In terms of developers, there is a mix of some health care groups and other private companies. A total of 24 (35%) apps contained advertisements, 10 (42%) of which were for products or medical companies targeting MSK disorders, leaving 14 (58%) random advertisements. In addition, all apps were asynchronous which means that they failed to deliver continuously updated application data to users. A total of 9 (13%) apps collect personally identifiable information from users and only 2 (22%) asked for their consent for collection. It appeared that none of the apps tracked user engagement. The characteristics of each app are presented in Multimedia Appendix 1.

MARS Quality Assessment

The mean MARS total score obtained from 69 applications was 2.4 out of 5 (SD 0.44). Table 1 summarizes the MARS total scores for each app. All apps were initially assessed using MARS for engagement, functionality, aesthetics, and information. Mean scores for each subscale (out of 5) were calculated. Of the 5 categories, apps scored highest in the functionality (mean 3.0, SD 0.55) domain, followed by aesthetics (mean 2.6, SD 0.61) and engagement (mean 2.1, SD 0.58). The information domain received the lowest score (mean 2.1, SD 0.46). The MARS total score and domain score for each app are shown in Multimedia Appendix 2.

Table 1. Mobile app rating scale scores (N=69 apps).

MARS[a] subscale	iOS, mean (SD)	Android, mean (SD)	Total, mean (SD)
Engagement	2.4 (0.52)	1.9 (0.55)	2.1 (0.58)
Functionality	3.1 (0.57)	3.0 (0.49)	3.0 (0.55)
Aesthetics	2.9 (0.57)	2.4 (0.47)	2.6 (0.61)
Information	2.3 (0.49)	1.9 (0.40)	2.1 (0.46)
MARS overall score[b]	2.6 (0.43)	2.3 (0.35)	2.4 (0.44)

[a]MARS: Mobile App Rating Scale.

[b]Average of 4 objective subscales.

Intervention Contents for LBP

The LBP interventions embedded with the included apps were mainly classified into 3 categories (Table 2). Of these, most (n=47, 68.1%) of the apps offered only an exercise program, while 14.5% (n=10) apps provided patient education alone, and 13.0% (n=9) apps recommended patient education in combination with an exercise program. The remaining 2.9% (n=2) apps provided some psychological intervention for LBP in combination with an exercise program. Finally, only 1.4% (n=1) app-prescribed combinations of patient education, exercise, and psychological intervention.

Table 2. Number and percentage of category for low back pain interventions used in included apps.

Main category	Value, n (%)
Patient education + exercise program + psychological intervention	1 (1.4)
Exercise program + patient education	9 (13.0)
Exercise program + psychological intervention	2 (2.9)
Patient education only	10 (14.5)
Exercise program only	47 (68.1)

More specifically, of the 69 apps included in this review, most (n=51, 73.9%) apps recommended muscle stretching as a self-management strategy for LBP. A total of 42 (60.9%) apps suggested muscle strengthening, 32 (46.4%) apps offered core stability exercises, and 19 apps (27.5%) recommended using yoga to manage LBP. Also, there were 17 (24.6%) apps providing information about LBP mechanisms, followed by advice to use medication (n=9, 13%), staying active (n=9, 13%), postural therapy (n=8, 11.6%), cold and heat therapy (n=8, 11.6%), and aerobic exercise (n=8, 11.6%). Only some apps mentioned manual therapy (n=4, 5.8%), cognitive behavioral therapy (n=4, 5.8%), meditation (n=4, 5.8%), mindfulness (n=3, 4.3%), McKenzie exercise (n=3, 4.3%), electrotherapy (n=3, 4.3%), acupuncture (n=3, 4.3%), and lifestyle advice (n=2, 2.9%). Concerning app intervention content, 14 (78%) of 18 interventions for LBP were aligned with the NICE guidelines and 4 included interventions that were not endorsed by the NICE guideline: postural therapy, electrotherapy, cold and heat therapy, and acupuncture [29]. Details of the interventions offered for LBP managed in the included apps are summarized in Table 3.

Table 3. Number and percentage of specific component for low back pain interventions used in included apps.

Specific components	Value, n (%)
Understanding LBP[a] mechanisms	17 (24.6)
Staying active	9 (13.0)
Postural therapy	8 (11.6)
Lifestyle advice	2 (2.9)
Electrotherapy	3 (4.3)
Cold and heat therapy	8 (11.6)
Manual therapy	4 (5.8)
Medication use	9 (13.0)
Core stability exercise	32 (46.4)
Muscle strengthening	42 (60.9)
Muscle stretching	51 (73.9)
McKenzie exercise	3 (4.3)
Aerobic exercise	8 (11.6)
Yoga	19 (27.5)
Mindfulness	3 (4.3)
Meditation	4 (5.8)
CBT[b]	4 (5.8)
Acupuncture	3 (4.3)

[a]LBP: low back pain.

[b]CBT: cognitive behavioral therapy.

Theoretical and Risk-Related Approaches

None of the 69 apps included in this review referred to or explained their theoretical care model. Only 1 app considered or incorporated a tailored approach to their intervention. A total of 18 (26%) of these apps provided an intervention program based on principles of gradual intervention progression. No app mentioned the age group for which their intervention content was appropriate and none set an age limit for their use. Even fewer, 11 (16%) apps offered safety checks for app users, including identifying red flags, signs, and symptoms of LBP that required medical attention or providing safety-netting advice if the back pain did not resolve or worsen (Multimedia Appendix 3).

Discussion

Intervention Content in LBP Apps

We attempted to benchmark the content of the included apps against the most recently published best practice guideline from NICE and found that most LBP self-management app components were consistent with those recommended by NICE. The NICE LBP guidelines [29] recommended the use of a group exercise program, including biomechanical, aerobic, mind-body, or a combination of approaches. Accordingly, muscle stretching, strengthening, core stability exercises, and yoga are the most common interventions in self-management apps. The findings of this review support a 2016 systematic review, which found that interventions in LBP selected by app developers were primarily based on clinical practice guidelines [31]. Similarly, the 2021 Cochrane review also reported moderate-certainty evidence suggesting that different types of exercise therapy are effective in treating LBP [32]. This means that most current LBP self-management apps offer evidence-based interventions.

However, while the content of most apps appears evidence-based, they are not often delivered in the context of a complex intervention and as such do not reflect the current LBP care models. We found that most self-management apps rely on exercise interventions, and very few apps incorporate social and psychological interventions for managing LBP. This suggests that current self-management apps emphasize a more biological care model to manage LBP rather than considering the influence of psychological and social factors in the development and maintenance of pain [33]. Research has emphasized interrelationships among biological changes, psychological status, and the sociocultural context and as such, they all need to be considered to understand the impact of chronic pain and its subsequent management [34]. The biopsychosocial model has been widely accepted as a holistic approach to increase efficacy and outcomes in managing chronic LBP [2,35]. Also, a complex multidisciplinary approach with a biopsychosocial model has been recommended in the early stages of LBP to reduce the likelihood of chronicity following acute LBP [36]. Thus, digital self-management interventions for LBP should consider adopting this model.

Quality Assessment in Self-Management Apps

Generally, apps for the self-management of LBP are of poor quality as assessed by MARS. Functionality (mean 3.0, SD 0.55) was the domain that scored the highest on the MARS test, as described by other authors [31,37]. This implies that the apps are functioning well, easy to learn and navigate, and efficient. However, the quality assessment revealed that these apps had low scores on the domains of "engagement" (mean 2.1, SD 0.58) and "aesthetics" (mean 2.6, SD 0.61). This indicates that the features that make the app equally engaging and important to a wide user base may have been overlooked. This was partly because most apps did not consider using specific strategies to increase involvement and aesthetics from the user's point of view (eg, entertainment, interactivity, customization, layout, and graphics). Involving patient users during the development of these apps might better identify their needs and characteristics, and increase adherence to improve self-management and health outcomes [38].

The lowest score on information (mean 2.1, SD 0.46) indicated weakness in the quality and trustworthiness of information presented in the included apps. This was evidenced through assessing credibility (MARS item 18) and evidence base (MARS item 19). In terms of MARS item 18, most apps were developed by either commercial businesses with a vested interest or a legitimate source without verification (eg, has no web page), yet few are developed by credible health organizations (eg, government or universities). The lack of health professional involvement is a consistent issue highlighted by Rizwana, who has expressed concern about the accuracy and trustworthiness of in-app information [39]. In addition, none of the apps available for LBP management were evaluated using a randomized controlled trial. This was evident in MARS item 19, which assesses whether the app has been trialed or tested in the published scientific literature, and therefore the effectiveness and safety of these apps remain unknown. These results align with previous reviews on mHealth apps directed at pain management, in which a lack of scientific basis of the outcomes was found to support the use of such apps [40,41]. A possible explanation could be that most of the apps are of commercial rather than scientific origin, which suggests that the need to promote cross-disciplinary collaboration between academic and commercial institutions might help develop the evidence base for using such apps [37,40].

Theoretical and Risk-Related Approaches

Current self-management apps do not appear to have used a theoretical rationale in their development. This aligns with the findings from a 2018 review, which found the development of current self-management mHealth apps for patient education programs lacks the support of underpinning theory or framework [42]. An underpinning theoretical model is widely recognized as a crucial component of health interventions and is important when trying to understand key components of the intervention, how they interact, and the mechanisms of the intervention [43-45]. Systematic reviews of existing evidence demonstrate that interventions underpinned by theory are more effective than those that are not [46,47]. Additionally, as a complex multifactorial condition, the management of LBP should consider theory development and identifying the evidence base in accordance with the MRC framework for complex interventions [48].

Regarding personalized care, almost all included apps provided limited customized service. Tailored communications provide individuals with information that is relevant to them and that fits their situation. This can lead to increased perceived personal relevance, user engagement, more in-depth processing of information, and consequently, more desire and motivation to engage in the health behavior change [49]. The importance of personalization of mHealth apps was emphasized in a qualitative review in 2019, which expressed that mHealth apps should meet patients' needs since they were created for use [22]. Also, our review suggests that the principle of gradual progression from simple to more advanced levels of intervention is not universal. Providing tools that help the user implement exercise progression ensures that the intervention progressively becomes more challenging to continually stimulate adaptations and maintain interest in the program [24]. The Coventry, Aberdeen, and London—Refined (CALO-RE) taxonomy of behavior change techniques highlighted the importance of setting graded tasks, breaking targeted behaviors into smaller, more manageable tasks, and facilitating progress in small increments [50].

Current apps do not evaluate the age limitation of intervention content for which LBP advice and treatments are appropriate, which may pose some risks for the users. Although age ratings in the App Store are often reported, it is based primarily on the degree to which an app contains sensitive information rather than on the applicability of an intervention to different age groups. It is also worth noting that the current NICE guideline for LBP published in 2016 is based on an adult population. A review from the Lancet showed that the evidence underpinning LBP guidelines is drawn almost exclusively from clinical trials of adults, and there are few trials on the treatment of back pain in children [51]. Thus, adult LBP care pathways may not be suitable for adolescents and children [52,53]. When applying these LBP management apps to nonadults, their scope of application needs to be considered. In addition, most included apps performed poorly in providing safety considerations. Safety check advice, including information on the natural history of the illness, advice on worrying symptoms to watch out for, and specific information on how and when to seek help, as well as advice about the follow-up of investigations and hospital referrals, can effectively address uncertainty in the process of LBP management [54]. A scoping review in 2020 discussed that safety concerns within apps were a primary concern [18]. Thus, such approaches will improve the likelihood of providing users with appropriate care and reduce clinical risks associated with self-management [55].

Evaluation Tool for LBP Apps

Although some self-management apps show relatively high scores on the MARS score, such as "Back Doctor/Pain Relief-1.03.24," "Perfect Posture&Healthy back-1.5.2," and "Back pain exercise at home-1.0.99," they perform poorly on the theoretical and risk-related framework, such as the personalization of care and the age group targeted. Conversely,

some self-management apps (eg, BackTrainer-2.0) adopted a tailored approach and addressed risk-related issues, but MARS' quality assessment scores were not high. Additionally, MARS has not effectively evaluated or included the biopsychosocial care model commonly used in chronic pain [34]. This indicates that current evaluation tools may be limited in their ability to assess LBP self-management apps comprehensively, and consequently, further study is needed to explore whether a holistic tool to evaluate LBP self-management apps is required.

Barriers to Holistic Digital Apps

Despite the overwhelming evidence recommending the use of holistic multidisciplinary interventions based on a biopsychosocial model for the self-management of LBP, the proliferation of back pain apps on the market that use simple interventions is concerning. It is hard to speculate why this is the case given the strong evidence for the use of a biopsychosocial model in the management of LBP. This may relate to current regulatory approvals. For an app to deliver a complex biopsychosocial intervention it would be classified as a medical device requiring such approvals. Further work is needed to explain why there are so many apps on the market that fail to address the model of care we seek in medical practice, and how current regulatory processes affect this.

Moreover, digital health interventions have been strongly advocated for and implemented in other domains and countries. Notably, draft guidance from NICE has informed digital programs using multidisciplinary models to assist the NHS in delivering specialized services for weight management [56]. Furthermore, the Federal Institute for Drugs and Medical Devices in Germany has authorized the entry of multidisciplinary health care apps with robust trial data into the market, with the overarching objective of empowering clinicians to prescribe health care apps for their patients [57,58]. This illustrates the feasibility of developing multidisciplinary mHealth apps for health care practitioners to recommend. However, it remains imperative to conduct a comprehensive evaluation of the apps using clinical studies to ascertain their efficacy and suitability for widespread prescription.

Limitations

Apps not specifically targeted for the self-management of LBP (eg, chronic pain, pain management, or MSK apps) were excluded from this review, which may result in potentially eligible apps being missed. While many LBP apps in different countries are available in app stores, our search was limited to the UK iTunes and Google Play stores for practical reasons relating to data-capturing capacity. Therefore, this review did not include apps exclusively available in other countries, and therefore may not represent the broader landscape relating to digital approaches for management of LBP. Only 1 independent reviewer assessed app quality using MARS and discussed uncertainties with 2 other research members until a consensus was reached, which may impact the reliability of the assessments.

Conclusions

In this review, we identified 69 apps related to the self-management of LBP and rated them using MARS. Most apps scored poor quality due to their approaches to engagement and information, and many emerged as tools for delivering passive information rather than active management apps. Most apps were aligned with guideline-based care. However, no app offered a holistic self-management intervention approach incorporating a biopsychological model. Most apps underestimated the importance of theoretical and risk-related aspects. Thus, current self-management apps for LBP are limited in what they offer.

Acknowledgments

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors. Imperial College London is the sponsor for the study and has no influence on the direction or content of the work. We are grateful to Rebecca Jones (Library Manager in Imperial College London) who offered advice and support for the building search strategy and screening process. We also wish to thank our colleagues in the MSK laboratory for their valuable and helpful comments and suggestions. Without these people, studying would have been impossible.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

TZ, DS, and AM conceived and designed the study. TZ takes responsibility for the acquisition of the data and the analysis of the data. TZ drafted the paper. DS and AM revised the paper critically for important intellectual content. All authors approved the final version to be published.

