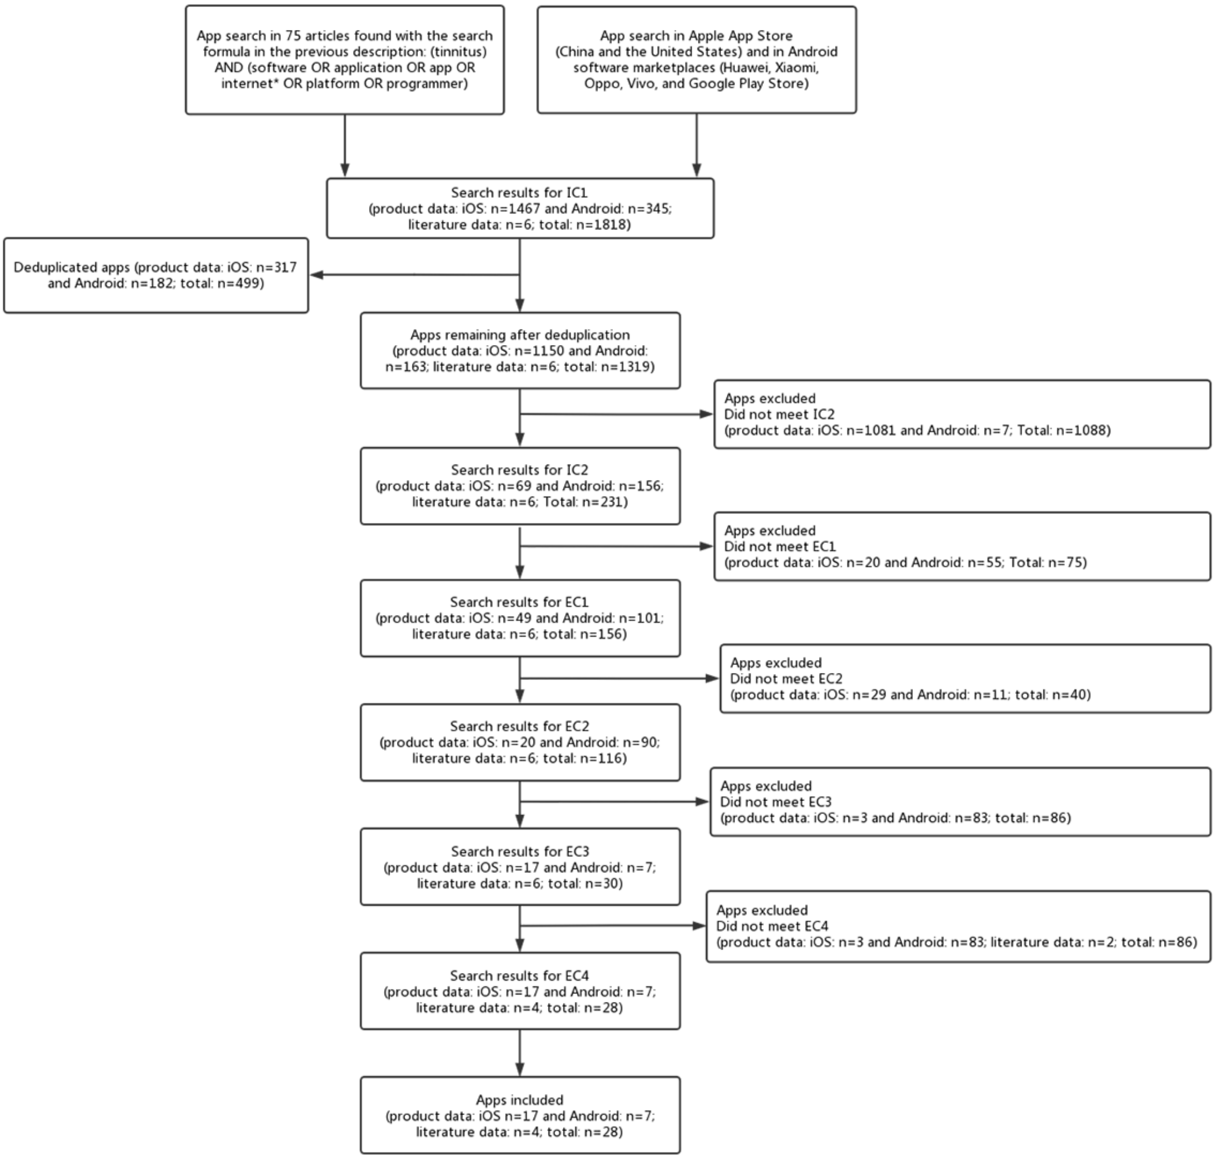
Inclusion criteria

- Inclusion criterion (IC) 1: apps identified with the search terms "tinnitus," "hearing test," "sound therapy," "cognitive behavioural therapy," "cbt," "perceptual mask," "perceptual masking," "retraining therapy," and "sleep"
- IC2: apps with either a health purpose or a medical purpose

Exclusion criteria

- Exclusion criterion (EC) 1: Apps consisting only of sleep aid, relaxation, or meditation software; pure mood journals; or diary functionalities (with or without cognitive behavioral therapy)
- EC2: apps consisting only of mobile hearing test, aid, or debugging software, pure mobile sound level meter software, or pure speech therapy software (not related to tinnitus)
- EC3: health management software for other diseases (not related to tinnitus)
- EC4: insufficient software information

Figure 2. The screening flowchart of the mobile health apps. EC1: exclusion criterion 1; EC2: exclusion criterion 2; EC3: exclusion criterion 3; EC4: exclusion criterion 4; IC1: inclusion criterion 1; IC2: inclusion criterion 2.



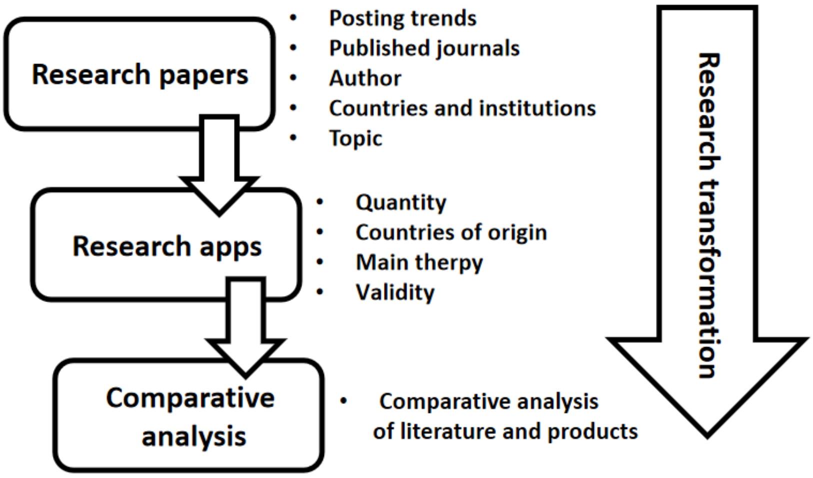
Extraction of App Information

In this study, we extracted general and specific information about 28 apps, using the Qimai app data analysis platform. General information about the apps included their names, reviews, and ratings. The specific information obtained on the apps was analyzed from 3 perspectives: time, space, and content. From a temporal perspective, the fields extracted from the specific information included the dates of product release and last update, as well as in-app, off-app, and unreleased stores. With regard to the spatial perspective, the specific information included the product's country of origin and the name, location, and size of the product manufacturer. From the content perspective, the specific information included type, purpose, input and output information, clinical role, main treatments related to the software, their effectiveness, and software scenario.

Data Analysis Methods

To review and summarize the current status of, and research trends in, mHealth treatments and interventions for tinnitus, we used a bibliometric and comparative product analysis approach, based on a *literature output-product output–literature versus product* chain. We used the *bibliometrix* package in R for data analysis and the *ggplot2* package for mapping. First, a bibliometric approach was used to analyze the literature data and obtain the current publication outputs. Second, product data were analyzed to obtain information about product outputs and applications. Finally, we compared the development of literature and product components. The purpose was to obtain the differences between the current state of research and its actual use, as well as to gain a preliminary insight into the translation of research in this field. The analysis chain and process are shown in Figure 3.

Figure 3. Analysis chain and process.



Results

Analysis of the Literature Output

Regarding the literature output, we analyzed the retrieved articles using bibliometric methods concerning 5 aspects: publication trends, journals, authors, countries and institutions, and themes.

Analysis of Publication Trends

As of February 2022, a total of 162 authors had published 75 relevant articles in 44 different journals. Among the 162 authors, 46 (28.4%) were lead authors. In addition, there were an average of 0.11 (SD 0.98) relevant articles per journal per year and an average of 0.46 (SD 1.27) articles per author. The evolution in the annual number of relevant studies published over the years is shown in Multimedia Appendix 3. With regard to the 75 articles included in this study, there was an overall increasing trend in the annual number of literature publications. There was an average annual increase rate of 24.46% (SD 0.69%), which resulted in 16 articles published in 2021. This trend demonstrates that an increasing amount of research is being carried out on this topic, indicating the increasing need for research in this field.

There was a substantially increased number of articles published in 2015 and 2021, in comparison with the previous and subsequent years. The authors of the 9 articles published in 2015 were mainly from Sweden and the United Kingdom, accounting for 3 (33%) and 2 (22%) articles, respectively. There were 4 articles by Gerhard Andersson as the lead author, from Linköping University (Linköping, Sweden), whose primary research interests were psychopathology and psychotherapy [14-17]. Of the 16 articles published in 2021, a total of 9 (56%) were from the United Kingdom, including 4 (44%) articles by Eldre Beukes, from Anglia Ruskin University, whose main research interest was audiology.

Analysis of the Major Publishing Journals

According to the Bradford law of scattering [18], all publications in a specific field, released during a given period, can be divided into core, related, or peripheral zones, according to the number of articles the zones include. The ratio of the number of publications in the 3 zones is 1:a:a^2, with the approximate value of a being 5. Core publications account for approximately 1 of 31 of the total number of publications. The core publications were calculated to correspond to the top 2 journals, which accounted for 36% (18/75) of the published articles: the *American Journal of Audiology* (12/75, 16%) and the *Journal of the American Academy of Audiology* (6/75, 8%). In 2021, the journal impact factors of these 2 journals were 1.636 and 1.249, respectively, and the journal citation reports divisions were Q4 and Q3, respectively. The remaining publications revealed minor differences in terms of the number of published articles.

Analysis of Article Authors

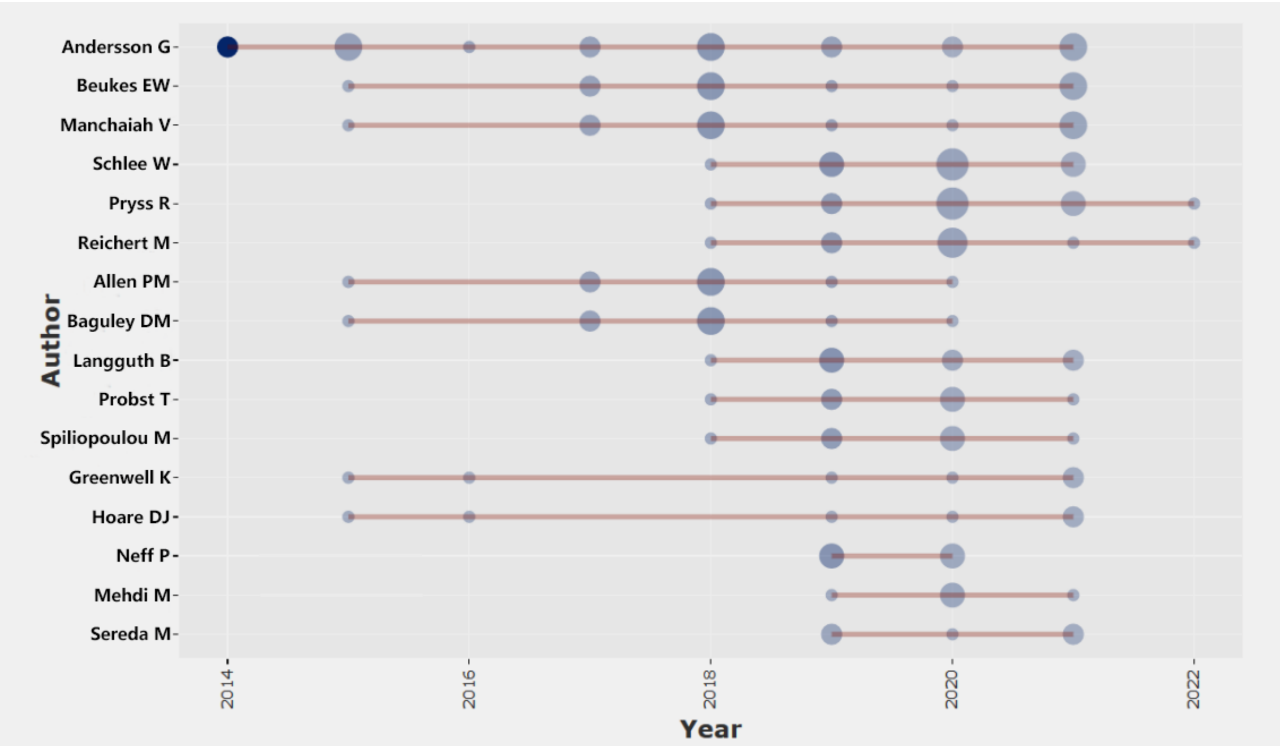
There were 162 authors in the included literature. According to the Lotka law [19], which states that authors with >0.749 times the square root of the number of papers published by the most prolific scientists, this study defined authors with >4 publications as high-producing authors, accounting for 9.9% (16/162). As can be seen in Table 1, Andersson G was the most prolific author, with 22 publications.

Next, we performed an analysis of the posting trends from highly productive authors. A graph of the annual posting trends of highly productive authors, based on their annual posting data and yearly citation frequencies, is shown in Figure 4. Here, the size of the circles indicates the annual posting volume, and the color shade indicates the annual citation frequency. Of the 16 most productive authors, 15 (94%) were found to have started focusing on mHealth-based treatments and interventions for tinnitus only after 2015. Of these 15 authors, 9 (60%) started publishing after 2018, and they have produced a steady annual output since then.

Table 1. Ranking of authors with >4 publications.

Rank by number of articles	Author's name	Articles (n=153), n (%)
1	Andersson G	22 (14.4)
2	Beukes EW	14 (9.2)
2	Manchaiah V	14 (9.2)
3	Schlee W	13 (8.5)
4	Pryss R	12 (7.8)
5	Reichert M	10 (6.5)
6	Allen PM	9 (5.9)
6	Baguley DM	9 (5.9)
7	Langguth B	8 (5.2)
8	Probst T	7 (4.6)
8	Spiliopoulou M	7 (4.6)
9	Greenwell K	6 (3.9)
9	Hoare DJ	6 (3.9)
9	Neff P	6 (3.9)
10	Mehdi M	5 (3.3)
10	Sereda M	5 (3.3)

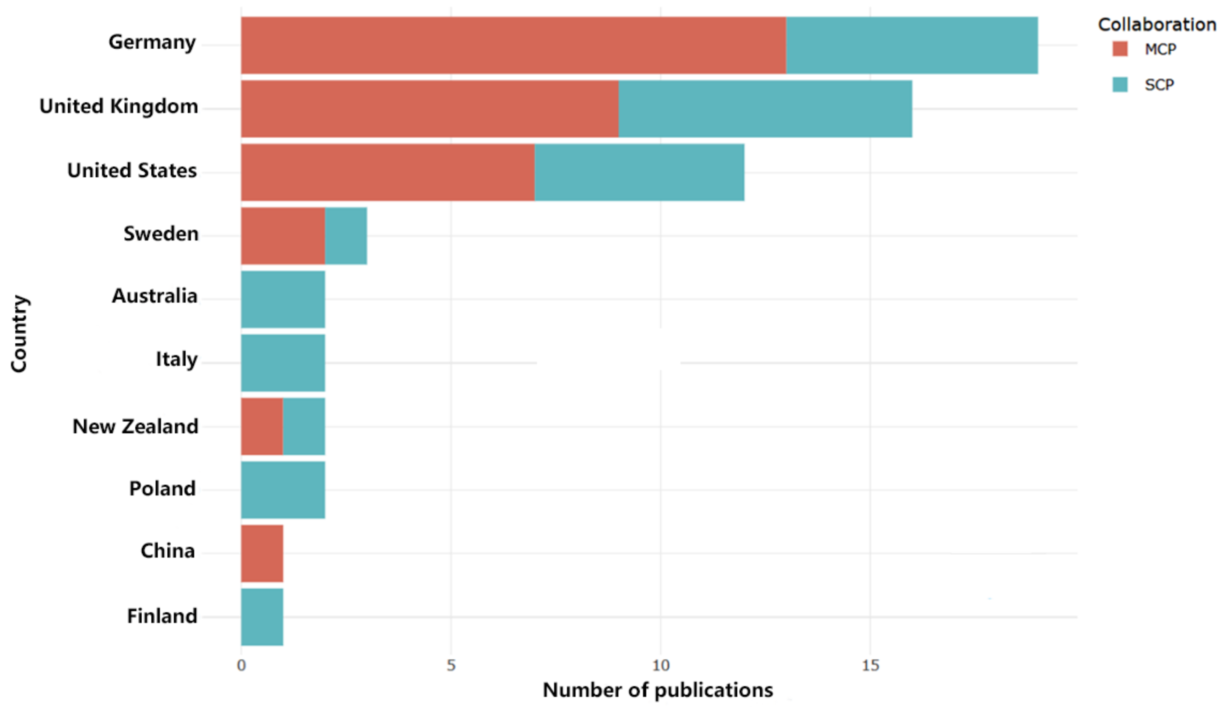
Figure 4. Productivity of the top authors over time.



Analysis of the Publication Country of Origin

The 162 authors in our literature pool were from 15 countries. The top 10 countries (corresponding authors' countries) are shown in Figure 5. Germany has published the largest number of articles in this field (19/75, 25%) and also has the largest number of international collaborations, followed by the United Kingdom (16/75, 21%) and the United States (12/75, 16%). The numbers of multicountry publications and single country publications for the top 10 high-output countries are shown in Figure 5.

Figure 5. Articles by country of corresponding author. MCP: multicountry publication; SCP: single country publication.



Analysis of Posting Themes

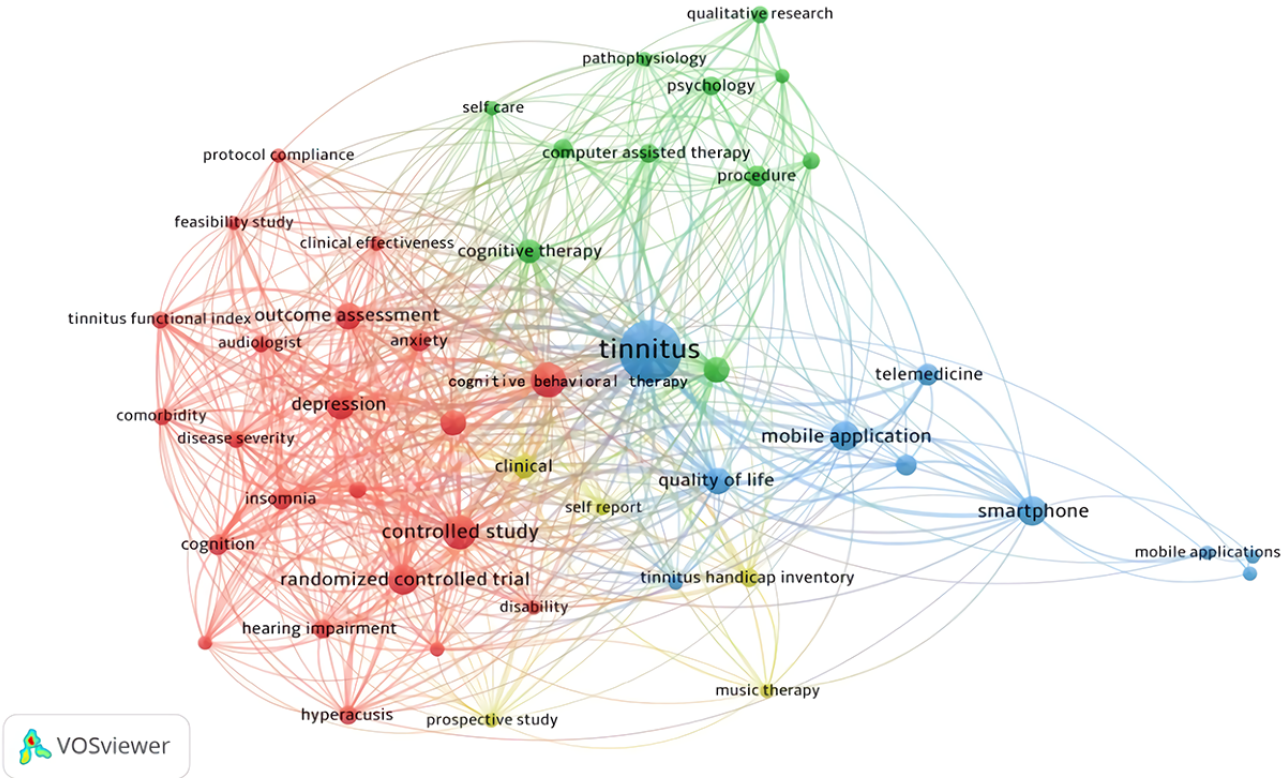
VOSviewer Keyword Clustering Analysis

In this study, we analyzed the themes of the publications in the field from 3 aspects. First, highly frequent keywords were extracted from the abstracts. These keywords referred to literature data, common aspects of highly frequent keywords, and their co-occurrence network. The main research themes were identified from the clustering results. Second, to explore current research hot spots, the thematic map method, proposed by Cobo et al [20], was used to cluster and map themes according to their density and centrality. Finally, trends in the evolution of themes in the field were analyzed from a time-course perspective.

Next, we conducted a visual analysis of highly frequent keyword co-occurrence networks. To obtain all keywords from the relevant studies, the abstracts of the included literature articles were divided, deactivated, and lexically normalized using Python (Python Software Foundation). As shown in Figure 6, a high-frequency keyword co-occurrence network was produced using VOSviewer [21]. As shown in this figure, clustering has divided all keywords into 4 main domains, which could be further combined into 3 categories: red and yellow, green, and blue. The red and yellow categories represent the main treatments currently available for tinnitus (including *cognitive behavioral therapy* and *music therapy*), as well as clinical trials and the main feelings experienced by patients with tinnitus. Clinical trial methods include *randomized controlled trials* and *clinical trials*. The subjective feelings of patients with tinnitus include *anxiety*, *depression*, and *insomnia*. The green category contains computer-related keywords such as *computer-assisted therapy and procedure*. By contrast, the blue category includes keywords such as *mobile app*, *smartphone*, and *telemedicine* for mHealth and mobile devices.

It was particularly interesting to note that *cognitive behavioral therapy* was used as a link between the words *disorder* and *computer*. The words linking *mHealth* and *computer* were mainly basic concepts such as *procedure*. The words linking *mHealth* and *disease* were mainly research methods such as *clinical study*, which were slightly less connected than the other 2 groups.

Figure 6. Keyword co-occurrence network diagram produced using VOSviewer [21].

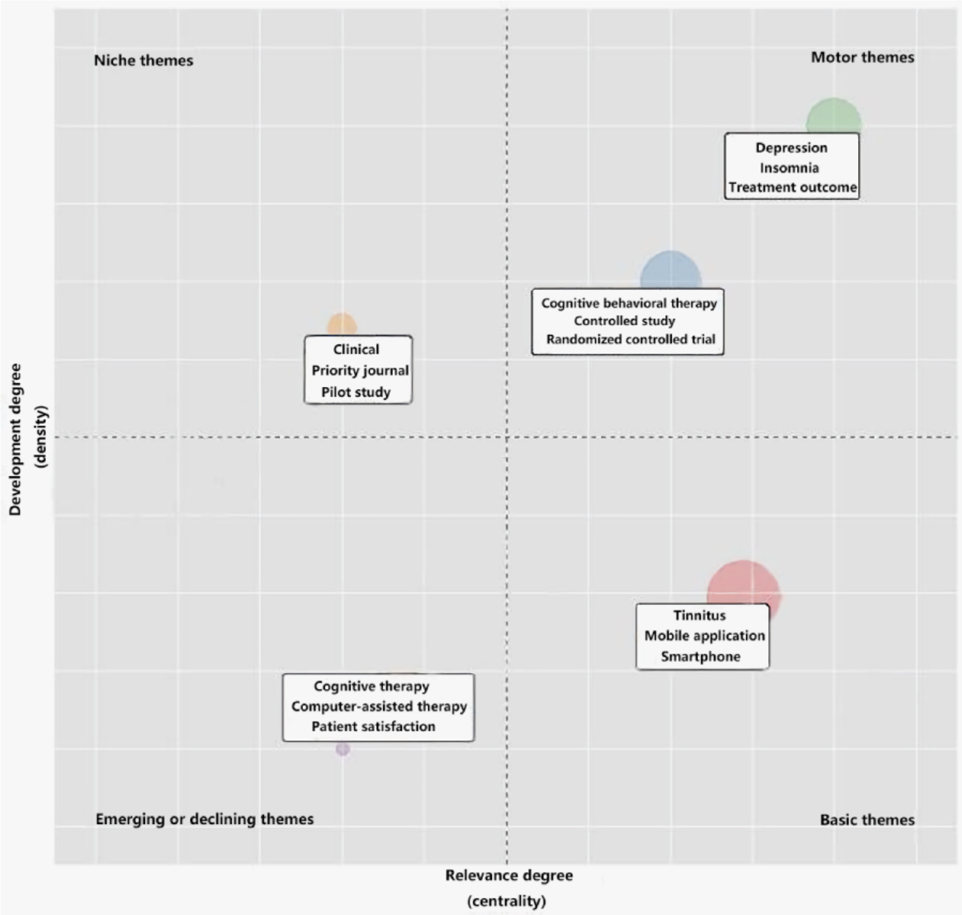


Thematic Map Analysis

Cobo et al [20] proposed the thematic map method, which uses the division of themes into quadrants to analyze the *hotness* and importance of a topic. Topics located in the first quadrant (niche themes) are well developed but relatively less important. Those in the second quadrant (motor themes) are well developed and essential. Topics located in the third quadrant (emerging or declining themes) are not well developed and relatively less compelling. The topics found in the fourth quadrant (basic themes) are not well developed but necessary and generally refer to basic concepts.

By calculating the density and centrality of the already clustered coword matrix, each of the 5 categories was visualized within the 2D coordinates, as shown in Figure 7. We found that, in the first quadrant, the vocabulary of research methods (terms such as *clinical* and *pilot study*) was predominantly used, as well as concepts that have developed well and are currently being phased out. In the second quadrant, we observed that cognitive behavioral therapy and treatment outcomes were essential and well-studied topics. In the third quadrant, we observed that computer-assisted therapy was a topic that has not been well developed yet. In the fourth quadrant, as basic technologies in the field, the concepts of tinnitus, smartphones, and mobile apps were predominantly used.

Figure 7. Thematic map with keywords divided into 4 domains.

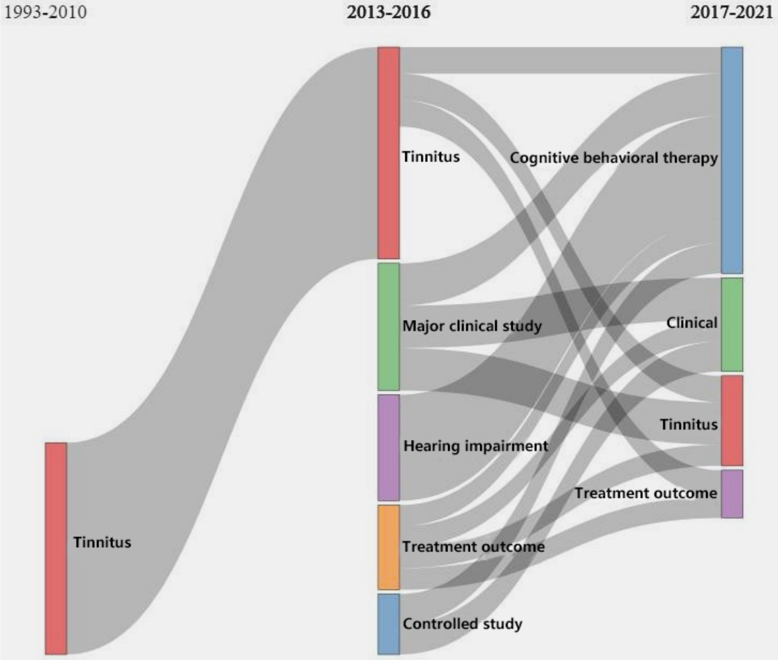


Sankey Diagram Analysis

A thematic evolution analysis was carried out using coword network analysis and clustering. This analysis incorporated the time dimension to analyze the evolution of the research themes from 1993 to 2021 and to create a Sankey diagram (Figure 8).

From this observation, it was clear that there were both changing and unchanging themes. Researchers from as early as the 1993-2010 period focused on tinnitus as a disorder, without introducing further meaningful concepts. During the 2013-2016 period, the traditional research themes did not entirely dissipate, but several research methods were added to these clinical studies. During the 2017-2021 period, research moved from primary to applied, with emerging concepts such as cognitive behavioral therapy. Since 2022, cognitive behavioral therapy has remained the main research topic, whereas the concept of mHealth has not received much attention.

Figure 8. Sankey diagram of trends in the evolution of research themes.



Analysis of the Software Development Stages Described in the Literature

In terms of the software development stages described in the literature, of the 75 papers, 49 (65%) referred to the design stage, 19 (25%) pertained to the clinical validation stage, and 7 (9%) concerned the marketing stage. This distribution reflects the negligible development of software for tinnitus treatment. Preliminary research found that the actual demand for such software was notably high.

Analysis of the Core Treatment Techniques Described in the Literature

Upon further analysis, it was found that 50 (67%) of the 75 papers primarily described treatments that used specific software. Of the remaining 25 studies, 12 (48%) mentioned only internet-based or web-based assessment tools for tinnitus, without any specific treatment associated. Of these 12 publications, 6 (50%) described mobile transient tinnitus assessment, and 4 (33%) used machine learning for predicting tinnitus, whereas 1 (8%) described a repository of tinnitus information, and 1 (8%) described a method for characterizing tinnitus heterogeneity. Of the 50 articles describing treatments, the mentioned treatments were mainly in the categories of cognitive behavioral therapy and sound therapy, with 30 (60%) and 13 (26%) papers, respectively. Of the remaining 7 studies, 1 (14%) included usual service therapy using artificial intelligence (AI) to expose the patient to the tinnitus environment, 1 (14%) used a tinnitus e-plan (an intervention coding method), 1 (14%) used visualized mobile electroencephalogram (EEG) for tinnitus detection, 1 (14%) used meditation (to help patients relieve tinnitus), 1 (14%) used both cognitive behavioral therapy and sound therapy, and 2 (29%) used a game training method related to the localization and perception of a sound source as well as auditory attention.

We compared the stage of software development reported in the literature with the therapies related to the respective software. We found that only a single software using cognitive behavioral therapy and sound therapy was in the market stage. With regard to software in the clinical validation stage, 9 (32%) of the 28 apps used cognitive behavioral therapy tools, 3 (12%) used sound therapy, and 2 (17%) used game training methods related to sound source localization perception and auditory attention. Of the 29 apps described in the literature that were in the design phase, 18 (62%) used cognitive behavioral therapy, 7 (24%) used sound therapy, 1 (3%) used habituation therapy (in which AI exposes the patient to the tinnitus environment), 1 (3%) used meditation, 1 (3%) used visualized mobile EEG, and 1 (3%) used an intervention coding approach.

Analysis of the Listed Apps

Analysis of the Number of Apps

Mobile tinnitus treatment software is currently in high demand. In this study, 28 apps were identified from software data sources (Figure 2), 4 of which were from software with specific names in the literature. These 28 apps consisted of 18 (64%) iOS apps and 10 (36%) Android apps (Multimedia Appendix 4). Most of these apps were developed by institutions (22/28, 79%); a few were developed by individuals (2/28, 7%). Among the 24 apps obtained from product data, 13 (54%) were medical apps, and 9 (38%) were health apps.

Regarding the software providers, of the 28 apps, 22 (79%) were available on the Apple App Store (China), and 21 (75%) were available on the Apple App Store (United States). In addition, 5 (18%) were available on the Google Play Store, and 5 (18%) were available on the Huawei, Xiaomi, Oppo, and Vivo marketplaces. Software activity can be reflected at the time of listing and at the time of the latest update. After data collection, we found that in 23 (82%) of the 28 apps, time information was complete.

Analysis of the Distribution of Source Countries

Multimedia Appendix 5 depicts the origin of the software developers. Of the 28 apps, 10 (36%) were developed in the United States, 8 (29%) in China, and 9 (32%) in other countries (n=1, 11% in the United Kingdom; n=3, 33% in Germany; n=3, 33% in Denmark; n=1, 11% in Poland; and n=1, 11% in New Zealand). Of the 28 apps, there was 1 (4%) whose country of origin could not be found. Regarding specific locations, the US software developers hailed from 7 states (3/10, 30% from Minnesota; 2/10, 20% from Texas; 1/10, 10% from Colorado; 1/10, 10% from Wisconsin; 1/10, 10% from California; 1/10, 10% from Florida; and 1/10, 10% from Oregon). Of the 8 software developers based in China, 7 (88%) were from regions within mainland China (n=3, 43% from Beijing; n=2, 29% from Jiangsu; n=1, 14% from Shanghai; and n=1, 14% from Guangdong), and 1 (13%) was from Hong Kong, China.

Analysis of the Functional Division of the Apps

When analyzing the 28 tinnitus treatment–related apps, this study divided them into three main categories: (1) screening and evaluation, (2) intervention and rehabilitation, and (3) education and information. Of the 28 software programs, 28 (100%) were related to intervention and rehabilitation, 11 (39%) were related to screening and evaluation, and 5 (18%) were related to education and information. Regarding the users of the software, of the 28 apps, 26 (93%) were intended to be used by patients or their families, and 2 (7%) were intended to be used by medical staff. In this study, we considered whether a professional was required to assist patients with the software and found that, in the case of 7 (25%) of the 28 apps, a professional was needed to assist the patient. By contrast, the remaining apps (21/28, 75%) could be used by patients without assistance from a professional.

When analyzing the specific functions of the apps, this study divided them into the following 6 areas: assessment, advice, detection, counseling, treatment, and relief. Of the 28 apps, 6 (21%) were dedicated to patient assessment, 4 (16%) could provide advice based on the actual patient situation, 5 (18%) could perform a preliminary test of the patient's tinnitus or hearing condition, another 5 (18%) had a web-based counseling function, and 13 (46%) could provide the user with a treatment plan for the different tinnitus conditions. The primary product information is described in Multimedia Appendix 6.

Analysis of Treatments Provided by the Apps

After examining the treatments mentioned in the app descriptions, we found that, of the 28 apps, 7 (25%) used masking therapy, 2 (7%) used habituation therapy, and 2 (7%) used cognitive behavioral therapy. Moreover, of the 28 apps, 1 (4%) used sound therapy, 1 (4%) used neuromusic therapy, 1 (4%) used play therapy and frequency discrimination therapy, 1 (4%) used transcallosal vagus nerve microcurrent stimulation, and 1 (4%) used neuromodulation therapy. The remaining apps (12/28, 43%) did not specify the type of treatment used.

Analysis of App Validity

Regarding the validity and reliability of the apps, we found that some of the apps (6/28, 21%) were created by developers in collaboration with specific authorities. The 6 partner organizations are the American Tinnitus Association; the Eye, Ear, Nose, and Throat Hospital affiliated to Fudan University (Shanghai, China); a team of doctors from Tsinghua University (Beijing, China); a team of tinnitus specialists from well-known tertiary hospitals and first-line tinnitus experts; a Canadian team with Food and Drug Administration (FDA)–approved tinnitus rehabilitation core technology; and the University of California (Los Angeles, California, United States).

Comparative Analysis of Literature and Apps

Regarding the target audience, the software described in the literature was mostly consistent with the marketed apps. Most of the apps (26/28, 93%) focused on patients and their families, whereas a few (2/28, 7%) targeted medical staff. Most of the apps (20/28, 71%) provided different types of sounds to relieve tinnitus. A few of the apps (5/28, 18%) required the use of hearing aids, being aimed at medical staff use.

In the comparative analysis of the app scenarios, there was a strong consistency between the 2 types of apps. Most of the apps focused on the home scenario (22/28, 79%), whereas a few of the apps (6/28, 21%) are meant to be used in hospitals or other institutions dedicated to professional audiology. The tinnitus treatment apps currently available for download and use are mostly rudimentary. Most of them (22/28, 79%) can only provide initial relief to the patients or provide an assessment of their condition

In a comparative analysis of the treatment techniques, the software described in the literature was predominantly based on sound therapy. This was a preferred approach, probably because, on the one hand, it was easier to implement in combination with mHealth software and, on the other hand, it was effective in tinnitus treatment. Half of the apps (16/28, 57%) listed in the app stores were based on acoustic and cognitive behavioral therapy, with significant user feedback available. Taking advantage of the psychoemotional characteristics of patients with tinnitus, a potential treatment method for tinnitus that involves transcranial magnetic electrical stimulation (containing 2 models: one for transcaudal vagus nerve microcurrent stimulation technology and one for neuromodulation therapy) needs to be developed. The other half (12/28, 43%) of the available apps did not describe the treatment method and lacked user evaluations. This was probably because of the relatively early stage of development of such apps and their limited user results.

A comparative analysis from a clinical standpoint showed that the apps mentioned in the literature were in the theoretical design stage. Relevant studies involving the application to human patients generally need ethics review committee approval, have to meet high product quality requirements, and have to sustain through long development and validation pathways, as well as overcome low translation rates. Individual apps are not marketed because they are not currently registered, despite having been rigorously designed at the theoretical level. Among the marketed apps, the proportion of those in the therapeutic intervention stage is high (5/7, 71%), with a relatively strong practicality and a modest performance.

Discussion

Current Status and Trends in Research

Literature Information

The number of studies in the field of tinnitus apps has increased yearly, with a rapid growth after 2015 and with the annual publication volume peaking in 2021. The articles were published in journals of moderate quality. Nevertheless, the acceptance rates of articles in the field by top medical journals were low. Of the 75 research articles in this field, 51 (68%) were included in the Web of Science core collection and had an average journal impact factor of 5.12 (spanning between 1.245 and 25.617 in the field of psychotherapy and psychosomatics). The studies were mainly published in the *American Journal of Audiology* and in the *Journal of the American Academy of Audiology*, with 18 (n=12, 67% and n=6, 33%, respectively) articles published as of February 2022, representing 24% (18/75) of the total number of articles. Nevertheless, the acceptance rates of articles in this field in top medical journals were poor, with no relevant studies published in the *New England Journal of Medicine*, *The Lancet*, the *Journal of the American Medical Association*, or *The BMJ*. The annual output of the most productive authors was the highest in 2021. In accordance with the Lotka law, this study identified 16 highly productive authors in the field, all of whom have published consistently in the last 3 years. This suggests that this area is steadily and rapidly growing. The authors were mainly from Germany (19/75, 25%), the United Kingdom (16/75, 21%), and the United States (12/75, 16%), with fewer authors from other countries (27/75, 36%), and only a single author from China (1/75, 1%). Of the 75 articles, 47 (63%) were published by authors from Germany, the United Kingdom, and the United States.

The current hot spot in this field is the research on sound and cognitive behavioral therapy, focusing on the outcomes for the treatment of patients with tinnitus. Thematic map analysis showed that the terms in the second quadrant of the thematic map included cognitive behavioral therapy, sound therapy, and tinnitus treatment outcomes. This indicates that research on cognitive behavioral therapy and sound therapy (with a focus on tinnitus treatment outcomes) is a current hot spot in the field of mHealth-based software interventions for tinnitus treatment. This area of research is well developed, with a focus on the assessment of tinnitus, but its importance is not sufficiently recognized yet. Our results are in agreement with those of relevant studies conducted in recent years [22].

App Information

Most of the apps (16/28, 57%) in this field have been newly developed and provide functional support for therapeutic interventions for tinnitus. Nevertheless, software development in this field lacks a research basis. Such software often has high requirements for ancillary apps [23], such as the sound quality and calibration of headphones. Cognitive behavioral therapy relies on professional tinnitus specialists for guidance. By contrast, it is difficult to achieve an accurate grasp of a user's criteria for the use of such apps with mobile phone sensors or wearable apps alone [24]. As a result, and in comparison with other fields, the number of diagnostic apps is relatively small.

The adoption of apps under development has been poor, with the vast majority of the available apps used in very few or no real-life scenarios. The results showed that only 28 designed apps were available for download from app stores. This limitation suggests that, although many tinnitus treatment–related apps have been developed by experts and academics in recent years, most of them still lack practical use. It also suggests that these apps have a very homogeneous collection of patient information and a single-center validation of their effectiveness; in addition, they lack validity studies for clinical retesting as well as user feedback [25]. The reasons behind these aspects could be related to other attributes of the apps, such as their effectiveness and ease of use. To develop and validate apps that can be used in the clinical setting, researchers should also focus on other attributes, such as the ease of use of the apps.

Translation Status

For many years, there has been a lack of translation of the results of tinnitus treatment interventions using mHealth software and apps. This lack of translation is consistent with the results of our study on the analysis of product applications in this area. The vast majority of these apps (22/26, 85%) require both research and development, with scientific validity and effectiveness in a state of urgent need, and are far from truly achieving their goal of an effective tinnitus treatment intervention [26].

Problems and Potential

The Overall Picture of Tinnitus Treatment Apps Is Unsatisfactory

Scoring Analysis of Tinnitus Treatment Apps

Regarding the ratings of the included 28 tinnitus treatment–related apps (n=24, 86% from product data and n=4, 14% from literature data) on the Qimai app data analysis platform, 17 (61%) had ratings as high as 5.00 out of 5.00 and as low as 1.00 out of 5.00 (with an average rating of 3.84 out of 5.00). Of these 17 rated apps, China and the United States accounted for 7 (41%) and 5 (29%), respectively. The 5 apps developed in the United States had ratings of 4.40, 4.80, 4.80, 4.90, and 5.00 (average rating: 4.78), whereas the 7 apps developed in China had ratings of 1.00, 1.80, 3.80, 4.00, 4.10, 4.30, and 4.70 (average rating: 3.39).

Evaluation Analysis of Tinnitus Treatment Apps

With regard to the information on the 28 tinnitus treatment–related apps provided on the Qimai app data analysis platform, 10 good reviews were collected over 1 year. All these reviews referred to 6 (21%) of the 28 apps and were about their usefulness and usability. After analyzing the geographical regions of origin, our study found that the developers of 5 (83%) of these 6 apps were from China, with 5 positive reviews and 3 negative reviews.

Traditional Treatment Methods Are Far From Satisfactory

There is currently no international uniform treatment protocol for tinnitus. Moreover, evidence-based medical research has not found a single method with definitive efficacy for all types of tinnitus. The available methods include medications, repetitive transcranial magnetic stimulation, electrical stimulation of the tympanic capsule, cochlear implants, electrical stimulation of the vagus nerve, and acupuncture [27]. The treatment of tinnitus relies on obtaining an accurate hearing profile of the patient as well as indicators of the central frequency and intensity of the sound produced by tinnitus. After excluding the etiologies associated with tinnitus, counseling, cognitive behavioral therapy, and sound therapy have become the main treatment approaches [28]. Other approaches include relaxation and sequential therapy [29]. The lack of adjunctive therapies to improve outcomes in complex conditions is a common problem in tinnitus treatment, recognized both domestically and internationally.

Clear Differences in Tinnitus Treatment Apps at the Research Level Versus the App Level

Current research has uncovered the lack of connection between mHealth apps and their applications. In recent years, national and international research scholars have recognized the roles of neural synchronization and remodeling the mechanisms of action in tinnitus [30]. On the basis of these findings, adjunctive sound therapy involves the administration of appropriate acoustic stimulation (of a specific frequency and duration) to break abnormal nerve synchronization and remodeling. This procedure seeks to form a new auditory center, thereby reducing or eliminating tinnitus [31]. The use of mHealth apps to provide appropriate auditory training for patients with tinnitus has proven effective at the research level. Nevertheless, important aspects are lacking and need to be addressed. These include a scientific basis for software function, the standardization and calibration of the sounds emitted, real-time guidance from experts during the use of the apps by patients, clinical validation and feedback from patients on product effectiveness, and the connection between research and apps in this field.

Significant Differences in the Status of Relevant Research and Apps Between China and Other Countries

Our study showed that, although most research and apps in this area were developed outside China, there are still important limitations. The sample size of research and apps in this field, both domestically and abroad, was small. The final number of apps found to meet all inclusion criteria was only 28, of which only 4 (14%) were documented in the literature. This limitation has a particular impact on the results of our study. Moreover, it also reflects the decreased volume of research in this field, which strengthens the innovation and value of our work.

Tinnitus Is Difficult to Treat and Requires Urgent Assistance From Emerging Technologies

With the increased stress levels in modern work and life, tinnitus does not appear in isolation. Nevertheless, it is a combination of symptoms closely related to the etiological mechanisms and aggravating factors of several systemic diseases. More than 50% of patients with tinnitus experience sleep disturbances [32]. In the United Kingdom, the prevalence rate of tinnitus in the adult population is 10.1%, with the disorder severely affecting the quality of daily life [33]. In the United States, the prevalence rate of tinnitus in adolescents is from 7% to 9%, and in older people, it is approximately 25% [34]. In Japan, the prevalence rate of tinnitus in the adult population is 11.9% [35]. Although there are no large-scale epidemiological data on the prevalence rates of tinnitus in China, available studies have reported its prevalence rate in the adult population to be approximately 10%. Approximately 5% of the patients with tinnitus seek medical treatment, and approximately 2% of the patients have tinnitus that severely affects their life, sleep, the ability to concentrate and work, and social activities [36]. The complex and heterogeneous etiology of tinnitus as well as its unclear pathogenesis have contributed to the poor treatment outcomes for this disorder. Nevertheless, as industry and technology continue to develop and society ages, the prevalence of tinnitus is gradually increasing, making its early detection, diagnosis, and effective treatment urgent.

The evidence-based guidelines for clinicians managing patients with tinnitus [1] recommend an acoustic therapy approach, in which any sound can be used to alter the perception of, and response to, tinnitus, for the patient's benefit. This therapy can be performed with environmental optimization devices such as hearing aids, sound generators, and tinnitus hybrid acoustic therapy devices, as well as commonly used devices such as mp3 players, smartphones, and radios. Tinnitus rehabilitation approaches must not disregard the integration of traditional methods with innovative technologies [37]. With the expansion and increased application of the mobile internet in various industries, health care–focused mobile internet technology has been receiving increased interest owing to its rapid development. Therefore, the combination of sound therapy and cognitive behavioral therapy for tinnitus has led to the development of an mHealth app model with this purpose.

Future Developments and Outlook

The Theory of mHealth for Adjunctive Treatment and Intervention in Tinnitus Is Logically Clear and Scientifically Solid

To address the ineffectiveness of traditional treatments for tinnitus, one of the 3 most difficult conditions plaguing human health in the otolaryngology field (the other 2 being deafness and vertigo), researchers have been exploring interdisciplinary avenues [38]. The evidence-based guidelines for clinicians managing patients with tinnitus recommend cognitive behavioral therapy for patients with chronic compensatory tinnitus, as well as effective and feasible acoustic treatment options provided by physicians or hearing aids for patients with tinnitus with hearing loss [39]. mHealth is unique in providing behavioral health interventions. One of its scientific theories is cognitive behavioral therapy. The future integration of mHealth for tinnitus treatment and intervention is in line with the recommendations of professional guidelines and has a sound scientific and theoretical basis.

The Pathway for mHealth to Be Used as an Adjunctive Treatment and Intervention in Tinnitus Is Clear and Highly Feasible

One of the theoretical foundations of mHealth is cognitive behavioral therapy. As of 2016, approximately 500 mHealth apps based on cognitive behavioral theory were available in the Apple App Store and Google Play Store. Current mobile apps are relatively well established in the use of cognitive behavioral therapy interventions in psychosocial health services to relieve anxiety, depression, and stress as well as treat other physical ailments and improve maladaptive behavioral problems (such as eating disorders and substance abuse). As a result, the product experience in mHealth is relatively mature. More than half of all patients with tinnitus have comorbid psychological problems such as anxiety, depression, and sleep disorders [40]. On the basis of the existing experience with mHealth, there is a clear and feasible pathway for adjunctive treatment and intervention in tinnitus.

The Use of mHealth for Adjunctive Treatment and Intervention in Tinnitus Is Effective and Has Good Generalizability

Our findings regarding mHealth use in mental health, disease management, and health behavior promotion indicate that mHealth apps, combined with cognitive behavioral therapy, were highly effective in reducing tinnitus pain, anxiety, and depression as well as in improving the patients' quality of life. In 2019, Aazh et al [41] found that the use of cognitive behavioral therapy for tinnitus was more effective when used 8 to 24 times per week for 60 to 120 minutes each time. The treatment could be remotely guided through an mHealth App to accommodate more patients and promote research progress on effective tools for treating tinnitus [42].

Limitations

Our study has some limitations. First, the data used were mainly from published literature (which included only scientific literature). Second, this study performed a simplified analysis of the product translation. We only analyzed the overall conversion rate and did not analyze specific apps and specific application scenarios. Finally, owing to the difficulty of obtaining complete data on apps and scientific research funds, we have only preliminarily explored the input-output relationship of some of the apps.

Conclusions

The field of monitoring, diagnosing, and treating tinnitus disorders using mHealth apps has shown rapid overall growth during recent years. Accordingly, there has been an increase in the number of relevant publications per year. Progress has been made in research on cognitive behavioral therapy, with a focus on the improvement of tinnitus symptoms and on the development of apps to support tinnitus monitoring and interventions. Nevertheless, the number of studies in this area is still low, international collaborations are lacking, the acceptance rates of articles in this field in refereed medical journals are poor, and most of the developed apps are not used in real-world settings. Future research should address the need for increasing tinnitus awareness and strengthening international collaborations to achieve an improved monitoring of tinnitus, using novel AI tools. In addition to the validation of tinnitus treatment apps, future research should also focus on the app properties that can promote the application of such apps in the real world.

Acknowledgments

The authors are grateful to the many students and research assistants at Peking University, Zhejiang University, and Zhejiang Chinese Medicine University who collaborated with us. This research was supported by the 2022 National College Student Innovation and Entrepreneurship Training Program (202210344001) and the 2022 Zhejiang Provincial Science and Technology Innovation Activity Plan for College Students (2022R410A045).

Abstract

Background: Oral health is a significant part of general health. Poor oral health can influence an individual's appearance, self-esteem, eating, and speaking. The use of mobile phone apps has been growing in the field of medicine, including dentistry. However, to date, there is no evidence related to the availability of mobile apps focusing on various branches of dentistry.

Objective: The aim of this study was to review the scientific literature on the use of patient-oriented mobile phone apps in oral health and summarize the key findings.

Methods: A scoping review of published scientific literature on the use of patient-oriented mobile phone apps in oral health was conducted in accordance with the Joanna Briggs Institute. A search was performed in PubMed and Scopus for studies published between January 2000 and June 2021 that were written in English. All study types except for those reporting developmental protocols were included in this review. In total, 2 reviewers independently screened the studies using the eligibility criteria. The study protocol was registered in the Open Science Framework registries in June 2021.

Results: The initial search yielded a total of 977 studies, 45 (4.6%) of which met the inclusion criteria. All the studies (45/45, 100%) were published after 2009. Most studies (31/45, 69%) concerned oral health promotion using mobile phone apps, followed by behavior management (5/45, 11%). More than half (23/45, 51%) of the included studies were conducted in Asian countries. Overall, 31% (14/45) of the studies focused on adolescents. A total of 51% (23/45) of the studies were randomized controlled trials (RCTs). Approximately 39% (9/23) of the included RCT studies reported a substantial reduction in dental plaque, and 26% (6/23) of the studies reported significant improvement in gingival health. Regarding dental anxiety management, 13% (3/23) of the RCT studies reported a significant decrease in mean heart rate and lower Facial Image Scale scores.

Conclusions: According to the literature, the use of mobile apps in oral health is increasing among patients, mainly children and adolescents. Many studies that have used mobile apps have focused on promoting oral health. However, other areas such as diagnostic and remote consultations (teledentistry) have until recently been neglected despite their great potential.

(JMIR Mhealth Uhealth 2023;11:e46143) doi:10.2196/46143

KEYWORDS

oral health; dentistry; mobile apps; mobile health; mHealth; mobile phone

Introduction

Background

Oral health is a significant part of general health. Poor oral health can influence an individual's appearance, self-esteem, eating, and speaking [1]. Poor oral health is also one of the leading causes of loss of work productivity, increased school absenteeism, and reduced academic performance [2,3].

The risk factors for the most common oral diseases, such as dental caries and periodontal diseases, include physical, biological, environmental, behavioral, and lifestyle-related factors [4,5]. Most of the behavioral and lifestyle-related factors responsible for oral diseases are also common to various systemic diseases [6]. For instance, frequent consumption of foods and drinks containing free sugar can lead to dental caries as well as obesity [7]. Similarly, tobacco use is a risk factor for periodontal diseases, cardiovascular disease, respiratory diseases, and cancer [6,8]. In addition, poor oral health has an adverse effect on individuals' general health. For example, periodontitis is considered one of the risk factors in the pathogenesis of diabetes mellitus, cardiovascular disease, kidney disease, and recurrent pneumonia [7,9]. Despite being preventable, >3.5 billion people have been affected by oral diseases worldwide, predominantly dental caries and periodontal diseases [10]. Although the concept of managing oral diseases has shifted toward prevention at the individual level, actions are being taken to move toward a more patient-centered management of oral diseases, focusing on promoting and maintaining good oral health in partnership with the patient [11].

Health promotion has been a key component in disease prevention. Behavior change approaches, such as communicating disease risk information and the self-monitoring of one's own health as part of health promotion, have been successful in modifying the health behavior of individuals. Behavior change approaches refer to the specific strategies used in interventions to promote behavior change [12,13]. Behavioral interventions involve people's decision-making process about their health.

Recently, the use of mobile technologies in the medical field (also known as mobile health [mHealth]) has been growing. With their many features and high use by consumers, mobile phones are one of the devices suitable for accessing health information, improving the quality and coverage of health care, and promoting health [14,15]. In addition, the use of mobile phone apps has been shown to have positive outcomes in general health. For instance, mobile apps are used for remote consultation [16], disease diagnosis [17], reminders for patients [18], and behavior modifications [19].

As of 2017, there were >325,000 mobile apps available on the Google Play Store and Apple App Store platforms that mainly focused on health and well-being [20]. Similarly, in dentistry, a total of 1075 oral hygiene apps were available as of 2018 [21]. Evidence on the availability of mobile apps focusing on various branches of dentistry is still unclear. In addition, with mHealth being popular, it is important for health professionals to know the availability of different kinds of mobile apps and be assured that the mobile apps are disseminating fact-based information [22]. Therefore, the aim of this study was to examine the main findings in the literature on the use of patient-oriented mobile apps in oral health.

Review Questions

The primary question is as follows: What are the main findings in the literature related to the use of patient-oriented mobile apps in oral health? The secondary questions are as follows: What types of evidence are available in the literature related to the primary question? and How has this research been conducted?

Methods

Information Sources and Search Strategies

This scoping review was conducted in accordance with the Joanna Briggs Institute methodology for scoping reviews [23]. A preliminary search of MEDLINE, the Cochrane Database of Systematic Reviews, and *JBI Evidence Synthesis* was conducted on January 22, 2021, and no current or ongoing systematic or scoping reviews on the topic were identified. The text words contained in the titles and abstracts of relevant articles and the index terms used to describe the articles were used to develop a full search strategy for PubMed and Scopus. The search strategy, including all the identified keywords and index terms, was adapted for each database included. The reference lists of all included sources of evidence were screened for additional studies. The search terms used were "Mobile Applications" (Medical Subject Headings [MeSH]) OR "Mobile Application*" OR "Mobile App*" (text word) OR "Mobile health" (text word) OR "mHealth" (text word) OR "Health app*" (text word) OR "smartphone app*" (text word) AND "Dentistry" (MeSH) OR "dental*" (text word) OR "Oral Health" (MeSH) OR "Oral Hygiene" (text word) OR "Oral Medicine" (text word).

The study protocol was registered in the Open Science Framework registries in June 2021 [24].

Eligibility Criteria

Overview

This scoping review considered all study types (experimental and quasi-experimental, cohort, case-control, cross-sectional, case series, case reports, descriptive cross-sectional studies, systematic reviews, and both qualitative and quantitative studies) that were published between January 2000 and June 2021 in English. Studies focusing on the development of mobile apps related to oral health were excluded. The participants, concept, and context guides for this scoping review are as follows.

Participants

This study included all age groups.

Concept

Patient-oriented mobile apps that are used in oral health were included.

Context

All areas, cultures, and sexes were included.

Study and Source of Evidence Selection

Following the search, all identified citations were collated and uploaded into the Covidence data screening and extraction tool, and duplicates were removed. To ensure the calibration, a pilot test was arranged. A total of 25 samples of titles and abstracts were selected for the pilot test by one of the team members (SK), 2 reviewers (AK-S and SH) conducted the pilot test using the eligibility criteria, and the agreement was 84% [23]. Following the pilot test, titles and abstracts were screened by 2 independent reviewers (AK-S and SH) for assessment against the inclusion criteria. Full texts of potentially relevant sources were retrieved, and their citation details were imported into the Mendeley Reference Manager (Mendeley Ltd). The full texts of selected citations were assessed in detail against the inclusion criteria by 2 independent reviewers. The reason for excluding sources was that the full text did not meet the inclusion criteria of this scoping review. Any disagreements between the reviewers at each stage of the selection process were resolved with an additional reviewer (SK). The results of the search and the study inclusion process were reported in full in the final scoping review and presented in a PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) flow diagram [25].

Data Extraction, Data Analyses, and Risk-of-Bias Assessment

The extracted data included specific details about the participants, concept, context, study methods, and key findings relevant to the review questions. On the basis of the extracted data, the proportions of year of publication, subgroups based on focus areas, and study types were calculated and presented in a table.

No risk-of-bias assessment was performed in accordance with the Joanna Briggs Institute methodology for scoping reviews [23].

Results

Selection of Studies

A total of 977 studies were found in the initial search, as shown in Figure 1. After removing duplicates, 64.4% (629/977) of the studies were screened. Studies that did not meet the inclusion criteria were excluded. The most common reasons for exclusion were that the study was not related to oral health, it did not include a mobile app, the full text was not available, or the study was not written in English. A total of 45 studies were included in the scoping review.

Data were extracted from the included studies (n=45), and their general characteristics are presented in Table 1. All the included studies (45/45, 100%) were categorized into different groups depending on the focus area of the mobile apps. The categories are oral health promotion, diagnostic, orthodontic, behavior management, trauma, and other.

Systematic review	4 (9)

[a]June 2021.

Characteristics of the Included Studies

Most studies (31/45, 69%) were categorized under oral health promotion. All studies (45/45, 100%) were published between 2009 and 2021. One-third (14/45, 31%) of the studies focused on adolescents aged 10 to 19 years, and 24% (11/45) of the studies focused on children aged <10 years. More than half (23/45, 51%) of the included studies were randomized controlled trials (RCTs). More than half (23/45, 51%) of the included studies were from Asia (Figure 2).

Table 2 shows the main findings of the included studies. Most of the included studies (21/45, 47%) focused on improving oral hygiene through effective toothbrushing. A total of 20% (9/45) of the studies focused on knowledge, attitudes, and practice [26-34]. In total, 11% (5/45) of the studies were based on treatment outcome [35-39], and 9% (4/45) of the studies reported on the use of mobile apps in the management of dental anxiety [40-43]. Only 2% (1/45) of the studies were based on disease diagnosis [44], and 2% (1/45) of the studies were based on remote dental care services [45]. Among the 45 studies, 4 (9%) systematic reviews were also included [46-49].

Approximately 39% (9/23) of the included RCT studies reported a significant reduction in dental plaque [26,46,53-57,59,63]. Similarly, 26% (6/23) of the studies reported significant improvement in gingival health measured via bleeding on probing [51,53-55,57,59], and only 4% (1/23) of the studies reported a reduction in enamel caries [59]. Regarding dental anxiety management, 75% (3/4) of RCT studies reported a significant decrease in mean heart rate and lower image scale scores compared with the controls [41-43].

Figure 2. Geographical areas of the included studies (n=45).

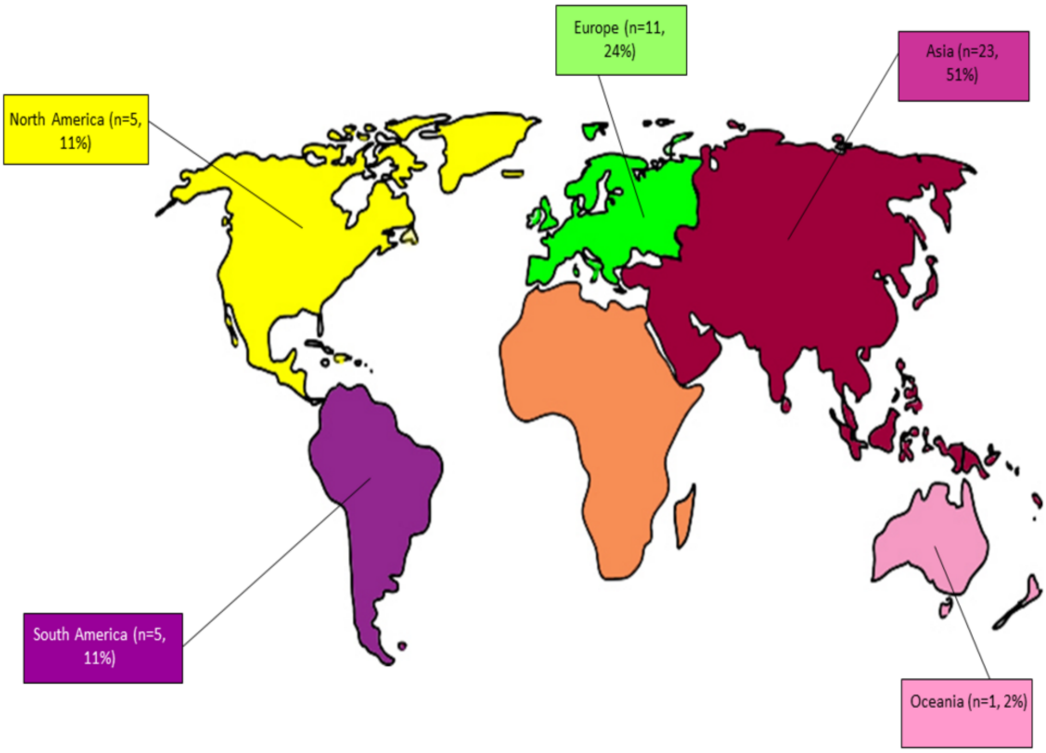

Table 2. Main findings of the included studies (n=45).