Abstract

Background: Mobile health interventions delivered through mobile apps are increasingly used in physiotherapy care. This may be because of the potential of apps to facilitate changes in behavior, which is central to the aims of care delivered by physiotherapists. A benefit of using apps is their ability to incorporate behavior change techniques (BCTs) that can optimize the effectiveness of physiotherapeutic interventions. Research continues to suggest that despite their importance, behavior change strategies are often missing in patient management. Evaluating mobile apps that physiotherapists can use to drive behavior change may inform clinical practice and potentially improve patient outcomes. Examining the quality of apps and exploring their key features that can support behavior change and physiotherapy care are important aspects of such an evaluation.

Objective: The primary aim of this study was to describe the range of mobile apps in app stores that are intended for use by patients to support physiotherapy care. The secondary aims were to assess app quality, BCTs, and their behavior change potential.

Methods: A systematic review of mobile apps in app stores was undertaken. The Apple App Store and Google Play were searched using a 2-step search strategy, using terms relevant to the physiotherapy discipline. Strict inclusion and exclusion criteria were applied: apps had to be intended for use by patients and be self-contained (or stand-alone) without the requirement to be used in conjunction with a partner wearable device or another plugin. Included apps were coded for BCTs using the Behavior Change Technique Taxonomy version 1. App quality was assessed using the Mobile App Rating Scale, and the App Behavior Change Scale was used to assess the app's potential to change behavior.

Results: In total, 1240 apps were screened, and 35 were included. Of these 35 apps, 22 (63%) were available on both the Apple App Store and Google Play platforms. In total, 24 (69%) were general in their focus (eg, not condition-specific), with the remaining 11 (31%) being more specific (eg, knee rehabilitation and pelvic floor training). The mean app quality score (Mobile App Rating Scale) was 3.7 (SD 0.4) of 5 (range 2.8-4.5). The mean number of BCTs identified per app was 8.5 (SD 3.6). BCTs most frequently included in the apps were instruction on how to perform a behavior (n=32), action planning (n=30), and self-monitoring of behavior (n=28). The mean behavior change potential score (App Behavior Change Scale) was 8.5 (SD 3.1) of 21 (range 3-15).

Conclusions: Mobile apps available to support patient care received from a physiotherapist are of variable quality. Although they contain some BCTs, the potential for behavior change varied widely across apps.

Introduction

Background

Digital health in physiotherapy is an emergent area. It continues to gather speed with its use in both clinical practice and research growing exponentially [1-3]. Many digital modalities, with varied functions, are relevant to physiotherapy practice; these might include the delivery of timely digital patient information and resources through websites and patient portals [4], digital patient assessment using connected Bluetooth and wireless-enabled devices [5], digital models of care (telehealth) supported by video-based consultation [6-8], remote monitoring of patient status through wearables [9,10], and mobile health (mHealth) apps used to prescribe, monitor, and support home exercise programs [1,11].

Mobile apps are one type of digital health modality of particular interest because of the ubiquity of smartphone use and their ability to deliver digital therapeutics [12-14]. They are relatively inexpensive and thus scalable [15]. They are also worthy of scientific attention within the physiotherapy community because of their ability to support interventions targeting several aspects of behavior change, otherwise known as behavior change techniques (BCTs) [16-19]. Facilitating positive behavior change in people with health conditions is often central to the management approach of physiotherapists, aimed at deriving the best possible therapeutic benefit from an intervention. For example, behavior change may be required for a person to follow physiotherapist advice regarding activity pacing or to adhere to exercise and physical activity recommendations [1,16,19,20]. BCTs can be thought of as the components of an intervention that regulate the behavior by altering cause and effect [21]. As defined by Michie and Johnston [22], they may be thought of as the "active ingredients" that facilitate intended behaviors. Apps have the ability to incorporate and deliver numerous BCTs, which can mediate a behavioral target of physiotherapy care [23-25].

The app space continues to grow exponentially, with well over 300,000 health apps now available and over 200 health apps added to major app stores daily [18]. Concurrently, despite a growing evidence base regarding the role of mobile apps in physiotherapy contexts, there remains a dearth of high-quality research using validated and rigorous scientific methods assessing the quality of physiotherapy-specific mobile apps and their behavior change aspects (eg, BCTs used and behavior change potential) [11,25].

Objectives

The primary study objective was to describe mobile apps, intended for use by patients, that can support physiotherapy care. The secondary objective was to evaluate app quality [26] and any BCTs contained within them [21], and to evaluate the behavior change potential of the apps [24].

Methods

Study Design

The detailed protocol for this systematic review was previously published [25]. As this study is a systematic review of apps (in app stores) and does not involve human participants, ethics approval was not required. The review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement's systematic review reporting principles, with minor adaptations as relevant for our search of app stores rather than research literature [27]. This method is common and adopted in other similar studies [18,28,29] (Multimedia Appendix 1) [30].

Search Strategy

Overview

A 2-phase search strategy was used to search the popular app stores (Apple App Store and Google Play), which was in line with other rigorous systematic reviews of health apps in app stores [29]. App store search strategy, keywords used, and steps can be seen in Textbox 1 [25]. Initial search was conducted in March 2021 and rerun in February 2023 to ensure further up-to-date coverage. To maintain the feasibility of the search, each search term combination was limited to the first 100 apps retrieved. This was also done to maintain the relevance of apps retrieved, which diminishes as the end of the search list is refreshed [28].

Textbox 1. Search strategy.

Step 1

"physiotherapy," "physio," "physical therapy," "physiotherapist," "physical therapist."

Step 2

"physiotherapy," "physio," "physical therapy," "physiotherapist," "physical therapist."

and

"assessment," "diagnosis," "digital," "eHealth," "evaluation," "examination," "exercise," "health promotion," "intervention," "physical activity," "plan," "care," "prevention," "rehabilitation," "screening," "pain," "self-management," "treatment," "support," "adherence."

Additionally, the websites of the top 10 member organizations of World Physiotherapy (the peak international physiotherapy body) based on number of members were searched for recommendation or endorsement of any specific apps that met our criteria. Only websites in English and with the relevant section not behind a paywall were searched.

Selection Process

The search was performed independently by 2 reviewers (MM and PV). The same reviewers independently screened the apps using 1 Apple and 1 Android device each. Screening was based on information in the respective app stores, including app title, description, and screenshots [31]. Apps eligible for full analysis were downloaded onto the devices for review by each reviewer independently, and any disagreements were resolved by discussion. A third reviewer (PM) was flagged as a mediator to resolve any nonconsensus, but this was not required [28].

Data Extraction

Overview

The 2 reviewers (MM and PV) independently extracted descriptive data about each app from the app stores, within the apps themselves, or from official websites of the apps (if readily apparent from information in the app store). All extracted data were computed in Microsoft Excel (Microsoft Corp). A full list of extracted descriptive characteristics is shown in Multimedia Appendix 2 [25].

Both reviewers (MM and PV) independently engaged with all of the app functions for a minimum of 10 minutes on each device, for familiarization. This allowed each reviewer to independently code and score the app quality, BCTs, and their behavior change potential.

Mobile App Quality

To appraise the quality of included apps, the 23-item Mobile App Rating Scale (MARS) was used [26]. MARS was used because of its reliability, simplicity, and wide applicability in mHealth research [26,32]. Its primary domains are engagement, functionality, aesthetics, and information, as well as a subjective rating of quality. Each domain has questions coded on a 5-point Likert scale (ranging from 1=inadequate to 5=excellent). Mean scores are calculated for each of the 4 domains, which are tallied and divided by the number of domains to produce an overall mean quality score out of 5. Mean scoring is used instead of total scores because individual items can be rated as "not applicable" [26].

Calculating the mean scores of the engagement, functionality, aesthetics, and information quality objective subscales and an overall mean app quality total score is how the MARS is scored. Mean scores instead of total scores are used because an item can be rated as "not applicable."

Both reviewers (MM and PV) completed MARS training before scoring each app independently. Any disagreements were rectified via discussion. A third reviewer (PM) was flagged as a mediator to resolve any nonconsensus, but this was not required.

Coding BCTs

Both reviewers (MM and PV) underwent and received certification in coding BCTs using the Behavior Change Technique Taxonomy version 1 (BCTTv1). This was to increase their competence in identifying and assessing BCTs and to improve coding agreement [33]. Based on the minimum of 10 minutes they engaged with app functions, each reviewer independently coded the BCTs incorporated in each app using the BCTTv1, a framework of 93 BCTs created for investigating behavior change interventions using valid and reliable methods [21]. Furthermore, the BCTs in the BCTTv1 are further arranged into 16 clusters, each including similar BCTs [21]. This clustering was helpful for coders when developing a novel codebook (Multimedia Appendix 3), as it helped clarify coding decisions when examining the behavior change potential of included apps [25]. Any disagreements were discussed to achieve consensus. Where consensus was not able to be achieved, a third reviewer (JJF; who is a behavior change expert and one of the original developers of the BCTTv1) helped resolve any disagreements.

Behavior Change Potential

The App Behavior Change Scale (ABACUS) was used to evaluate the behavior change "potential" of each app, which is a scale of 21 items [24]. Apps are scored by identifying any of the 21 items and summing these item scores to give a score out of 21. The ABACUS focuses on 4 BCT clusters: knowledge and information, goals and planning, feedback and monitoring, and actions [24]. Using clustered BCTs identified, we developed the aforementioned novel coding rulebook to support reporting, and the 2 reviewers (MM and PV) scored behavior change potential together using the ABACUS. Any disagreements were discussed at the time, and a third reviewer (JJF) decided in the case of nonconsensus.

Data Synthesis

App characteristics are reported as descriptive and categorical data and a proportion (percentage), including app name, data privacy transparency (yes or no), companion app (yes or no), platform (Apple App Store, Google Play, or both), focus of the app (specific condition or region or whether more general), physiotherapy specialty (eg, musculoskeletal, pelvic health, and pediatric), target behaviors, simplified target behaviors, country of origin, developer qualifications (not clear or health care professional [HCP] or non-HCP), app version number, payment method (free or in-app purchases or one-off payment), and cost. Overall mean (SD) and individual domain scores are presented for MARS and ABACUS scores, as well as total BCT identification frequency and BCTs coded per app.

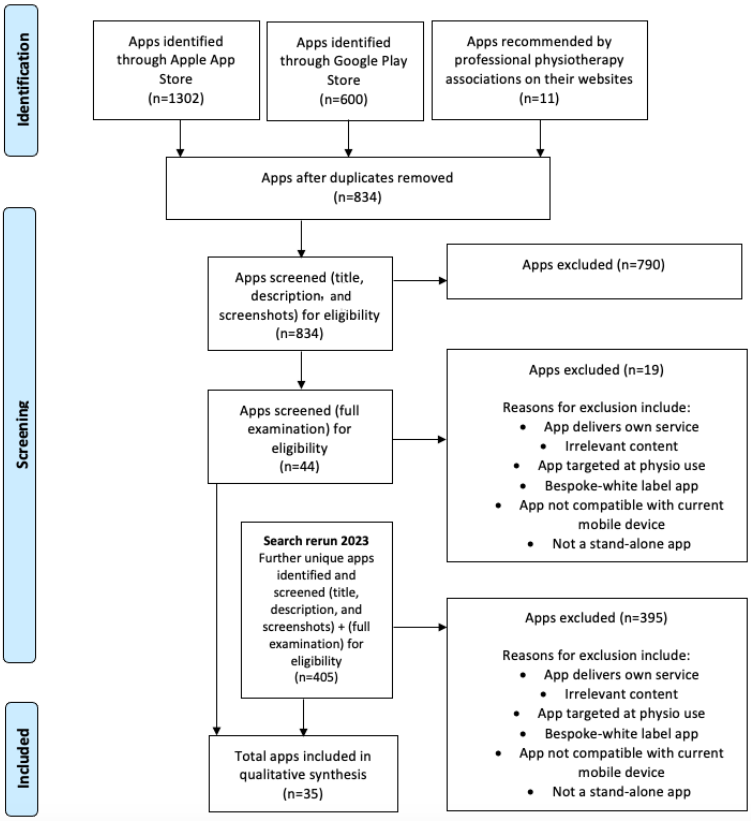
Results

Search

Our initial search identified a total of 1913 apps (Figure 1). This included 1302 unique apps from the Apple App Store, 600 apps from the Google Play Store, and a further 11 apps identified on the websites of professional physiotherapy associations. Overall, 834 were left after duplicates were removed. Following screening of app name, description, and screenshots, a further

790 were excluded. In total, 44 apps were screened fully, of which 19 were excluded. Reasons for exclusion included non-English language, costing more than Aus $10 (a currency exchange rate of Aus $1=US $0.72 is applicable), delivering its own service, irrelevant content, targeted at physiotherapist (clinician use) rather than the patient, being a bespoke or white-labeled app (ie, standard architectures licensed to a business or brand for private use), incompatibility with a current mobile device, and not a stand-alone app. This left 25 included apps for data extraction. Search update was rerun in February 2023, yielding an additional 405 unique apps. Following screening, this yielded a further 10 included apps for data extraction. Thus, a total of 35 apps were examined.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.



Descriptive Characteristics of Included Apps

App characteristics are described in Multimedia Appendix 2. Overall, 22 (63%) apps were available on both Apple App Store and Google Play platforms, and 12 (34%) only on Apple App Store. Only 1 (3%) app was solely available on Google Play. Country of origin was clear for 24 (69%) apps, with 6 apps originating from the United Kingdom, 6 from the United States, and 5 from Australia. Regarding price, 26 (74%) were free to download, and 9 had a one-off payment price ranging from Aus $1.49 to $9.99. Additionally, 10 apps offered in-app purchases (including subscriptions). Just under half of the apps (n=16, 46%) were not clear about the developer's qualifications, a further 17 (49%) were developed by HCPs (ie, physiotherapists, orthopedic surgeons, exercise physiologists, and chiropractors), and 2 (6%) were developed by non-HCPs. Overall, 15 (43%) apps had an obvious physiotherapist companion feature (ie, dashboard, desktop software, or precise login for therapists to access and engage with patients), and 31 (89%) apps had information about privacy and security in the app store. The focus of most apps was general in nature (eg, not condition-specific; n=24, 69%), while 11 (31%) had a specific target (eg, knee rehabilitation and pelvic floor training). This included 3 apps focusing on pelvic health and 1 app each focusing on wrist or hand, knee, hemophilia, core stability, wheelchair-bound individuals, cerebral palsy, osteoarthritis, and back pain.