Study, year	Country of origin	Study design	Sample size	Age	Purpose	Key findings
Alkilzy et al [50], 2019	Germany	Randomized controlled trial	60 recruited; 49 completed	Children aged 5-6 y	Investigate the efficacy of a manual toothbrush with a gravity sensor and mobile app for improving manual toothbrushing	At the 6- and 12-week follow-ups, the test group showed statistically significantly better oral health indexes than the controls. After the 6-week follow-up, the Quigley-Hein Plaque Index was 0.8 (SD 0.5) for the test group and 1.88 (SD 0.9) for the control group (*P*<.001), and the Papillary Bleeding Index was 0.08 (SD 0.1) for the test group and 0.26 (SD 0.2) for the control group (*P*<.001). After the 12-week follow-up, the Quigley-Hein Plaque Index was 0.44 (SD 0.5) for the test group and 1.49 (SD 0.7) for the control group (*P*<.001), and the Papillary Bleeding Index was 0.05 (SD 0.18) for the test group and 0.21 (SD 0.1) for the control group (*P*<.001).
Chang et al [51], 2021	Taiwan	Randomized controlled trial	150 recruited; 88 completed	26-77 y	Investigate the effectiveness of a mobile app (OSCA[a]) in improving OHS[b] and OHBs[c]	After the 4- to 8-week follow-ups, no significant difference in OHS improvement measured using the O'Leary PCR[d] was found between the control and intervention groups (mean OHS improvement was 17.0, SD 18.84 in the control group and 26.17, SD 21.76 in the intervention group; *P*=.06). OHBs (frequency of toothbrushing, duration of toothbrushing, interdental cleaning, and tongue cleaning) in both the control and intervention groups improved significantly (*P*=.007 and *P*<.001, respectively).
Alkadhi et al [52], 2017	Saudi Arabia	Randomized controlled trial	44	≥12 y	Investigate the impact of using mobile app active reminders to improve oral hygiene compared with verbal oral hygiene instructions	Both PI[e] and GI[f] significantly decreased after 4 weeks of using active reminders of oral hygiene instructions on a mobile app compared with verbal oral hygiene instructions (*P*=.04 and *P*=.02, respectively). For mobile app users, mean PI was 0.8007 (SD 0.4062) at baseline and 0.6677 (SD 0.3146) after 4 weeks, and mean GI was 0.3450 (SD 0.2955) at baseline and 0.2273 (SD 0.2256) after 4 weeks. For verbal oral hygiene instruction recipients, mean PI was 0.8959 (SD 0.4824) at baseline and 0.9891 (SD 0.5244) after 4 weeks, and mean GI was 0.4927 (SD 0.3005) at baseline and 0.5941 (SD 0.5679) after 4 weeks.
Farhadifard et al [53], 2020	Iran	Randomized controlled trial	120	15-25 y	Evaluate the efficacy of a smartphone app (Brush DJ) for oral hygiene compliance of patients with fixed orthodontic appliances	Significant improvements in PI and GI were observed in the group using the smartphone app (Brush DJ) compared with conventional oral hygiene instruction recipients after 4 weeks (T1), 8 weeks (T2), and 12 weeks (T3; *P*<.001). For mobile app users, mean PI was 75.21 (SD 13.36) at baseline, 73.39 (SD 12.50) at T1, 69.18 (SD 11.84) at T2, and 67.84 (SD 12.33) at T3, whereas the mean GI was 1.29 (SD 0.49) at baseline, 1.20 (SD 0.04) at T1, 1.04 (SD 0.04) at T2, and 1.00 (SD 0.05) at T3. For conventional oral hygiene instruction recipients, mean PI was 76.59 (SD 12.76) at baseline, 76.89 (SD 11.11) at T1, 78.90 (SD 8.89) at T2, and 80.82 (SD 10.05) at T3, whereas the mean GI was 1.49 (SD 0.59) at baseline, 1.35 (SD 0.04) at T1, 1.41 (SD 0.04) at T2, and 1.37 (SD 0.05) at T3.
Deleuse et al [54], 2020	Belgium	Randomized controlled trial	44 recruited; 38 completed	12-18 y	Compare the use of an oscillating electrical toothbrush with an internet-based oscillating electrical toothbrush connected to a brushing aid app in adolescent patients treated with fixed multibracket orthodontic appliances	PI and GI decreased significantly in both the control and intervention groups. WSL[g] score was stable for both groups. PI was significantly lower in the app group than in the control group (*P*=.01) after 12 weeks. GI decreased significantly in each group (control group: *P*=.003; test group: *P*=.001), and no difference was observed between the 2 groups. WSL scores remained stable in each group (control group: *P*=.07; test group: *P*=.73), and no difference was observed between the 2 groups (*P*=.28)

Study, year	Country of origin	Study design	Sample size	Age	Purpose	Key findings
Desai et al [55], 2021	India	Randomized controlled trial	247	4-6 y	Test the impact of a mobile app (Brush Up) on OHB in children	After the 1-month follow-up, plaque scores measured using the visible biofilm index was lower in the mobile app group (mean rank scores were 112.5 and 70.9 at baseline and follow-up, respectively) than those of the video demonstration group (mean rank scores were 114.8 and 112.5 at baseline and follow-up, respectively) and the manual demonstration group (mean rank scores were 134.8 and 176.8 at baseline and follow-up, respectively; *P*<.001). There was also significant change in the frequency and duration of toothbrushing, cleaning of the lingual surfaces of the teeth, and tongue cleaning in all groups (*P*<.001).
Kay and Shou [56], 2019	United Kingdom	Randomized controlled trial	108 recruited; 103 completed	18-69 y	Investigate the effectiveness and acceptability of a smartphone app used in conjunction with a movement sensor toothbrushing attachment (device) for reducing plaque levels	After the 4-week follow-up, mean full mouth plaque scores declined from 40.1 to 11.7 in the test group compared with a reduction from 29.1 to 20.5 in the control group (*P*<.001).
Marchetti et al [26], 2018	Brazil	Randomized controlled trial	291 recruited; 263 completed	14-19 y	Study the effectiveness of an app associated with common education methods in adolescents' oral health	After the 1-month follow-up, a significant difference in mean KS[h] between the adolescents who used the app (mean 4.77, SD 0.52) and those who did not (mean 4.35, SD 0.66; *P*<.001) was observed, and OHI-S[i] decreased significantly among app users (mean OHI-S scores were 1.31, SD 0.37 at phase I and 0.24, SD 0.18 at phase IV, with *P*<.001, for the oral guidance plus app arm and 1.21, SD 0.39 at phase I and 0.23, SD 0.22 at phase IV, with *P*<.001, for the video guidance plus app arm). GBI[j] decreased significantly among app users (mean GBI scores were 11.57, SD 5.09 at phase I and 2.03, SD 1.56 at phase IV, with *P*<.001, for the oral guidance plus app arm and 9.76, SD 4.07 at phase I and 1.87, SD 2.23 at phase IV, with *P*<.001, for the video guidance plus app arm).
Shida et al [57], 2020	Japan	Randomized controlled trial	118 recruited; 112 completed	≥18 y	Compare the effectiveness between brushing teeth with the help of a mobile app and usual brushing instructions	The mean 6-point PCR score at week 4 was 45.05% in the intervention group and 49.65% in the control group. The change of PCR score from baseline was −20.46% in the intervention group and −15.77% in the control group, indicating no statistically significant difference (95% CI −0.70 to 10.07; *P*=.09).
Zotti et al [58], 2016	Italy	Randomized controlled trial	80	Control group: mean age 13.6 y; study group: mean age 14.1 y	Study the effectiveness of the use of a mobile app via chat room participation (WhatsApp) to improve oral hygiene in adolescents wearing fixed appliances	After 6, 9, and 12 months, study group patients had significantly lower scores for both PI and GI and a lower incidence of new WSs[k] compared with the control group. Mean PI scores at 12 months were 1.06 (SD 0.47) for the study group and 1.79 (SD 0.54) for the control group (*P*<.001). Mean GI scores at 12 months were 0.67 (SD 0.36) for the study group and 1.40 (SD 0.57) for the control group (*P*<.001). The number of patients with WSs was 7 for the study group and 16 for the control group (*P*<.05).
Scheerman et al [59], 2020	The Netherlands	Randomized controlled trial	132 recruited; 124 completed	12-16 y	Study the effectiveness of the use of a mobile app (WhiteTeeth) to improve oral hygiene in adolescent patients with fixed orthodontic appliances	At the 6-week follow-up, the intervention led to a significant decrease in gingival bleeding (B=−3.74, 95% CI −6.84 to −0.65; *P*=.02) and an increase in the use of fluoride mouth rinse (B=1.93, 95% CI 0.36-3.50; *P*=.02). At the 12-week follow-up, dental plaque accumulation (B=−11.32, 95% CI −20.57 to −2.07; *P*=.02) and the number of sites covered with plaque (B=−6.77, 95% CI −11.67 to −1.87; *P*=.007) had decreased significantly more in the intervention group than in the control group.

Study, year	Country of origin	Study design	Sample size	Age	Purpose	Key findings
Patil et al [46], 2021	Saudi Arabia	Systematic review	N/A[l]	N/A	Review the effectiveness of the use of mobile apps to improve oral hygiene in patients with orthodontic appliances	Mobile apps have a significant short-term effect for improving oral hygiene when measuring using PI and GI scores. The intervention groups (62%) had a lower level of plaque at a 12-week interval as compared with the control group (72%).
Underwood et al [60], 2015	United Kingdom	Cross-sectional survey	189	All age groups	Evaluate the user experience of using a mobile app (Brush DJ) to provide a basis for future research	A total of 70% of respondents reported that their teeth felt cleaner since using the app. A total of 88% of respondents reported that the app motivated them to brush their teeth for longer. A total of 92.3% of respondents would recommend the app to their friends and family.
Toniazzo et al [47], 2019	Brazil	Systematic review and meta-analysis	N/A	N/A	Assess the effectiveness of the use of mobile apps and SMS text messages and compare them with conventional oral hygiene instructions to improve oral hygiene	The use of mobile apps and SMS text messages significantly improved oral health compared with conventional oral hygiene instructions. The pooled SMD[m] for the PI was −9.43 (95% CI −14.36 to −4.495; I^2=99%; *P*<.001), and that of gingival bleeding was −8.54 (95% CI −13.16 to −3.91; I^2=99%; *P*<.001).
Rasmus et al [61], 2021	Finland	Longitudinal study (follow-up)	36	Children aged 4-12 y and their parents	Investigate the acceptability of a mobile app (Denny the Tooth and Denny the Timer) and evaluate OHB change	After the 5-week follow-up, most of the children considered the Denny the Tooth app clear (n=34), amusing (n=31), and useful (n=29). Denny the Timer was useful, and the odds for toothbrushing frequency significantly increased (OR[n] 8.9, 95% CI 1.29-60.60; *P*=.03).
Scheerman et al [62], 2020	Iran	Randomized controlled trial	791 recruited; 718 completed	12-17 y	Study the effectiveness of a mobile app (Telegram) to promote and improve OHB	Increases in adolescent toothbrushing at the 1- and 6-month follow-ups in both intervention groups (adolescents only [A] and adolescents and their mothers [M+A]) compared with the control group were observed (1-month follow-up: B=3.74, SE 0.28, and *P*<.001 for the M+A group and B=2.64, SE 0.29, and *P*<.001 for the A group; 6-month follow-up: B=3.90, SE 0.27, and *P*<.001 for the M+A group and B=2.78, SE 0.29, and *P*<.001 for the A group). Adolescents in both intervention groups showed a significantly greater improvement in their VPI[o] scores than adolescents in the control group at the 1- and 6-month follow-ups (*P*<.01; 1-month follow-up: B=−0.60, SE 0.05, and *P*<.001 for the M+A group and B=−0.29, SE 0.07, and *P*<.001 for the A group; 6-month follow-up: B=−0.64, SE 0.08, and *P*<.001 for the M+A group and B=−0.33, SE 0.06, and *P*<.001 for the A group).
Humm et al [63], 2020	Switzerland	Randomized controlled trial	20	≥18 y	Determine whether a smartphone app used with an electric toothbrush improves plaque removal compared with the use of an electric toothbrush without the app; in addition, the compliance and consideration of user-friendly were evaluated	No relevant difference in plaque score was found between the test and control groups (*P*=.39). However, PI improved by 8.5% (*P*=.10) in the intervention group compared with 4.7% (*P*=.56) in the control group.
Alqarni et al [27], 2018	Saudi Arabia	Longitudinal study	120	Parents of infants to adolescents aged 15 y	Develop a mobile app (Your child's smile) and evaluate its efficacy in improving the dental health knowledge of parents	After the 15-day follow-up, most responders showed highly significant (*P*<.01) or significant (*P*<.05) improvement in their knowledge on tooth development (8.33%-40%), importance of deciduous teeth (25%-33%), importance of regular dental checkups (20%-34%), pit and fissure sealants (24%-32%), and consequences of early loss of deciduous teeth (19%-37%). A total of 75% of parents favored the use of mobile apps as an effective child dental health knowledge tool.

Study, year	Country of origin	Study design	Sample size	Age	Purpose	Key findings
Zahid et al [64], 2020	Saudi Arabia	Nonrandomized quasi-experimental study	271 recruited; 234 completed	Mean age 16.6 (SD 0.96) y	Compare the impact of a mobile app (Brush DJ) and an educational lecture on knowledge and behavior regarding oral health	After the 3-month follow-up, both the mobile app and educational lecture groups showed significant improvements on knowledge and behavior regarding oral health except for the frequency and duration of toothbrushing in the app group.
Krishnan et al [65], 2021	India	Nonrandomized controlled trial	60	13-17 y	Evaluate the effectiveness of visual cards and a mobile-based app (Brush Up) on oral health education among adolescents with ASD[p]	At 6 and 12 weeks after the intervention, no statistically significant difference in PI (1.023 and 0.812; *P*=.91) and GI scores (0.264 and 0.283; *P*=.93) between visual pedagogy (group A) and the Brush Up mobile app (group B) was observed. For group A, mean plaque scores were 2.02 (SD 0.06) at baseline, 1.00 (SD 0.00) at 6 weeks, and 0.45 (SD 0.13) at the 12-week follow-up. Mean GI scores were 1.05 (SD 0.13) at baseline, 0.61 (SD 0.14) at 6 weeks, and 0.28 (0.10) at the 12-week follow-up. For group B, mean plaque scores were 2.01 (SD 0.06) at baseline, 1.00 (SD 0.00) at 6 weeks, and 0.46 (SD 0.11) at the 12-week follow-up. Mean GI scores were 1.03 (SD 0.17) at baseline, 0.58 (SD 0.16) at 6 weeks, and 0.24 (SD 0.11) at the 12-week follow-up.
Setijanto et al [28], 2021	Indonesia	Longitudinal study	47	17-45 y	Evaluate the effectiveness of a mobile app to increase knowledge about oral health among pregnant women	There was a significant (*P*<.001) improvement in the knowledge about oral health at posttest measurement (87%) compared with at pretest measurement (56%).
Fernández et al [48], 2021	Chile	Systematic review and meta-analysis	N/A	N/A	Determine the effect of teledentistry on oral health promotion and prevention as compared with other conventional strategies	Teledentistry was found effective—mostly mHealth[q] (messages and apps)—when compared with conventional strategies. SMD for PI was −1.18 (95% CI −1.54 to −0.82; I^2=92%; low certainty). SMD for GI was −2.17 (95% CI −3.15 to −1.19; I^2=97%; moderate certainty). Risk ratio for WSLs was 0.48 (95% CI 0.35-0.66; I^2=0%; moderate certainty).
Bohn et al [29], 2018	United States	Cross-sectional study	25	22-89 y	To assess preferences and perceptions regarding the use of apps in dental care	Participants believed that apps should be used in conjunction with a dentist's explanation about a procedure. Participants felt that the apps would be more beneficial if they could be customized to individual dental needs. Participants favored esthetic images of teeth that did not show structural anatomy. Participants preferred the internet-based apps.
Rahaei et al [66], 2022	Iran	Randomized controlled trial	158	10-12 y	Compare the effectiveness of an educational mobile app (My Tooth) with conventional oral health education among elementary school students	Before the intervention, the mean scores of behavior were 13.69 (SD 3.89; intervention group) and 13.93 (SD 3.02; control group). After the intervention, mean scores of behavior increased significantly in the intervention group (16.02, SD 3.48; *P*<.001).
Nayak et al [30], 2018	India	Randomized controlled trial	159 recruited; 150 completed	18-24 y	Evaluate the feasibility and effectiveness of a mobile app (WhatsApp) to improve knowledge about oral cancer among college students	After the 1-month intervention, a statistically significant increase in KS was observed in both groups, with highly significant improvement in the intervention group (mean KS was 28.72, SD 5.9 at baseline and 49.56, SD 5.4 after the intervention; *P*<.001).

Study, year	Country of origin	Study design	Sample size	Age	Purpose	Key findings
Zolfaghari et al [67], 2021	Iran	Randomized controlled trial	58	Children aged 1-6 y and their parents	Design a gamified mobile app and evaluate its effectiveness on educating mothers about their children's oral health	The mean KS of mothers in the pretest was 10.5 (SD 2.1) in the simple app group and 11.3 (SD 11.9) in the gamified app group, which changed to 13.1 (SD 1.6) and 14.3 (SD 2.0), respectively, in the posttest (*P*<.001). The mean practice score of mothers in the pretest was 4.4 (SD 2.4) in the simple app group and 4.8 (SD 3.2) in the gamified app group, which changed to 8.5 (SD 1.7) and 8.0 (SD 2.2), respectively, in the posttest (*P*<.001). The mean dental PI of children in the pretest was 0.8 (SD 0.4) in the simple app group and 1.0 (SD 0.3) in the gamified app group, which changed to 0.5 (SD 0.3) and 0.5 (SD 0.3), respectively, in the posttest. Children had better plaque control in the gamified app group (*P*<.001).
Panchal et al [68], 2017	India	Longitudinal study	150 recruited; 132 completed	Children aged 2-6 y and their parents	Study the efficiency of a mobile app (Cariometer) in monitoring diet and oral hygiene habits	There was a significant improvement in the dietary pattern followed by the patients at day 7 as compared with day 1 (mean dietary score was 1.51, SD 0.24 at day 1 and 0.07, SD 0.14 at day 7; *P*<.001). Approximately 90% of children brushed twice a day at day 7 after the use of the Cariometer app. There was an increase in the frequency of rinsing after meals at day 7 as compared with day 1 after the use of the Cariometer app.
Lotto et al [31], 2020	Brazil	Randomized controlled trial	104	Children aged 36-60 months and their parents	Assess the efficiency of educational messages via mobile app (WhatsApp) to control early childhood caries	Proportion of participants with the increment of maximum ICDAS[r] did not increase significantly in the intervention group (15.4%-23.1%; *P*=.13), differently from that observed in the control group (21.2%-36.5%; *P*=.008) between the 3- and 6-month follow-ups. eHEALS[s] scores increased significantly in the intervention group (+10.32%; *P*=.001) in contrast to a nonsignificant decrease observed in the control group (−2.65%; *P*=.38).
Wang et al [32], 2020	Taiwan	Nonrandomized controlled trial	120 recruited; 100 completed	48-66 y	Evaluate an educational mobile app regarding changes in the care needs and quality of life of patients with oral cancer	The overall improvement in quality of life was higher in the experimental group than in the control group (−7.24 vs −4.36; *P*=.22). The physiological care needs decreased in the experimental group compared with the control group (experimental group: 26.33 and control group: 21.33 before the intervention; experimental group: 20.67 and control group: 20.25 after the intervention; *P*<.02).
Lozoya et al [69], 2019	United States	Nonrandomized quasi-experimental study	33 recruited; 26 completed	Children (mean age 3.48, SD 0.93 y) and their parents	Evaluate the effect of a smartphone app on the OHBs of the parents of preschoolers	Parents' behavioral intentions or OHBs with their children did not significantly change from before to after the intervention (*P*>.05). SNs[t] and PBC[u] predicted behavioral intentions before the intervention and behavior change after the intervention. Thematic analysis revealed that parents' belief in the importance of establishing oral health habits and brushing reminders and videos delivered via a mobile app supported efforts to form oral health habits.
Jacobson et al [70], 2019	United States	Quasi-experimental study	34	Children aged 5-6 y and their parents	Evaluate a mobile app (Brush Up) to improve toothbrushing behaviors among children	After 7 days, toothbrushing duration increased significantly (*P*<.001). Mean time (in seconds) consumed toothbrushing was 46.2 (SD 31.3) at baseline and 69.4 (SD 30.4) after 7 days (*P*<.001). After 2 weeks (n=15), mean time (in seconds) consumed toothbrushing was 39.9 (SD 21.0) at baseline and 108.9 (SD 47.6) after 14 days (*P*<.001).
Tobias and Spanier [44], 2020	Israel	Longitudinal study	44	≥18 y	Classification of gum health based on the MGI[v] score using dental selfies via a mobile app (iGAM[w]).	The mobile app produced accurate classification of gum health based on the MGI. Area under the curve ranged between 1.0 and 0.84.

Study, year	Country of origin	Study design	Sample size	Age	Purpose	Key findings
Al-Moghrabi et al [35], 2020	United Kingdom	Randomized controlled trial	84 recruited; 64 completed	12-21 y	Assess the effectiveness of a mobile app (My Retainers) on objectively assessed TPR[w] wear time, stability, periodontal outcomes, patient experiences, and knowledge related to retainers	Use of the mobile app resulted in slightly higher median wear time (0.91 h/d, 95% CI −4.01 to 2.19; *P*=.56). No significant differences were found in terms of stability (β=.002, 95% CI −.03 to .04; *P*=.92), plaque levels (β=−.02, 95% CI −.07 to .03; *P*=.44), bleeding on probing (β=−.01, 95% CI −.05 to .03; *P*=.61), and probing depth (β=−.01, 95% CI −.09 to .07; *P*=.79). Similar levels of patient experiences (*P*=.94) and knowledge related to retainers (*P*=.26) were found.
Moylan et al [36], 2019	United States	Cross-sectional study	12	10-17 y	Study the reliability and accuracy of mobile app monitoring of tooth movement in patients with orthodontic appliances	The intercanine and intermolar measurement differences between intraoral video scans using the monitoring software's smartphone app (Dental Monitoring) and plaster models were on average 0.17 mm (90% CI 0.00-0.34) and −0.02 mm (90% CI −0.26 to 0.29), respectively.
Li et al [37], 2016	China	Randomized controlled trial	343 recruited; 224 completed	Mean age 17.6 (SD 5.7) y	Evaluate the effectiveness of a messaging mobile app (WeChat) in improving patients' compliance and decreasing the length of orthodontic treatment	Duration of orthodontic treatment in the WeChat group was shorter than that in the compared group (median 80.5, range 66-93 weeks vs median 84.5, range 75-103 weeks; *P*=.007). There was less failed attendance (3.1% vs 10.9%; *P*<.001), late attendance (20.1% vs 29.9%; *P*<.001), and bracket bond failure (11.8% vs 16.1%; *P*<.001) in the WeChat group than in the control group. There was no difference in orthodontic PI or MGI between the 2 groups before and after treatment.
Hannequin et al [38], 2020	France	Case report	N/A	21 y	Use dental monitoring software to manage aligner-mediated tooth movement on a woman aged 21 years treated with corticotomy-accelerated presurgical decompensation with Invisalign clear aligners	The software allowed for fewer chairside appointments and remote monitoring and allowed for early detection and correction of an error on the aligner. This case was managed in 6 months instead of 10-15 months for the presurgical decompensation phase and 3-4 months after surgery in conventional orthodontic treatments.
Henzell et al [39], 2013	New Zealand	Cross-sectional study	130	≥10 y	Investigate the use of internet-based social media sites by patients with orthodontic appliances and whether a web-based application or mobile app would be considered helpful in improving cooperation in orthodontic treatment	Internet-based social media sites were used by 80.8% of patients, with Facebook being the most popular. Approximately 13.3% of the sample had posted comments about braces on these social media sites, and only 6.7% had considered obtaining information about orthodontic treatment from internet-based social media sites, with most (81%) preferring to seek this information directly from their orthodontist. Nearly two-thirds of those who had difficulty remembering to wear their orthodontic appliances reported that a reminder app on their phone would be beneficial.
Al-Musawi et al [33], 2017	Kuwait	Longitudinal study	87	Not reported	Evaluate the effectiveness of a mobile app (Dental Trauma App) in delivering information to schoolteachers about the optimal emergency management of traumatic dental injuries and compare it with the traditional lecture-based method	Participants using the app only had a significantly higher mean score (12.72, SE 0.47) than participants receiving the lecture only (mean 11.20, SE 0.44; *P*=.02) and participants in the lecture and app group (mean 9.87, SE 0.50; *P*<.001).
Iskander et al [34], 2016	United States	Cross-sectional study	89	Not reported	Compare effectiveness and user preference of a mobile app and conventional poster for first aid to dental trauma	Individuals using the mobile app were more likely to select "put the tooth back in place" (71.1%) compared with those using the poster, who chose "put the tooth in milk" (56.8%; *P*=.004). Less educated individuals were willing to pay more for the app (*P*=.02) and were more likely to report being interested in receiving dental information through mobile technology in the future (*P*=.006). Most of the respondents preferred the mobile app.

Study, year	Country of origin	Study design	Sample size	Age	Purpose	Key findings
Abbasi et al [40], 2021	Pakistan	Randomized controlled trial	160	Children aged 4-10 y	Evaluate the effectiveness of a mobile app (Little Lovely Dentist), a dental song, and TSD[x] techniques in pediatric patients	A statistically significant difference in mean heart rate of participants was observed in the Little Lovely Dentist, dental song, and control groups, whereas no difference was observed in the TSD group. For the mobile "Little Lovely Dentist" app group, mean heart rate before and after the intervention was 107.9 (SD 8.2) and 104.9 (SD 6.8), respectively (*P*=.002). For the YouTube "dental video song" group, mean heart rate before and after the intervention was 106.6 (SD 6.1) and 104.0 (SD 7.6), respectively (*P*=.001). For the TSD group, mean heart rate before and after the intervention was 101.4 (SD 15.6) and 108.2 (SD 7.5), respectively (*P*=.68). For the control group, mean heart rate before and after the intervention was 102.8 (SD 5.3) and 107.5 (SD 5.9), respectively (*P*=.68). FIS[y] scores decreased significantly in participants in the Little Lovely Dentist and dental song groups, whereas the scores increased in the TSD and control groups. For the mobile "Little Lovely Dentist" app group, mean FIS scores before and after the intervention were 2.80 (SD 1.06) and 2.52 (SD 0.87), respectively (*P*=.03). For the YouTube "dental video song" group, mean FIS scores before and after the intervention were 1.80 (SD 0.96) and 2.47 (SD 0.84), respectively (*P*=.04). For the TSD group, mean FIS scores before and after the intervention were 2.60 (SD 0.74) and 3.30 (SD 0.96), respectively (*P*=.001). For the control group, mean FIS scores before and after the intervention were 2.91 (SD 0.92) and 3.52 (SD 1.24), respectively (*P*=.01).
Elicherla et al [41], 2019	India	Randomized controlled trial	50	7-11 y	Evaluate the effectiveness of a mobile app (Little Lovely Dentist) compared with the TSD technique in managing anxiety and fear in children during their first dental visit	A statistically significant difference in mean heart rate of the participants was observed in the Little Lovely Dentist group, whereas no difference was observed in the TSD group. For the mobile "Little Lovely Dentist" app group, mean heart rate before and after the intervention was 108.2 (SD 12.8) and 97.4 (SD 12.3), respectively (*P*<.001). For the TSD group, mean heart rate before and after the intervention was 95.9 (SD 10.0) and 97.2 (SD 12.3), respectively (*P*=.32). RMS pictorial scores decreased significantly in participants in both the Little Lovely Dentist and TSD groups. For the mobile "Little Lovely Dentist" app group, mean RMS pictorial scores before and after the intervention were 3.20 (SD 1.04) and 1.32 (SD 0.5), respectively (*P*<.001). For the TSD group, mean RMS pictorial scores before and after the intervention were 2.6 (SD 0.8) and 1.5 (SD 0.6), respectively (*P*<.001).
Kevadia et al [42], 2020	India	Randomized controlled trial	75	6-9 y	To evaluate the effectiveness of 3 different behavioral management techniques: a mobile app (My Little Dentist), Tell, Play, Do, and the film modeling technique	All the index scores were significantly lower among children who received the Tell, Play, Do (group II) intervention than in those who received the film modeling intervention (group I) and the mobile dental app (group III). Average heart rate was *P*=.03 for group II vs group I and *P*=.046 for group II vs group III. FIS was *P*=.03 for group II vs group I and *P*=.03 for group II vs group III. Venham pictorial index scores were *P*=.04 for group II vs group I and *P*=.045 for group II vs group III.
Zink et al [43], 2018	Brazil	Randomized controlled trial	40	9-15 y	Development and evaluation of a mobile app for patient-professional communication during dental visits of patients with ASD	The decayed, missing, and filled primary and permanent teeth index was similar for both groups (*P*=.60), being 1.5 (SD 3.0) for the app group and 0.7 (SD 1.3) for the Picture Exchange Communication System group. There were statistically significant differences in the number of attempts required for the pictures to acquire each skill proposed (room, ground, dentist, and 3-in-1 air and water syringe; *P*<.05) between the 2 groups, which were lower for the app group.

Study, year	Country of origin	Study design	Sample size	Age	Purpose	Key findings
Cunningham et al [49], 2021	United Kingdom	Systematic review	N/A	N/A	To examine and identify studies that apply virtual reality or bespoke smartphone apps in dentistry to decrease patient anxiety and to study the effectiveness of these apps	In total, 3 studies using virtual reality in a dental setting demonstrated decreased pain and anxiety compared with no intervention. A fourth study used a bespoke dental app and imagery to prepare patients with ASD for dental treatment, finding statistically significant decreases in both the number of appointments and number of attempts required to carry out a procedure.
Lin et al [45], 2014	Taiwan	Cross-sectional study	26 dentists and 32 patients	Not reported	To improve dental care services using a mobile app (Dental Calendar) combined with cloud service	Results of assessments through interviews and questionnaires indicated a significant increase (*P*<.05) in both dentists' and patients' overall experiences. Total mean increment in after and before test for dentists was 5.875 (95% CI 1.968-9.782; *P*=.009). Total mean increment in after-before test for patients was 18.500 (95% CI 13.625-23.375; *P*<.001). Patients' ability to reschedule appointments for sudden worse prostheses was 0.385 (95% CI 0.081-0.689; *P*=.02). Appointment reminding was 0.844 (95% CI 0.242-1.445; *P*=.007), appointment rescheduling for sudden worse prostheses was 0.781 (95% CI 0.204-1.359; *P*=.01), and dentist-patient relationship was 0.500 (95% CI 0.007-0.993; *P*=.047)

[a]OSCA: oral self-care mobile app.
[b]OHS: oral hygiene status.

[v]MGI: Modified Gingival Index.
[w]TPR: thermoplastic retainer.
[x]TSD: Tell, Show, Do.
[y]FIS: Facial Image Scale.

Discussion

Principal Findings

The aim of this study was to present the main findings in the literature on the use of mobile phone apps in oral health and evaluate the evidence available in the literature. This scoping review identified and reviewed 45 papers published between January 2000 and June 2021. Half (23/45, 51%) of the included studies were from Asian countries and focused on children and adolescents. In addition, most of the included studies (31/45, 69%) focused on oral health promotion using mobile phone apps, followed by behavior management. There was limited evidence of diagnostic and remote consultations using mobile phone apps.

A total of 47% (21/45) of the publications focused on improving oral hygiene through effective toothbrushing. Dental plaque is a biological component in the initiation of dental caries and periodontal diseases [71]. Therefore, it is important to remove dental plaque from tooth surfaces through daily toothbrushing with fluoridated toothpaste to prevent tooth decay and periodontal diseases [71]. This scoping review found that several of the RCT studies (9/23, 39%) reported a significant reduction in dental plaque among mobile phone app users compared with their controls. Hence, mobile phone apps can be used for oral health education and to teach patients good home care skills. A recent systematic review and meta-analysis showed good results in decreasing plaque, thereby improving gingival health and preventing the development of dental caries when both education and skills are incorporated [72].

In total, 11% (5/45) of the publications focused on behavior management, and in these publications, mobile apps were used to reduce the dental anxiety of patients. Dental anxiety usually develops in childhood, and its prevalence ranges from 5% to 20% among children [73,74]. Patients with dental anxiety can easily avoid or miss dental appointments and, therefore, might have poorer dental health [75]. New situations in dental clinics are unfamiliar to children. Mobile apps used beforehand are an effective tool to familiarize a child with dental appointments and instruments and help improve cooperation between a dentist and a child during dental treatments [43,49].

More than half (23/45, 51%) of the included studies were from Asia, especially from India. The population of Asia was 4.7 billion in 2022, and the 2 most populous countries in Asia are China (1.37 billion) and India (1.29 billion) [76]. Thus, the rate of mobile phone use is higher in Asia than in other continents. For the same reason, the production and use of mobile phone apps are also higher in Asia than in other continents. In addition, none of the included studies were published in Africa. This could be due to various challenges, such as infrastructure, scientific technologies, and resources in implementing mHealth interventions in Africa, as described by Kruse et al [77] in their systematic review. Regarding the European region, the General Data Protection Regulation law drafted and implemented by the European Union on May 25, 2018, may have affected the conduct of research that requires the processing of sensitive data (eg, oral health data) despite protecting patients' privacy [78]. Cagnazzo [79] also argued that the overlap of the General Data Protection Regulation and the European Clinical Trials Regulation is creating a state of confusion among the scientific community. Furthermore, the author has argued about the bureaucratic issues related to follow-up clinical studies [79]. However, these aspects need further research.

This review also found that most of the included studies (25/45, 56%) focused on children (aged <10 years) and their families as well as on adolescents aged 10 to 19 years. The studies in this review did not include older adults as a focus group, which may be explained by the fact that the younger population has grown up with smartphones and is more familiar with using them. Using smartphones is part of adolescents' daily routine, and smartphones tend to move around with them throughout the day. In addition, smartphones are highly valued by adolescents; they are easy to use and easily switched on [15]. Thus, approaching children and adolescents via smartphone is more convenient. In addition, the use of smartphones gives people the possibility to access information anywhere and anytime, and this increases patients' autonomy and comfort [80].

Despite excluding studies focused on the development of mobile apps in dentistry, half (23/45, 51%) of the included studies were published between 2020 and 2021. This implies that the field is constantly evolving and growing. Furthermore, the COVID-19 pandemic started at the end of 2019 and changed dental care in many aspects. The use of teledentistry increased during the pandemic, and dentists with a clinical practice considered teledentistry to be the most effective way to reschedule patients' appointment times and provide dental hygiene education and emergency advice [81,82]. In this scoping review, we found only 1 study [45] that focused on remote health care services. However, more studies on teledentistry and the use of artificial intelligence for diagnosis and remote consultations are necessary. In addition, topics related to the uses and importance of teledentistry and artificial intelligence must be added to the curriculum of undergraduate and postgraduate dental studies [83].

Limitations

This study has some limitations. First, only studies written in English were included. Second, the search was carried out in only 2 databases (PubMed and Scopus), therefore leaving out literature from other databases and gray literature. However, a recent meta-research study suggests that searching at least 2 databases is sufficient to increase coverage and decrease the risk of missing eligible studies [84]. In addition, an information specialist was consulted for searching the databases. Another limitation would be not undergoing any peer-review for electronic search strategies.

The field of mobile apps is still new and under development. New research must be conducted along with the development of new patient-oriented apps.

Conclusions

The use of mobile apps in oral health is increasing among patients, mainly children and adolescents. In the literature, there are many studies related to mobile apps that are focused on promoting oral health. Other areas such as diagnosis and remote consultations are neglected in the current studies. There are potential uses for improving oral hygiene, knowledge, and behavior via mobile apps, but more studies are required.

Acknowledgments

The authors would like to acknowledge Kirsi Vähäkangas, informatician, Oulu University Library, for her help. The European Regional Development Fund (project: *digileap of oral health toward virtual reception*; A76934) is gratefully acknowledged for supporting this work. AK-S and SK received a research grant from the Finnish Dental Society Apollonia to conduct this research.

Abstract

Background: The adoption of digital health care within health systems is determined by various factors, including pricing and reimbursement. The reimbursement landscape for digital health in Europe remains underresearched. Although various emergency reimbursement decisions were made during the COVID-19 pandemic to enable health care delivery through videoconferencing and asynchronous care (eg, digital apps), research so far has primarily focused on the policy innovations that facilitated this outside of Europe.

Objective: This study examines the digital health reimbursement strategies in 8 European countries (Belgium, France, Germany, Italy, the Netherlands, Poland, Sweden, and the United Kingdom) and Israel.

Methods: We mapped available digital health reimbursement strategies using a scoping review and policy mapping framework. We reviewed the literature on the MEDLINE, Embase, Global Health, and Web of Science databases. Supplementary records were identified through Google Scholar and country experts.

Results: Our search strategy yielded a total of 1559 records, of which 40 (2.57%) were ultimately included in this study. As of August 2023, digital health solutions are reimbursable to some extent in all studied countries except Poland, although the mechanism of reimbursement differs significantly across countries. At the time of writing, the pricing of digital health solutions was mostly determined through discussions between national or regional committees and the manufacturers of digital health solutions in the absence of value-based assessment mechanisms. Financing digital health solutions outside traditional reimbursement schemes was possible in all studied countries except Poland and typically occurs via health innovation or digital health–specific funding schemes. European countries have value-based pricing frameworks that range from nonexistent to embryonic.

Conclusions: Studied countries show divergent approaches to the reimbursement of digital health solutions. These differences may complicate the ability of patients to seek cross-country health care in another country, even if a digital health app is available in both countries. Furthermore, the fragmented environment will present challenges for developers of such solutions, as they look to expand their impact across countries and health systems. An increased emphasis on developing a clear conceptualization of digital health, as well as value-based pricing and reimbursement mechanisms, is needed for the sustainable integration of digital health. This study can therein serve as a basis for further, more detailed research as the field of digital health reimbursement evolves.

Introduction

Background

The COVID-19 pandemic has significantly accelerated the digital transformation of the health care sector, providing an opportunity to leverage software to prevent, manage, or treat disease [1-6]. Digital health solutions encompass a broad range of technologies that promote, improve, or support health system functioning and the delivery of health care, including electronic health records, telemedicine, mobile health apps, health data analytics, and digital therapeutics [7,8]. These solutions can be used for a range of functions, including web-based consultations with medical professionals, tools and software for remote patient monitoring, real-time updates of algorithms based on patient data, and the delivery of health care interventions. Recent studies have indicated that combining medication with digital health solutions can lead to improved outcomes for a variety of chronic conditions such as type 2 diabetes, cardiovascular diseases, and psychiatric and mental health conditions [9,10].

The adoption of digital health solutions within health systems is subject to various factors, including pricing and reimbursement [8,9,11-13]. Pricing models in health comprise mechanisms such as cost-based pricing (ie, the price of a product is based on the cost of care provided to patients and allowable covered costs), the use of cost-effectiveness thresholds (ie, the price or quality-adjusted life-year is compared with a preset threshold), external price referencing (ie, the price of a product is based on the prices set in other countries), and value-based pricing (ie, the price is based on the value that an intervention adds to the health care process, such as improved health outcomes or reduced costs) [14,15]. The latter approach is recognized as a promising solution to optimize resource allocation and address numerous challenges faced by health systems [11]. National price regulations that incorporate value-based elements, such as the price regulations in Germany, have also been shown to more closely align the prices paid for medical products with their benefit to patients [16]. Value-based pricing also supports evidence-based decision-making in health care procurement by providing a benchmark for what constitutes a high-quality intervention [17]. However, applying a value-based framework to digital health care requires the use of comprehensive frameworks to determine the value of digital interventions and can be challenging because of the continuous improvement of digital health apps through performance data and patient feedback [11,12]. Finally, there is a dearth of data and assessment frameworks in use to evaluate the cost-effectiveness of digital health care [18,19] as well as a scarcity of established pricing models that can be used to streamline the introduction of digital health apps to the health care market [20].

Robust reimbursement mechanisms are vital in facilitating the access and affordability of new health technologies [15], although the reimbursement landscape for digital health in Europe remains underresearched and poorly characterized. Although various emergency reimbursement decisions were made during the COVID-19 pandemic to enable health care delivery through videoconferencing and asynchronous care [21,22], such tools represent only a small set of digital health approaches. Additonally, research so far has primarily focused on the policy innovations that facilitated this outside of Europe. As an example, studies have focused on the Australian government’s recent expansion of Medicare-subsidized telehealth services to facilitate the remote delivery of care and mitigate the risk of virus transmission. Consequently, telehealth services became eligible for reimbursement through the Australian Medicare system and eventually became subject to copayments [22,23]. In the United States, research has highlighted the rapid modification of coverage and payment parity policies by states in response to the COVID-19 pandemic to promote the adoption of telehealth and minimize physical contact, thereby overcoming a significant use barrier [21,24]. In comparison, developments in Europe, particularly in terms of the eligibility of digital health apps (ie, software designed to provide a specific form of therapy with or without the involvement of a health care professional) for reimbursement, remain largely unexplored (a notable exception being Germany, which created the first combined regulation and reimbursement pathway for digital health apps in 2019, which has been described in the literature) [25].

Objective

This study presents information on the reimbursement practices for digital health in 9 countries within the World Health Organization European Region (WHO/Europe): Belgium, France, Germany, Israel, Italy, the Netherlands, Poland, Sweden, and the United Kingdom. These countries were chosen based on the availability of information on the reimbursement of digital health and feedback received from the Data and Digital Health Unit at WHO/Europe [11,26-29]. We aim to map and compare four distinct reimbursement characteristics across the studied countries: (1) whether digital health solutions are recognized as a reimbursable form of health care, (2) what mechanisms are used to reimburse digital health solutions, (3) how digital health solutions are priced and whether value-based health care frameworks are embedded in that process, and (4) whether any funding is available to reimburse digital health solutions outside of public or private insurance policies.

Methods

Policy Mapping Framework

This study uses a policy mapping framework, which has been used and validated by previous research in the fields of autism, disability, and substance abuse policy [30-35]. The policy mapping framework is based on the foundation of a scoping review, which allows for the rapid mapping of the key concepts underpinning a broad research area that is particularly valuable for complex issues that have not been reviewed comprehensively to date [36,37]. The established framework is suited to analyzing the development of health and social policy over time and across multiple layers of governance. In the context of this study, we only sought to collect information on current digital health reimbursement practices; as such, the longitudinal aspect of the policy mapping framework was not applied. We further developed this policy mapping framework from a cross-country analysis lens by presenting both individual country information in tabulated form and cross-country differences narratively. This approach is also supported by previous policy mapping exercises [38-40].

Data Collection and Analysis

In line with the Joanna Briggs Institute Manual for Evidence Synthesis for Scoping Reviews [41], we searched MEDLINE (Ovid), Embase (Ovid), Global Health (Ovid), and Web of Science on January 20, 2023, and conducted a follow-up search on August 18, 2023, for articles addressing the reimbursement and financing of digital health apps in Belgium, France, Germany, Israel, Italy, the Netherlands, Poland, Sweden, and the United Kingdom. These databases were chosen to cover both the health-specific and interdisciplinary academic fields. To identify gray literature, Google Scholar (first 300 hits [42]) was used. To be eligible for inclusion, a record had to capture a part of the reimbursement or financing pathway of digital health apps in the studied countries. Only records from 2018 onward were eligible for inclusion as this timeframe captures the developments before and during the COVID-19 pandemic in terms of digital health reimbursement and financing as well as the launch of the first country-level reimbursement policy for digital health apps in Germany in late 2019 [25]. The policy mapping framework, in contrast to a traditional scoping review, takes a broader approach to the types of evidence that are eligible for inclusion. Specifically, after searching exclusively for original research and literature reviews, we identified only 14 articles eligible for inclusion, which was too scarce to provide information on existing digital health reimbursement pathways in the studied countries. As such, we expanded the eligibility criteria to include editorials, commentaries, viewpoints, and gray literature as these documents may provide important details of policy developments before these are more rigorously captured in empirical research. We did not directly search for policy repositories as is common practice in the policy mapping framework seeing as we aim to map reimbursement processes rather than the legal basis for reimbursement. Given our specific interest in policy developments in the WHO/Europe region, articles without a focus on the abovementioned countries were excluded.

Table 1 shows the build-up of the search strings for the academic database searches as well as the number of hits per query. The search string was reviewed and validated by an information specialist at the London School of Economics and Political Science Library. The search terms for the supplementary searches in Google Scholar consisted of the phrases "reimbursement of digital health," "reimbursement of digital therapeutics," "financing of digital health," "financing of digital therapeutics," "digital health tariff," "digital health pricing," "telehealth pricing," "telehealth tariff," and "financing of telehealth" combined with the respective country. This combination of keywords ensured that less complex forms of digital health solutions (eg, telehealth and telemedicine) and more complex forms (eg, digital health apps or digital therapeutics) were covered in the search string. If the dominant language was a language other than English, we used Google Translate to translate the search phrases into the desired language [43]. To minimize the potential bias introduced through machine translations, experts from the studied countries were asked to assist in searching and interpreting the digital health reimbursement landscape for their respective countries. Additional articles were identified through a review of the references of the studies included through database search. Policy contents and mechanisms were identified from the selected references and reviewed using thematic content analysis. After finalizing the data collection and analysis, country experts reviewed the collected information to validate the findings and, where necessary, add additional expertise and insights. Finally, individual country information was tabulated per studied reimbursement characteristic and the disparities between countries were narratively synthesized.

Ethical Considerations

This study has no inherent ethical implications or considerations.

Results

Search Results

Our search strategy yielded a total of 1536 records (1235 documents through academic database searching and 301 through supplementary searches). A further 23 records were identified through the country experts. After deduplication, 1266 documents were screened for eligibility, and 2.57% (40/1559) were ultimately included in the analysis. Most documents were excluded because they did not discuss the current reimbursement or financing pathways in place in the studied countries. We included 9 original research articles [11,20,44-50], 5 reviews [8,18,27,51,52], 4 conference abstracts [53-56], 18 gray literature sources [28,57-73], 3 reports [74-76], and 1 commentary [25]. In terms of country focus, 3 documents focused on Belgium [57-59], 8 on France [11,28,51,54-56,60,61], 6 on Germany [18,27,44,52,54,62], 3 on Israel [45,63,76], 4 on Italy [46-48,64], 5 on the Netherlands [8,20,49,65,75], 5 on Poland [50,66-68,74], 3 on Sweden [69-71], and 6 on the United Kingdom [28,53,54,56,72,73]. Figure 1 shows a PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the data collection process. The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist is shown in Multimedia Appendix 1. Table 2 shows the details of country-specific digital health reimbursement.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the screening process.

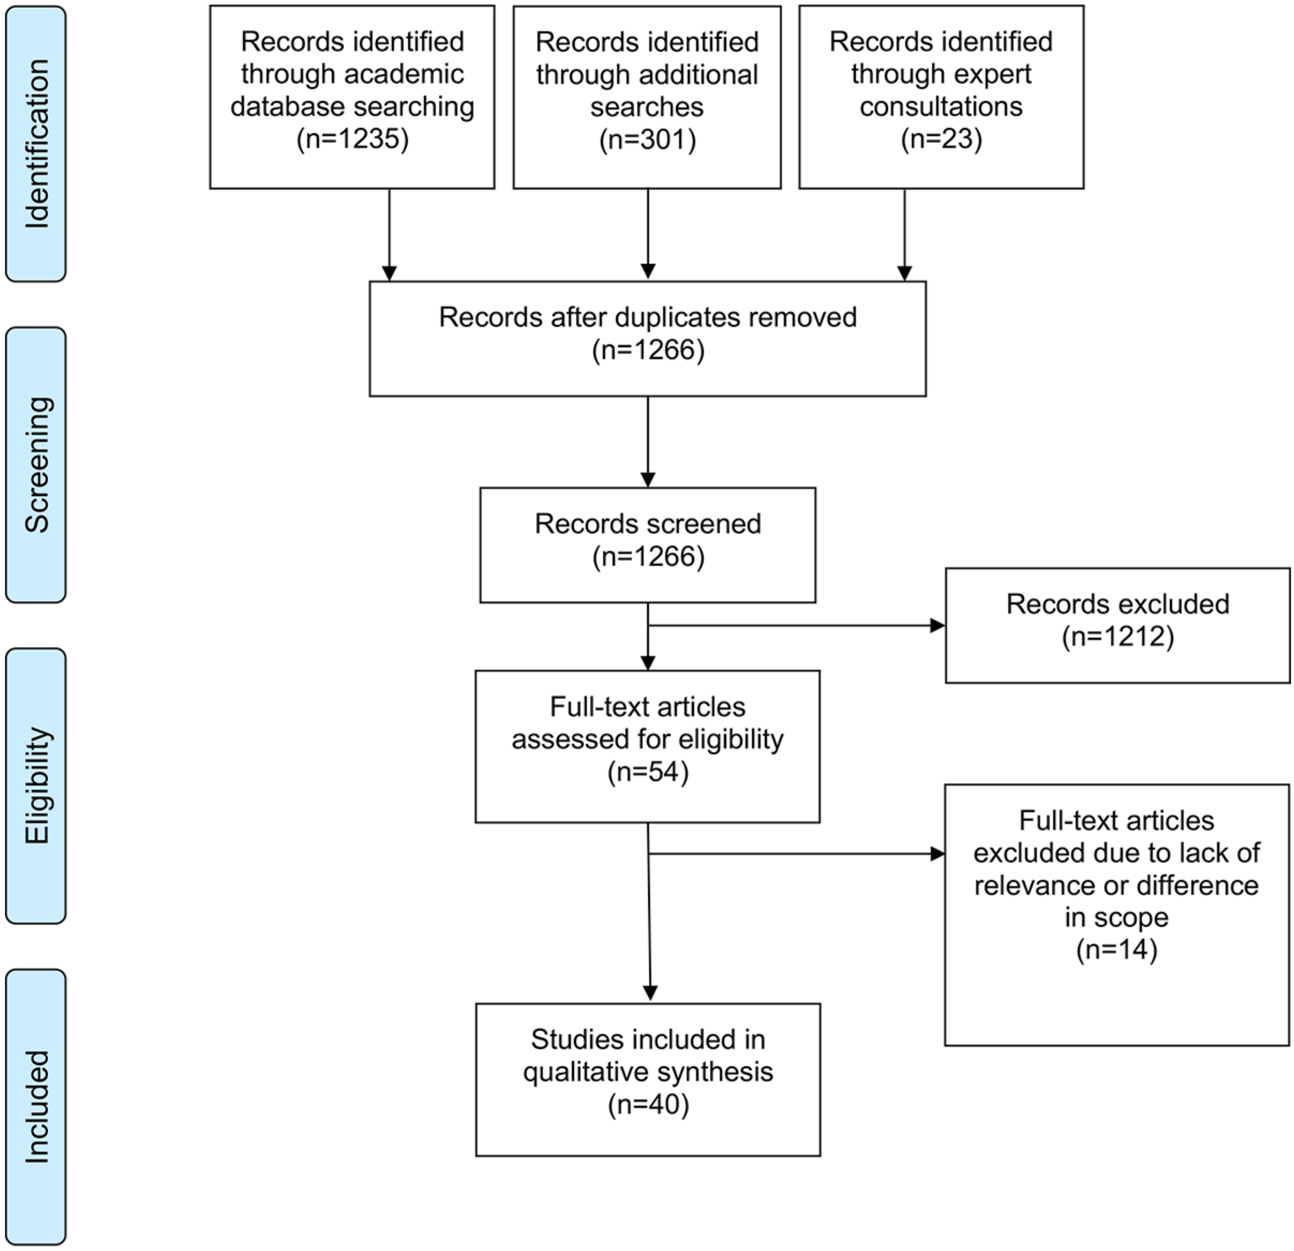

Table 2. Country-specific details on the reimbursement and financing of digital health solutions and apps.

Country	Reimbursement characteristics			
	Eligible for reimbursement	Mechanism of reimbursement	Pricing of digital health	Noninsurance reimbursement
Belgium	Yes	• Reimbursement of digital health solutions does not focus on reimbursing the solution itself. Rather, the Belgian reimbursement system covers a particular health care trajectory holistically and digital health solutions may be deployed by the practitioner as part of the health care process [57].	• Once a digital health solution has reached the highest level of the mHealth[a] validation pyramid, the pricing is done within the context of the health care process that the app will be integrated into. Each health care process requires its own price determination [58].	The TBM[b] program aims at contributing to the implementation of new therapies, diagnostic techniques, and preventive methods, which, without government funding, would not make it to the patient due to a lack of industrial interest [59].
France	Yes	• Reimbursement of digital health solutions can occur through the centralized pathway of medical devices. Connected medical devices have recently been added to the scope of the French National Authority for Health's directory of products that qualify for reimbursement within the statutory health insurance [28,54,55]. After the pricing process has been completed, the National Union of Health Insurers adds the digital health solution to a directory of reimbursable products and sets a reimbursement rate for the next 5 y that matches the digital health solution's clinical benefits assessment [11,54]. • Following the success of the ETAPES[c] experimental program, a reimbursement pathway was introduced in French law under the 2022 Social Security Act (Article 36). This pathway aims to deploy novel remote monitoring apps and requires an evaluation by the French National Authority for Health, much like the existing pathway of medical devices. In case digital health solutions also have therapeutic functions, this pathway can only be applied to the telemonitoring parts of the digital health solution [60]. • In 2023, the French Ministry of Health and Prevention introduced an early access pathway for the reimbursement of sufficiently developed digital medical devices (ie, digital health apps) through the PECAN[d] program [61]. The PECAN program allows 1 y of special coverage by the French health care system, enabling the manufacturer to be reimbursed while they finalize the demonstration of their clinical or organizational benefits.	• The Economic Committee for Health Products (CEPS[e]) negotiates the pricing of digital health solution within the statutory insurance with the manufacturer [11,51]. Currently, there are no specific value-based pricing guidelines for digital health solution available [51].	Until December 2022 inclusive, a second reimbursement pathway existed in the form of the experimental program for telemonitoring in France (ETAPES), which focused on the development of telemonitoring approaches in 5 health specialties: heart failure, kidney failure, respiratory failure, diabetes, and implantable cardiac devices [28,56].

Country	Reimbursement characteristics			
	Eligible for reimbursement	Mechanism of reimbursement	Pricing of digital health	Noninsurance reimbursement
Germany	Yes	• Digital health apps specifically can be reimbursed under the statutory health insurance as long as they are approved by the Federal Institute for Drugs and Medical Devices and listed in the national digital health directory [18,25,44,52,54]. It is prescribed on a fee-for-service basis [18,27,62].	• For the first 12 mo of being listed in the digital health app directory, the manufacturer is generally able to freely set the sales price and pricing model of their digital health app. After 12 mo, the set price is a negotiated price between the manufacturer and the National Association of Statutory Health Insurance Funds [18]. • Before the start of the pricing negotiations, the following details have to be clarified [18]: 1. The evidence on general requirements and positive health effects. 2. The results of the studies conducted as part of the possible trial phase. 3. Information on prices for self-payers; 4. Information on prices in other European countries. 5. The complete notification of the Federal Institute for Drugs and Medical Devices about the inclusion of the digital health app in the national directory. 6. The number of activation or prescription codes redeemed for the digital health app in the period from inclusion in the national directory to 5 d before submission.	Financial support for the development of digital health apps can be obtained from the German Innovation Fund, funded by the German Health Insurance (Gestzlicher Krankenversicherung) [27].
Israel	Yes	• Health maintenance organizations are obligated to provide the services described in the National List of Health Services to their insured population [63,76]. The list is updated annually by an appointed Public Committee, with additional budget allocated to these new additions. As the national list is part of the health insurance law, the technologies not considered as stand-alone technologies but as entitlement to the medical service provided by these technologies. The health maintenance organizations may choose to use digital health solutions to provide an existing entitlement, instead or in parallel to the more traditional methods. • Health maintenance organizations can also decide to purchase digital health solutions as part of a service that is not included in the national list. In this case, they fund it through their internal basket or through the complementary insurances [63].	• When a new technology is added to the national list, its price is estimated by subcommittee adjacent to the public committee and used for budgeting purposes [45,76]. However, the actual price of the technology is negotiated between each of the health maintenance organizations and the manufacturer [63].	• Other funds that are available to reimburse digital health solutions outside insurance policies mostly include Ministry of Health grant programs specifically aimed at supporting the development and implementation of digital health solutions. These funds are used to support the development of new digital health solutions or to help fund the adoption and implementation of existing solutions [63].

Country	Reimbursement characteristics			
	Eligible for reimbursement	Mechanism of reimbursement	Pricing of digital health	Noninsurance reimbursement
Italy	Yes	• Digital health solutions can be reimbursed under the national health system [46], although the reimbursement procedures of digital health apps represent an open challenge and is open to multiple approaches [47]. All regions in Italy adopted tariffs for telehealth and matching reimbursement procedures for all modes of service delivery (digitally supported or in person) [64]. These tariffs should follow a payment parity mechanism, indicating health care providers are paid a fixed amount/patient, regardless of the services provided and their mode of provision [64].	• Digital health solutions that enhance the current health care and therapies process may be merged and embedded into an updated price list of existing services. Pricing protocols for digital health solutions that require a fee-for-subscription attached to a drug or medical device have not yet been established [47].	• Pilot projects within the national health system promote the integration of digital health solutions into the delivery of health care through public health services [48].
Netherlands	Yes	• The Dutch Healthcare Authority has published guidance documents to help health professionals in the Netherlands distinguish between clinical medical apps and assistive health apps. This distinction is important in the Dutch health care context to determine whether a digital health solution has to be reimbursed under individual health insurance companies (in the case of use in primary care, home, or community settings) or whether they can be reimbursed by the basic health insurance package under the diagnosis-related groups (in the case of hospital-based specialist care) [65].	• Pricing of (digital) health solutions in the Netherlands currently involves a negotiation between the health insurers, health providers, the Dutch Healthcare Authority (NZa[f]), and the Dutch Health Institute (Zorginstituut Nederland), though no specific guidelines for the pricing of digital health solutions have been established [49,75].	• The Dutch Healthcare Authority offers a financing mechanism for “promising types of healthcare” until 2023 inclusive, which cover treatment options currently not yet covered by the basic health insurance [65]. • In addition, some digital health solutions are made available through sponsorships from nongovernmental organizations (eg, Alzheimer Netherlands sponsoring 2 digital health apps for dementia) [8,20].
Poland	No	• A reimbursement pathway within the National Health Fund for digitally delivered health services was created as part of an emergency COVID-19 pandemic policy. The scope of digital health in Poland is currently limited to tool of digital consultation between health care professionals and patients, consultations between health care professionals, as well as the e-prescription system [50]. This situation is further strengthened by the limitation that reimbursable digital health care should be performed by a health care professional whose services are already covered under the National Health Fund [66].		• Although no concrete alternative financing pathways are laid out, the Program for the Development of eHealth in Poland for the years 2022-2027 indicates that funds can be obtained for this purpose from programs, such as the Regional Operational Programme, Operational Programme Infrastructure and Environment, National Recovery Plan, and the Digital Europe Programme [68].

Country	Reimbursement characteristics			
	Eligible for reimbursement	Mechanism of reimbursement	Pricing of digital health	Noninsurance reimbursement
			• Health care services tariffing involves the President of the National Health Fund, the Tariffing Council, and the Minister of Health [74]. The Tariffing Council is responsible for providing an opinion on the determination of the tariff of the service, whereas the Minister of Health is responsible for approving the tariffing plan. The report on the determination of the tariff of the service includes a description of the health care service subject to tariffing, an analysis of demand and current and desired supply of the health care service subject to tariffing, a description of the manner and level of financing of the health care service subject to tariffing in other countries, an analysis of cost data, a draft tariff of the service, an analysis of the financial effects on the health care system, and other available data necessary to determine the tariff of the service. The Tariffing Council is required to issue an opinion on the determination of the tariff of the service within 30 d of receipt of the report. The Supreme Audit Office notes that the pricing of individual telemedicine services reimbursed by the National Health Fund usually takes much less time than the pricing of other services [67].	
Sweden	Yes	• For the purpose of streamlining the remuneration of digital health care, Sweden drafted recommendations in 2019 on what regions or local authorities should be reimbursed for if a citizen from another region seeks digital health care within their region [69].	• Each region is responsible for the price-setting of digital health care services and the corresponding copayments for patients. However, patients are not limited to only seek health care in their region of residence, resulting in a complicated system with different prices for digital health care outside the county and for physical care within the region [70].	• Public funding for early-stage innovations can be acquired through Vinnova, Sweden's innovation agency [71].
United Kingdom	Yes	• Once a digital health app receives a positive recommendation from the NICE[g], the app becomes eligible for purchase by the integrated care boards pending negotiations [28,56]. Delivery of digital health apps to patients is free of charge at the point of service [72].	• In their assessment, NICE provides recommendations on a value-based pricing for a digital health app. However, pricing negotiations occur individually with the 42 integrated care boards (the replacement of the clinical commissioning groups) [28,53,54,56].	

Country	Reimbursement characteristics			
	Eligible for reimbursement	Mechanism of reimbursement	Pricing of digital health	Noninsurance reimbursement
				• In England, the MedTech funding mandate can reimburse the costs of using digital health apps for a duration of up to 4 y, though a positive assessment of the NICE is required to be eligible for this funding scheme [73]. The NHS[h] Innovation Accelerator aims to fast-track digital innovations into the NHS by supporting high-impact, evidence-based interventions and providing bursaries for scaling across the NHS. The Innovation and Technology Tariff has been introduced in 2017 to foster the adoption and centralize funding of 6 innovations deemed suitable for NHS-scale deployment (one of which is a digital health intervention) [53].