Assessment of Quality (MARS)

Table 1 shows app quality scores using the MARS. Individual app quality scores ranged from 2.8 to 4.5, with a mean score of 3.7 (SD 0.4) of a maximum of 5. The apps with the highest MARS scores were Squeezy: CF (4.5), Squeezy (4.4), AllyCare (4.3), Squeezy for Men (4.2), and TeleHab (4.2). Of the appraised MARS domains, "aesthetics" (mean 3.9, SD 0.6) and "functionality" (mean 3.8, SD 0.5) were the highest scoring sections, while "subjective app quality" (mean 3.4, SD 0.8) and "engagement" (mean 3.4, SD 0.5) were the lowest. To the best of our knowledge, only 4 (11%) apps met criterion 19 (has the app been trialed or tested and published in scientific literature), including ReHand, Hand Rehabilitation, Squeezy, Embodia, and PhysiApp. Only 1 (2.9%) app (ReHand, Hand Rehabilitation) has been evaluated in a randomized controlled trial (RCT), showing positive outcomes for physiotherapy patients [34,35].

Table 1. Mobile App Rating Scale scoring.

App	Section A: engagement	Section B: functionality	Section C: aesthetics	Section D: information	Mean app quality score (section A to D)	Section E: subjective app quality
A Rehab Diary	3.6	3.0	2.7	3.2	3.1	2.5

Behavior Change: Target Behaviors and BCTs

The most frequently observed target behaviors in the apps included recording information about exercise (n=28, 80%), performing therapeutic exercise (general; n=25, 71%), and communicating with a health professional (n=12, 34%; Multimedia Appendix 2). Other observed target behaviors included performing therapeutic exercise (men's health, women's health, hand therapy, knee, and perioperative), connecting with a health professional (make an appointment), connecting with friends, general self-care, and postsurgical self-care.

Coded BCTs by frequency can be observed in Multimedia Appendix 4, with a glossary of BCTs presented in Multimedia Appendix 5. The mean number of BCTs identified per app was 8.5 (SD 3.6). The apps with the highest number of unique BCTs were AllyCare (16), My Exercise Messages (14), ReHand, Hand Rehabilitation (14), and PhysiApp, BlueJay Engage, A Rehab Diary, and TeleHab (all with 13 BCTs identified). The most frequently coded BCTs were BCT 4.1 (instruction on how to perform a behavior; coded in n=32, 91% apps), BCT 1.4 (action planning; coded in n=30, 86% apps), BCT 2.3 (self-monitoring of behavior; coded in n=28, 80% apps), BCT 2.2 (feedback on behavior; coded in n=27, 77% apps), BCT 6.1 (demonstration of the behavior; coded in n=27, 77% apps), BCT 7.1 (prompts or cues; coded in n=25, 71% apps), and BCT 9.1 (credible source; coded in n=25, 71% apps).

Assessment of Behavior Change Potential (ABACUS)

Table 2 shows ABACUS scores for each app. The behavior change potential of included apps was a mean of 8.5 (SD 3.1) of a maximum of 21 (range 3-15). Of the 4 domains assessed by the ABACUS, section 1 (knowledge and information: mean score 3.0, SD 0.9) and section 3 (feedback and monitoring: mean score 2.9, SD 1.6) scored the highest, while section 2 (goals and planning: mean score 0.3, SD 0.8) and section 4 (actions: mean score 2.4, SD 1.0) scored the lowest. The apps (n=21) with the highest ABACUS scores included AllyCare (n=15, 71%), My Exercise Messages (n=14, 67%), ExorLive Go (n=14, 67%), A Rehab Diary (n=13, 62%), and both BlueJay Engage (n=12, 57%) and ReHand, Hand Rehabilitation (n=12, 57%).

Discussion

Principal Findings

Implications

The primary aim of this study was to describe apps, intended for use by patients, that can support physiotherapy care. The secondary aims were to evaluate app quality, examine BCTs they contained, and evaluate behavior change potential. The findings of this study offer valuable insights into the current landscape of apps that may be used to support physiotherapy care and shed light on their ability to facilitate behavior change and potentially improve patient outcomes.

We identified 35 eligible apps, highlighting the popularity and increasing recognition of digital strategies for supplementing physiotherapy care [2,36]. It must also be noted that there is a growing number of apps within the broader exercise medicine and rehabilitation science space that may not have met the specific eligibility criteria for this systematic review but may still be of value in supporting physiotherapy care [1,18]. The rising number of available mobile apps necessitates careful and considered evaluation and selection of apps by clinicians and researchers to ensure that patients are accessing high-quality, effective, and safe apps that are evidence-based [1,11,37,38].

App Characteristics

Analysis of the app descriptive characteristics revealed interesting findings. Just under two-thirds of apps were cross-platform compatible (available on both the Google Play Store and Apple App Store). As smartphone ubiquity continues to grow, broader availability may contribute to wider accessibility and increase the uptake of apps to supplement physiotherapy care by both patients and physiotherapists [39]. The physiotherapy profession has recognized the value of mHealth tools to serve under-resourced communities and regions [40]. It is encouraging to note that in terms of price, the majority of the apps included in our review were free to download for patients. It must also be acknowledged that our review only examined apps that cost Aus $10 or less, which is in line with similar studies of apps for the management of arthritis, back pain, and persistent pain [29,31,32,41]. This follows similar research, suggesting that health consumers are less likely to buy health apps costing more than this [42]. However, there may well be more expensive apps available for purchase that were not included in our review. Conversely, while there are many seemingly free-to-download apps, several of the included apps require the physiotherapist to prescribe the patient a program from a companion app or dashboard before they can use it (eg, PhysiApp and TeleHab). In situations like this, the use of apps to support care is contingent on factors such as willingness to engage with digital health, acceptance, and digital health literacy of treating physiotherapists [2,37,38].

Relevant to an evidence-based profession like physiotherapy, the credibility of apps to support care remains an important consideration, and research suggests that this is a central factor in user engagement and satisfaction [43,44]. Less than half of the apps 16 (46%) provided clear information about the qualifications or background of the developers. Similarly, only 17 (49%) apps were clearly developed by health professionals (including physiotherapists). Research suggests that apps developed by or with health professionals may contribute to improved efficacy and safety, outcomes, and evidence-based care delivered by the apps [45]. However, while this may be true, a counterargument stands that while said to be developed by health professionals, it remains unclear what evidence was used in developing these apps.

Quality

A key aim of this study was to assess the quality of mobile apps relevant to physiotherapy care. While app quality is somewhat subjective, and measurement scales continue to emerge (eg, the recently released Deakin Health E-technologies Assessment Lab framework) [46], the MARS remains the most used, published, and validated [1,26,29]. Overall mean app quality in this study was 3.7 (SD 0.4), which is similar to previous research validating the MARS [47]. The authors reported a mean health app quality score of 3.74 (SD 0.6) of 5 and considered this as “moderate” quality. Notably, there is no universally accepted threshold for interpreting MARS scores. This suggests that the current landscape of physiotherapy apps has a little way to go in terms of quality. Our MARS data for the domains of “aesthetics” and “functionality” suggested that the included apps generally offer a good user experience and technical performance. These findings align with a quality appraisal of mobile apps for self-management of persistent pain conditions [29] but contrast to the relatively low scores obtained for apps specific to the management of low back pain [32].

Given that the physiotherapy profession is an evidence-based discipline, it is alarming that we found that only 4 (11%) of included apps met MARS criterion 19 (has the app been trialed or tested and published in scientific literature). Further, only 1 (3%; ReHand, Hand Rehabilitation) has been examined in an RCT [34,35,48]. However, the SMS-based precursor, which informed the development of My Exercise Messages, has undergone rigorous RCTs, showing positive patient outcomes [48,49]. An RCT studying the My Exercise Messages app is currently underway, and the protocol has been published [50]. As digital physiotherapy practice evolves, a combination of (1) greater assessment and scrutiny of digital health tools (eg, apps) through standardized validated measures and (2) high-quality well-designed RCTs and systematic reviews will assist in building evidence for and ultimately trust in digital tools that can support physiotherapy care [51-53].

Behavior Change

Another aim was to determine the BCTs included in apps and the apps’ potential for behavior change. Facilitating patient behavior change is an important aspect of physiotherapy care that may determine the effectiveness of many physiotherapy interventions [54-56]. Analysis of target behaviors suggested that the apps included in this review most commonly targeted behaviors linked to recording information about exercise, performing therapeutic exercise, and communicating with a health professional. This is encouraging, as these behaviors are often central to the core aims of many physiotherapeutic interventions [55,57]. The most frequently occurring BCTs coded within the included apps were instruction on how to

perform a behavior, action planning, self-monitoring of behavior, feedback on behavior, demonstration of the behavior, prompts or cues, and credible source, and these align very well to digital behavior change interventions using apps reported in literature on physical activity in osteoarthritis, various musculoskeletal conditions, and falls prevention exercise [58-60].

The potential for behavior change (based on ABACUS findings) could only be considered modest, given the mean ABACUS score of 8.5/21 (SD 3.1; 41%) across the 35 apps evaluated. This is similar to a recent comprehensive analysis of mobile apps to support behavior change in patients with a chronic disease or multimorbidity. In that study, mean ABACUS score was 8.07/21 (38%) [19]. Given that the developers of the ABACUS [24] have highlighted that the clinical implications of ABACUS score are still to be determined, it is not possible to determine whether the apps included in this study are effective or not at changing behavior or if they are likely to be effective at improving clinical outcomes from physiotherapy care. Future prospective research is required to evaluate if the apps included in our review can change patient behavior over time.

Limitations

The study has limitations. The review only analyzed apps in the English language, which limits the generalizability of the findings. Importantly, the search strategy had specific and stringent inclusion or exclusion criteria, which may lead to interpretative bias. For instance, apps had to be directly identifiable as being supportive of care between a patient and their physiotherapist. While several apps in app stores may indirectly support physiotherapy (eg, general exercise or informational apps), these were out of scope. Similarly, our search was based on a specified set of keywords, and thus, retrieval may not have captured all relevant apps. Furthermore, some apps originally identified in the search strategy were not able to be trialed for several reasons such as no free trial readily available, not available in the select region, or no response by developers for limited-time access by the study authors. A similar scenario occurred for apps that were subscription-based. In these cases, free trials were examined where possible, which may have not included full app functionality, thus potentially leading to more conservative quality, BCT, and behavioral potential scores. Regarding app quality, this was not appraised by patients themselves in this study. Should this have occurred, a different version of the MARS, the user-MARS, would have been required [61]. It is possible that patients may achieve a different quality rating for the apps. This is an area worthy of future research.

In addition, our protocol involved apps being trialed for a minimum of 10 minutes [25,29]. Vaghefi and Tulu [62] suggest "... most users tend to withdraw from mHealth apps before the end of the first week." This raises the possibility that engaging with each app for a limited amount of time can make it difficult to get a complete picture of an app, with certain features and BCTs not being immediately apparent. This was observed firsthand in the case of "My Exercise Messages," which scored 14/21 on the ABACUS in this study but scored 17/21 when rated by its developers who are intimately familiar with all the features of the entire 24-week app program [50]. The discrepancy is likely due to the fact that the more BCTs become apparent, the longer a user engages with the app over 6 months. A similar issue lies in the possibility that important descriptive data about an app may be missed or inaccurate because we relied on limited data sources. For instance, not all the necessary detailed information about an app can be found in the app itself or within its app store description. In select cases, this information may be identifiable if publications about the app exist. However, our protocol was deliberately designed to more closely mimic how a lay user would likely find and interact with an app through an app store. For these reasons, the findings reported in this study may be conservative for some apps, and it is possible that quality and behavior change scores would be higher with proper in-depth use. We thus urge readers to use caution in interpreting our findings.

Finally, this study focused primarily on app descriptive characteristics, quality, BCTs, and behavior change potential. It was not an aim of this review to evaluate the clinical effectiveness of these apps in changing behavior or their efficacy toward improving patient health outcomes.

Conclusions

Mobile apps available to support patient care received from a physiotherapist are of variable quality and contain relatively few BCTs. The potential for behavior change varied widely across apps. This study has provided the first comprehensive examination of mobile apps specifically supporting the care of patients receiving physiotherapy.

Acknowledgments

This study was supported by a University of Melbourne Early Career Researcher Grant Scheme (MM). KLB is supported by a National Health & Medical Research Council Leadership Investigator Grant (1174431). RSH is supported by a National Health & Medical Research Council Senior Research Fellowship (1154217).

Conflicts of Interest

RSH and KLB designed the app My Exercise Messages, which was included in this systematic review. They were not involved in the screening or data extraction or analysis processes for any app in this review. KLB also reports receiving royalties from Wolter Kluwers for production of the UpToDate knee osteoarthritis clinical guidelines.

Abstract

Background: Home assessment is a critical component of successful home modifications, enabling individuals with functional limitations to age in place comfortably. A high-quality home assessment tool should facilitate a valid and reliable assessment involving health care and housing professionals, while also engaging and empowering consumers and their caregivers who may be dealing with multiple functional limitations. Unlike traditional paper-and-pencil assessments, which require extensive training and expert knowledge and can be alienating to consumers, mobile health (mHealth) apps have the potential to engage all parties involved, empowering and activating consumers to take action. However, little is known about which apps contain all the necessary functionality, quality appraisal, and accessibility.

Objective: This study aimed to assess the functionality, overall quality, and accessibility of mHealth home assessment apps.

Methods: mHealth apps enabling home assessment for aging in place were identified through a comprehensive search of scholarly articles, the Apple (iOS) and Google Play (Android) stores in the United States, and fnd.io. The search was conducted between November 2022 and January 2023 following a method adapted from PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses). Reviewers performed a content analysis of the mobile app features to evaluate their functionality, overall quality, and accessibility. The functionality assessment used a home assessment component matrix specifically developed for this study. For overall quality, the Mobile Application Rating Scale (MARS) was used to determine the apps' effectiveness in engaging and activating consumers and their caregivers. Accessibility was assessed using the Web Content Accessibility Guidelines (WCAG) 2.1 (A and AA levels). These 3 assessments were synthesized and visualized to provide a comprehensive evaluation.

Results: A total of 698 apps were initially identified. After further screening, only 6 apps remained. Our review revealed that none of the apps used thoroughly tested assessment tools, offered all the functionality required for reliable home assessment, achieved the "good" quality threshold as measured by the MARS, or met the accessibility criteria when evaluated against WCAG 2.1. However, DIYModify received the highest scores in both the overall quality and accessibility assessments. The MapIt apps also showed significant potential due to their ability to measure the 3D environment and the inclusion of a desktop version that extends the app's functionality.

Conclusions: Our review revealed that there are very few apps available within the United States that possess the necessary functionality, engaging qualities, and accessibility to effectively activate consumers and their caregivers for successful home modification. Future app development should prioritize the integration of reliable and thoroughly tested assessment tools as the foundation of the development process. Furthermore, efforts should be made to enhance the overall quality and accessibility of these apps to better engage and empower consumers to take necessary actions to age in place.

Introduction

Home modifications are essential procedures for individuals with various functional limitations, enabling them to live independently within their own community. Traditionally seen as targeted biopsychosocial interventions, these modifications aim to address the functional limitations experienced by aging adults and individuals living with disabilities in their home environments. Additionally, home modifications are frequently used as part of hospital discharge planning after medical treatments such as geriatric and stroke rehabilitation [1,2]. Conducting a timely home assessment using a valid instrument and promptly implementing home modifications is crucial in assisting individuals recovering from medical procedures. These steps help maintain their functional abilities and ensure a reasonable quality of life in their homes [1,3,4].

The current gold standard for home modifications necessitates a systematic home assessment conducted by trained professionals, often performed by occupational therapists, as a prerequisite [3]. However, accessing such services remains challenging for many consumers [2,5,6]. Several contributing factors include (1) the lack of standardized and validated assessments and limited knowledge of best practices [7]; (2) the shortage of professionals trained to conduct these assessments, particularly in rural areas [6,8-10]; (3) the consumer's perceived burden from participating in comprehensive assessments [11,12]; and (4) the complexity and cost involved in conducting home assessments [13-16].

Reliable and validated home assessment tools do exist, albeit in a paper-and-pencil format. In a systematic review of the psychometric properties of available home accessibility assessment tools, Patry et al [7] identified several tools that meet critical psychometric properties, including In-Home Occupational Performance Evaluation (I-HOPE) [17], I-HOPE Assist [18], Housing Enabler (HE) [19,20], Comprehensive Assessment and Solution Process for Aging Residents [21], and Home and Community Environment [22]. However, challenges still exist in using these tools, such as the laborious and time-consuming measurement process and the difficulty in getting reimbursement for the cost of an occupational therapist's time [23]. The lack of objective environmental measurement has also been identified as a weakness of these tools, except for the HE [24].

The cost barrier and limitations in objectively measuring the physical environment have prompted researchers to explore the use of teleconferencing for remote home assessment tools [8,9,25]. More recently, several entities have started developing mobile health (mHealth) apps that integrate 3D modeling [26], virtual reality [27], and augmented reality (AR) tools [28,29] to measure, store, and share spatial data required for home modification solutions. However, what remains less understood and documented are the functionality, quality, and accessibility of mHealth apps. This is problematic as the number of mHealth apps for home assessment continues to increase, and there is no available evidence-informed guidance on which ones to use and why.

Therefore, the objective of this study was to systematically identify and evaluate publicly available mHealth apps available in the United States that focus on home modification in the context of aging in place, using three important criteria: (1) comprehensiveness of functionality, (2) overall quality leading to consumer engagement and follow-up actions, and (3) accessibility. A well-developed tool with all necessary functions can help professionals and consumers perceive that the app possesses the features and qualities they need to support collaboration with home modification providers in achieving desired goals [10,30].

Methods

App Identification

The research team conducted a systematic search across multiple information sources, including a database search of peer-reviewed journal papers on home assessment, the Apple (iOS) and Google Play (Android) stores in the United States, and fnd.io. The team followed PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses [31]) guidelines whenever applicable (Multimedia Appendices 1 and 2) and referred to reviews focused on mHealth apps [32-34]. The initial search was conducted between November 2022 and January 2023.

The first author (JS) conducted a search of 4 databases, including Academic Search Premier, APA PsycInfo, Consumer Health Complete—EBSCOhost, and MEDLINE. The search terms used were ("home assessment" or "home modifications" or "home mods" or "home adaptations") AND "occupational therapy" AND (technology or application or computer or tablet or mobile phone or smartphone or internet). Titles and abstracts were then reviewed using the following criteria:

- Years considered: 1990-2022
- Language: English
- Publication status: Published
- Publication type: Includes articles in peer-reviewed journals, encompassing all types of publications
- Home assessment focus: Accessibility, covering parts of or the entire house
- Types of functional limitations: All forms of functional limitations, including both physical and mental

- Exclusion criteria: Gaming apps for occupational therapy or medical training and exclusive use of technology for communication (telehealth)

In addition to articles on individual apps, the database search yielded 3 recent research publications conducting a meta-analysis of home assessment tools [10,23,35], prompting further manual searches.

The app store search was carried out by JL. JL systematically conducted individual searches on the Google Play store using a Samsung Galaxy S21 phone and on the Apple App Store using an iPhone 11. The search terms used were consistent with those used in the database search. To ensure comprehensive coverage of potentially relevant apps, the same method was applied to searches on the fnd.io website by the author RS.

All 3 reviewers (JS, RS, and JL) convened to establish common exclusion criteria and reach consensus on the final list of apps for analysis. The exclusion criteria encompassed (1) apps not intended for home assessment; (2) unstable operations that impeded effective use, such as frequent crashes and errors; (3) regional restrictions that limited access to certain apps for US users; and (4) apps with dubious objectives, such as prioritizing product promotion over facilitating home modifications for enhanced accessibility.

Data Extraction

Between January 2023 and March 2023, three distinct tools were used to evaluate the quality of the chosen apps: an app component matrix developed for this study, the Mobile App Rating Scale (MARS) [36], and the Web Content Accessibility Guidelines (WCAG) 2.1 (created by the World Wide Web Consortium) [37].

The analysis of app components focused on evaluating the features, capabilities, and operations of each home assessment tool to understand its usefulness compared with traditional paper-and-pencil evaluations [23]. The primary objective of this evaluation was to assess the potential of each app to be effectively used by professionals or consumers in the field. Traditional and validated home assessment tools, such as I-HOPE [17] and HE [38,39], typically enable evaluators to assess the functional limitations of residents and evaluate the physical aspects of the home environment to identify necessary adjustments for the identified functional limitations. These assessments typically do not encompass suggestions for subsequent home modifications, as such considerations lie beyond the purview of home assessments. Nonetheless, given that a significant number of the reviewed apps featured recommendations, the incorporation of recommendations was introduced into the component matrix for this study. Overall, the examination centered on assessing whether each app empowers users to appraise functional limitations, conduct home environment assessments (through checklists or measurements), generate assessment outcome reports, and offer recommendations.

The MARS is a reliable and objective tool used for classifying and assessing the overall quality of mHealth apps [36]. Unlike star ratings in app stores or subjective app reviews, the MARS provides a systematic approach to evaluate mHealth apps, offering a more comprehensive and reliable measure of their quality. Studies conducted by Stoyanov et al [36] and Terhorst et al [40] have reported a high level of construct and concurrent validity, as well as reliability and objectivity, with an intraclass correlation coefficient ranging between 0.82 and 0.85. This indicates a strong level of consistency among different MARS raters, further highlighting the reliability of the scale. Moreover, the MARS has been used by researchers to assess the ability of mHealth apps to engage and activate patients [34].

The MARS consists of 3 main components: App Quality Questions, App Subjective Quality Questions, and App Specific Questions. The App Quality Questions cover various categories to provide a comprehensive evaluation of the app. These categories include engagement (A), functionality (B), aesthetics (C), and information quality (D). The engagement category assesses factors such as fun, interest, individual adaptability, interactivity, and target group. Functionality focuses on the app's performance, usability, navigation, and gestural design. Aesthetics evaluates the layout, graphics, and visual appeal of the app. Information quality examines the accuracy, quantity, and quality of information provided, including the credibility and evidence base of the app.

In addition to the App Quality Questions, the MARS includes App Subjective Quality Questions to capture the reviewer's personal opinion and the perceived impact on the user. The reviewer's personal opinion (E) covers aspects such as app recommendation, willingness to pay for it, anticipated frequency of usage, and an assigned star rating. The perceived impact on the user (F) assesses how the app affects the user's knowledge, attitudes, intentions to change, and the likelihood of actual change in the target health behavior.

Each question in the MARS is aligned with a 5-point scale (1=inadequate, 2=poor, 3=acceptable, 4=good, 5=excellent). This scale provides a standardized framework for rating the app's performance across different categories. The unique structure and scale of the MARS allow reviewers to holistically evaluate mobile apps, considering both objective quality indicators and subjective assessments.

The research team also used the WCAG 2.1 [37]. These guidelines are designed to make web content more accessible to all users but is highly relevant to web and nonweb mobile phone content [41]. Considering that the target population of home assessment apps includes people with functional limitations, ensuring accessibility is deemed critical for the successful deployment of these apps. In comparison with the MARS rating, which primarily provides a general evaluation of mHealth apps, the WCAG assessment offers a comprehensive framework for evaluating accessibility criteria.

The WCAG 2.1 has four criteria categories: (1) perceivable, (2) operable, (3) understandable, and (4) robust. The "perceivable" category highlights the importance of users being able to perceive all presented information using their available senses. "Operable" refers to an interface that is easily navigable and usable by a wide range of users. The "understandable" category includes criteria ensuring that users should have no difficulty comprehending both the content and the user interface. Lastly, "robust" ensures that the content is consistently and accurately

interpreted by a diverse range of user agents, including assistive technologies.

WCAG 2.0 was initially released in December 2008 and was adopted into Section 508 of the Rehabilitation Act (29 USC 794d) in 2018. Any project receiving federal funds must adhere to Section 508 of the Rehabilitation Act. WCAG has 3 conformance levels: A, AA, and AAA, with level AAA being the highest level. To understand how WCAG operates, it is crucial to recognize that content meeting a higher level of compliance also satisfies all the criteria of a lower level. Additionally, it is worth highlighting that achieving full compliance with high-level standards is uncommon among apps, mainly due to the inherent difficulties and resource-intensive nature involved in meeting these criteria. This study used both the A and AA levels of WCAG 2.1 to evaluate the accessibility of all identified apps.

Data Analysis

The identified mHealth apps underwent testing and assessment by 3 reviewers (RS, JL, and ZS), with each being evaluated one at a time. All apps were installed and tested using an iPhone 13. The diverse training backgrounds of the 3 reviewers represented a mix of professionals likely to use or be involved in app development. ZS brings 2 years of experience in occupational therapy. RS has training and professional experience in architecture and landscape architecture, with substantial knowledge of building accessibility. JL's training encompasses interior design, user interface design, and graphic design expertise; she also has substantial knowledge of building accessibility.

The reviewers individually examined each app and determined if it included assessment components commonly found in traditional paper-and-pencil home assessment tools: functional limitations, physical environment assessment area, mode of measurement (checklist vs measurement), final report, and recommendations. As they evaluated these components, they considered observations during app usage and information from the app store. The components were agreed on during a postassessment meeting before being included in a matrix.

The MARS rating procedures followed the recommendations specified in the original study [36]. All 3 reviewers familiarized themselves with the MARS and watched the training video to gain a thorough understanding of its components and dimensions. Before assessing apps, they engaged in extensive discussion and consensus building to clarify the meaning and relevance of each MARS assessment item.

Subsequently, the reviewers extensively used each selected app for review to gain a comprehensive understanding of its features, functionality, content, and user experience. After individually assessing the apps, the reviewers convened to reach a consensus on the final scores and tabulated the mean scores. The mean scores were compiled from each section of the MARS, namely, (A) engagement, (B) functionality, (C) aesthetics, and (D) information. The app quality mean score was calculated by averaging the scores from these 4 sections. App subjective quality (E) and app-specific (F) scores were separately averaged and treated as distinct measures. The questions in the (F) section, which evaluate the perceived impact of the app on the user's knowledge, attitudes, intentions to change, and the likelihood of actual change in the target health behavior, were specifically responded to considering the target behavior of home assessment and modification, aligning them with the scope of this study. The agreed-on ratings were then compiled into a matrix to facilitate comparisons and analysis of ratings and data across the apps.

The accessibility assessment involved checking apps against all WCAG 2.1 criteria. During a preassessment meeting, the reviewers engaged in a detailed discussion of each of the 50 WCAG criteria. They collaboratively developed concise descriptions in the newly created WCAG evaluation form (Multimedia Appendix 3) and established a consensus on how to assess the apps based on these criteria. Individually, the reviewers assigned a pass, fail, or NA (not applicable) designation to each of the 50 WCAG criteria. The NA designation was used when a particular criterion covered a function that was not present in the app being evaluated.

In the postassessment meeting for each app, the reviewers convened to deliberate on the designations for each WCAG criterion and worked together to reach a consensus. Subsequently, the passing percentage for each WCAG category (perceivable, operable, understandable, and robust) was calculated, along with an overall passing percentage. The passing percentages were determined by excluding any criteria assigned an NA designation from the calculation.

The results of the quality and accessibility appraisal were visualized in a map. The map represents the quality appraisal using the MARS on the horizontal axis and WCAG 2.1 on the vertical axis. To enhance the objectivity of the MARS as a measure of app quality [36], we used the average score from the objective MARS items on the horizontal axis. On the vertical axis, we considered 2 levels of WCAG 2.1, namely, A and AA. Apps that scored higher on both parameters indicate high quality and accessibility, suggesting a greater potential for user engagement and activation [34,36].

Results

Identification

The initial database search yielded 104 articles, which were then reduced to 36 after eliminating duplicates. Among these, 3 meta-analyses on home assessment tools were included. After a comprehensive review of all identified articles from the database search, 3 mHealth apps were identified: HESTIA, MapIt Mobile, and Magicplan. After an initial assessment of downloadable apps, HESTIA was excluded due to its ongoing development and unavailability for download.

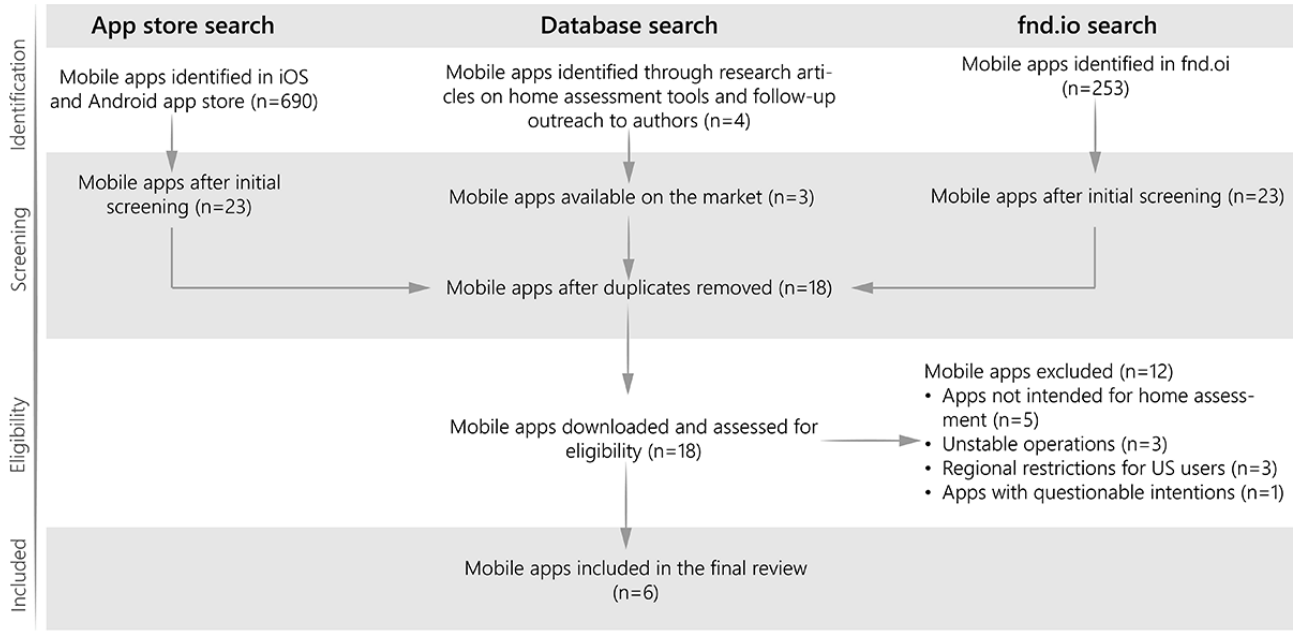
On engaging with the development team of MapIt, it was discovered that the desktop version of the app offered significantly enhanced functionality compared with its mobile counterpart. Because of the distinct interfaces between the 2 versions, separate evaluations were conducted for each. Although MapIt Desktop is not classified as an mHealth app, it was included in the evaluation due to its close association with the mobile app and its robustness in offering 3D

measurement capabilities in the context of home assessment, which were not found in any other apps.