Eligibility and Mechanism of Reimbursement Through Insurance

All studied countries except Poland allowed for some reimbursement of digital health solutions. However, the reimbursement mechanisms differed substantially across countries, which can be attributed in part to the differences in how the health systems are financed. Two reimbursement archetypes could be derived from the studied countries: countries either reimbursed the digital health solution itself (France, Germany, Italy, the Netherlands, Poland, Sweden, and the United Kingdom) or reimbursed the clinical pathway that the digital health solution is part of (Belgium and Israel). Further variation was observed across the studied countries in terms of how the digital health apps were classified. Belgium, France, and Israel classify digital health solutions under the traditional paradigm of medical devices, whereas Germany, Italy, the Netherlands, Poland, Sweden, and the United Kingdom recognize digital health solutions as their own classification. Italy was the only country to implement an explicit system of parity for the reimbursement of digital health solutions. This means that health providers are paid a fixed fee regardless of whether health care is delivered face-to-face or through digital health.

Pricing of Digital Health Solutions or Apps

Pricing mechanisms were found to be at different stages of development across countries. France, Germany, Israel, and Poland each have a dedicated committee that decides on the price of digital health solutions or apps within their respective national insurance systems, although only Germany reports a concrete framework upon which the prices of digital health apps are based. In contrast, Sweden and the United Kingdom delegate pricing negotiations to the regional level, with each region being responsible for reaching an agreement with the digital health manufacturer. The Netherlands exhibited a combination of both approaches, depending on whether a specific digital health solution was included in their mandatory health insurance package or the optional insurer-determined insurance package. In contrast, Belgium and Italy determine the price of digital health solutions in the context of the health care process in which they are deployed. Italy reported having no concrete pricing framework in place for digital health apps even though they are deployed on a fee-for-service basis. Despite using differentiated approaches, all countries adopted a variation of cost-based pricing for digital health except for Belgium, where it is integrated in a value-based pricing system and Germany, where price negotiations need to be based on the demonstrated value of the digital health solution.

Financing Digital Health Solutions or Apps Outside Insurance

The studied countries reported an array of options for financing digital health solutions that were not reliant on their inclusion in health insurance packages. France offered an experimental program for digital health solutions in the fields of heart failure, kidney failure, respiratory failure, diabetes, and implantable cardiac devices until January 2023. Belgium, Germany, Israel, Italy, the Netherlands, Sweden, and the United Kingdom offer innovation grants that finance treatment options currently under development and are not yet covered by their respective national health insurance frameworks, which can cover digital health solutions. However, in Germany, digital health apps that are approved via Germany's fast-track process, which combines regulation and reimbursement, have to be directly reimbursed in the statutory health insurance system. Furthermore, certain nongovernmental organizations in the Netherlands offer access to disease-specific digital health solutions outside of insurance packages. In this scenario, they are purchased by the nongovernmental organization and distributed to its members free of charge. Poland was the only country that did not report any concrete funding mechanism for digital health solutions.

Discussion

Principal Findings

Although there is nascent literature on national reimbursement practices vis-à-vis digital health solutions, this study is, to the best of the authors' knowledge, the first to compare reimbursement pathways across countries in the WHO/Europe region with and without specified digital health pathways and to do so for a broader set of digital health tools and approaches. Our findings reveal that the reimbursement pathways for digital health are varied and that value-based pricing frameworks are rare. Although this can be partly attributed to the distinct systems for financing health care in the examined countries, it also emphasizes how the absence of a consistent definition and classification of digital health can contribute to disparate policy and implementation approaches. The present conceptualization of digital health solutions can encompass a range of meanings, including technology, user experience, individual service, product, or process, and can be viewed as part of the broader ecosystem of health services [2]. Although this expansive definition allows for significant flexibility in integrating digital health into existing health care delivery and reimbursement frameworks, it can also lead to uncertainty regarding where and how digital health is meant to fit within a health system. For instance, digital health solutions are regarded as stand-alone health care products in France, Germany, Italy, the Netherlands, Poland, Sweden, and the United Kingdom, whereas they are framed as tools to deliver traditional health care in Belgium and Israel. Furthermore, Belgium, France, Germany, Italy, and the United Kingdom have specific policy frameworks in place that outline the concept of digital health apps, whereas the other countries categorize digital health apps under either the broader digitalization of health care or medical devices [18,28,56,60,65].

Overall, the observed differences may be explained by the novelty and unprecedented nature of digital health tools and approaches, especially in light of how change resistant the health care sector can be [77]. Another contributing factor may be the lack of digital health literacy among both clinicians and patient users and the necessity (but not sufficient) for adoption training of the health workforce and policy makers to understand the scope, potential benefits, and limitations of these digital transformations [5,78,79]. Furthermore, the acute need to act during the COVID-19 pandemic resulted in divergent policies being implemented across Europe [38,40]. When combined, these factors may help explain why disparate digital health reimbursement policies are currently in place across the studied countries.

In the specific context of digital health apps, we found 2 broad categories of approaches toward reimbursement in the studied countries. On the one hand, digital health apps may be reimbursed per use cycle (ie, the period in which the digital health app must be used to produce positive health benefits). This fee-for-service approach has historically been easy to develop and implement, reflects the actual number of services rendered, and can create an incentive for health care providers to increase access to and use of health care services [80]. However, this reimbursement approach has a significant and oft-cited disadvantage, namely providing health care professionals with the incentive to induce demand [81,82]. In the context of digital health care, which can function autonomously and asynchronously, this risk may be exacerbated as health professionals no longer have to consider their own time constraints in prescribing this form of health care (although it could be tempered when a digital health solution is expected to be a substitute for billable services by a clinician). Consequently, a digital health economic paradox can arise, namely that digital health care has the potential to reduce health care costs relative to in-person services, but can equally inflate health care spending if poorly implemented, although this is dependent on the reimbursement methods applied and whether digital health tools serve as a complement or substitute for in-person care—or a combination of the 2. On the other hand, reimbursement for digital health apps may be included as part of the remuneration of a larger health care process, which is more compatible with diagnosis-related groups or global budget approaches to paying for health care. Both these approaches may be more suited than fee-for-service for realizing the potential for digital health care to reduce costs, as they characteristically introduce incentives to improve efficiency in processes and in the allocation of resources.

Furthermore, reimbursement parity for digital health solutions was explicitly introduced in Italy, although the Belgian and Israeli reimbursement approaches could produce a degree of parity as well. Parity systems are considered enablers for the uptake of digital health [21,24], although concerns exist that parity systems could impede the development of innovative care delivery models, which could limit the potential of telehealth to address high health care costs and complicate the introduction of value-based models [24].

Among the countries examined, the pricing of digital health solutions and apps was mostly determined through discussions between committees at the national or regional level and the digital health app developers and manufacturers. However, it is presently unclear what criteria must be met to participate in these committees and whether the designated institutions have the necessary capabilities to assess the worth of digital health solutions or apps [11,83]. Only France, Germany and the United Kingdom have reported the use of value-based frameworks with clear information requirements to help stakeholders navigate the price negotiations for digital health apps. These 3 countries are at a more advanced stage of digital health implementation and both patients and professionals have more experience with digital health apps and their effects, which is an important foundation for the introduction of value-based reimbursement models [17].

We found that, except for Poland, there were many opportunities for financing digital health solutions and apps outside of insurance-based frameworks in the studied countries. However, there were discrepancies in the specificity of these funding opportunities, as it was unclear whether they targeted digital health specifically or health innovations more generally. Nonetheless, such funding initiatives can alleviate the financial risk for health insurers and allow patients, professionals, and insurers to become accustomed to the use and effects of digital health solutions and apps, which is a key factor in their uptake [84].

Limitations

Some limitations of this study need to be considered. As is common with scoping reviews, the quality of the included studies was not assessed, which should be considered when interpreting the results. However, as the aim of this study was not to validate methodological rigor to ascertain confidence in the data synthesis but rather to collect information about reimbursement processes in different countries, the absence of a quality assessment does not inhibit the validity of this study. In fact, the information collected did not solely rely on scientific articles as country experts also ensured that the collected information was complete and correct. We also recognized the possibility of selection bias and failed to capture all relevant studies as only 3 academic databases and Google Scholar were used, and the search strategy was not exhaustive. This study focused on 9 countries in the WHO/Europe region, which may not reflect the realities of other regions or countries. Furthermore, the lack of a uniform definition and classification of digital health across countries may have influenced the interpretation and comparison of the reimbursement pathways. Therefore, caution should be exercised when interpreting and generalizing the findings of this study. Moreover, the rapidly evolving nature of digital health and its reimbursement pathways means that the information presented in this study may become outdated relatively quickly. Finally, this study did not explore the potential impact of reimbursement policies on patient outcomes, which could be an area of future research.

We have identified several avenues for future research. First, the composition of committees that determine the price of the digital health solutions in the studied countries could be better characterized and assessed. Second, the expertise requirements to adequately assess the value and price of digital health solutions could be further investigated and potentially pooled into a comprehensive framework. Third, a comprehensive, value-based, and value-sensitive framework for the assessment of digital health apps should be developed. Although some research in this area has already been conducted [19,85-87], no comprehensive assessment of how digital health apps generate value across different levels of health systems has been conducted so far. Fourth, a comparative assessment of health expenditure (eg, in the management of a particular disease) after the introduction of digital health care in the studied countries can offer a more sophisticated insight into how digital health interacts with different reimbursement systems to affect overall health expenditure. Fifth, it is unclear whether these findings apply to the broader spectrum of novel health technologies. Digital health is a particular type of innovation in health care and future work can explore how these findings translate to, for instance, the growing role of artificial intelligence in health care, where artificial intelligence–based digital health solutions represent a unique subset of digital health products. Sixth, future research should investigate how digital health solutions or apps would be reimbursed in case of cross-country health service delivery and how these reimbursement practices interact with current international and European Union legislation. Finally, future research should investigate how digital health policy has evolved over time across multiple layers of governance (eg, international, national, and regional where applicable) and even before the COVID-19 pandemic to better understand the extent to which the pandemic accelerated the development of digital health policy holistically and how that affected the formation of reimbursement-specific policy for digital health.

Conclusions

The studied countries have been pursuing heterogeneous approaches to the reimbursement of digital health care. Although no approach is inherently superior, a fee-for-service approach might encourage more prescribing of certain digital health solutions or apps, which may be desirable to increase digital health use for purposes such as screening, yet it equally opens the possibility of supplier-induced demand and thus inflating health care expenditure. Ultimately, reimbursement policies should aim to stimulate the value-based integration of digital health into the health care ecosystem to promote equitable access to innovative health care technologies and improve health outcomes for patients. A clearer understanding of reimbursement and its accompanying incentives at present will help to shape more thoughtful, value-based reimbursement policies going forward. This study can therein serve as a basis for further, more detailed research as the field of digital health reimbursement evolves.

Data Availability

No primary data were collected for this study.

Authors' Contributions

RvK was involved in study conceptualization and methodology, software analysis, validation, formal analysis, investigation, data curation, writing the original draft including reviewing and editing, visualization, and project administration. DS and IK were involved in study conceptualization and methodology, software analysis, validation, formal analysis, investigation, writing the original draft including reviewing and editing, and visualization. GM was involved in validation, writing the original draft including reviewing and editing. DNO, WWZ-C, GN, ADS, and GW performed the data curation, validation, writing the original draft including reviewing and editing. EM was involved in study conceptualization and methodology, validation, formal analysis, writing the original draft including reviewing and editing, and supervising the study.

Conflicts of Interest

DNO is a staff member of the World Health Organization and is solely responsible for the views expressed in this publication, which do not necessarily represent the decisions or policies of the organization. ADS reports consulting income from the US Department of Health and Human Services outside of the context of this project and sits on the Scientific Advisory Board of the German Society for Digital Medicine and on the Strategic Advisory Board of HumanFirst.

Abstract

Background: Patients with head and neck cancer (HNC) often experience various types and degrees of complications and functional impairment following surgery or radiotherapy. Consequently, these patients require extensive postdischarge rehabilitation, either at home or in the community. Numerous studies have shown the advantages of mobile Health (mHealth) technology in assisting patients with cancer with self-management and rehabilitation during the postdischarge period. However, few reviews have focused on the intervention, management, and evaluation of mHealth technology in postdischarge patients with HNC.

Objective: This study aimed to conduct a scoping review of mHealth technology apps and interventions currently available to patients discharged from hospitals after receiving treatment for HNC. This study sought to identify and summarize the types and effectiveness of existing mHealth interventions as well as the differences in their outcome assessments.

Methods: The PubMed, Embase, Web of Science, and CINAHL databases were used to identify studies with no publication time limits. The keywords "mobile health technology" and "head and neck cancer" were combined to address the main concepts of the research questions.

Results: Of the 1625 papers identified, 13 (0.8%) met the inclusion and exclusion criteria. Most studies (n=8, 61.5%) were randomized controlled trials (RCTs) and cohort studies. These studies were conducted in 6 countries. The main aims of the mHealth interventions in these studies are as follows: (1) symptom monitoring and assessment, (2) rehabilitation training, (3) access to medical health information, (4) telehealth advisers, (5) peer communication and support, and (6) follow-up/review reminders. The outcome evaluations of the 13 included studies were grouped into 4 categories: (1) technology usability and patient satisfaction, (2) self-management of symptoms and patient-reported outcome–related indicators, (3) adherence, and (4) health-related quality of life.

Conclusions: A limited number of studies have investigated the use of mHealth technology in the postdischarge self-management of patients with HNC. The existing literature suggests that mHealth technology can effectively assist patients with HNC in self-management and postdischarge interventions. It plays an important role in addressing patients' health information needs, reducing both their somatic and psychological burdens, and improving their overall quality of life. Future research should prioritize conducting additional high-quality RCTs to evaluate the usability and analyze the cost-effectiveness of mHealth technology.

Introduction

Background

Malignant head and neck tumors, one of the most common malignancies, are classified according to the site of tumor origin into oral cavity, nasopharyngeal, oropharyngeal, and laryngeal cancers. Among these, head and neck squamous cell carcinoma (HNSCC) accounts for >90% of all head and neck tumors. The latest statistics of the International Agency for Research on Cancer (IARC) GLOBOCAN on global cancer incidence and mortality in 2020 revealed 890,000 new cases of HNSCC, with 450,000 resulting deaths annually [1]. The incidence of HNSCC is continuing to rise and is expected to increase by 30% by 2030, reaching an estimated 1.08 million new cases of HNSCC per year [1].

Surgical resection, radiation, chemotherapy, targeted therapy, and a combination of these therapies are the available treatment options for head and neck cancer (HNC). Patients with various tumor stages and locations receive individualized treatment approaches [2]. However, both surgical treatment and radiotherapy can result in various types and intensities of complications, which can negatively affect patients' somatic function, outward appearance, and psychological well-being. For example, physical dysfunctions, such as swallowing disorders, mouth-opening issues, and shoulder syndrome, as well as psychological difficulties, such as social and workplace reintegration due to an altered outward appearance, can result from both surgical treatment and radiotherapy [3].

Studies have shown that patients with HNC frequently experience increased functional impairment and negative side effects after surgery or radiotherapy. Short-term home rehabilitation after discharge is crucial for enhancing patients' function and long- and short-term quality of life (QoL) because brief rehabilitation care treatment during hospitalization is insufficient to assist patients in achieving full recovery. Although patients have continuous access to medical care and guidance from doctors and nurses while they are in the hospital, they must assume responsibility for their own functional rehabilitation and self-care after discharge, whether they return home or move to other facilities, such as community nursing homes. Most patients and their family caregivers lack a medical background, and despite receiving necessary verbal health education or health information booklets by doctors and nurses before discharge, forgetfulness inevitably occurs over time. As a result, survivors of HNC may continue to experience significant debilitating issues with swallowing, speech, hearing, and psychological effects due to loss of function and changes in their body image as a result of treatment. Survivors of HNC often experience a lower QoL [4-6]. Studies have shown that their QoL is lower compared to survivors of other cancer types [7]. Therefore, improving the ability of patients with HNC to manage their own care after leaving hospital is a challenging and complex research subject.

With the increasing application and popularity of mobile health (mHealth) technology, numerous studies have shown that mHealth technology has the potential to assist patients with cancer and other chronic diseases in self-management [8,9]. mHealth is defined as "medical and public health practice through the use of mobile devices such as mobile phones, patient monitoring devices, personal digital assistants (PDAs) and other wireless devices" [10]. Currently, mHealth technology is used in a variety of devices and formats, including telephones, mobile phones apps for calls or videos, web-based platforms, and tablets, which are more commonly used in home environments. Although existing studies have systematically evaluated the use of mHealth technology in patients with HNC, the primary focus of these studies is not on patients' self-management after hospital discharge. The included studies mainly include randomized controlled trials (RCTs), excluding other relevant studies [11]. Therefore, this study aimed to explore how patients can use mHealth technology for self-management and functional rehabilitation, along with assessing the associated outcome indicators, in both the short and the long term, following discharge from treatment.

Objectives

This study systematically reviewed the use of mHealth technology in the postdischarge self-management of patients with HNC. The review centered on 2 sections: intervention and outcome evaluation. The aims of this study were (1) to summarize the categories of mHealth interventions and their main types of functions/services for the postdischarge self-management of patients with HNC through a systematic review of the existing literature and (2) to examine how these mHealth interventions are evaluated and the differences that exist between outcome indicators across studies.

Methods

Study Design

This study used the 5-stage methodological framework outlined by Arksey and O'Malley [12] to define the scope of the review: (1) identifying the research question, (2) identifying relevant studies, (3) selecting relevant papers for the review, (4) charting the data, and (5) collating, summarizing, and reporting the results.

Stage 1: Identifying the Research Question

The study population included adult patients with HNC who had been discharged from the hospital after surgical treatment or radiotherapy and were recovering at home or in the community. The type of intervention involved the use of mHealth technology. The research questions were developed based on an initial literature search and further refined through iterative discussions within the research team. The research questions were as follows: (1) What mHealth technologies exist to support patients with HNC after hospital discharge? (2) How are these mHealth technologies used to implement interventions? (3) How are mHealth interventions evaluated?

Stage 2: Identifying Relevant Studies

A systematic search strategy was used to identify the literature related to the research questions. We combined the keywords “mobile health technology” and “head and neck cancer” according to the patient/problem, intervention, comparison, and outcome (PICO) principles of literature search, which identified the 2 main concepts of the research questions and summarized the subject terms and free words related to these 2 main concepts. Systematic searches were conducted in the PubMed, Web of Science, Embase, and Cumulative Index to Nursing & Allied Health (CINAHL) databases. Two independent researchers (authors LYF and CWH) searched the databases for references to identify papers published between the time of database creation and March 1, 2023. The search terms and strategy used are presented in Multimedia Appendix 1.

Stage 3: Selecting Relevant Papers for the Review

The inclusion and exclusion criteria for this review are presented in Textbox 1. The citations obtained from each database were imported into Endnote Reference Manager for bibliographic analysis. Duplicate papers were excluded. Each level was assessed by 2 reviewers, who independently considered studies based on the inclusion and exclusion criteria. The first screening process involved reviewing the titles and abstracts to make the following decisions: (1) if at least 1 reviewer agreed with the inclusion criteria or found the abstract or title inconclusive, the study was moved to the second level of screening, and (2) if both reviewers agreed to exclude a study, the study was excluded. Two independent reviewers evaluated the full texts at the second level of screening. Any disagreements between the reviewers were resolved through discussion or by a third reviewer.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria:

- Adult patients including both males and females (≥18 years old)
- Patients with head and neck cancer (HNC) who have been discharged from the hospital to recover in a nonmedical setting, such as their homes or communities, after undergoing at least 1 surgical or radiotherapy treatment
- Use of mobile health (mHealth) technology to implement interventions
- English papers only
- Contains at least 1 quantitative result
- Selection of a paper by the same research team (same app) on a specific system for inclusion in the analysis

Exclusion criteria:

- Participants aged <18 years (pediatric, adolescent)
- Integrated interventions that do not use mHealth technology alone but in other collaborative ways, such as multidisciplinary cooperation
- Full-text documents not available, such as conference abstracts or protocols, as well as review papers
- No specific outcome evaluation indicators related to HNC

Stage 4: Charting the Data

We collaborated to develop a graphical form of the data and to identify variables to be extracted. Descriptive graphical information included (1) a general description of the paper (first author and year, study design, study site, and patient population) and (2) intervention-specific information (purpose of the intervention and mHealth app, key features, delivery methods, duration and follow-up period, data collected, outcomes measured, and findings); see Multimedia Appendix 2.

Stage 5: Collating, Summarizing, and Reporting the Results

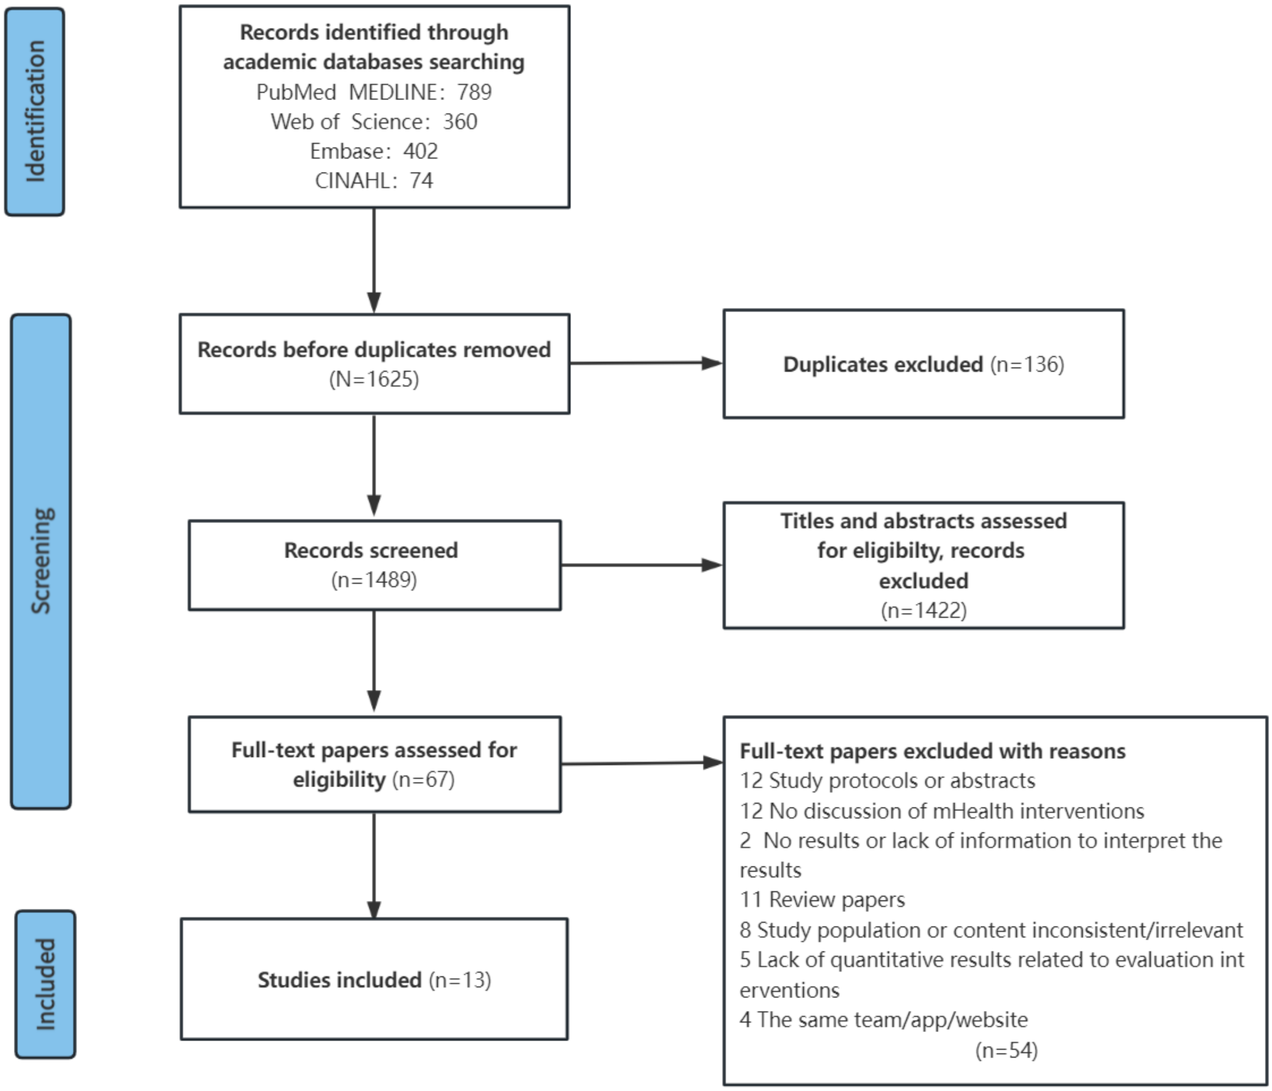
General descriptions of review papers were collated according to the descriptive characteristics. Following a concurrent review of the chart data, we conducted a thematic content analysis of the interventions and associated outcomes for each study. First, codes were developed and applied to analyze the data. The coding segments for all chart data were created using color-coded quotes. The code summaries were organized in a Microsoft Excel table for thematic content analysis. The table was sorted by code and density, looking for repeating patterns addressed by the included papers, including a comparison of the studies across the data set and within each study until key themes were identified. The results of this study summarize the objectives.

Results

Search Results

In total, 1625 papers were retrieved, of which 1489 (91.6%) different papers remained after removing duplicate data. Figure 1 displays the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) flow diagram of the retrieved literature, the level of screening, and the included studies. Finally, 13 (0.9%) studies, projects, or reports were included in this review.

Figure 1. The Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) flow diagram.



General Characteristics of the Included Studies

Of the 13 studies included in this review, RCTs (n=6, 46.2%) were the most common type [13-18], followed by 2 (15.4%) cohort studies [19,20] and 5 (38.5%) other types (n=4, 80%, quasi-experimental studies and n=1, 20%, mixed study) [21-25]. The quality of the included studies was assessed using the JBI critical appraisal tools, and detailed information is provided in Multimedia Appendix 3. The general characteristics of the included studies are presented in Table 1.

Types of mHealth Interventions Currently Being Implemented

Current mHealth interventions and management services for the population with HNC postdischarge include 6 main categories: (1) symptom monitoring and assessment reports (n=8, 61.5% [15,16,19,20,22-25]), (2) home rehabilitation training (n=4, 30.8% [13,16-18]), (3) medical health information access (n=7, 53.8% [13,14,16,17,22-24]), (4) telehealth support (n=7, 53.8% [14,18-21,23,25]), (5) peer-to-peer communication (n=2, 15.4% [23,24]), and (6) follow-up/review reminders (n=2, 15.4% [14,22]). These mHealth interventions were delivered through various technology platforms, including smartphones (n=9, 69.2%), personal digital assistants (PDAs)/tablets (n=2, 15.4%), web-based platform (n=1, 7.7%), and home monitoring or telemonitoring unit or telemetry system (n=1, 7.7%). The results are summarized in Table 2.

Table 2. mHealth[a] intervention tools and categories.

Characteristics	Studies (N=13), n (%)

Follow-up/review reminders	2 (15.4)

[a]mHealth: mobile Health.

Intervention evaluation indicators for patients with HNC adopting mHealth technology mostly included general patient characteristics, QoL indicators, adherence, symptom self-reporting, patient satisfaction, and evaluation of technology usability. The thematic content analysis identified 4 main themes for outcome evaluation: (1) technology usability and patient satisfaction, (2) indicators related to self-management of symptoms and patient-reported outcomes (PROs), (3) adherence, and (4) health-related quality of life (HRQoL).

This study found that mHealth technology plays a more beneficial role in the postdischarge management of patients with HNC. The mHealth program helped improve physical and psychological symptoms after discharge, enabled patients to gain more knowledge about health care, and enhanced their self-management of behaviors and functional rehabilitation exercises after leaving the hospital. Patients in these studies showed high levels of satisfaction with and acceptance of mHealth technologies.

Self-Management of Symptoms and PRO-Related Indicators

Of the 13 included studies, 8 (61.5%) focused on the impact of mHealth technology on symptoms and the validity of outcome reporting.

Of these 8 (61.5%) studies, 2 (25%) discussed the impact of mHealth technology on the effectiveness of PROs. Ma et al [20] found that using a fully automated interactive chatbot to provide support and assist patients in self-reporting outcomes during the postradiotherapy period for HNC treatment resulted in good consistency between PROs and clinician-reported outcomes (CROs). According to the study results [20], 61% of the patients felt that the chatbot helped with symptom self-management and reduced the need to call the care team, demonstrating that mHealth technology can be effective in helping patients with self-reporting outcomes.

Due to the significant symptom burden associated with HNC, mHealth technology may be beneficial in assisting patients with symptom management. Van Cleave et al [19] developed a web-based platform, Electronic Patient Visit Assessment (ePVA), to explore patients' reports of symptoms and functional limitations. ePVA can inquire about and document 21 common symptoms and functional limitations associated with HNC and generate an ePVA report. The HNC care team members can use the ePVA report to implement real-time clinical interventions based on their clinical judgment and the patients' knowledge. The study phase results showed that patients with the most symptoms and functional limitations reported a significantly poorer HRQoL, demonstrating that ePVA may be a proven mHealth tool that can be used as a real-time intervention for patient reporting.

Next, 6 (75%) studies discussed the effect of mHealth technology on patients' symptom self-management. The mobile app SwallowIT was tailored to provide telepractice-assisted therapy to patients with swallowing disorder during radiotherapy and after HNC treatment to support home practice of the pharyngeal program [13]. The program provides instructional videos, images, and text descriptions for each exercise, allowing patients to record the number of motor repetitions and the perceived effort as they complete each exercise. Results of the study during the outcome evaluation phase showed no significant differences between the conventional and experimental groups in terms of swallowing, nutrition, or functional measures. However, more patients (76%) preferred using SwallowIT to receive instructions compared to instructing themselves during exercises.

Lin et al [24] developed an oral care mobile app to provide medical health information and oral mucosal care advice to patients during radiotherapy for HNC. The results of the study showed that the Patient-Generated Subjective Global Assessment scores of the group using mHealth technology were significantly lower than those of the control group at all 3 nodes during the intervention. Additionally, the severity of oral mucositis grading was also significantly lower in all groups. These findings indicate that the use of mobile apps is effective in improving the nutritional status and reducing the side effects in patients with HNC treated with concurrent radiotherapy.

The mobile app Oncokompas, developed by Dutch academics, can support symptom self-management by providing medical information and a personalized overview of supportive care options aimed at reducing the symptom burden among survivors of cancer [16]. The results of the study indicated that the mHealth technology group showed statistically significant improvements in the clinical course and symptom burden scores for oral pain, social eating, swallowing, cough, and dental symptoms compared to the control group.

Wang et al [18] used telephone calls to help patients with oral cancer after radical surgery perform functional exercises for their trismus, monitor training progress, and obtain appropriate feedback. After the 12-week intervention period, the change in the maximum interincisional opening was 10.30 mm (95% CI 8.22-12.37) greater in the experimental group than in the active control group. The change in the mandibular functional impairment score was –0.36 (95% CI –0.44 to –0.28) greater in the experimental group than in the active control group. This study provides evidence supporting the effectiveness of the intervention program in reducing dental and mandibular functional impairments in patients undergoing radical oral cancer surgery.