The initial app store search yielded a substantial 690 apps. After reviewing titles, descriptions, preview photos, and keywords, 23 apps remained. The fnd.io search yielded a total of 253 apps, which were then narrowed down to 16 apps using the same screening method used for the app store search.

After removing duplicates from all 3 sources, 18 apps remained, all of which were downloaded for eligibility evaluation. Eventually, 12 apps were eliminated due to exclusion criteria, leaving 6 apps for detailed analysis: BEAT-D, DC Carehomes, DIYModify, HomeFit AR, MapIt Mobile, and MapIt Desktop (Figure 1).

Figure 1. Identification process of mobile health apps for home assessment in the United States.



Characteristics of the Included Apps

The characteristics of the included apps are presented in Table 1. Of the 6 apps reviewed, 4 (67%) apps were developed in university settings, 1 (17%) app was developed by a private company, and 1 app was developed by AARP, a nonprofit organization in the United States. Geographically, 3 (50%) apps (BEAT-D, DC Carehomes, and DIYModify) were developed in Australia, whereas 2 (33%) apps (MapIt Mobile and MapIt Desktop) were developed in Canada. The latter 2 apps were developed by the same entity, and they are functionally complementary to each other. Of the 6 apps, 1 (17%) app (HomeFit AR) was developed in the United States.

All the apps were designed for the iOS environment. Moreover, DC Carehomes and DIYModify were also developed for the Android platform. All apps were free to download. None of the reviewed apps were categorized as medical products nor had they published trials evaluating the effectiveness of the apps.

Among the 6 apps, only 2 (33%) apps (MapIt Mobile and MapIt Desktop) allowed the users to take actual measurements of the environment. These apps provided a feature for users to gather specific measurements. In contrast, all other apps were questionnaire-based interactive decision-making tools that asked a series of questions to the users as part of the home assessment process (Tables 1 and 2).

Table 1. Operating characteristics and summary of identified mobile health apps.

App name	Logo	Platform and operating system	Developer	Assessment characteristics: app summaries
BEAT-D		Mobile, tablet, and iOS	University of Wollongong, Australia	Questionnaire: a guided questionnaire assessment for buildings designed to accommodate individuals with dementia. The user's responses are compiled into a comprehensive report, which identifies areas that need improvement in order to reduce confusion, agitation, and depression.
DC Carehomes		Mobile, web, tablet, iOS, and Android	Private Company: Hammond Care, Australia	Questionnaire: a guided questionnaire assessment for care homes, units, or households catering specifically to individuals with dementia. The app generates a comprehensive report that offers recommendations based on the assessment findings.
DIYModify		Mobile, iOS	University of New South Wales, Australia	Questionnaire: an interactive decision-making tool that concentrates on 5 particular home modifications and provides guidance. It helps users select appropriate product types that match their needs and offers instructions on taking necessary measurements before shopping for home modifications. The app includes real-life stories of individuals who have undergone these specific adaptations, allowing users to learn from their experiences.
HomeFit		Mobile, tablet, and iOS	Nonprofit: AARP, United States	Questionnaire: an interactive decision-making tool assists users in identifying potential home improvements for aging in place. The app generates a comprehensive report, including tips, suggestions, and a checklist, based on the user's responses. The checklist distinguishes between tasks suitable for do-it-yourself and those requiring professional assistance. While the app uses AR[a] to recognize specific features such as a kitchen sink, it does not use AR for actual measurement purposes.
MapIt		Mobile, tablet, iOS, and Android	University of Sherbrooke, Canada	Measurement: the app uses AR and the LiDAR[b] sensor on the phone to create a 3D scan of a room. Users can then add measurements to specific areas of interest within the scan, catering to accessibility needs. The scan can be exported and viewed in the MapIt Desktop version, enhancing the overall measurement experience.
MapIt Desktop		Windows desktop, Mac OS X, and Windows	University of Sherbrooke, Canada	Measurement: this desktop app leverages MapIt on an iPhone to capture 3D scans of rooms, which can subsequently be imported to facilitate space measurements.

[a]AR: augmented reality.

[b]LiDAR: Light Detection and Ranging.

Table 2. Functional components and mode of assessment of the reviewed apps.

App name	Functional assessment	Environmental assessment				Summary report	Recommendation	Mode of assessment
		Entrance	Bathroom	Kitchen	Bedroom			
BEAT-D	—[a]	N[b]	N	N	N	Yes	Yes	Checklist
DC Carehomes	—	N	N	N	N	Yes	Yes	Checklist
DIYModify	—	T[c]	T	—	—	—	Yes	Checklist

MapIt Mobile	—	Generic	Generic	Generic	Generic	—	—	Measurement
MapIt Desktop	—	Generic	Generic	Generic	Generic	—	—	Measurement

[a]Not available.

[b]N: nontargeted.

[c]T: targeted.

Component Analysis of the Included Apps

Table 2 includes a summary of the component analysis. Among the 6 apps assessed, none of them considered the functional limitations of the resident. Consequently, none of the apps enabled the evaluation of the physical environment tailored to the resident's individual functional capacities.

DIYModify and HomeFit AR stood out by delivering concentrated assessments for certain critical spaces, notably the entrance, bathroom, kitchen, and bedroom, designated as "targeted" (T) in Table 2. DIYModify, in particular, enabled users to assess essential elements within entrance and bathroom areas, while HomeFit emphasized assessment of the bathroom, kitchen, and bedroom areas. However, it is worth noting that no single app assessed all of the key areas comprehensively. Conversely, the remaining apps either lacked specific evaluations for the designated target spaces—although they did include questions related to those areas, classified as "nontargeted" (N)—or presented generalized assessment tools adaptable to any area, categorized as "Generic" in Table 2.

The reporting modules within these apps should ideally furnish a concise overview of assessment findings on each evaluation's conclusion, aiding users in comprehending the assessment outcomes and strategizing potential home modifications. Among the 6 apps under scrutiny, only HomeFit, DC Carehomes, and BEAT-D yielded a comprehensive report after completion of the assessment. Notably, HomeFit AR, DIYModify, DC Carehomes, and BEAT-D offered recommendations. Conversely, DIYModify omitted the provision of a report, whereas both MapIt Mobile and Desktop were deficient in both report and recommendation functionalities.

Quality Appraisal of the Included Apps: MARS

The MARS scores for the 6 parameters of (A) engagement, (B) functionality, (C) aesthetics, (D) information, (E) subjective rating of the app overall, and (F) subjective ratings of app-specific features are presented in Table 3. Very few apps received a rating of "good" (4 or above [36]) across the measured parameters, although many of them achieved an "acceptable" (3 or above and below 4) range.

Table 3. Mobile Application Rating Scale (MARS) objective and subjective quality criteria and the assessment result.

App name	Objective quality					Subjective quality		
	(A) engagement	(B) functionality	(C) aesthetics	(D) information	Overall objective quality	(E) app overall	(F) app specific	Overall subjective quality
BEAT-D	1.6	3.75	3.3	3.4	3.0	2	3.0	2.5
DC Carehomes	2	3.5	3.3	4[a]	3.2	2	3.2	2.6
DIYModify	3	3.75	4[a]	4[a]	3.7	3.5	4.7[a]	4.1[a]
HomeFit AR	2.8	3	3.7	2.83	3.1	1.75	2.7	2.2
MapIt Mobile	3	2.75	3	3.25	3.0	3	1.5	2.3
MapIt Desktop	3.2	3.5	3.7	3.25	3.4	3.5	2.5	3

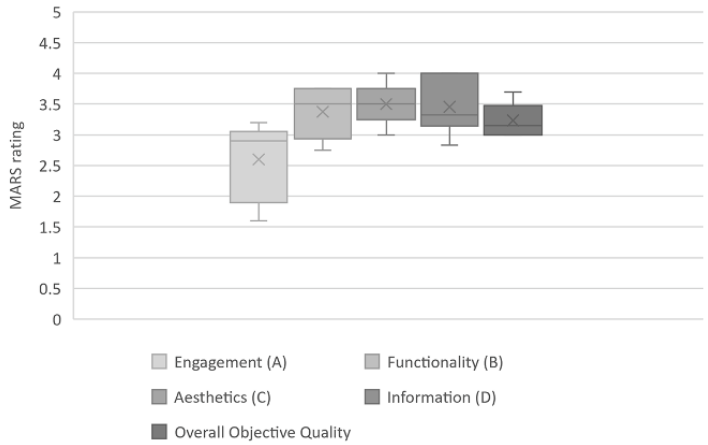
[a]Apps considered "good" (4 or above) under subcategories of the MARS assessment criteria.

When using the MARS objective quality criteria, none of the apps were rated as good in the categories of (A) engagement and (B) functionality. In the (C) aesthetic category, only DIYModify achieved a good rating with a score of 4. In the (D) information category, 2 apps, namely DC Carehomes and DIYModify, scored 4 and were thus classified as good. However, when considering the overall objective quality of the apps (mean of A, B, C, and D), none of the apps reached the threshold of 4.

Ratings for the MARS subjective quality were even lower. None of the reviewed apps reached the threshold of "good" in the (E) subjective rating of the app overall, and only half of them reached an "acceptable" level. Apps performed similarly in (F) subjective ratings on the app-specific features. However, DIYModify achieved an exceptionally high score of 4.7 out of 5. The incorporation of real-life video stories showcasing practical and effective home modifications within the app contributed to the high score, as it significantly enhanced the app's potential to positively influence the user's knowledge, attitudes, and actual behavior change in relation to home assessment.

When considering all reviewed apps together and focusing solely on the MARS objective quality criteria, the apps showed a tendency to perform better in the (C) aesthetics category (range 3-4; mean 3.50, SD 0.35) and (D) information category (range 2.84-4; mean 3.46, SD 0.46). However, their performances in (A) engagement were much lower (range 1.6-3.2; mean 2.6, SD 0.64; Figure 2). This discrepancy may be attributed to the "customization" score under the (A) engagement category, which scored the lowest (mean 1.33, SD 0.82 out of 5). On the other hand, the "gestural design" under the (B) functionality category scored the highest (mean 4, SD 0.63 out of 5), contributing to a slightly higher overall "functionality" score.

Figure 2. Box and whisker plot of the MARS objective quality assessments of all apps. MARS: Mobile App Rating Scale.



Accessibility Appraisal of the Included Apps: WCAG 2.1

The results from the accessibility evaluation using WCAG 2.1 are presented in Table 4. None of the reviewed apps conformed to either the A or AA version of WCAG 2.1. Conformance to these standards means that there is no content that violates the success criteria [42]. Considering that the multitude of criteria and any single issue such as a broken link or lack of voice-over recognition of a piece of text can cause an app to fail, this outcome is not surprising.

When evaluated against the overall success criteria for WCAG 2.1A, which is the most used standard in the field to meet basic accessibility requirements, apps achieved a conformance rate ranging from 65% to 86%. However, this range dropped to 53% to 71% when evaluated against WCAG 2.1AA. BEAT-D and DIYModify received the highest ratings in both evaluations (Table 4).

It is worth noting that all apps fulfilled at least 1 or 2 subcriteria of the WCAG. For example, DIYModify met all criteria under the "understandable" and "robust" categories of both the A and AA versions of WCAG 2.1. BEAT-D also met both criteria but only for WCAG 2.1A. Furthermore, all apps met the "robust" criteria of WCAG 2.1A (Table 4).

On examining the individual assessment items, we found that all apps passed at least a couple of items in each success criterion. In the "perceivable" category, all apps successfully met the assessment items of info and relationships (1.3.1) and meaningful sequence (1.3.2). Similarly, in the "operable" category, all apps passed the assessment items of 3 flashes (2.3.1) and pointer cancellation (2.5.2). Moving to the "understandable" category, the apps fulfilled the assessment items of language of page (3.1.1), language of parts (3.1.2), on focus (3.2.1), consistent navigation (3.2.3), and consistent identification (3.2.4). Lastly, in the "robust" category, the apps satisfied the assessment items of parsing (4.1.1) and name, role, value (4.1.2).

However, none of the reviewed apps managed to pass 3 assessment items. These items include resize text (1.4.4), which evaluates the ability to zoom in and enlarge text; reflow (1.4.10), which assesses the ability to reflow and adjust the content to fit the screen when zoomed in; and text spacing (1.4.12), which examines the ability to customize text characteristics. All these criteria are measured against the WCAG 2.1 AA level standards.

Table 4. Web Content Accessibility Guidelines (WCAG) 2.1 assessment success criteria and the assessment.

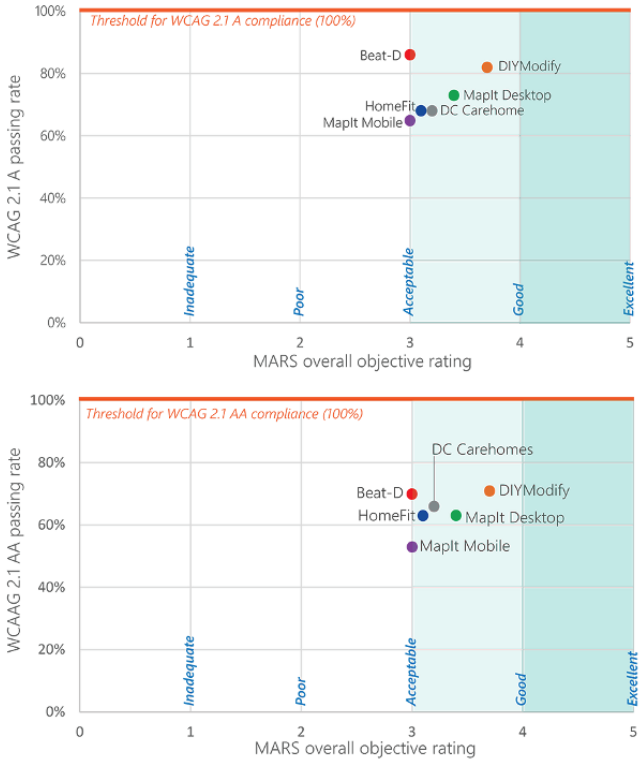
App name	Success criteria for WCAG 2.1 A					Success criteria for WCAG 2.1 AA				
	Perceivable	Operable	Understand-able	Robust	Overall passing	Perceivable	Operable	Understand-able	Robust	Overall passing
BEAT-D	4/5	7/9	5/5[a]	2/2[a]	0.86	6/13	9/12	9/9[a]	2/3	0.70
DC Carehomes	4/5	6/10	73/5	2/2[a]	0.68	8/13	8/13	7/9	2/3	0.66
DIYModify	6/9	6/7	4/4[a]	2/2[a]	0.82	8/17	8/9	7/7	2/2[a]	0.71
HomeFit AR	5/5[a]	4/8	2/4	2/2[a]	0.68	8/12	4/10	6/8	2/2[a]	0.63
MapIt Desktop	1/4	7/10	3/4	2/2[a]	0.65	1/11	8/13	6/7	3/3[a]	0.53
MapIt Mobile	1/4	8/8[a]	3/5	2/2[a]	0.73	4/11	8/10	6/9	2/2[a]	0.63

[a]Apps fulfilled a subcriterion of the WCAG 2.1. These items show that all apps met at least 1 or 2 subcriteria of the WCAG 2.1 despite their failure to meet WCAG 2.1 in its entirety.

The Objective Quality and Accessibility: Visual Synthesis of MARS×WCAG

The synthesis of the results from the MARS objective quality and WCAG assessments is visually represented in Figure 3. This visualization illustrates the performance of different apps based on the MARS overall objective quality appraisal and the WCAG 2.1 accessibility criteria. Although none of the apps met the thresholds to be considered both accessible and "good" according to WCAG 2.1 A and MARS, respectively, all of them were fairly close to these thresholds. Notably, DIYModify and MapIt Desktop achieved high scores for both accessibility and the MARS objective quality. While BEAT-D performed well in terms of accessibility, there is room for improvement in its overall MARS quality. On the other hand, HomeFit AR, MapIt Mobile, and DC Carehomes scored lower in both accessibility and MARS objective quality (Figure 3).

Figure 3. The visualization of apps' MARS quality and accessibility using the WCAG 2.1 A and AA criteria. This visualization indicates that all reviewed apps fall within the "acceptable" range, yet they fall short of achieving the "good" range as measured by the MARS tool. None of the apps managed to meet accessibility compliance when evaluated against both WCAG 2.1 A and AA standards. The lower visualization illustrates a greater level of challenge in meeting the WCAG 2.1 AA standard, which is a more stringent criterion than WCAG 2.1 A. MARS: Mobile App Rating Scale; WCAG: Web Content Accessibility Guidelines.



Discussion

Principal Findings

mHealth apps are expected to empower users with the capability to assess an individual's functional capacities and the environmental conditions crucial for comprehensive home evaluations [43]. Key areas such as the entrance, bathroom, kitchen, and bedroom hold significant importance in home assessments, which is reflected in conventional paper-and-pencil assessment tools and should thus be integral components of the app [21,38]. Furthermore, these apps should not only offer a succinct summary of the assessment but also motivate users to take up the subsequent steps after assessment, fostering engagement among all parties involved, including health care and housing professionals, as well as consumers and their caregivers. The manner in which these apps facilitate these processes should embody comprehensiveness, engagement, and accessibility.

Our findings demonstrate that, currently, there are no apps available in the United States that meet all of these criteria. Specifically, none of the apps allowed for the assessment of functional limitations of consumers, a crucial element in identifying areas requiring assessment. The MARS ratings revealed that all the apps were near the lower threshold of the acceptable range, with the exception of DIYModify; however, none of them reached the "good" range. The low scores in the "engagement" category, in particular, need further exploration as significant factors contributing to these apps' lower ratings. Furthermore, none of the reviewed apps met the accessibility criteria.

Despite these findings, our team notes that DIYModify scored the highest in our multidimensional assessment. We also observed that when used collectively, MapIt Mobile, MapIt Desktop, and the creator's instruction website demonstrate strong potential. Although we assessed them separately based on the parameters of our review, we found that using the entire suite together was highly effective for visualizing multiple measurements on a 3D scan. Offering an alternative viewing option on a larger screen device could prove beneficial for apps with complex user interfaces or content. On the other hand, the other apps (HomeFit AR, BEAT-D, and DC Carehomes) were

primarily questionnaire based and could have been easily accomplished without the need for an app.

Comparison With Prior Work

Our findings align with previous meta-analyses of home assessment tools, encompassing both paper-and-pencil formats as well as technology-assisted formats [10,23]. These studies have consistently revealed a lack of comprehensive and user-friendly technology tools that can be used to assess the home environment in relation to the functional abilities of its residents. Using technology to assess home environments in order to enhance accessibility and prevent falls and other injuries has remained challenging despite the rapid advancements in 3D modeling, virtual reality, and AR over the past few decades [10,23].

Within the limited pool of tools identified in previous studies, the majority were either pilot studies or exploratory qualitative studies [10]. Only a small fraction of these tools successfully transitioned into commercially available products, as confirmed by our search process across multiple app stores. Furthermore, review studies evaluating the efficacy of home assessment tools in all formats consistently demonstrated that the traditional paper-and-pencil assessment method was more effective in identifying issues [10]. This indicates a continued preference for the traditional method over digital alternatives among occupational therapy professionals. The findings of our study, which revealed that none of the reviewed apps allowed users to assess functional limitations, are in line with these earlier observations. This limitation hampers the effectiveness of the apps in detecting problematic areas and assessing accessibility.

Our study expands on previous research by evaluating the overall quality and accessibility of mHealth home assessment tools, emphasizing their significance in promoting consumer engagement and their follow-up actions. Specifically, we found that all of the reviewed apps met the minimum acceptable quality, but none reached the threshold of “good” quality. Additionally, none of the apps met the accessibility criteria as measured by the WCAG. This is a glaring omission as the home assessment and the subsequent modification are to help aid individuals with functional limitations in their home. To facilitate the active engagement and informed decision-making of older adults and individuals with functional limitations in their health care, as well as to empower them to undertake necessary home modifications, the development of apps that prioritize engagement, activation, and accessibility becomes imperative.

We anticipate that meeting this goal will remain challenging in the foreseeable future. Developing a mobile app may seem straightforward on the surface but can quickly become a multimillion-dollar project for several reasons. First, the development of mHealth apps for home assessment, with a focus on reliability, precision, and user-friendliness, necessitates robust interdisciplinary collaboration involving occupational therapists, building professionals, and user interface and user experience design experts.

Second, the inherent limitations in precision with current 3D scanning and AR technology, along with the need to meet the requirements of various devices, quickly add another layer of complexity to the endeavor [44-47]. Third, creating user-friendly apps requires extensive usability testing across diverse populations. In the case of home assessment, this involves testing with individuals exhibiting various functional limitations and their caregivers, contributing to the overall complexities and high cost of conducting such studies.

In contrast, the current funding landscape shows a tendency to prioritize research emphasizing cutting-edge scientific discovery or direct health outcomes with large-scale clinical trials. While the benefits of home modification have been studied either through indirect measures such as falls and emergency department visits via secondary data analysis [48,49], or a clinical trial [50], measuring the direct health outcome of the home assessment itself remains rather obscure.

Additionally, the transition from discovery to commercialization, as discussed earlier, introduces additional intricacies. Deploying the app in the market sustainably necessitates ongoing support, updates, and maintenance, contributing to the long-term cost of app development, which academic endeavors are not well suited for, often impeding the provision of free or affordable consumer apps. Above all, the lack of awareness and appreciation of the benefits that come from home assessments and home modification in the general public appears to be a key hindrance [11,12], discouraging adequate investment in this critical domain. With the rapid aging of the population and increasing interest and awareness from both the consumer market and the government alike, we hope that adequate resources are invested, fostering innovations in academia and the commercial realm alike.

Strengths and Limitations

Our review boasts several strengths. First, our comprehensive search encompassed scholarly databases, the US Google Play Store, Apple App Store, and fnd.io, ensuring a thorough exploration of available resources. The convergence of these searches instilled confidence in the thoroughness of our efforts. Furthermore, the significant disparity between the results of the scholarly database search and the app store search shed light on the challenges associated with translating scholarly endeavors into practical applications through the commercialization process.

Another strength lies in the complementary use of multiple rigorous assessments, focusing on both quality and accessibility. For instance, the BEAT-D app achieved a high passing percentage for WCAG criteria, yet it ranked lower in the MARS evaluation. On the other hand, MapIt Desktop had a lower score in WCAG, but ranked higher in the MARS. This discrepancy emphasizes the importance of conducting both assessments, particularly in the context of home assessment tools where individuals with functional limitations play a crucial role.

Finally, while evaluating apps with the MARS assessment is standardized and relatively straightforward, assessing apps based on WCAG criteria requires a more substantial time investment to grasp each of the 50 criteria, which is extensively explained on the WCAG’s website. To facilitate the use of WCAG, our research team has developed an evaluation form that includes

concise summaries of each criterion, which can be used in future studies, streamlining the evaluation process (Multimedia Appendix 1).

The review also presents certain weaknesses that deserve attention. First, despite our efforts to conduct a comprehensive search for all available home assessment tools, the inclusion of apps was limited by their availability in the US market. It is worth highlighting that several apps, discovered via our database search, fnd.io search, and personal connections, demonstrate promise but remain unavailable on US app stores.

Second, our testing of multiplatform apps was focused solely on the iPhone versions of all reviewed apps. This limitation was observed during the assessment of WCAG criterion 1.3.4 (orientation), which assesses the device's capacity to transition between portrait and landscape modes. Notably, the iPhone variant of BEAT-D did not meet this criterion, while the iPad version might have passed had it been evaluated. To ensure a more comprehensive assessment, it would be advantageous to test these apps on all compatible devices, including those running on Android operating systems.

Finally, while assessing apps with the MARS and WCAG provided valid insights into the overall quality and accessibility of apps based on established criteria, future studies will have to take into consideration consumer-level feedback, particularly focusing on the firsthand experiences of those with various functional capacities and their caregivers.

Conclusions

A proficient home assessment tool, designed to engage consumers, health care providers, and housing professionals, should offer reasonable functionality and possess objective quality and accessibility. However, our findings bring to light that none of the currently available home assessment mHealth apps in the United States align with these benchmarks. None of the apps offered sufficient methods to assess individuals' functional capacity and conduct comprehensive environmental assessments, and they fell short of meeting the WCAG accessibility criteria. Furthermore, although every app reached an "acceptable" level, none of them attained a "good" level in the MARS quality evaluations.

Acknowledgments

The review received funding from the RRF Foundation of Aging, the Fall Research Competition, and the School of Human Ecology at the University of Wisconsin-Madison.

Authors' Contributions

JS and RS played a leading role in conceptualizing, designing, and planning the review. App identification involved the contributions of JS, RS, and JL. Content analysis and quality or accessibility appraisal were conducted by RS, JL, and ZS under the supervision of JS. The initial draft of the manuscript was prepared by JS, incorporating the key technical findings provided by RS. All authors contributed to the manuscript by providing comments and suggestions for improvement, ultimately approving the final version.

Abstract

Background: In China, the current situation of myopia among children and adolescents is very serious. Prevention and control of myopia are inhibited by the lack of medical resources and the low awareness about eye care. Nevertheless, mobile apps provide an effective means to solve these problems. Since the health app market in China is still immature, it has become particularly important to conduct a study to assess the quality of eye-care apps to facilitate the development of better eye-care service strategies.

Objective: This study aimed to evaluate the quality, functionality, medical evidence, and professional background of eye-care apps targeting children and adolescents in the Chinese app stores.

Methods: A systematic search on iOS and Android app stores was performed to identify eye-care apps for children and adolescents. The general characteristics, development context, and functional features of the apps were described. Quality assessment of the apps was completed by 2 independent researchers using the Mobile App Rating Scale.

Results: This study included 29 apps, of which 17 (59%) were developed by commercial organizations and 12 (41%) had a design with relevant scientific basis. The main built-in functions of these apps include self-testing (18/29, 62%), eye exercises (16/29, 55%), and eye-care education (16/29, 55%). The mean overall quality of eye-care apps was 3.49 (SD 0.33), with a score ranging from 2.89 to 4.39. The overall Mobile App Rating Scale score exhibited a significant positive correlation with the subscale scores (r=0.81-0.91; P<.001). In addition, although most apps provided basic eye-care features, there are some deficiencies. For example, only a few apps were developed with the participation of medical organizations or professional ophthalmologists, and most of the apps were updated infrequently, failing to provide the latest eye-care information and technology in a timely manner.

Conclusions: In general, the quality of eye-care apps for children and teenagers in Chinese app stores is good. These apps fulfill users' needs for eye-care services to a certain extent, but they still suffer from insufficient medical background, low user engagement, and untimely updates. In order to further improve the effectiveness of eye-care apps, cooperation with medical institutions and professional ophthalmologists should be strengthened to enhance the scientific and authoritative nature of the apps. At the same time, interactive features and regular updates should be added to enhance user participation and the continuity of the apps. This study provides a reference for future development or improvement of eye-care apps, which can help promote myopia prevention and control.

Introduction

Children and adolescents are currently facing complex and serious health challenges, such as obesity, myopia, and anxiety and depression [1,2]. Children and adolescents represent the future of society; thus, more attention should be paid to their growth and development. Nearsightedness has been recognized as the most common eye disorder among children and adolescents [3]. Patients with shortsightedness experience blurred vision at a distance. High myopia is also associated with pathologic myopia, which can lead to complications such as retinal tear and detachment, macular degeneration, and irreversible vision damage [4]. Meanwhile, there is a link between shortsightedness, astigmatism, anisometropia, and amblyopia, which may interact with each other and work together to affect the visual health of children and adolescents [5,6].

A government statistical report in 2021 stated that the overall incidence of nearsightedness among Chinese children and adolescents was 52.7% and that the number of patients was about 100 million; shortsightedness is highly prevalent among children and adolescents and shows a trend of decreasing age of incidence [7]. However, prevention and control of myopia are hindered by insufficient medical resources, regional limitations, insufficient existing knowledge of healthy eye use, and low awareness about myopia [8-10]. Nevertheless, mobile health (mHealth) apps bring a new possibility to solve the aforementioned problems [10,11].

With their robust functionality, mobile apps have become a valuable tool for improving health care delivery and providing low-cost interventions [12,13]. In the domains of hypertension [14], nutrition and diet [15], exercise and medication adherence [16,17], chronic disease management [18,19], and so on, the significant effects of the use of apps on clinical, knowledge, behavioral, and psychosocial outcome improvement have been demonstrated [20,21]. Mobile apps have not only been recognized as an effective means to raise awareness of eye health [22,23], but have also efficiently provided myopia screening services and vision monitoring services [24,25].

Further integration of mobile apps with the internet has also significantly improved mHealth app accessibility [26]. Meanwhile, the number and types of apps have rapidly increased. The use of mobile apps is not limited to a specific time and place [27], which can help effectively overcome barriers such as insufficient health care resources and regional restrictions. In particular, eye-care app enables children and adolescents with no access to specialized eye education due to geographic location and economic status to receive high-quality eye-care services. Eye-care apps have attracted increasing attention with the discovery of the many advantages of mobile apps and the growing demand for eye-care services [28].