Regarding complication management, an RCT [14] with patients with nasopharyngeal cancer who were discharged from the hospital after radiotherapy used a mobile app to provide the patients with information about the disease, including observation and treatment of radiotherapy complications and reminders for regular review. The aim was to enhance the self-management skills of the patients, enabling them to cope effectively with radiotherapy complications [14]. The results of this study showed that the incidence of oral mucositis, dry mouth syndrome, difficulty in opening the mouth, and nasal congestion was significantly lower in the intervention group than in the control group 5 months after discharge, suggesting that the intervention can effectively help patients improve their ability to cope with and manage complications and reduce their occurrence. In contrast, another retrospective controlled trial [25] was conducted in which patients were followed up over the phone within 72 h of discharge as well as by wound visits to answer their questions in order to reduce emergency department visits and readmission rates. The results of this study showed a statistically significant reduction in emergency department visits compared to the previous year, with no change in readmission rates, demonstrating the potential of telephone interventions in the early postoperative period to reduce unnecessary emergency department visits.

Technology Availability and Patient Satisfaction

Of the 13 included studies, 4 (30.8%) investigated technology usability and patient satisfaction in outcome evaluations. Patients demonstrated higher satisfaction with the mHealth technologies in all study outcomes.

In terms of technology usability, software usability refers to the extent to which a particular user can use a product in a specific context and achieve a particular goal effectively, efficiently, and satisfactorily. Patient satisfaction with a fully automated interactive chatbot [20] reached 89%, with 83% of patients finding it easy to use, 79% feeling confident in using the chatbot, 71% finding the chatbot functionality well integrated, and 86% feeling they did not need additional training or technical support (80%) to use the chatbot.

In the SwallowIT study [13], 76% of patients preferred SwallowIT or clinician guidance. In a study [21] on coping with somatic imagery, 89% of patients were very satisfied with BRIGHT, found its use effective, and would recommend it to other survivors of HNC. In a quasi-experimental study in Taiwan [22], the acceptability score of the mHealth app significantly improved (*P*<.05) in terms of the intention to use, perceived usefulness, and ease of use after 3 months of the intervention.

These data show that patients' use of and familiarity with mHealth apps reduce their uncertainty and improve their acceptance of the new technology. This, in turn, can promote better adoption and use of mHealth technology in the future and enhance its overall usability.

Health-Related Quality of Life

Most studies (n=9, 69.2%) measured and evaluated the HRQoL. Of these, 6 (66.7%) studies [14,19,21-24] used the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Core 30 (EORTC-QLQ-C30) and the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Core 35 and Head and Neck Module (EORTC-QLQ-H&N35), 2 (22.2%) studies [13,15] used the Functional Assessment of Cancer Therapy—Head and Neck (FACT-H&N) scale, 2 (22.2%) studies [16,19] used the HRQoL scale, and 1 (11.1%) study [17] used the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire and Provisional 25-item Information Module (EORTC-QLQ-INFO-25) to assess the QoL of survivors of HNC.

There were mixed results regarding the improvement in the QoL with mHealth technology in the studies. The mobile app SwallowIT was not associated with statistically significant improvements in the final overall QoL [13]. However, BRIGHT was associated with improvements in the social eating disorder and social contact disorder substructural domains of the EORTC-QLQ-H&N35 [21]. Additionally, a greater number of reported symptoms and functional limitations were associated with lower EORTC-QLQ-C30 overall QoL health scores [19]. Furthermore, 5 (55.6%) studies demonstrated higher overall improvements in the QoL in the experimental group using mHealth technology than in the control group [14,15,22-24], and 1 (11.1%) study reported that increased adherence was associated with a better patient-reported QoL [17].

Intervention Adherence

Of the 13 included studies, 5 (38.5%) reported on adherence to the use of mHealth technology. In the SwallowIT app [13], it was found that adherence decreased significantly over time for the entire cohort, with low adherence at 6 weeks in all groups (27%). However, adherence was relatively high in the group with clinician guidance and the group using SwallowIT [13].

The results of an RCT [14] showed that adherence to mouth-opening exercises and nasal rinsing was higher in the intervention group than in the control group at 3 and 6 months postdischarge (*P*<.05). However, changes in adherence within groups were not elaborated. The researchers concluded that mHealth technology can provide pictures and videos to be viewed repeatedly, and all these activities can be performed with the help of relevant videos as a means to improve patient adherence.

The ePVA study [19] showed that 59 of 64 (92.2%) patients completed the ePVA, with 1 or more follow-up visits within the 6-month study window, with high completion rates and adherence. The investigators concluded that the high completion rate results were related to the study team accommodating patients' needs regarding completion times during treatment, such as allowing patients to delay completion until a convenient time.

The HNC Virtual Coach study [17] conducted as a pre-radiotherapy prophylactic swallowing rehabilitation demonstrated that 80% of patients used the app and over 50% completed at least 1 swallowing exercise per day, with better, although not statistically significant, adherence in the experimental group. Although adherence declined in both groups during radiotherapy, the results showed that higher adherence was associated with a better patient-reported QoL.

Additional support for the intervention exercise program for patients with restricted mouth opening was provided by remote telephone support [18], which showed that at week 12, the experimental group had 299.67 minutes (95% CI 223.44-357.89) more intervention exercise time than the control group. From baseline to week 12, the change in the maximum interincisional opening was 10.30 mm (95% CI 8.22-12.37) greater in the experimental group than in the active control group. This demonstrates that the use of mHealth technology can help enhance patient compliance with intervention programs and, in turn, improve functional impairment outcomes.

Discussion

Principal Findings

In this review, 13 papers were analyzed. Some studies have indicated that patients with HNC frequently experience increased functional impairment after surgery. Brief rehabilitation during hospitalization may not be adequate to help patients recover, while long-term home-based rehabilitation after discharge plays a crucial role in improving patients' function and long- and short-term QoL. Therefore, this study focused on assessing how patients use mHealth technology for self-management, functional rehabilitation, and related outcome evaluation indicators after hospital discharge.

This scoping review summarized the existing literature on mHealth technology for the postdischarge self-management of patients with HNC and the intervention tools, intervention methods, and types of outcome evaluations of mHealth technology in the currently available literature, following a generalization and thematic summary.

Advantages of mHealth Technology in Postdischarge Self-Management of Patients With HNC

mHealth technology can accelerate patient communication, facilitate home monitoring and self-management, and improve overall patient health. The use of mHealth in the postdischarge self-management of patients with HNC addresses many issues and offers several advantages, including the following:

- Real-time monitoring and tracking: Although patients are the best recorders of their daily health experiences, clinicians and others are unlikely to have full access to patients in their living environments after hospital discharge. Consequently, capturing timely information about patients' actual experiences, health status, and outcomes can be challenging. mHealth apps can help patients monitor and track their health in real time. Using sensors and devices, patients can measure physiological metrics (eg, heart rate, respiration, blood pressure, and weight) and record them. These data can be shared with doctors to better understand their condition and make necessary adjustments to the treatment plans. Meanwhile, because PROs have become the focus of health care research, scholars have begun to explore whether mHealth technology can be an effective tool for PROs. Findings have shown that the use of mHealth technology can help patients with daily symptom recording and outcome reporting. Furthermore, PROs have demonstrated strong concordance with CROs [20].
- Personalized health management: mHealth technology can provide a platform for patients and their families to obtain different health services in the face of different needs, as well as better intervention and management of patients after they leave the hospital. mHealth apps can provide personalized health management solutions tailored to individual patient differences and needs. The apps can provide customized dietary advice, exercise plans, medication reminders, follow-up reminders, and other functions according to the patient's condition and treatment plan, thereby helping them effectively manage their health.
- Education and information resources: While patients are receiving treatment within a hospital, doctors and nurses can provide a steady stream of health care support, including daily treatment, health information, and guidance. In contrast, once patients are discharged, although doctors and nurses may initially explain the key points of posthospitalization rehabilitation and care, the passage of time and various factors, both subjective and objective, such as patient compliance, can make it challenging for patients to effectively self-manage their physical and psychological well-being. mHealth apps can provide patients with health education and the necessary information resources they require anytime, anywhere. Patients can access professional medical knowledge about diseases, treatment options, medication, and more through these apps while they are at home, helping them better understand their condition, treatment options, recovery methods, etc.
- Social and psychological support: Due to factors related to the disease and treatment modalities, patients with HNC usually face issues concerning an altered body image, which may also affect their ability to resume work and engage in social activities. Therefore, social and psychological support for these patients requires careful consideration. However, this is a long-term process that cannot be fully addressed and promptly implemented during hospitalization. mHealth apps connect patients with other patients or health care professionals to provide social and psychological support. Patients can use these apps to share their experiences and offer advice to other patients. Moreover, they can have online consultations and communications with health care professionals, thus reducing anxiety and the feeling of isolation.
- Improving adherence: Undoubtedly, for doctors and nurses, managing and providing follow-up care for discharged patients pose a significant challenge. The brief, 1-time health education at the time of discharge makes it difficult to address the various medical, health, and psychosocial difficulties encountered by patients during home rehabilitation and to help patients establish good self-management ability and compliance with home treatment. Patients who leave the hospital often experience problems during the follow-up phase, including difficulty in communication, difficulty in management, poor adherence, suboptimal recovery, and a poor QoL. mHealth apps, however, can provide medication reminders, treatment plan tracking, and other functions to help patients better follow doctors' advice and treatment plans.

These findings suggest that novel mHealth technology is more likely to be welcomed by the patient population than traditional forms of follow-up and that patients who use mHealth technology show better adherence [13,14,17-19]. This suggests that mHealth technology may be an effective tool to provide follow-up and enhance the self-management of postdischarge patients in the future.

Overall, the advent of mobile technology has transformed the health ecosystem by changing the way individuals communicate and providing patients and health care providers with a wide range of supportive tools to monitor and manage health information, thereby facilitating better health care delivery. The advantages of mHealth in the home self-management of patients with HNC after discharge from the hospital include real-time monitoring, personalized health management, access to educational and information resources, social and psychological support, and improved treatment adherence. These benefits can help patients more effectively manage their health, improve their QoL, and work closely with their health care teams.

Limitations of mHealth Technology in Postdischarge Self-Management of Patients With HNC

Although most studies have demonstrated the positive impact of mHealth technology on the postdischarge self-management of patients with HNC, some have shown no significant improvement in patient self-management with respect to other outcome indicators [16]. This may be because mHealth technology is just beginning to be applied to the population with HNC and the amount of available literature on its application is limited. Although the number of RCTs among the available studies is relatively high, the research questions and outcome indicators vary significantly across these studies. Therefore, there is a scarcity of directly comparable studies in terms of outcome evaluation.

In addition to physical and psychological outcome indicators, few studies have examined standard technical usability evaluations and economic efficiency indicators. Wall et al [26] reported associated health service costs (service time, consumables, treatment resources), patient-related costs (travel and wages), and patient-related HRQoL statistics. Their study resulted in a comparison of the total costs of different forms of mHealth interventions, revealing significant cost savings for health care services and consumers with HNC, while achieving comparable HRQoL outcomes at a lower cost [26]. However, apart from this study, there is limited existing literature that reports on the social and economic benefits of using mHealth technology for both patients and hospitals. Various factors, such as software development and operational costs, equipment use and maintenance costs, actual changes in patient financial stress, and the overall social and economic benefits to hospitals, are areas where further data and research are needed. Such research is essential to demonstrate the technological advantages of mHealth and the associated individual societal benefits generated.

As the number and scale of mobile apps increase with the increasing use of mHealth technology, more attention should be paid to usability evaluation throughout the software development process. Timely usability evaluation before, during, and after development is an important measure for understanding user needs, improving the design of software features, and improving user experience and satisfaction. However, this is not well described in existing research.

At the same time, we must also consider the impact of mHealth technology on doctors and nurses, even as it brings convenience to patients. Questions regarding whether the use of mHealth technology consumes additional time for health care professionals, whether it increases their workload beyond their regular work, whether health care professionals are satisfied with their mHealth technology experience, and how hospital managers reconcile conflicts and contradictions arising from this technology are all aspects that have received less attention in existing research. Therefore, future research should explore these areas to achieve a comprehensive understanding.

Finally, the issues of data privacy and security should be given sufficient attention. mHealth apps handle large amounts of personal health data; therefore, data privacy and security are important concerns. Ensuring the security and privacy of patient data is challenging, and appropriate security measures must be adopted to protect such data.

Implications for Future Research

By addressing the limitations and research weaknesses of this study, future research can advance to explore the effectiveness of mHealth technology in the postdischarge self-management of patients with HNC. This can be achieved through rigorous methods, such as conducting an RCT with a robust study design, expanding the scope of the study and the number of users, and adopting scientific theoretical guidance for the selection and evaluation of outcome indicators.

Hotspots for future research will also focus on the application of artificial intelligence in mHealth, the integration of virtual reality and augmented reality technologies in oncology treatment, and the development of remote monitoring and diagnosis based on mobile devices. Future research will also need to overcome various challenges, including issues related to data privacy and security, technology usability and ease of use, data analysis and use, and evaluation of the effectiveness and efficacy of mHealth apps. Addressing these challenges requires interdisciplinary collaboration and sustained research efforts.

Limitations

This study was a scoping review conducted to broadly include and summarize the existing literature. In addition, this study only included studies published in English, and studies published in other languages were excluded from the discussion.

Conclusion

mHealth technology has been applied to the postdischarge self-management of patients with HNC. The main interventions in mHealth technology for improving postdischarge self-management include symptom monitoring and reporting, functional rehabilitation training, access to health care information, telehealth service support, peer-to-peer communication, and follow-up/review reminders. Outcome evaluations of the use of mHealth technology were discussed in terms of technology usability and patient satisfaction, indicators related to self-management of symptoms, PROs, adherence, the HRQoL, and the impact on somatic/psychological aspects, with most studies showing a positive impact.

Therefore, based on the limited research data available to date, mHealth technology can effectively help patients with HNC in self-management and postdischarge interventions. This plays an important role in meeting patients' health information needs, reducing their somatic and psychological burdens, and enhancing their QoL. Future research should aim to conduct higher-quality RCTs for usability evaluation and cost–economic benefit analysis.

Acknowledgments

This study was supported by the Shanghai Association for Science and Technology (21002411300), the Innovation Research Team of High-level Local Universities in Shanghai (SHSMU-ZDCX20212802), and the establishment of a clinical multicenter oncology integrated Chinese and Western medicine nursing database (Hlgy1901sjk).

Authors' Contributions

LYF designed the study, developed the search strategy, performed the literature search, analyzed the data, and was the lead author of the manuscript. CWH oversaw the process, codeveloped the search strategy, provided guidance on the development of inclusion and exclusion criteria, discussed the findings, and contributed to the editing of the manuscript. LYJ and YL participated in the codevelopment of the search strategy and analyzed and discussed the findings. HLL provided guidance on reporting the study results; contributed to the analysis, methods, and discussion; and edited the manuscript. All authors have read and approved the final version of the manuscript.

Abstract

Background: During the COVID-19 pandemic, the provision of and access to health care have been uniquely challenging, particularly during lockdowns or when dealing with COVID-19 cases. Health care professionals have had to provide patients with the necessary health care. However, delivering health care services while reducing face-to-face interaction puts an immense strain on health systems that are already overburdened. Against this backdrop, it is now more critical than ever to ensure the accessibility of health care services. Such access has been made increasingly available through mobile health (mHealth) apps. These apps have the potential to significantly improve health care outcomes and expectations and address some of the challenges confronting health care systems worldwide. Despite the advantages of mHealth, its acceptance and adoption remain low. Hence, health care organizations must consider the perceptions and opinions of physicians if the technology is to be successfully implemented.

Objective: The objective of this systematic review was to explore and synthesize the scientific literature on the factors influencing the acceptance and adoption of mHealth among physicians during the COVID-19 pandemic.

Methods: A systematic review of the studies published between March 2020 and December 2022 was conducted using the MEDLINE, Scopus, Embase, and ProQuest databases. The database search yielded an initial sample of 455 potential publications for analysis, of which 9 (2%) met the inclusion criteria. The methodology of this review was based on PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses).

Results: The factors influencing mHealth acceptance and adoption by physicians were divided into perceived barriers and perceived facilitators, which were further grouped into the following 3 major thematic categories: technological, individual, and organizational barriers and facilitators, respectively. The technological barriers were accessibility, technical issues, usefulness, and data management; individual barriers were perceived patient barriers, time and workload pressure, technical literacy, knowledge of mHealth, and peer support; and organizational barriers were financial factors, management support and engagement, data security, telemonitoring policy, and collaboration. The technological facilitators of uptake were technical factors, clinical usefulness, and data management; individual facilitators were patient-related care, intrinsic motivation, collaboration, and data sharing (individual); and organizational facilitators were workflow-related determinants, organizational financial support, recommendation of mHealth services, and evidence-based guidelines.

Conclusions: This review summarized the evidence on the factors influencing mHealth acceptance and adoption by physicians during the COVID-19 pandemic. The main findings highlighted the importance of addressing organizational readiness to support physicians with adequate resources, shifting the focus from technological to patient-centered factors, and the seamless integration of mHealth into routine practice during and beyond the pandemic.

Introduction

Background

On March 11, 2020, the World Health Organization (WHO) declared the outbreak of the COVID-19 pandemic [1], a crisis that has put pressure on health care systems around the world [2,3], with multiple waves of infections and deaths [4,5]. A recent report by the WHO stated that there have been 757,264,511 confirmed cases of COVID-19, of which 6,850,594 (0.9%) have been fatalities [6].

During this period, the provision of and access to health care have been uniquely challenging [3,7,8], particularly during lockdowns or when dealing with COVID-19 cases. Health care professionals have had to provide patients with the necessary health care. However, delivering health care services while reducing face-to-face interaction puts an immense strain on health systems that are already overburdened [9]. Against this backdrop, it is now more critical than ever to ensure the accessibility of health care services. Such access has been made increasingly available through mobile health (mHealth) apps, given the advancements in information and communication technology. These apps have the potential to significantly improve health care outcomes and expectations and address some of the challenges confronting health care systems worldwide [10-14].

mHealth falls under the broader umbrella of eHealth, which encompasses the use of electronic technologies and digital communication to enhance health care delivery [15-17]. However, mHealth technologies differ from conventional eHealth technologies in that they are specifically designed for use on mobile devices, and as such, mHealth apps do not rely solely on computers and wired internet connections, which makes them more accessible [18]. In addition, mHealth extends beyond medical consultations (more commonly known as telemedicine), offering features such as symptom tracking, mental health support, fitness tracking, medication reminders, personalized support, and access to health-related information [18-21]. Using mHealth is a popular strategy because it is user driven, readily available, and often reasonably priced [22].

The WHO [23] acknowledged that there is no widely accepted definition of mHealth, but it could be understood as the practice of using mobile devices for health care. More specifically, it refers to the capability to use mobile devices to collect health care–relevant data from patients in real time and use such information to monitor, diagnose, and treat patients [24]. It has the potential to benefit both health care professionals and patients during the COVID-19 pandemic [14,25,26]. For instance, it can improve the delivery of health care services, reduce health care professional and patient exposure to infectious diseases, and minimize patient demand for facilities [27,28]. In addition, mHealth apps use location data and proximity alerts to notify users if they were in close contact with someone who later tested positive for COVID-19 [29,30]. These timely alerts empower people to self-isolate, get tested, and inform their health care providers, helping break the chain of transmission [29,31]. It also offers opportunities for health care professionals to remotely consult and share data with their colleagues [32,33]. Furthermore, mHealth not only enables patients to receive remote consultation but also improves their adherence to medication and delivers disease education [20,25,33,34].

Despite the above-mentioned advantages, the acceptance and adoption of mHealth remain low [35-38]. The factors that influence technology acceptance and adoption are likely to vary across target users [39,40]. Physicians, for example, can stimulate changes in the health care sector and play a critical role in mHealth acceptance and adoption, depending on whether they themselves embrace this new technology. As explained by Cajita et al [41], patients are willing to accept and adopt mHealth when their physicians recommend it. Hence, health care organizations must consider the perceptions and opinions of physicians if the technology is to be successfully implemented [42].

Objectives

Before the COVID-19 pandemic, the acceptance and adoption of technology for work duties were a matter of personal or organizational preference [43]. This orientation was changed by the crisis, which compelled technology use in work environments, thereby accelerating the process of digitization in all sectors, including health care. As previously stated, physicians have been forced to provide health care services remotely [44], and they have accepted and adopted mHealth because of physical distancing restrictions. This situation may affect their continued use of the technology, which is one of the success factors for acceptance and adoption [38]. However, Keuper et al [44] found in their study that only a few physicians intend to continue offering remote health care services in the future. A possibility is that the COVID-19 pandemic has changed the behavioral intentions and perceptions of people regarding digital transformation [45,46]. Thus, the factors influencing technology acceptance and adoption have also likely changed [47], or new factors might have emerged. Shedding light on these factors can facilitate the acceptance and adoption of mHealth and help health care professionals provide services during the COVID-19 pandemic and other similar crises in the future.

Although previous reviews have analyzed mHealth acceptance and adoption by physicians [42,48,49], to the best of our knowledge, none of these reviews have focused on this topic in the context of the COVID-19 pandemic. This systematic review intended to fill this void. This review can benefit policy makers and mHealth providers by presenting an updated and thorough assessment of important issues that affect mHealth acceptance and adoption among physicians. This review can also help them design a strategy for promoting mHealth acceptance and adoption and derive potential benefits from this technology. Finally, this review provides opportunities for follow-up research by identifying potential gaps in mHealth acceptance and adoption.

Methods

Overview

The methodology of this review was based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) [50], which provides guidelines for a reliable and rigorous literature review (Multimedia Appendix 1). The review protocol was registered and published in advance with PROSPERO (CRD42022356125). The review focused on quantitative, qualitative, and mixed method studies to identify the factors that influenced the acceptance and adoption of mHealth among physicians during the COVID-19 pandemic.

Search Strategy

MEDLINE (Ovid), Scopus (Elsevier), Embase (Ovid), and ProQuest databases were searched for studies published in the English language. As the aim of this review was to explore mHealth acceptance and adoption factors during the pandemic, the time frame selected was from 2020 to 2022. The search strategy was established based on the population, intervention, comparator, and outcome (PICO) framework [51]. Specifically, we searched for studies revolving around physicians (population); the use of mHealth apps, including smartphones, portable digital devices, and tablets (intervention); and mHealth acceptance and adoption (outcome). Comparators were not relevant to this review.

Initially, combinations of Medical Subject Headings (MeSH) terms, keywords, and terminologies were used with reference to the following 3 categories: "mHealth," "acceptance or adoption," and "physician" (Multimedia Appendix 2). The more specific search terms used were as follows: "mobile health," "mHealth," "mHealth," or "mobile app"; "adoption," "acceptance," "barrier," or "attitude"; and "physician," "doctor," or "practitioner."

Study Selection

We used Covidence (Veritas Health Innovation, Ltd), a web-based collaboration software platform, to support the screening of the identified studies, all of which were uploaded onto the platform. A 2-step screening procedure was conducted to evaluate the relevance of the studies. In the first step, the titles and abstracts of the studies were screened independently by 2 reviewers (SA and SH). Any disagreements between the reviewers at the first step were discussed until a consensus was reached, or a third reviewer assisted in resolving the disagreement. In the second step, the studies that met the inclusion criteria were subjected to full-text screening carried out independently by 2 reviewers (SA and ML). Any disagreements at this point were resolved through discussion, or a third reviewer (SH) aided in the resolution.

Inclusion and Exclusion Criteria

The inclusion criteria were studies that (1) focused on the acceptance and adoption of mHealth primarily by physicians, (2) addressed factors influencing acceptance and adoption, (3) were peer reviewed, and (4) were published in English. The exclusion criteria were studies that (1) examined other health care technologies, such as electronic health records and electronic medical records; (2) focused solely on participants other than physicians (ie, patients, nurses, and midwives); and (3) collected data before the COVID-19 pandemic.

Quality Assessment

The studies included in the final data synthesis were assessed for methodological quality using the Quality Assessment with Diverse Studies (QuADS) criteria [52]. The QuADS is a 13-criteria tool developed to evaluate the quality of different designs, including quantitative, qualitative, and mixed methods research. For each criterion, a study can derive a score ranging from 0 (no mention at all) to 3 (full details), with the maximum possible score being 39. A QuADS score was calculated for each study, after which the item scores were summed and divided by the maximum possible score to obtain an overall quality assessment for each study. Studies with scores lower than 50%, ranging from 50% to 70%, and greater than 70% were classified as being of low, moderate, and high methodological quality, respectively [53]. Two authors (SA and SH) independently assessed the studies, and disagreements were resolved through discussion (Multimedia Appendix 3 [28,54-61]).

Data Extraction and Synthesis

Given the heterogeneous factors identified in the included studies, conducting a meta-analysis synthesis was not possible. Instead, the results on factors influencing the acceptance and adoption of mHealth among physicians were narratively synthesized. The selected studies were subjected to data extraction, with their titles, abstracts, and full texts screened, after which the required information was obtained using a predefined data extraction form. This form included the following details: authors, year of publication, location, study design, sample size, targeted population, theoretical framework, and influencing factors. To ensure the validity of these details, 2 reviewers (SA and ML) independently recorded them. Differences or disagreements were resolved through discussion.

Results

Overview

The database search yielded an initial sample of 455 potential publications for analysis. Of these 455 publications, 117 (25.7%) duplicates were eliminated. The titles and abstracts of the remaining 338 (85.3%) publications were reviewed, resulting in 314 (92.9%) publications being discarded at this stage for failing to meet the inclusion criteria. This remaining 24 (7.1%) publications underwent full-text review, of which 15 (62%) were eliminated because they did not meet the inclusion criteria (Figure 1). The final sample consisted of 9 published papers, whose key features are highlighted in Table 1.

[a]QuADS: Quality Assessment with Diverse Studies.

[b]NR: not reported.

[c]UTAUT: Unified Theory of Acceptance and Use of Technology.

Characteristics of the Included Studies

As shown in Table 1, of the 9 included studies, 2 (22%) each were conducted in the United States [57,58] and Canada [28,54], whereas 1 (11%) each was conducted in India [55], Australia [59], China [61], Egypt [60], and Germany [56]. A total of 5 (56%) studies focused on physicians [55-57,60,61], and 2 (22%) studies included patients as well [28,59]. Moreover, 1 (11%) study included practicing nurses in addition to physicians and patients [54], whereas another (11%) involved physicians, nurses, diabetes educators, dietitians, and lactation counselors [58]. From the perspective of specialization, most studies (5/9, 56%) involved physicians with multiple specialties [55-57,60,61], whereas other studies (4/9, 44%) involved cardiologists and obstetricians [28,54,58,59]. More than half (5/9, 56%) of the studies did not mention the use of a theoretical framework. A total of 2 (22%) studies used the Unified Theory of Acceptance and Use of Technology [55,61], 1 (11%) adopted a stakeholder co-design framework [58], and another used the Chaudoir multilevel framework [28]. Most studies (5/9, 56%) followed a qualitative approach that entailed conducting semistructured interviews and focus group discussions [28,54,57-59]. Overall, 3 (33%) studies adopted a quantitative approach entailing questionnaire administration [55,60,61], and only 1 (11%) used a mixed methods approach, in which questionnaires were administered and semistructured interviews were conducted [56].

Quality Assessment

As mentioned earlier, the studies were assessed using the QuADS tool to evaluate quality and risk of bias [52]. The methodological quality of the examined studies ranged from 51% to 87%. Overall, 4 (44%) studies had high-quality methodologies (scores of 72% to 87%), 5 (56%) studies had moderate-quality methodologies (scores ranging from 51% to 69%), and no study had low scores.

Factors Affecting Physicians' Acceptance and Adoption of mHealth Technologies

Perceived Barriers

Overview

All but 1 (11%) [61] of the 9 reviewed papers reported on perceived barriers to the acceptance and adoption of mHealth technologies by physicians. These barriers are summarized in Table 2. The literature is characterized by inconsistency in the use of theoretical frameworks to categorize barriers, and no single framework captures all relevant factors without some form of extension. Therefore, in this review, perceived barriers were grouped based on common themes and mapped into the following 3 major thematic categories: technological, individual, and organizational barriers (Figure 2).

Table 2. Barriers to the acceptance and adoption of mobile health (mHealth) technologies among physicians.

Study	Technological barriers	Individual barriers	Organizational barriers
Aquino et al [54]	• Lack of availability of telemonitoring systems for patients at a high risk for preeclampsia • Clinical utility: additional value in care management	• Increased clinician workload	• Lack of health system policies: limited guidelines for the telemonitoring of patients at a high risk for preeclampsia • Lack of access to appropriate resources (eg, validated BP[a] cuffs) • Financial cost (eg, cost of home BP monitor for patients)
Artanian et al [28]	• Lack of preparedness to implement telemonitoring: uncertainty regarding the functionality, operationalization, and integration of technology	• Patient preference for face-to-face contact • Patient acceptance of long-term technology use	• Lack of resources for supporting telemonitoring intervention: in the absence of a dedicated coordinator, time consuming for clinicians • Financial and economic factors: costs associated with resources for sustaining telemonitoring (eg, additional staff) • Physician remuneration: lack of compensation for services
Bhatt and Chakraborty [55]	• NR[b]	• Limited confidence (technology anxiety) • Lack of skill set for using mHealth services	• NR
Dahlhausen et al [56]	• Technical concerns: training needs, technical integration issues, and lack of technical support • Clinical utility: uncertainties about benefits and insufficient medical evidence • Low availability of technology	• Increased workload • Lack of awareness • Perceived low competence due to insufficient knowledge about differentiating mHealth platforms • Medicolegal concerns about potential liabilities for mistreatment	• Data protection and security • Financial factor: lack of reimbursement for mHealth-related medical services • Limitations of infrastructures: workflow-related issues (eg, workflow adjustments and training needs)
Fleddermann et al [57]	• Lack of adequate access to technology (among patients) • Challenges in navigating the technology • Competition from other similar apps • Lack of relatable content	• Lack of time • Competing priorities • Perceived lack of patient motivation (resistance to change) • Lack of peer support during internet-based treatment • Lack of in-person interaction for guiding patient use of mHealth	• Uncertainty regarding privacy and confidentiality • Limited organizational support and engagement • Limitations of infrastructures and workflows • Pandemic impact: disruption to the provision of services and challenges in shifting to hybrid care delivery and retaining patients
Jackson et al [58]	• Lack of evidence-based mHealth resources • Reliability of internet resources • Concern over ease of use and operationalization • Lack of credibility	• Limited familiarity, awareness, and knowledge of mHealth availability and utility • Low patient engagement in the long term	• Formal organizational structure: reliance on provider knowledge networks
Li et al [59]	• Accuracy of devices and uncertainty about technology reliability • Challenges related to integration with other health record systems • Clinical utility or usefulness: lack of evidence on the effectiveness of mHealth monitoring in pregnancy	• Pregnant women needing training to measure BP correctly • Difficulty with the sustainability of and compliance with the collection of data on pregnant women, especially due to cultural and linguistic barriers • Extra workload due to the review of monitoring data • Skill set required to accurately analyze the data	• Limited communication among clinicians from multiple disciplines: multidisciplinary approach or communication needed to consider pregnancy symptoms, risk factors, test findings, and data about babies • Concerns about patient data privacy • Limitation of resources for supporting mHealth • Financial cost of technology (especially among patients from low socioeconomic backgrounds)

Study	Technological barriers	Individual barriers	Organizational barriers
Mansour [60]	• Lack of training on using mHealth technologies • Lack of appropriate and relevant content • Failure of mobile network connection • Potential for the misuse of collected information	• Lack of time for using technology • Lack of technical skills • Lack of interest in, knowledge about, or awareness of the benefits of mHealth technologies • Lack of language skills • Communication barriers: demographic characteristics of patients (age, education, and gender)	• Financial cost of technology implementation • Concerns about personal data privacy and security
Wu et al [61]	• NR	• NR	• NR

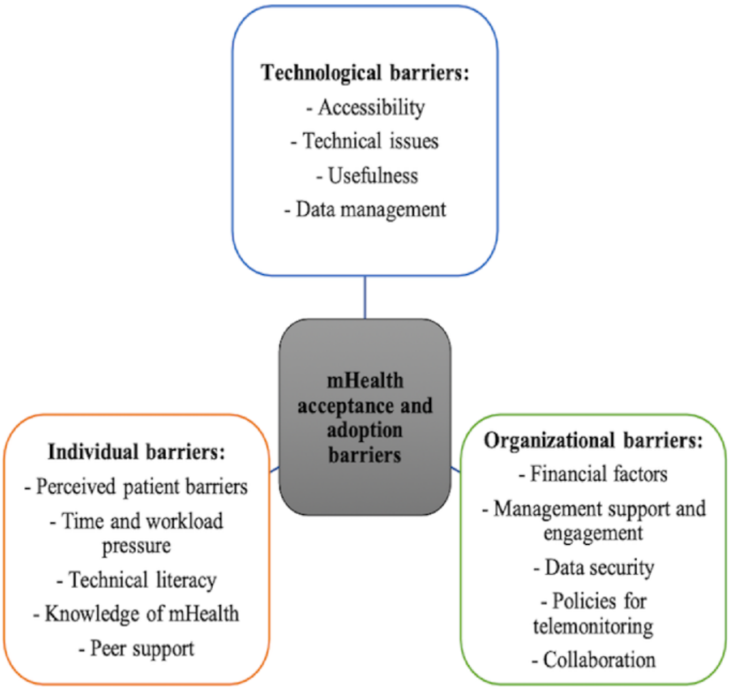
[b]NR: not reported.