Nowadays, studies on the content and quality of eye-care apps are scarce [29]. In a study of eye-care–related apps in Chinese app stores, the researchers assessed the quality of the app through its general characteristics [30]. However, the professional background and built-in functionality of the app are also significant. The built-in functions of an app are an important reference for people to choose them, and the presence or absence of a professional background affects the user's trust on the app [31-33]. Due to the immature health app market in China [34], it becomes particularly important to conduct assessment studies on the quality of eye-care apps to facilitate the development of better strategies for eye-care services [35,36].

Therefore, this study aimed to summarize the general characteristics of eye-care apps for children and adolescents in Chinese app stores and to assess the quality of these apps. This will help users identify high-quality eye-care apps and provide a realistic basis for app development and improvement.

Methods

Systematic Search Strategy

In this study, a systematic search was performed on Chinese app stores to identify eye-care apps applicable to children and adolescents on February 15, 2023. At present, the sources of app stores are mainly categorized into third party companies and mobile phone manufacturers. According to the comprehensive ranking of Chinese app stores [37], Huawei AppGallery is the largest Android app store, and My app is the largest third-party app store in China. Therefore, Apple App Store (iOS) as well as Tencent My App and Huawei AppGallery (Android) were searched.

Through literature search and group discussion, the following keywords were used: eye care, myopia, eye health, vision, adolescent eye care, eye protection, and childhood myopia. Combining the age definition of child and adolescent as well as the age-applicable interpretation of app stores, we have added review criteria for targeted apps. The aforementioned keywords were searched in the app stores using an account that was not logged into any user, and all search results were recorded. If an app existed on both iOS and Android with identical design and content, considering the dominance of Apple App Store in app development [38], we evaluated the iOS version of the app.

Eligibility Criteria

After eliminating duplicate apps from the recorded search results, 2 researchers performed 2 rounds of app screening based on software description and usage. In the first round of screening, apps that satisfied all of the following conditions were included (Textbox 1):

Textbox 1.

Inclusion criteria

- The topic and content of the apps are related to eye care and the apps provide eye-care services
- The target audience of the apps is people needing eye-care services
- The target users of the apps are people aged 18 years or younger, and
- The apps are available in Chinese version

Exclusion criteria

- The apps focus on content unrelated to eye-care services, such as games, timers, and brightness adjustment on cell phones that do not provide eye care
- The apps are targeted only at eye-care service providers, such as doctors, nurses, research scholars, and other health professionals
- The apps do not have a Chinese version

In the second round of screening, apps were excluded if they were not successfully downloaded (after 2 attempts) or could not be logged in for use due to technical errors or special authentication.

Information Extraction

Information of the apps was extracted by 2 researchers, which included platform, developer, applicable age, last update time, star rating, number of downloads, and professional development background (Table 1). The general characteristics of the apps were described based on the information of the apps was extracted. Furthermore, through literature review and group discussion, the main functions of the eye-care apps were categorized into self-testing, eye exercises, monitoring of eye use data, eye-care education, patient record management, physical eye protection, medical consultation, online community, and eye-care mall. All disagreements were resolved through discussion between the researchers.

Table 1. General information collected for each app.

Assessment measure	Definition and values
Platform	Huawei (AppGallery), Apple (Apple App Store), Tencent (My App).
Developer	Commercial organizations, professional ophthalmology organization, individual developer.
Applicable age	Children (12 years or younger), adolescents (13-17 years).
Last update time	The latest update time when retrieving.
Star rating	Star rating (out of 5) left by users in the app store.
Downloads	Number of app downloads in the app store.
Evidence-based and professional background	Does the app claim that the design is based on relevant eye care theory, academic research, or the opinions of health professionals?

App Quality Assessment

To assess the quality of the apps more objectively, the Mobile App Rating Scale (MARS), a reliable tool for classifying and assessing the quality of mHealth apps [39], was used. MARS has been used to assess the quality of different apps, such as mental health [27], nutritional and diet-related [40,41], and chronic disease management [42,43] apps. It consists of 4 objective quality subscales of engagement, functionality, aesthetics, and information quality and 1 subjective quality subscale. As this study aimed to objectively assess the quality of apps, the subjective quality subscales were discarded. Before the formal scoring, 2 researchers randomly selected 5 apps to determine the MARS scoring rules so as to ensure that their understanding of the MARS questions and scoring criteria was consistent. To fully experience the services offered by the apps, the 2 researchers downloaded and used each app for at least 20 minutes during the formal scoring.

Data Analysis

To ensure the quality assessment reliability of the 2 researchers, within-group correlation coefficients (2-way random, average measure and absolute agreement) were used to assess researchers' agreement at the subscale and overall score level [44]. Pearson's correlation coefficients were used to explore the correlation among the overall MARS score, subscale scores, and user ratings. All statistical analyses were conducted in SPSS (version 26, IBM Corp).

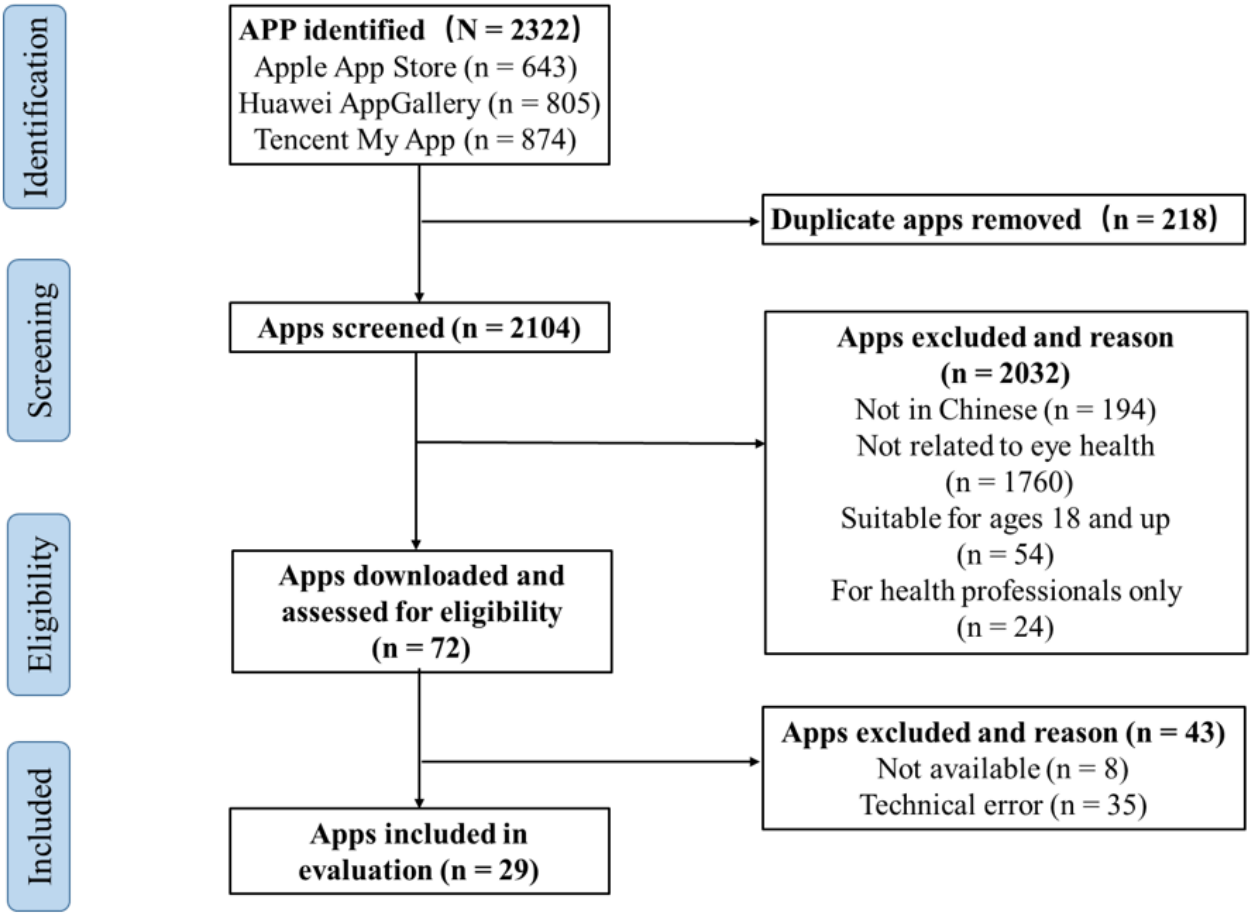
Results

App Selection

Through keyword search, 2322 apps were identified. Tencent My Apps had the highest number of apps (n=874, 37.6%), followed by Huawei AppGallery (n=805, 34.7%) and then Apple App Store (n=643, 27.7%). First, the search results of the apps were consolidated, and 218 apps were excluded due to repeated occurrence. Subsequently, 2032 (87.5%) apps were also

excluded based on the first round of screening criteria. The second round of operability screening was performed on the remaining 72 apps. Of the apps excluded in this round, 35 (48.7%) could not be downloaded or properly used due to technical reasons and 8 (11.1%) required special authentication to log in for use. Finally, after 2 rounds of screening, 29 (40.2%) apps were included in the study (Figure 1).

Figure 1. Flowchart for the systematic search and selection of apps.



General Characteristics of the App

The sources of the included apps were counted, and it was found that 18 (62%) apps were from Apple App Store, 8 (28%) from Tencent My Apps, and 3 (10%) from the Huawei AppGallery. Furthermore, more than half of the apps (17/29, 58%) were developed by commercial organizations, 8 (28%) by individual developers, and 4 (13%) by professional ophthalmology organizations. Simultaneously, based on the update time of the apps, 3 (10%) apps were updated within 1 month; 16 (55%), more than 1 month but less than 1 year; and 10 (34%), before 1 year (Table 2).

Table 2. Descriptive information on the apps reviewed.

Assessment measure	Apps, n (%)
Platform	
Apple App Store	18 (62)
Huawei AppGallery	3 (10)
Tencent My App	8 (28)
Developer	
Commercial organizations	17 (59)
Professional ophthalmology organizations	4 (13)
Individual developer	8 (28)
Applicable age	
Children	23 (80)
Adolescents	29 (100)
Last updated	
<1 month	3 (10)
>1 month and <1 year	16 (55)
>1 year	10 (35)
Evidence-based and professional background	
Participation of professional ophthalmologists	8 (28)
Verified methods and theories	3 (10)
Peer-reviewed academic research	1 (3)
Not mentioned	17 (59)

Evidence-Based and Professional Background

The details of the apps were checked, which indicated that 17 (59%) of them did not have an app design with a relevant scientific basis. As for the remaining 12 (41%) apps, their details indicated that their design was based on relevant scientific foundation: 8 (28%), designed with the involvement of medical professionals (eg, clinicians, ophthalmologists); 3 (10%), designed using a validated methodology such as ocular muscle training; and 1, designed based on scientific basis coming from peer-reviewed academic research.

Functional Review

The results of the statistical analysis indicated that eye-care apps provide a wide range of eye-care services for children and adolescents. More than half of the apps offered functions including self-testing (18/29, 62%), eye exercises (16/29, 55%), and eye-care education (16/29, 55%). About a quarter of the apps offered functions including patient record management (10/29, 34%), online community (7/29, 24%), and monitoring of eye use data (7/29, 24%). Furthermore, less than a quarter of the apps offered functions such as eye-care mall (6/29, 21%), medical consultation (6/29, 21%), and physical eye protection (5/29, 17%; Multimedia Appendix 1). The most common combination among multifunctional apps was that of self-testing and eye-care education (12/29, 41%), followed by a combination of self-testing and eye exercises (7/29, 24%).

Self-Testing

The self-testing function is mainly used to detect the user's vision level and other eye disorders. The vision testing function (18/18, 100%) was developed based on the E Vision Scale or C Vision Scale. The users participated in the test through manual selection as well as gesture and voice recognition. Meanwhile, the eye disease screening function (10/18, 56%) includes screening for color blindness, color deficiency, astigmatism, macular degeneration, and other diseases. Regular visual acuity screening of children and adolescents provides timely information on the current status of their vision and enables detection of eye disorders such as astigmatism, macular degeneration, and refractive errors.

Eye Exercises

A total of 16 apps offered the eye exercise function. The services included in this function were eye relaxation exercises, eye focus training, and amblyopia correction training. Eye exercise function is presented in the form of animations (12/16, 75%), games (6/16, 37.5%), and eye exercises (5/16, 31%). As one of the most important functions in eye-care apps, whether or not the eye exercise function has a scientific basis affects users' trust and willingness to use it. After reading the introduction of the apps offering eye exercises, only 6 apps were found to have functions based on scientific evidence, such as eye muscle training and the theory of eye exercises. Furthermore, details of the "FireEye" app clearly state that its function is developed

based on the results of big data analysis and professional optometry academic research.

Eye-Care Education

More than half of the apps (16/29, 55%) offer eye-care education function. The types of eye-care information provided include eye-care science articles (16/16, 100%), eye-care news (4/16, 25%), and eye-care instructional videos (7/16, 44%). Articles on eye-care science had the highest readership and attention. These articles focused on how to use eyes healthily and were presented in a combination of text and animation. In addition, based on the quality assessment results of the apps, eye-care education in the form of videos was found to be more attractive owing to its vivid sound and picture effects than eye-care education in the form of text.

Patient Record Management

The patient record management function is mainly used to record the vision conditions of children and adolescents at different periods. The eye diseases that can be recorded by this function include nearsightedness, hyperopia, strabismus, and amblyopia. A total of 10 apps offered the vision record management function. Further analysis of this function revealed that 6 apps not only recorded basic information, such as name, age, and recording time, but also provided patients with treatment reports or training plans based on the results of the vision records.