Figure 2. Themes of barriers to mobile health (mHealth) acceptance and adoption by physicians.



Technological Barriers

The technological barriers to acceptance and adoption were further classified into the following 4 key subthemes identified from 8 (89%) of the 9 examined studies: accessibility, technical issues, usefulness, and data management. Technical issues were the most frequently reported barriers, including functionality (eg, concern over ease of use and operationalization) [28,57,58] and technical support (eg, technical issues in daily operations) [56]. Features related to usefulness, such as the clinical utility, added value, and evidence-based effectiveness of mHealth in care management (eg, lack of or insufficient evidence of benefit for patients), were other significant impediments to the use of mHealth technologies [54,56,58,59]. Concerns related to data management, including integration issues (eg, challenges with integration into clinical health records and poor integration or compatibility with existing practice software and tools) [28,56,59], were also raised. Lack of access [54,56,57], reliability [58,59], and limited connectivity (eg, concern about weak or failure of mobile network connectivity) [60] were cited by the rest of the studies.

Individual Barriers

Individual intrinsic (eg, confidence) and extrinsic (eg, technical competence) barriers emerged from the 8 (89%) of the 9 explored studies and were categorized into the following 5 key subthemes: perceived patient barriers, time and workload pressure, technical literacy, knowledge of mHealth, and peer support. Patient-related factors were the most prominently cited individual barriers, with patient acceptance or motivation (eg, perceived lack of patient motivation due to resistance to change) and sustained compliance with long-term technology use (eg, difficulty with the sustainability of and compliance with the collection of data on patients, especially due to cultural and linguistic barriers) being central concerns [28,57-60]. Time pressure and extra workload (eg, the additional work required for physicians to monitor patient data) [54,56,57,59,60] were reported as impediments to mHealth use by health care professionals. Other barriers mentioned were limited technical skills and confidence (eg, lack of language skills and technology anxiety) [55,57-60], the lack of knowledge about differentiating between mHealth platforms and awareness of mHealth benefits [56,58,60], and the lack of peer support [57].

Organizational Barriers

Organizational barriers were divided into 5 central subthemes: financial factors, management support and engagement, data security, technology policy, and collaboration. The most commonly reported barrier at the organizational level was financial factors, including the cost of mHealth apps and reimbursement issues. These issues involved costs associated with mHealth implementation (eg, the cost of devices) for both physicians [60] and patients [54,59], especially for those with low socioeconomic status [59], and the lack of or insufficient reimbursement for mHealth-related medical services (eg, responding to follow-up questions from patients) [56]. Other central barriers included the need for organizational engagement, lack of human resource support (eg, hiring a dedicated mHealth coordinator to reduce the workload of clinicians), lack of infrastructure [28,54,56-59], and lack of training [60]. The rest of the hindrances to mHealth uptake were the lack of policies related to data security (eg, uncertainty about the privacy and security of personal health data) [56,57,59,60], lack of evidence-based telemonitoring guidelines [54], and lack of communication among health care providers [59].

Perceived Facilitators

Overview

All the included studies discussed the perceived facilitators of mHealth acceptance and adoption by health care providers (Table 3). Similar to the barriers, the facilitators were categorized into technological, individual, and organizational facilitators (Figure 3).

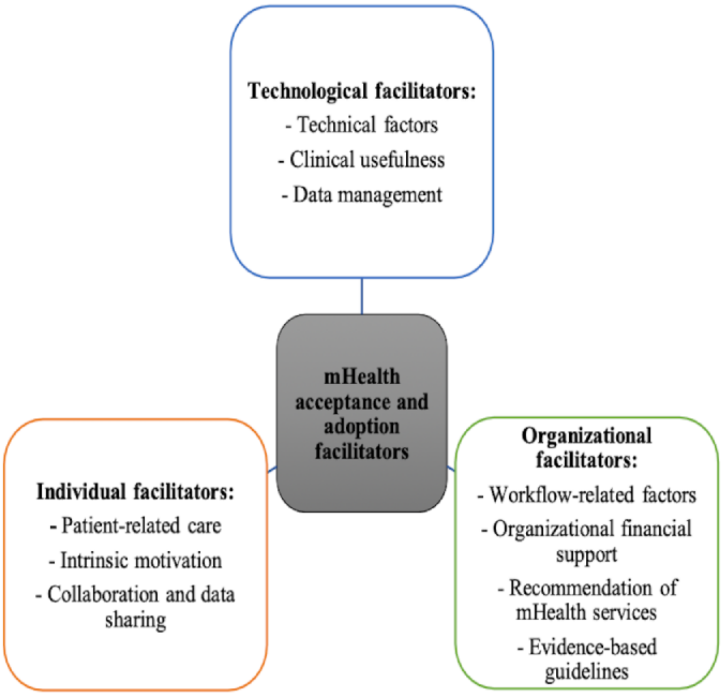
Table 3. Facilitators of the acceptance and adoption of mobile health (mHealth) technologies among physicians.

Study	Technological facilitators	Individual facilitators	Organizational facilitators
Aquino et al [54]	• Evidence-based action prompts generated from patient data based on guidelines for patients at a high risk for preeclampsia • Functionality: automatic data entry into telemonitoring systems	• Perceived benefits: self-management tool for patients • Effective display of patient data to facilitate trend detection and the visualization of patient health status	• Facilitation of decision-making for clinicians by integrating evidence-based protocols and standards for patients at a high risk for preeclampsia
Artanian et al [28]	• Functionality: ease of use of telemonitoring systems and their seamless integration into clinical practice and patient's daily routine • Clinical utility: access to daily data for providing accurate information about patient well-being	• Engagement of eligible patients in telemonitoring	• Availability of organizational resources: dedicated staff • Advantageous over standard care owing to overcoming limitations in clinic space and the optimization of clinical resources • Establishment of reimbursement models • Adequate information on how to implement telemonitoring
Bhatt and Chakraborty [55]	• Streamlined data handling for patient care management	• Self-confidence or self-efficacy of physicians in handling technology requirements • Performance expectancy • Personal innovativeness	• NR[a]
Dahlhausen et al [56]	• Clinical utility: data and more accessible medical evidence • Functionality: opportunities to navigate or test mHealth apps • Additional information about mHealth platforms • Compatibility of mHealth with existing infrastructures and workflows	• Patient motivation or patient request to use mHealth tools	• Recommendations by peers or medical associations • Provision of provider reimbursement for mHealth-related medical services • Extensive training with incentives (eg, certification for continuing medical education)
Fleddermann et al [57]	• Integration of technology use into routine workflows • Technological support for facilitating engagement	• Significant levels of clinician engagement for supporting patient use of mHealth platforms, especially for supporting the management of challenges encountered by patients unable to access typical in-person treatment during isolation • Collaboration with other staff using mHealth technologies	• Recommendation by physicians for potential mHealth benefits • Ongoing training
Jackson et al [58]	• Functionality: patient-centered participatory design of customized functions and educational features, including data-tracking, motivational feedback, and bidirectional communication capabilities • Clinical utility: potential to streamline clinical activities and resources • Clinical integration (into routine prenatal care)	• Provision for continued practical patient education to promote self-care management • Clinician engagement with patient education	• Integration of activities related to behavioral health changes into the patient's daily routine

Study	Technological facilitators	Individual facilitators	Organizational facilitators
Li et al [59]	• Functionality alert: function for the early detection of issues and timely interventions • User-friendly and comes with an automatic data capture feature • Access to data from multiple sources and integration of data with health records • Demonstration of impact and evidence-based evaluation studies before implementation • Compatibility with current practices of risk assessment and care for pregnant women with potential for multidisciplinary approach	• Integrated tailored educational content and feedback for pregnant women based on conditions and risks • Additional education and monitoring for pregnant women at high risk to improve data collection compliance and engagement	• Recommendations by clinicians with indications for potential benefits • Provision of ongoing education and training on using mHealth technologies
Mansour [60]	• Simplicity, user-friendliness, and convenience of mHealth apps (eg, detection of COVID-19 symptoms, pulse oximeter, and COVID-19 health-monitoring apps) • Access to COVID-19–related services and updated information • Clinical utility: support for frequent health monitoring and preventive health care	• Self-confidence in using technology • Increased patient knowledge, improved patient engagement and medication adherence, and faster access to providers • Communication and consultation with peers or colleagues and data sharing with other providers	• Recommendation of mHealth use by physician
Wu et al [61]	• Effort expectancy (ease and simplicity of mHealth)	• Behavioral intention of physicians to use mHealth was significantly affected by intrinsic motivations (altruism and cognitive trust) • High internet-based ratings affect sense of self-worth and contribute to positive participation in web-based health services	• Integration of mHealth into the national health system • Facilitating conditions, such as technical and human resource support, have a positive effect on mHealth adoption

[a]NR: not reported.

Figure 3. Themes of facilitators of mobile health (mHealth) acceptance and adoption by physicians.



Technological Facilitators

The 3 main subthemes related to technological facilitators were technical factors, clinical usefulness, and data management. Technical factors were subdivided into access, functionality, and technical support domains, which were discussed in most of the reviewed studies (8/9, 89%) [28,54,56-61]. Specifically, of the 9 reviewed studies, 7 (78%) highlighted functionality and ease of use as important features for engaging providers [28,54,56,58-61]. For instance, the clinicians participating in these studies applauded the ease with which patients with diabetes can use mHealth systems to track blood sugar levels in real time and the advantage of direct feeds to providers [54]. Technological support was a critical facilitator of mHealth use [57]. Of the 9 studies, 2 (22%) identified access to mHealth services, such as data collection from multiple sources [59] and updated information [60], as facilitators of successful uptake by health care providers.

Among the 9 included studies, 5 (56%) discussed clinical utility and usefulness as factors that favor adoption [28,56,58-60]. Providers are more likely to use mHealth services when they perceive mHealth technologies as potentially streamlining patient management care and clinical resources; some examples are technologies that allow the monitoring of prescription changes and updating of medical charts or clinical notes [58]. Usefulness pertained primarily to the availability of accurate real-time information about patient well-being [28], additional support for current prenatal care practices [59], and frequent health monitoring [60]. Evidence-based evaluation studies and accessible evidence of the usefulness of mHealth platforms also potentially facilitate the adoption of mHealth technologies by health care providers [56,59]. Finally, facilitators that support adoption and sustained use were data management, including the integration of mHealth technologies into routine clinical practice and health records [28,56-59] and streamlined data handling for patient management [55].

Individual Facilitators

Individual facilitators were divided into the following 3 central subthemes: patient-related care, intrinsic motivation, and collaboration and data sharing. Facilitators related to patients were central in most of the reviewed studies (7/9, 78%). These included the perceptions (of physicians) that mHealth technologies have the potential to support self-managed care and provide real-time feedback [54,58], allow faster access to health care providers [60], integrate mHealth into patient routines with tailored content [59], improve patient engagement [58-60], and provide support to patients who are unable to access typical in-person clinical treatment given the isolation prompted by the COVID-19 pandemic [57]. In particular, physicians are predisposed to use mHealth services when their integration increases the efficiency of daily patient flow, data management, patient diagnosis, and other clinical activities [55,58]. During the pandemic, especially when clinic access was largely restricted, the promotion of mHealth as a patient self-care management tool was one of the key factors in physicians' decision to adopt this innovation as a critical supportive tool in clinical care [54,57,58]. This decision is further supported by the effectiveness of mHealth in advancing multidisciplinary communication, as is the case, for example, with pregnancy care, for which access to data from multiple disciplines or sources is needed [59]. In addition, health care professionals with self-confidence, self-efficacy [55,60], altruism, and cognitive trust [61] in the reliability of technology are inclined to engage with and use mHealth platforms. These factors were rounded up through collaboration with peers or other users to share experiences and knowledge as well as data sharing with other providers [56,57,60].

Organizational Facilitators

Organizational facilitators were divided into the following 4 key subthemes: workflow-related factors, organizational financial support, recommendation of mHealth services, and evidence-based guidelines. Among the 9 included studies, 3 (33%) pinpointed workflow-related factors, such as the availability of support for streamlining clinical resources and activities and improvement of infrastructure for seamless workflow, as key facilitators [28,58,61]. In particular, organizational human resource support, such as the hiring of a dedicated coordinator to reduce physician workload [28] and address training needs [56,57,59,61], was highly advocated as a facilitator of mHealth uptake by physicians. Moreover, widespread adoption was found to be motivated by organizational financial support deployed via the establishment of reimbursement models [28] and the provision of financial incentives or reimbursement for mHealth services [56]. Effective implementation was also regarded as facilitated by the recommendation of mHealth services by trusted leaders, such as medical associations [56] or other physicians [57,59]. Other important facilitators of successful uptake included the integration of evidence-based standards and guidelines for telemonitoring into practice to facilitate clinical decision-making [54] and the integration of mHealth into the national health system [61]. None of the included studies reported specific facilitators regarding legal issues related to the security and privacy of patient data.

Discussion

Summary of the Main Findings

The COVID-19 pandemic has clearly been a catalyst of the wider acceptance and adoption of mHealth interventions worldwide, with studies frequently reporting benefits such as minimized risk of transmission, increased patient involvement, and reduced burden on hospitals and health care expenditure [9,62,63]. Nevertheless, the move toward mHealth apps as a model of care delivery during the pandemic has revealed several shortcomings in stimulating physicians' uptake of such technologies. This review explored the factors influencing mHealth acceptance and adoption by physicians as the COVID-19 pandemic evolves. Factors related to the technological, individual, and organizational domains were identified.

Critical Barriers to mHealth Acceptance and Adoption

Evidence suggests that a number of barriers have persisted since the prepandemic period [42,48,49]. This finding corresponds to the work of Zakerabasali et al [42], who reviewed evidence from 18 articles and identified 18 technical, individual, and health care system barriers. Similar to the findings in this review, the authors identified the lack of technical infrastructure, concerns about privacy issues, and the lack of workflow compatibility as barriers to mHealth adoption. Other principal barriers were limited technical literacy, preference for face-to-face interaction, financial factors, and health system policies [42]. Another prepandemic systematic review conducted in 2020 identified 55 barriers, including the lack of clinical training, the lack of technical support, the lack of compatibility with the existing workflow, and patient-related factors [48]. Consistent with the aforementioned studies, a systematic review conducted in 2016 identified 81 barriers, with emphasis placed on cost and time issues as well as difficulties in patient-professional interaction [49].

Although some of the perceived barriers that we found were similar to those identified in explorations carried out before the pandemic, we were able to identify other factors that are specific to acceptance and adoption during the pandemic. Examples include challenges accompanying the shift to hybrid care delivery to retain patients affected by the implementation of mHealth tools by physicians. The transition to internet-based treatment during the COVID-19 pandemic has disrupted services by dramatically reducing clinical caseloads, an issue that highlights patients' preference for face-to-face appointments. Clinicians also lamented the considerable difficulty involved in assisting and guiding patients in downloading and signing up to an mHealth app [57]. As can be seen, the pandemic has highlighted the need to improve organizational readiness by making workflow adjustments to allow time for the introduction of mHealth tools to patients and the effective implementation of such innovations in practice. Another novel finding of this systematic review is that physicians perceive low competence in dealing with mHealth technologies as a result of insufficient knowledge and information regarding differentiating between mHealth platforms [56]. Collectively, these findings point to the importance of organizational support during *business as usual* periods to provide physicians with adequate education and training on the use of emerging mHealth tools.

Systematic reviews conducted before the pandemic differently emphasized barriers to mHealth adoption. Whereas cost issues and patient-professional interaction were reported as the most common barriers in an early systematic review [49], technical difficulties, particularly the lack of technical support, the lack of compatibility with the existing workflow, and patient-related challenges, were underscored as principal impediments in a more recent analysis [48]. In addition to technical and cost factors, privacy concerns were one of the most cited barriers in the examined studies [42]. To these lists, our study added limited financial support and technical and privacy issues as common barriers to uptake. However, in contrast to prepandemic reviews, this review identified patient-related factors, such as patient preference, engagement, and compliance, as the most frequently reported determinants of uptake during the pandemic. On these bases, we can conclude that the pandemic has shifted the focus from a technological perspective to a more patient-centered perspective in recognizing the main challenges to mHealth adoption and integration into practice.

Leading Facilitators of mHealth Acceptance and Adoption

Some of the common facilitators of mHealth uptake evaluated in this study were consistent with those reported before the pandemic. These include perceived usefulness and ease of use, perceived patient-related benefits (eg, improved patient care, interprofessional collaborations, and data sharing), ongoing technical support and training, and financial support for technology implementation and integration with practice systems [48,49]. However, this review is distinct from prior research in terms of facilitators that are specific to the context of the pandemic.

The most prominent facilitators before the pandemic were those related to organizational workflow, such as infrastructure, training, resource allocation, perceived efficiency, improved reimbursement, and compatibility with workflow [48,49]. Against the backdrop of the pandemic, the central facilitators were the individual factors associated with the intrinsic motivation of physicians and patient-related matters. For instance, the behavioral intention of physicians to use mHealth apps was significantly influenced by self-efficacy [55], and intrinsic motivation was potentially strengthened by altruism and cognitive trust (perceived reliability) linked to competence in using mHealth platforms [61]. Recent studies confirmed that cognitive trust strongly influences the use of digital technologies, suggesting that it is essential to cultivate physicians' trust in mHealth adoption through their sense of altruism [64] while their self-efficacy in the sustained intention to use mHealth platforms is elevated [65].

In our review, individual factors related to patient acceptance for greater engagement in and long-term commitment to using mHealth services were demonstrated to be critical to sustained uptake by physicians. High levels of physician engagement in promoting the benefits of mHealth apps for treatment [57] and clinician involvement with patient education [58] were also regarded as necessary for supporting patient access and the use of mHealth tools. This was especially important during periods of enforced isolation, as mHealth use fostered connections and supported the management of patients unable to access face-to-face treatment [57].

Furthermore, although addressing legal issues was one of the organizational factors that facilitated mHealth adoption before the pandemic [48], none of the reviewed studies discussed security and data protection. This deficiency can be attributed to the changes to regulations made by some countries during the global outbreak to provide further security guidance and support the more extensive use of telehealth [66]. In this situation, the attention of physicians could have been diverted from legal issues to concerns about their patients. Altogether, the available evidence highlights the importance of physicians' intrinsic self-motivation in supporting a patient-centered approach. The focus should be directed to patient benefits as critical facilitators of successful acceptance and adoption in the context of the COVID-19 pandemic.

It is worth noting that there are varying factors influencing the acceptance and adoption of mHealth across limited-resource and high-resource countries. For instance, in limited-resource countries, Mansour [60] and Bhatt and Chakraborty [55] highlighted barriers, including the lack of language, technical skills, and training. By contrast, some studies in high-resource countries emphasized that mHealth apps were easy to use and integrated well into clinicians' routines [28,58]. This variation can be attributed to the fact that health care systems in high-resource countries commonly have well-established training programs that integrate the latest medical advancements for health care professionals. By contrast, limited-resource countries may face challenges in providing sufficient training and education programs for health care professionals because of limited resources and funding [67-70]. Consequently, health care professionals in limited-resource countries may have limited opportunities for training and may not have the same skills and knowledge as their peers in high-resource countries.

Although our findings indicate that health care professionals have a generally positive attitude toward mHealth, there are variations in attitudes across various medical specialties [56,60]. For example, Dahlhausen et al [56] highlighted that neurologists have a mostly favorable perspective toward mHealth apps, whereas orthopedists and trauma surgeons hold somewhat less positive attitudes toward these apps. In line with our findings, a survey conducted by Zaslavsky et al [39] revealed differences in attitudes toward implementing mHealth apps across different medical specializations. Understanding these differences is crucial for customizing strategies to promote the adoption of mHealth among various medical specialties.

Limitations and Recommendations for Future Research

Although this review contributes to the understanding of the factors influencing the acceptance and adoption of mHealth technologies among physicians, some limitations must be acknowledged. Most studies (6/9, 67%) were conducted in developed countries (eg, the United States, Canada, and Germany) [28,54,56,57], which means that our understanding of the factors influencing the acceptance and adoption of mHealth among physicians in developing countries is limited. Moreover, more than half (5/9, 56%) of the studies [28,54,57-59] used qualitative methods, such as semistructured interviews and focus group discussions, to gather data. Therefore, generalizing the results of this review may be challenging. In addition, this review might not have incorporated relevant papers that were not listed in the databases that were searched and that were published in a language other than English, which would have helped identify more factors that influence the acceptance and adoption of mHealth among physicians.

We provide several recommendations for future research. Identifying the factors that affect the acceptance and adoption of technologies such as mHealth is an ongoing process [57]. Hence, there is a need for more extensive research on these behaviors of physicians, especially in limited-resource countries. Research in limited-resource countries is necessary to understand whether there are different opportunities and constraints. In addition, robust methodologies, such as mixed methods approaches, are required to uncover the factors influencing acceptance and adoption. Mixed methods research can overcome the disadvantages associated with quantitative or qualitative approaches, thereby enriching the findings. For example, some researchers claim that quantitative exploration insufficiently advances the understanding of contexts or areas in which people live, as the voices of participants are not directly heard [71]. Qualitative studies might be considered deficient because of a researcher's subjective interpretations, the bias that results from these, and the difficulty in generalizing findings [71]. Finally, the identified factors could help policy makers make decisions aimed at implementing mHealth successfully. These factors may facilitate physicians' acceptance and adoption of mHealth technologies.

Conclusions

The pandemic has highlighted and expanded the avenues in which mHealth can aid clinical decision-making and improve the quality of care. This review summarized the evidence on the factors influencing mHealth acceptance and adoption by physicians during the COVID-19 pandemic. The main findings of this review highlighted the importance of addressing organizational readiness to support physicians with adequate resources, shifting the focus from technological to patient-centered factors, and the seamless integration of mHealth into routine practice during and beyond the pandemic.

Authors' Contributions

SA, the first author, wrote the manuscript, and ML and SH provided insightful feedback on the manuscript. All the authors were involved in screening the studies, extracting data, and synthesizing the findings. SA was funded by a Doctor of Philosophy (PhD) scholarship from the Saudi Arabian Cultural Mission in Australia. All the authors approved the final manuscript.

Abstract

Background: The rapid growth of digital health apps has necessitated new regulatory approaches to ensure compliance with safety and effectiveness standards. Nonadherence and heterogeneous user engagement with digital health apps can lead to trial estimates that overestimate or underestimate an app's effectiveness. However, there are no current standards for how researchers should measure adherence or address the risk of bias imposed by nonadherence through efficacy analyses.

Objective: This systematic review aims to address 2 critical questions regarding clinical trials of software as a medical device (SaMD) apps: How well do researchers report adherence and engagement metrics for studies of effectiveness and efficacy? and What efficacy analyses do researchers use to account for nonadherence and how appropriate are their methods?

Methods: We searched the Food and Drug Administration's registration database for registrations of repeated-use, patient-facing SaMD therapeutics. For each such registration, we searched ClinicalTrials.gov, company websites, and MEDLINE for the corresponding clinical trial and study articles through March 2022. Adherence and engagement data were summarized for each of the 24 identified articles, corresponding to 10 SaMD therapeutics. Each article was analyzed with a framework developed using the Cochrane risk-of-bias questions to estimate the potential effects of imperfect adherence on SaMD effectiveness. This review, funded by the Richard King Mellon Foundation, is registered on the Open Science Framework.

Results: We found that although most articles (23/24, 96%) reported collecting information about SaMD therapeutic engagement, of the 20 articles for apps with prescribed use, only 9 (45%) reported adherence information across all aspects of prescribed use: 15 (75%) reported metrics for the *initiation* of therapeutic use, 16 (80%) reported metrics reporting adherence between the initiation and discontinuation of the therapeutic (*implementation*), and 4 (20%) reported the discontinuation of the therapeutic (*persistence*). The articles varied in the reported metrics. For trials that reported adherence or engagement, there were 4 definitions of initiation, 8 definitions of implementation, and 4 definitions of persistence. All articles studying a therapeutic with a prescribed use reported effectiveness estimates that might have been affected by nonadherence; only a few (2/20, 10%) used methods appropriate to evaluate efficacy.

Conclusions: This review identifies 5 areas for improving future SaMD trials and studies: use consistent metrics for reporting adherence, use reliable adherence metrics, preregister analyses for observational studies, use less biased efficacy analysis methods, and fully report statistical methods and assumptions.

Introduction

Background

There are over 350,000 health-related apps on the market, each claiming to improve certain aspects of physical or mental health [1]. A small fraction of these apps is subject to Food and Drug Administration (FDA) regulations. Regulators, health care providers, and patients need to understand how these apps compare with alternatives (eg, pharmaceuticals) that undergo rigorous evaluation. As with pharmaceuticals, the risks and benefits of apps depend on how well people use them. Incorrect assumptions about adherence in clinical trials can lead to incorrect regulatory and treatment decisions. With pharmaceuticals, these risks are reduced by the gold standard practice of intent-to-treat analysis, which estimates effectiveness based on actual, typically imperfect, use. This standard is not the norm in trials of digital health apps, leading to an unknown risk of bias (ROB) in the estimated effects. Here, we provide a systematic review of current practices in FDA-regulated apps, leading to recommendations for reducing the risks of bias revealed by the review.

The FDA focuses on the regulation of software as a medical device (SaMD) therapeutics intended to prevent, diagnose, or treat diseases [2]. If a predicate therapeutic exists, applicants may use the FDA's 510k pathway to prove that their therapeutic is substantially equivalent to the predicate therapeutic (ie, with the same intended use, technological characteristics, and benefits and risks of an approved or cleared therapeutic [3]). In the absence of a predicate therapeutic, SaMD therapeutics follow the FDA's De Novo pathway, which requires evidence that the therapeutic is safe and effective. The FDA established the Digital Health Center of Excellence to create innovative ways to regulate SaMDs [4], which, for example, are easier to update than pharmaceuticals. One such innovation, reviewed under the FDA's precertification pilot program, conducted *excellence appraisals* of software companies. This program tested a streamlined approach to approving and updating therapeutics for companies that have demonstrated quality practices [5,6]. Other innovations have been applied across all FDA departments, such as allowing clearance, approval, and marketing claims based on "real-world evidence" [7]. There are also proposals, created outside FDA, specifying standard processes (eg, performance reporting standards) for clinical trials of low-risk digital health apps not subject to regulatory oversight [8]. Given the novelty of SaMDs and the associated regulatory environment, the FDA has the need and opportunity to create guidance and requirements for addressing adherence in future trials. We hope to inform that process.

A systematic review by Milne-Ives et al [9] found that approximately three-fourths of digital health app trials collected and reported basic adherence information, such as the number of dropouts. These trials reported a variety of app engagement metrics, with only one-third reporting >60% use. Prior systematic reviews of digital health apps reported similar simple summary statistics (eg, average adherence and dropout rates), with few details on how adherence data were collected and analyzed [9-14]. This systematic review extends that work by examining, in detail, how adherence and engagement information is collected, analyzed, and reported. It considers how those practices affect the estimates of *effectiveness* and *efficacy*, defined as the app's effect in the entire sample, regardless of adherence, and the app's effect in the adherent subgroup, reflecting the moderating effect of adherence. This review focuses on digital health apps with a reasonably well-defined evidentiary base, namely, those that followed the FDA's De Novo or 510k pathways.

Criteria for Evaluation

ROB Framework

Imperfect adherence can cause underestimation or overestimation of the safety and efficacy of a SaMD. For example, a therapeutic's efficacy and side effects may be underestimated, if trial participants use it sparingly, but consistent use is assumed. Conversely, efficacy may be overestimated if adherence reflects neglected confounding variables (eg, income and lifestyle factors). As a hypothetical example, researchers evaluating an app to reduce the risk of preeclampsia may observe a reduced rate not because of participant adherence but because participants adhering to the app were recipients of commercial health insurance. To evaluate the ROB owing to imperfect adherence, we used the adherence components of the Cochrane ROB Assessment (version 2.0) [15], a well-documented tool for systematic reviews and meta-analyses. To determine the ROB from nonadherence, the ROB tool first asks, "Was there nonadherence to the assigned intervention regimen that could have affected participants' outcomes?" If outcomes could have been affected, the ROB tool then asks, "Was an appropriate analysis used to estimate the effect of adhering to the intervention?" We developed criteria to answer each question based on research regarding adherence metrics and common methods of analyzing efficacy.

Adherence and Engagement Metrics

Adherence refers to how well participants use an intervention, as defined by a protocol or recommendation for use. Engagement refers to how participants use an intervention, irrespective of the intended use of the app. Engagement data can be used to measure adherence for a digital health app. As both adherence and engagement can affect the outcomes of a trial, we have reported both. When collecting and reporting adherence and engagement statistics, researchers must consider 3 facets of use [16]: *initiation*, when a person starts using an intervention; *implementation*, how a person uses the intervention between initiation and discontinuation; and *persistence*, how long a person uses the intervention before discontinuation.

Which metrics are collected and how they are collected can also affect the ability to conduct efficacy analyses and the analyses' potential bias. For instance, adherence with recommendations from the therapeutic (eg, using backup contraception when an app detects fertility) could also affect effectiveness estimates. Without collecting this information, researchers would be unable to analyze efficacy in terms of adherence to behavioral recommendations. Therefore, we report adherence and engagement with both the therapeutic and its recommendations. The mechanism of collecting adherence and engagement information can act as a potential confounder if it prompts additional engagement with the therapeutic compared with real-world engagement. Reminders used to increase adherence (eg, email messages) can also be confounders if they are not part of the therapeutic design. To account for these potential confounders, we recorded whether reminders and mechanisms for measuring adherence and engagement were internal to the app or external (ie, an additional component not found in the marketed app). We found few prior studies or analysis plans that determined the level of adherence or engagement required to have a clinical effect. This level of adherence can vary depending on the therapeutic being used. Without a study or trial analysis plan defining low adherence or evidence of the level of adherence needed to produce a clinical effect, we cannot conclusively assess whether adherence is low or not because of insufficient information.

Analysis of Efficacy

In evaluating efficacy analyses, we ask how well a trial or study fulfills the assumptions required by its efficacy analysis method. There are 3 commonly used estimates of efficacy: the *average treatment effect* (ATE), *per-protocol effect*, and *dose-response effect*. Table 1 describes each estimate, the common analysis methods for calculating estimates, and the assumptions required for unbiased estimates. Multimedia Appendix 1 [17-22] includes definitions of the following assumptions: consistency, positivity, ignorability, exclusion restriction, strong monotonicity, and the stable unit treatment value assumption (SUTVA). In addition to the requirements in Table 1, researchers should preregister their analyses of effectiveness and efficacy to reduce the risk of capitalization on chance [23].

Table 1. Methods of analysis commonly used to account for imperfect adherence and the assumptions required for unbiased estimates.

Estimate of efficacy and common analysis methods	Assumptions for unbiased estimates
ATE[a]: estimates the average effect of treatment	

• ATE analysis
  • Evaluates groups according to their treatment group regardless of adherence.
  • Estimates efficacy if adherence is modified with regular reminders to participants.
	• SUTVA[b]
	• Consistency[c]
	• Positivity
	• Ignorability

• ITT[d] analysis
  • Evaluates groups according to their assigned treatment regardless of adherence.
  • Estimates efficacy if adherence is modified with regular reminders to participants.
	• SUTVA
	• Consistency[c]
	• Randomization (fulfills positivity, exclusion restriction, and ignorability)

Per-protocol effect: estimates the average effect of adhering to the treatment assignment	

• Complier average causal effect or local average treatment effect
  • Evaluates the per-protocol effect for the adherent subpopulation.
  • Evaluates groups based on an adherence threshold. Nonadherent participants in the treatment group are labeled as never-takers. It is assumed that the effect of the never-takers is equal in both groups.
	• SUTVA
	• Consistency[c,e]
	• Randomization (fulfills positivity, ignorability, exclusion restriction, and strong monotonicity)

• Generalized estimation • Evaluates groups based on an adherence threshold. Groups are evaluated based on adherence over time such as never-takers, early-takers, late-takers, and always-takers.	• SUTVA • Consistency[c,e] • Positivity • Ignorability (sequential exchangeability)
• As-treated analysis • Evaluates groups based on an adherence threshold. Nonadherent participants in the treatment group are considered part of the control group.	• SUTVA • Consistency[c,e] • Positivity • Ignorability (conditional independence of adherence and outcomes)
• Per-protocol analysis • Evaluates groups based on an adherence threshold. Excludes nonadherent participants in the treatment group.	• SUTVA • Consistency[c,e] • Positivity • Ignorability (conditional independence of adherence and outcomes)
Dose-response effect: estimates the effect of adherence on the treatment	
• Dose-response analysis (IV[f] method) • Evaluates adherence as a mediator for all participants using an IV to fulfill the mechanism ignorability assumption.	• SUTVA • Consistency[c,e] • Randomization (fulfills positivity, ignorability, exclusion restriction, and strong monotonicity)
• Dose-response analysis (confounder adjustment) • Evaluates adherence as a mediator for all participants using confounder adjustment to fulfill the mechanism ignorability assumption.	• SUTVA • Consistency[c,e] • Positivity • Ignorability (conditional independence of adherence and outcomes)

[a]ATE: average treatment effect.

[b]SUTVA: stable unit treatment value assumption.

[c]Consistent definition of treatment.

[d]ITT: intent-to-treat.

[e]Consistent definition of adherence.

[f]IV instrumental variable.

We applied our framework, which was developed based on the Cochrane ROB, to evaluate how well existing trials and studies meet our standards, with the goal of improving future trials. We examined the completeness of their reporting and the appropriateness of the procedures reported. By focusing on SaMD therapeutics, the most rigorously evaluated digital health apps, we sought to identify improvements for future studies on all digital health apps.

Methods

Screening

A 2-stage search strategy was used to identify all product codes and registrations for patient-facing SaMDs, with intended repeated use for at least 2 weeks, that the FDA had approved or cleared before March 2022. In the first stage, 2 reviewers independently searched the FDA product code database for product codes related to SaMDs. We searched the device name, definition, physical state, and technical method attributes for the keywords "software," "mobile," "digital," and "application." In the second stage, we searched the FDA registration database for these product codes. We examined each registration's supporting documents, De Novo decision summaries, and 510k decision summaries to determine whether the product met our inclusion criteria.

We then searched ClinicalTrials.gov, product websites, and MEDLINE for peer-reviewed publications corresponding to each included product. For the ClinicalTrials.gov search, we used the product and company names as keywords, individually and in combination, to identify clinical trials. We included all publications that evaluated the effectiveness or efficacy of the included products, including both randomized controlled trials (RCTs) and observational studies. We reviewed all publications listed at the end of the ClinicalTrials.gov registration for potential inclusion. For the MEDLINE search, product and company names were used as keywords. For the product website search, publications listed as clinical evidence on company websites were included. Two reviewers independently screened each publication, examining the title and abstract as well as the full text, where appropriate. Reviewer disagreements were reconciled by discussion. We screened and included only those articles published before March 2022. We did not include pilot or feasibility studies.

For example, the first stage of the search identified the PYT product code when the "device name" field was searched for "software." All registrations coded as PYT (ie, "Device, Fertility Diagnostic, Contraceptive, Software Application") were then evaluated for inclusion based on corresponding supporting documents, 510k decision summaries, and De Novo decision summaries. One included 510k for this product code was for the Clue app, K193330. In the second stage, we searched ClinicalTrials.gov using the keywords "Clue," "Clue Birth Control," "Biowink," "Dynamic Optimal Timing," and "Cycle Technologies." We searched MEDLINE using the keywords "Dynamic Optimal Timing," "Biowink," and "NCT02833922." Finally, we searched the product website [24] for clinical trial documents.

Data Extraction

For each publication, one reviewer extracted data and the other reviewer checked the accuracy of the data. Differences were reconciled by discussion between the reviewers. The Cochrane Data Collection Form for Intervention Reviews [25] was completed with clinical trial characteristics, including the design, number of participants, sampling method, interventions, and outcomes.

The remainder of the data extraction form was created using the criteria for reporting adherence metrics described in the *Adherence and Engagement Metrics* section and the assumptions for the associated efficacy analysis method described in the *Analysis of Efficacy* section. Given the diversity of the apps and outcomes, we reported each metric that a clinical trial or study reported separately, without averaging across different metrics. When evaluating efficacy analyses, we categorized trials or studies as fulfilling the positivity condition if they had a control group. We categorized trials as fulfilling the consistency condition if they had definitions of treatment and adherence that avoided hidden variations of treatment that might affect participants differently.

Some assumptions, referenced in Table 1 and described in Multimedia Appendix 1, could not be fully evaluated. One such assumption is SUTVA, which requires no interaction between units of observation that could affect a result. Although it is impossible to prove that this assumption holds, some trial designs afford greater confidence than others. For example, if a trial has no central clinical team and treatment is administered only through an app, it would be difficult for participants to interact with the clinical research staff. By contrast, if clinical research staff interact with both the control and treatment groups, they might treat participants in the 2 groups in ways that affect their independence. We categorized a trial as fulfilling SUTVA if it had no central clinical team or if it had mechanisms for reducing the risk of interaction between participants or between participants and staff.

Similarly, it is impossible to fully evaluate the assumption that there are no unmeasured confounders. Instead, we asked whether the researchers demonstrated awareness of confounders by listing potential confounders explicitly and reporting their rationale for selecting them.

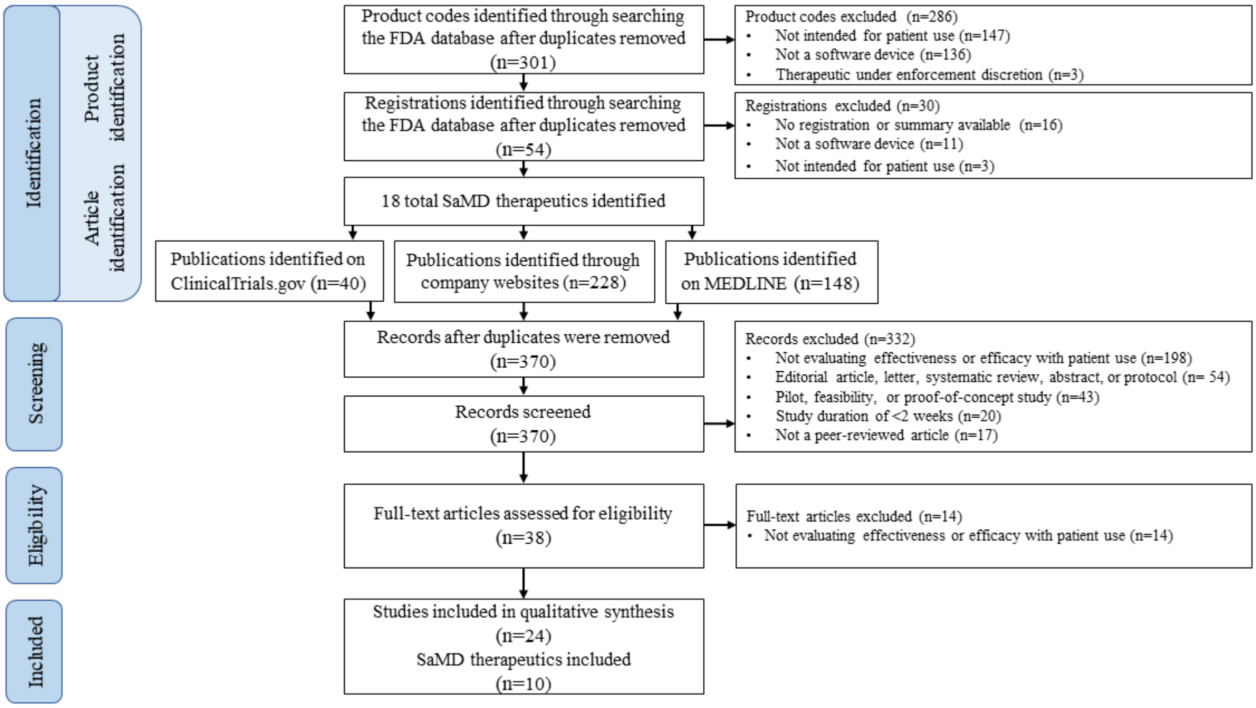
The results in the *Adherence Metrics* section and *Analysis of Efficacy* section below summarize practices for the included trials using means or counts as appropriate. Given the heterogeneity of the therapeutics and outcomes, we did not estimate the overall impact of all biases. The protocols and preregistrations referenced in the included articles were used as supporting documents. The protocol for this review was registered on the Open Science Framework [26], which includes the data extraction forms and extracted data. Article screening data, extracted data, and summarized extracted data are also available in Multimedia Appendices 2-4 [27-50].

Results

Included Trials

Figure 1 shows the completed PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram. The 2-stage search for SaMD therapeutics identified 5% (15/301) of product codes and 44% (24/54) of registrations as potential SaMDs. These registrations included 18 unique SaMD therapeutics. Our search of ClinicalTrials.gov, company websites, and MEDLINE identified 40, 228, and 148 articles, respectively. After screening and removal of duplicate articles, 24 articles, involving 10 products, met all the inclusion criteria. A total of 8 products were excluded because clinical trials or observational studies evaluating efficacy for at least 2 weeks were not found in our literature search.

Figure 1. The 2-stage strategy used to identify trials and studies of software as a medical device (SaMD) therapeutics. The Food and Drug Administration (FDA) databases were first searched for SaMD therapeutics that would be used by patients for at least 2 weeks. In the second stage, ClinicalTrials.gov, MEDLINE, and company websites were then searched for articles evaluating effectiveness or efficacy for these products when used by patients for at least 2 weeks.



As seen in Tables 2 and 3, the 24 included articles (22 total trials) studied a variety of SaMD therapeutics, including those intended to treat irritable bowel syndrome, insomnia, substance use disorder, and attention-deficit/hyperactivity disorder. All the SaMD therapeutics were mobile apps and will be referred to as apps for the remainder of the article. Table 3 shows an even mix of apps intended for continual use or module-based apps. Most trials (18/22, 82%) specified a recommended dose for their app, such as the frequency of use or the number of modules to complete. Overall, 11 (50%) trials or studies studied apps used a module-based design with a recommended dose for the app [27,34-39,45-50], whereas 7 (32%) trials or studies studied apps used a continual use design with a recommended dose for the app [31,32,40-44]. Apps without a recommended dose only used the continual use design (4/22, 18%) [28-30,33].

Table 2. Included articles and associated products.

[a]ADHD: attention-deficit/hyperactivity disorder.

[b]CBT: cognitive behavioral therapy.

[c]IBS: irritable bowel syndrome.

[d]Everitt et al [37] and Everitt et al [38] were based on the same trial.

[e]SUD: substance use disorder.

[f]OUD: opioid use disorder.

[g]Christensen et al [46] and Maricich et al [49] were based on the same trial.

Table 3. Summary of devices and trials included in the study (n=22).

Characteristics	Values
Therapeutic indication for use, n (%)	
Contraceptive	7 (32)
Videogame treatment for ADHD[a]	3 (14)
Irregular arrhythmia notification	1 (5)
Diabetes management	4 (18)
Cognitive behavioral therapy	7 (32)
IBS[b]	2 (9)
Insomnia	1 (5)
Substance use disorder	4 (18)
Type of therapeutic, n (%)	
Recommended use with module design	11 (50)
Recommended use with continual use design	7 (32)
No recommended use with module design	0 (0)
No recommended use with continual use design	4 (18)
Trial design	
RCT[c] [28,29,34,37-39,45,46,50], n (%)	8 (36)
Participants (in comparison groups), mean (SD)	290 (120)
Trial length (d), mean (SD)	300 (270)
Observational [27,30-33,35,36,40-44,47-49], n (%)	14 (64)
Participants (in comparison groups), mean (SD)	5100 (7000)
Trial length (d), mean (SD)	230 (140)

[a]ADHD: attention-deficit/hyperactivity disorder.

[b]IBS: irritable bowel syndrome.

[c]RCT: randomized controlled trial.

Most trials (14/22, 64%) were observational, with the remainder being RCTs (8/22, 36%). On average, the RCTs recruited 290 (SD 120) participants and lasted 300 (SD 270) days. On average, the observational trials recruited 5100 (SD 7000) participants and lasted 230 (SD 140) days.

Adherence Metrics

Table 4 summarizes how the articles measured and reported each of the 3 aspects of adherence. As each article could report different adherence metrics for the same trial or study and report separate analyses, duplicate trials and studies were counted twice. Of the 24 articles, 23 (96%) collected information about app engagement. All apps that provided recommendations (8/8, 100%) also collected information about adherence to their recommendations [27,31,32,40-44]. Of the 23 articles that collected adherence information, 2 (9%) reported that adherence information was collected externally from the marketed app [31,32]. Three articles reported that researchers attempted to increase adherence by notifying inactive patients [34-36]. One reported the use of in-app notifications and 2 reported using email notifications.

Table 4. Summary of adherence metrics (N=24)[a].

Adherence metrics	Values, n (%)	Each reported metric (%), mean (SD)
Trial collected information about app engagement	23 (96)	N/A[b]
Trial collected information about adherence to recommendations (n=8 articles for apps that gave recommendations)	8 (100)	N/A
Adherence information collected outside of the marketed app (n=23 articles for apps that collected adherence information)	2 (9)	N/A
Adherence notification sent outside of app (n=3 articles reported sending adherence notifications)	2 (67)	N/A
Engagement metrics (metric is not measuring prescribed use)		
Initiation	2 (8)	N/A
Initial app use, core completion, or activity use [30,33]	2 (8)	52 (35)
Implementation	2 (8)	N/A
Completed sessions, modules, or activities [29,30]	2 (8)	20 (22)
Log-in days [29]	1 (4)	23[c]
Persistence	7 (29)	N/A
Percentage of participants continuing use at 1 y [31,32,40,41,43,44]	6 (25)	52 (12)
Number of days participants used the app [30]	1 (4)	153[c]
Adherence metrics (metric is measuring prescribed use)		
Initiation	15 (63)	N/A
Provided at least 20 d of data [40-44]	5 (21)	100 (0)
Initial app use, core completion, or activity use [35,36,38,47-50]	7 (29)	98 (4)
Entered at least 2 period start dates [31,32]	2 (8)	100 (0)
Initiation of video in response to app alert [27]	1 (4)	44[c]
Implementation	16 (67)	N/A
Completed sessions, modules, or activities [34-36,45,49]	5 (21)	88 (16)
Completed at least 4 sessions and 1 call [37-39]	3 (13)	64 (5)
Completed half of the modules [47,48]	2 (8)	76 (13)
Completed ≥8 core modules [47,48]	2 (8)	87 (9)
Percentage of logged intercourse on red days [43,44]	2 (8)	23 (0)
Percentage of total days intercourse logged on red days (ie, days where the user did not follow app recommendations) [42]	1 (4)	2[c]
Percentage of perfect use cycles (ie, menstruation cycles where the user followed all trial recommendations) [32,41]	2 (8)	17 (10)
Log-in days [40,43,44]	3 (13)	47 (19)
Persistence	4 (17)	N/A
Participants using the app at week 12 [47,48]	2 (8)	4 (17)
Completed all core modules [38,47,48,50]	2 (8)	49 (19)
Study reported all prescribed facets of adherence (n=20 studies that prescribed a recommended use of the app)	9 (45)	N/A

[a]The left-hand columns report what percentage of articles reported adherence or engagement information and what metrics were used by each article. The right-hand columns report the mean and SD for all the articles that reported that metric.

[b]N/A: not applicable for summary of facets of adherence.

[c]SD values are not applicable as only 1 article was included.

A total of 4 articles studied a product without prescribing how often to use the app. Engagement was reported in 3 articles on these products. Of the 24 articles, engagement was reported for 2 (8%) in terms of initiation, 2 (8%) in terms of implementation, and 1 (4%) in terms of persistence. Two continual use therapeutics prescribed app use in terms of initiation and implementation but not persistence. As such, 25% (6/24) of the articles studying these apps reported engagement persistence metrics.

Of the 24 articles, 15 (63%) reported initiation in 4 different ways (eg, the number of users who finished the first app module and the number of users who entered 20 data points into the app). Seven articles excluded participants who did not initiate app use, leading to a high adherence for their adherence metrics. Of the 24 articles, 16 (67%) reported implementation, with 9 different definitions (eg, proportion of days between starting and stopping the use of an app that users logged their temperature and the number of perfect use cycles reported by women [ie, abstaining or using contraception on all high-risk days]). Of the 24 articles, 4 (17%) reported persistence, with 2 different definitions (participants using the app over the prescribed period and participants completing the prescribed number of modules). Table 4 reports the percentage of studies and the average adherence across trials and studies that used each metric. Of the 20 articles that prescribed use of the app, only 9 (45%) reported all prescribed facets of adherence [32,39-44,47,48].

ROB: "Nonadherence to the Assigned Intervention Regimen"

Of the 24 articles, 4 (17%) only reported engagement information, as there was no prescribed amount of app use. We found that the outcomes of the remaining articles could have been affected by nonadherence. Of the 83% (20/24) of articles for apps with prescribed use, 25% (5/20) reported adherence at or below their definition of low adherence for at least 1 facet of adherence. Of the remaining 15 articles, 12 (80%) reported that there was some nonadherence with the app for any prescribed facet of adherence or the app's behavior recommendations but did not provide a definition of low adherence. These articles provided insufficient information to determine whether adherence was sufficient for each app. The remaining 3 articles did not report sufficient information about each prescribed facet of adherence to judge adherence.

Analysis of Efficacy

Table 5 summarizes the effectiveness and efficacy estimates from each article. Of the 24 articles, 20 (83%) estimated the app's effectiveness as the ATE for all participants. Of these 20 articles, 11 (55%) preregistered their analysis of effectiveness. A higher percentage of RCTs preregistered their effectiveness analysis (7/9, 78%) compared with observational studies (4/11, 36%). Of the 24 articles, 15 (63%) estimated efficacy in terms of the ATE, per-protocol effect, or dose-response effect. Of these 15 articles, only 5 (33%) preregistered an efficacy analysis. Preregistration was more common for RCTs (3/6, 50%) than for observational trials (2/9, 22%).

Table 5. Summary of efficacy estimates (N=24).

Efficacy estimates	Values, n (%)	References
Effectiveness estimate	20 (83)	—[a]
None	4 (17)	[30,33,34,36]
Average treatment effect	20 (83)	[27-29,31,32,35,37-50]
Preregistered effectiveness analysis (n=20)	11 (55)	—
RCT[b] (n=9)	7 (78)	[28,29,37,39,45,49,50]
Observational (n=11)	4 (36)	[27,31,32,35]
Efficacy estimate	15 (63)	—
None	9 (38)	[27,28,31,35,40,42,45,49]
Average treatment effect	2 (8)	[34,36]
Per-protocol effect	10 (42)	[30,32,33,37-39,41,43,44,50]
Dose-response effect	3 (13)	[29,47,48]
Preregistered efficacy analysis (n=15)	5 (33)	—
RCT (n=6)	3 (50)	[34,37,39]
Observational (n=9)	2 (22)	[32,36]

[a]References not listed for summary rows.

[b]RCT: randomized controlled trial.

Table 6 characterizes the articles in terms of how well they meet the assumptions for their method of analysis. Of the 24 articles, 2 (8%) estimated efficacy in terms of ATE [34,36]. One of them used intent-to-treat analysis and met the relevant reporting requirement [34], and the other article calculated the ATE for an observational trial [36]. It met the criteria for SUTVA and had a clear definition of the treatment condition. However, it did not meet the positivity condition and lacked a control condition. The study adjusted for 1 confounder without saying how it was chosen.

Table 6. Fulfillment of required assumptions for efficacy analyses (n=14).

Estimate category, analysis method, and article	SUTVA[a], n (%)	Positivity, n (%)	Consistency, n (%)		Exclusion restriction, n (%)	Strong monotonicity, n (%)	Assignment mechanism ignorability			
			Clear treatment definition	Clear adherence definition			Randomization, n (%)	Conditional independence of treatment and outcomes	Sequential exchangeability	Conditional independence of adherence and outcomes

[a]SUTVA: stable unit treatment value assumption.

[b]NR: not required (for the analysis method).

[c]No included articles used the analysis method.

[d]N/A: not applicable (count is not applicable for listed control variables).

[e]ISI: insomnia severity index.

[f]IMD: index of multiple deprivation.

[g]IBS-SSS: irritable bowel syndrome symptom severity score.

[h]IV: instrumental variable.

Of the 14 articles that estimated efficacy, 9 (64%) estimated efficacy in per-protocol effect terms (ie, treatment effect for adherent participants). One trial (2 articles) calculated the complier average causal effect (CACE), or local ATE (LATE), and provided evidence of meeting its assumptions [37,38]. Three articles used as-treated analysis [30,33,50]. Three of these articles had strong support for the SUTVA assumption. Two articles met the requirements for consistency, whereas the third article did not, as it defined treatment loosely. Two articles accounted for confounders but did not mention how they were chosen. Five articles used per-protocol analysis [32,39,41,43,44]. All articles had strong support for the SUTVA assumption and clear definitions of treatment and adherence. One article used an RCT design, provided evidence of positivity, and accounted for the baseline predictors of missingness. Four articles had no control cohort and did not account for any potential confounders of adherence.

Three articles estimated dose-response effects [29,47,48], treating adherence as a moderator. All 3 articles had strong support for the SUTVA assumption and provided clear definitions of treatment and adherence. In total, 33% (1/3) of the articles used an RCT design, providing evidence of positivity. This paper corrected for 1 confounder without saying how it was chosen.

ROB: "Analysis Used to Estimate the Effect of Adhering to the Intervention"

Of the 20 articles with a recommended dose, only 2 (10%) used an appropriate method of analysis to estimate the impact of nonadherence. Both reported on a trial that calculated CACE or LATE based on a preregistered plan, demonstrating compliance with its assumptions [37,38].

Discussion

Recommendations for Future Trials

Our systematic review of the SaMD literature found 24 articles evaluating the clinical evidence for 10 unique apps. These apps covered a breadth of treatment areas, risk levels, and prescribed uses.

Adherence Metrics

On the basis of our evaluation of adherence metrics, we identified the following key issues and opportunities to address them in future SaMD trials and studies:

1. Trial and study reporting was inconsistent. Many trials did not report all 3 facets of adherence. Trials used many definitions for each facet of adherence, limiting comparisons.
2. Some trials measure, analyze, and report adherence in ways likely to produce estimates inconsistent with those experienced with actual use.

As mentioned in the *Adherence Metrics* section of the results, most trials (23/24, 96%) collected some engagement information, but only a minority (9/20, 45%) reported all the prescribed facets of adherence. Most trials reported metrics for initiation (17/24, 71%) and implementation (18/24, 75%), and fewer trials (11/24, 46%) reported metrics for persistence. Persistence may have been reported less often because studies often reported persistence solely in terms of study dropout (adherence to trial or study protocols) but not discontinued app use. For example, 1 common outcome of trials evaluating an app treating substance use disorder was the number of days until the last face-to-face therapy session. This metric addresses 1 aspect of persistence for the treatment but neglects persistence for use of the app.

When an app offered behavior recommendations, adherence was often reported only for adherence to app recommendations or app use. For example, many contraceptive studies had complete reports on sexual activity but no reports on how often the temperature or cycle start information was logged. Such missing information could help physicians reviewing the literature to provide recommendations or warnings to patients regarding products with low adherence or engagement, better informing their patients' consumer choices.

Within just these few articles, there were many definitions of adherence, even for apps with similar treatment mechanisms or application areas. This variety limits the possibilities for meta-analysis or app comparisons (eg, is engagement higher when 75% of users complete half of the modules or when users complete 75% of the modules on average?). In an ideal world, patients or their care providers would be able to compare adherence and engagement metrics across similar apps to choose the app that has the best outcomes and highest levels of engagement.

We recommend that the FDA's guidance or voluntary standards determine which metrics should be collected and reported. Both guidance and standards could recognize that the most important metrics would vary across treatment areas and app design. The FDA's guidance could provide broad recommendations for researchers to collect and report adherence information for all prescribed facets of adherence. Voluntary standards for each treatment could benefit from further studies of engagement, which would identify which metrics are most important for each treatment area. Standards would enable developers, providers, and consumers to compare the usability and efficacy of similar apps and researchers to conduct meta-analyses for apps in a treatment area. STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) and CONSORT (Consolidated Standards of Reporting Trials) provide examples of reporting protocols that could be adapted. The required information could be reported in the text, as supplemental material, or on an external site such as the Open Science Framework.

Several trials included external notifications intended to increase engagement that nontrial users would not have, such as manual notifications prompted by nonadherence. For example, most trials of an app treating attention-deficit/hyperactivity disorder sent email notifications to participants in response to nonactivity. This raises the question of how the app would perform without these notifications. The collection of trial-related information can itself introduce statistical bias if the information is solicited differently than would be the case with normal use. For example, studies on a contraceptive app collected information about sexual behavior daily within the study's app version, whereas the marketed version did not collect that information at the time of approval. Users in the trial might have been more engaged with the app; therefore, they were more likely to follow its recommendations compared with typical users. The marketed version of the app has since been updated to allow users to report sexual activity.

We recommend either regulatory guidance or voluntary standards that require trials to collect adherence information in ways similar to actual use. We recognize that, for some therapeutics, in-app notifications would not be practical or as effective. In such cases, regulators could demand postmarket evidence that measured effectiveness in real-world settings without manual notifications or external mechanisms for collecting adherence used in trials or studied are absent, aligns with measured effectiveness.

Analysis of Efficacy

On the basis of our evaluation of efficacy analysis, we identified the following key issues and opportunities to address them in future SaMD trials and studies:

1. Preregistration is common for analyses of effectiveness, especially for RCTs. Preregistration is uncommon for efficacy analyses of RCTs or observational studies.

2. Many articles analyzed efficacy with statistically biased methods.
3. Few articles reported evidence of meeting the assumptions for their efficacy analyses.

Preregistration is the accepted practice for protecting studies from *p-hacking* (ie, capitalization on chance), such as trying different analyses until a desired or expected result is obtained. Efficacy analyses for app trials are particularly susceptible to such practices, given their many variables and alternative definitions of metrics. For example, estimates of per-protocol effects depend on how researchers dichotomize participants into adherent and nonadherent groups. Different thresholds can produce different estimates.

Currently, regulators recommend that observational studies used to generate real-world evidence create and follow a protocol and analysis plan [7]. They also recommend that manufacturers follow a presubmission process to receive feedback on the plan. This consultation process is different than preregistration, where researchers publicly state their planned analyses and outcomes. Although both processes can reduce the risk of p-hacking, preregistration has the advantage of allowing the public to access study information in a standard, time-stamped manner.

In addition, we found that preregistration was more common for effectiveness analyses than for efficacy analyses. Effectiveness is likely to be the primary outcome of interest for a study and would be the primary concern for regulators reviewing an analysis plan. To protect against statistical bias, it is also important to specify in advance which analyses will be conducted in the case of low adherence and how low adherence will be defined. The analysis plan for 2 articles studying an app for the treatment of irritable bowel syndrome provides an excellent reference for defining adherence metrics and specifying analysis for low-adherence cases [37,38].

We recommend that regulators require preregistration of all app trials, in a standard format that specifies the planned metrics and analyses. Prespecified plans should include the analytical method used, any threshold for dichotomizing adherence, and the plan to account for confounders. Preregistrations should also address the conditions and methods for analyzing efficacy, such as the threshold for low adherence that would trigger efficacy analyses. Voluntary standards could mandate preregistration before updated regulatory requirements are implemented. Scientific journals might impose standards more quickly than regulatory bodies, as they have for preregistration of interventional trials [51,52].

Most trials studied efficacy and effectiveness using various methods. Most studies estimated a per-protocol effect using as-treated or per-protocol analysis, methods that studies have found to produce statistically biased results owing to insufficient adjustments for selection bias and confounders [53,54]. Our review also found insufficient accounting for confounders.

Only 1 trial (2 articles) used the preferred CACE, or LATE, analysis [37,38]. However, many other trials could have used this method, given their RCT designs. CACE, or LATE, analysis accounts for confounders without perfect knowledge of the relationships between outcomes and confounders using randomization as an instrumental variable.