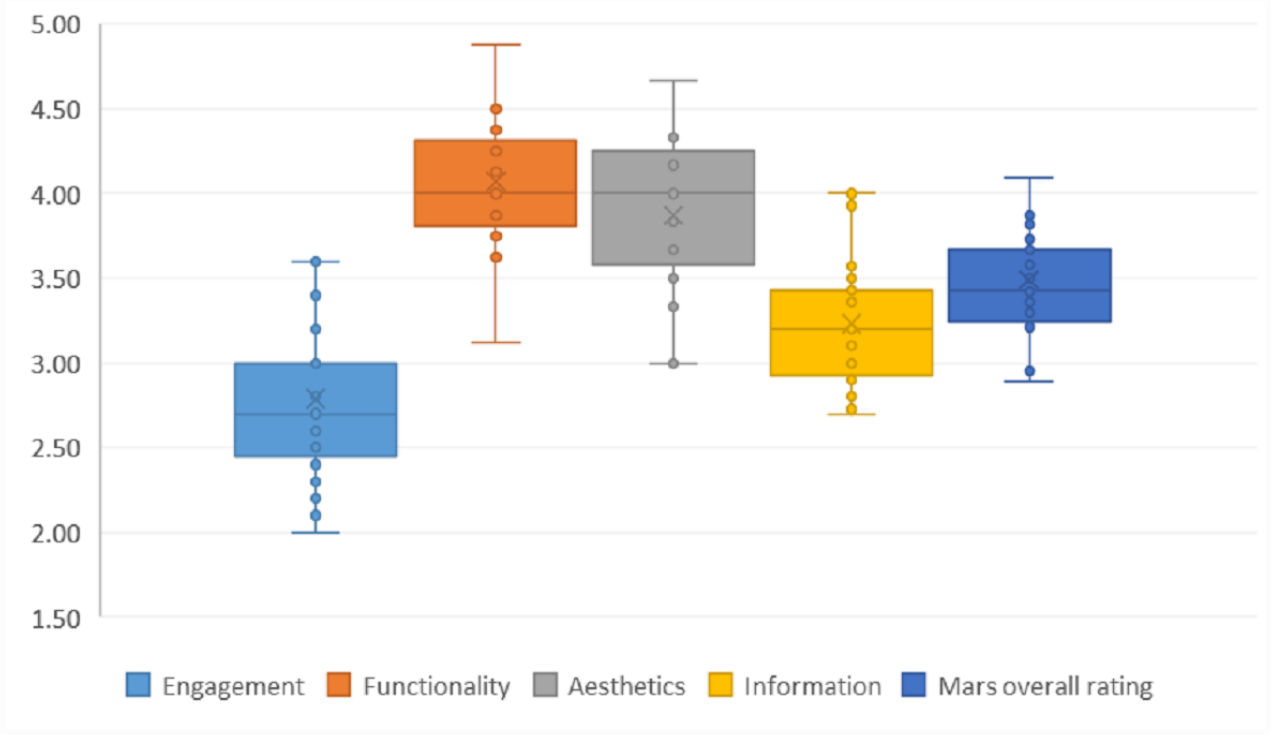
Online Community

The online community function embodies the great advantages of eye-care apps: proximity, interactivity, and convenience. The online community function exists in 7 (24%) apps, providing a social platform for eye care. In this community, doctors, patients, and others can communicate with each other through text and images. This function can effectively solve problems on consultation fees, long waiting time, and communication barriers that may exist in the actual medical service area. When users and doctors interact with each other through the platform, the distance between them is significantly shortened. Furthermore, patients suffering from the same disorder can come together to discuss the symptoms and treatment of the disease through this platform [45].

Mobile App Rating Scale Evaluation

The overall MARS scores exhibited high inter-reviewer reliability (intraclass correlation coefficient [ICC] 0.95, 95% CI 0.90-0.98). Meanwhile, the 4 subscales demonstrated good consistency: engagement ICC of 0.91 (95% CI 0.82-0.96), functionality ICC of 0.81 (95% CI 0.60-0.91), aesthetics ICC of 0.94 (95% CI 0.87-0.97), and information ICC of 0.90 (95% CI 0.79-0.95). The overall average MARS score of the eye-care apps was 3.49 (SD 0.33). The span of score between the highest scoring app (“Plano Eyes,” 4.39) and the lowest scoring app (“Eye 3D”, 2.89) was 1.5 (on 5-point Likert scale). The average scores for each subscale were as follows: engagement score, 2.79 (SD 0.47); functional score, 4.07 (SD 0.36); aesthetic score 3.87, (SD 0.43); and information score, 3.23 (SD 0.36). The engagement subscale had the largest span of scores (2.0-4.0). In terms of the app score distribution, 2 apps had MARS scores above 4 and 2 apps with scores below 3. Figure 2 presents the distribution of the overall quality of the apps and the scores on the 4D subscales.

Figure 2. Graphical representation of the distribution of the Mobile App Rating Scale overall and subscale score (N=29).



Correlation of Mobile App Rating Scale Scores and User Ratings

Further analysis of the correlation among the MARS overall score, subscale scores, and user ratings on the app store revealed that the MARS overall and subscale scores were positively correlated (r=0.81-0.91, P<.001). Table 3 summarizes the results of the correlation analysis.

By combining the professional background of the apps and update time, apps with an update time of less than 1 month (3.66) or with a medical professional development background (3.95) were found to have an overall average MARS score higher than the overall average MARS score (3.49). Meanwhile, the overall average MARS score for apps that were updated for more than 1 year (3.33) or did not have a background in medical specialty development (3.39) was lower than the overall average MARS score.

Table 3. Correlation between the Mobile App Rating Scale subscale and the overall score and the user star score.

Characteristic	Engagement, correlation	Functionality, correlation	Aesthetics, correlation	Information, correlation	Overall rating. correlation
Engagement	—[a]	—[a]	—[a]	—[a]	—[a]
Functionality	0.40	—[a]	—[a]	—[a]	—[a]
Aesthetics	0.46[b]	0.54[b]	—[a]	—[a]	—[a]
Information	0.73[c]	0.60[c]	0.66[c]	—[a]	—[a]
Overall rating	0.81[c]	0.75[c]	0.82[c]	0.91[c]	—[a]

[c]P≤.001.

[d]Apps with zero user star ratings were excluded.

Discussion

Principal Findings

This study discussed the general characteristics, main functions, and professional context of eye-care apps and also assessed the quality of these apps.

The main functions of the eye-care app included 9 categories: self-testing, eye exercises, monitoring of eye use data, eye-care education, patient record management, physical eye protection, medical consultation, online community, and eye-care mall. In terms of the number of built-in functions in apps, the average number of built-in functions was 3.1. In addition, the app with the most built-in functions contains 6 of the 9 categories of functions. The most common combination of functions was that of vision tests and screenings and eye-care information. The distribution of features in eye-care apps was broadly similar compared with previous studies, with an increase of 0.8 in the average number of built-in features in apps and an increase in the frequency of online community features [30,46,47]. There is a trend toward multifunctionality combination in the development of eye-care apps. Most eye-care apps in Chinese app stores include multiple eye-care–need services in one app. However, in the global app stores, these apps are usually considered to be designed for specific diseases or ophthalmic treatments, such as myopia surgery and cataract surgery [8,48].

In our count of app development backgrounds, only 1 app (FireEye) explicitly stated that its usability had been confirmed by peer-reviewed academic research. However, apps' lack of medical context can affect users' trust in them. Summary studies of apps for mental health, chronic disease management, exercise, and medication adherence found that the lack of scientific validation of apps was a recurring issue [14,18,19,22,23]. Of the 29 app developer statistics, 17 (59%) apps were developed by commercial organizations; 4 (13%), by professional ophthalmology organizations; and 8 (28%), by individual developers. These statistics indicated that the lack of involvement of medical professionals or scientific theories in the development of apps is a significant issue. Thus, the involvement of medical professionals in app design and function development is an important means to improve the professionalism of apps [15,40,49].

By counting the last update time of the apps, it was found that only 3 (10%) had been updated within 1 month and 10 (34%) for more than 1 year. Apps that are not updated for a long time may exhibit system vulnerabilities that are more easily exploited by lawbreakers, which in turn threatens the security of users' personal information [28,50]. By updating apps in a timely manner, developers can not only ensure the security of users' information but also increase the attractiveness of the apps to users by adding function modules to the apps [27,51].

Through an in-depth exploration of the functions of eye-care apps, one of the apps with a rating of more than 4 (Eye Nurse) has developed intelligence-guided diagnosis function based on artificial intelligence (AI). In this function, users can initially diagnose their disease by selecting age, gender, relevant symptoms, and disease duration. Simultaneously, the AI customer service generates a self-diagnostic report that includes a review of the condition, possible diseases, and doctor's recommendations. Initial diagnosis of patients using the intelligence-guided diagnosis function can effectively alleviate

the problem of insufficient health care resources. Existing research also confirms the feasibility of AI application to the diagnosis and treatment of relevant diseases [52-54]. The overall MARS scores for these apps ranged from 2.89 to 4.39, suggesting that the quality gap for apps was within the normal range [55]. However, these apps had lower mean scores on the engagement and information subscales (2.79, 3.23). This indicates that developers should focus on the improvement of user engagement and information quality during app development. In terms of how to improve user engagement, one of the apps with an engagement score of 4 (Plano Eyes) provided the following strategies: on the one hand, the app designed a punch-card module with daily life tasks, such as outdoor exercise, eye-care habits, and electronic use, which enhances the interaction between the app and the user. On the other hand, the app used audiovisual animations suitable for children and adolescents in eye exercises and eye-care education functions and constructed the eye exercise function in the form of a minigame. Related studies have also demonstrated that the form in which the functions of the apps are presented is an important factor influencing user engagement [56].

The mean MARS score suggests that the overall quality of eye-care apps for children and adolescents in Chinese app stores is acceptable. Meanwhile, by grouping and comparing the 2 factors of update time and presence or absence of a professional background, these 2 factors were found to have a potential association with the quality of the app. Furthermore, there may not be a correlation between user star ratings and MARS, which is consistent with the findings of quality correlation studies with mental health, family assessment, and breast cancer management apps [27,57,58], but food allergy app studies have found a strong correlation [8]. Perhaps the star ratings in the app store came from earlier versions of the app or may have been influenced by other factors and therefore do not fully represent the quality of the app [59]. Previous studies have also found that app quality depends not only on functionality but also on the content and design approach [60].

Contribution

In this study, a content analysis of eye-care apps for children and adolescents in Chinese app stores was conducted and the quality of these apps was assessed using a scale. Through the results of the study, deficiencies in eye-care apps at this stage, such as insufficient professional medical background, untimely updates, and low user engagement, were identified. At the same time, reference suggestions for the upgrading of eye-care apps were provided. In addition, we found that incorporation of AI technology may lead to technological breakthroughs in preliminary diagnosis.

Limitations and Future Work

This study has some limitations. We cannot guarantee that all apps are included or that all services (eg, connecting with a certified professional) are provided as requested. Furthermore, the app stores are constantly changing, and apps are on and off the shelves of the app store at all times. In addition, our research was conducted by only 2 researchers; thus, we were unable to advise on app development from the perspective of the target users. Therefore, as a next step, we intend to approach the subjective perspective of users requiring eye-care services to obtain the most realistic views of actual users of eye-care apps. Certainly, evaluation of the efficacy of a certain function in the app, such as relieving eyestrain and self-testing, would also be a good research direction.

Conclusions

This study analyzed the content and quality of 29 apps in Chinese app stores that are suitable for eye care for children and adolescents. The results of the study indicate that the quality of these apps is acceptable. However, the lack of medical background in apps affects user trust, leads to low app engagement, and reduces user dependence. Furthermore, apps that are not updated for a long time can threaten the security of users' information. Meanwhile, combining eye-care apps with AI technology may bring about dramatic changes in the popularity and quality of eye-care services in the foreseeable future. These findings provide a realistic basis for the improvement and development of eye-care apps in the future.

Abstract

Background: The use of mobile technology to meet health needs, widely referred to as mobile health (mHealth), has played a critical role in providing self-management support for chronic health conditions. However, despite its potential benefits, mHealth technologies such as self-management support apps for spinal cord injury (SCI) have received little research attention, and an understanding of their public availability is lacking. Therefore, an overview of these apps is needed to complement findings from the literature for a complete understanding of mHealth self-management support tools for SCI to support the selection and improvement of existing apps and the development of new ones.

Objective: This study aimed to identify and describe quantity, quality, focus, strengths, and weaknesses of self-management support apps for SCI available on major mobile app digital distribution platforms.

Methods: A systematic search of the Google Play Store and Apple App Store was conducted to identify and summarize apps for SCI that have been updated since 2017. A supplementary systematic literature review was conducted across 11 bibliographic databases to identify publications that provided more detailed descriptions of the identified apps than what is typically available in app stores. The data synthesis was guided by self-management tasks and skills taxonomies. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines informed the reporting.

Results: The 13 apps included in the final synthesis were launched between 2013 and 2021, mostly originating in the United States, with availability in 72 countries and support for 14 languages. Most apps used the Android operating system (10/13, 77%), while 31% (4/13) used iOS. The identified apps mainly focused on activities of daily living, physical activity promotion, health literacy, and therapeutic exercise. All 3 self-management tasks (medical, role, and emotional management) and most self-management skills and support activities were supported by the apps. The mean Mobile App Rating Scale score was 3.86 (SD 0.54), indicating good overall quality. No publications were found describing these apps.

Conclusions: Despite their good overall quality, as measured by the Mobile App Rating Scale assessment, the 13 identified apps, alone or combined, do not appear to offer a comprehensive self-management approach that incorporates theory-based strategies. Besides working to improve comprehensiveness, future research and practice should consider adopting new technologies, such as artificial intelligence, to enhance future self-management support apps for SCI. Furthermore, adopting new app development methods, such as low-code development platforms, could help reduce barriers to development, such as time, cost, and securing scarce expertise.

Introduction

Background

Spinal cord injury (SCI) is a life-altering condition caused by traumatic or nontraumatic events, leading to temporary or permanent disruption of the normal motor, sensory, or autonomic functions of the spinal cord. It affects the physical, social, and psychological well-being of the patient and places an important burden on health care systems, families, and communities [1]. SCI is a chronic health condition that causes multiple limitations in daily functioning, such as limitations in walking, eating, grooming, working, or caring for oneself, and secondary health conditions, such as spasticity, constipation, urinary tract infections, chronic pain, sexual dysfunction, fatigue, and mental health disorders [2,3]. Therefore, people with SCI frequently rely on specialized and costly health care services, often facing significant unmet health care needs and challenges, particularly in low- and middle-income countries. These challenges are primarily due to the costs of health care services, transportation, and limited service availability [4]. Self-management support, such as the provision of social support and equipment [5], is essential for people with SCI to independently manage the challenging symptoms, treatment, and lifestyle changes associated with having a SCI [6-8].

Besides traditional self-management support, such as in-person counseling sessions, the adoption of mobile health (mHealth) self-management support is growing in the self-management of chronic health conditions such as SCI [9]. mHealth involves using mobile and wireless information and communication technologies, including smartphones, tablets, and wearables, to support meeting health needs [10]. Therefore, mHealth provides more person-centered, available, accessible, and scalable self-management support options than many traditional alternatives, such as institutional- and paper-based options [11]. Smartphones have one of the highest adoption rates among mHealth technology [12,13] and are essential tools for improving diagnostics, personal health monitoring and tracking, access to health care, and the development of health literacy [14].

However, mHealth self-management support tools for SCI have seemingly received little research attention despite the unique self-management support necessitated by the distinctive pathophysiology of SCI. To the best of our knowledge, the most relevant overviews of these tools are provided by systematic literature reviews by Wellbeloved-Stone et al [15] and Bernard et al [16]. Although insightful, the first study does not account for the expected rapid increase in the development of mHealth tools over the last 6 years and identifies 1 tool [15], and both studies are biased toward published literature as they potentially neglect apps that are available through digital distribution platforms and are not mentioned in published literature [15,16]. While mHealth self-management support apps for chronic health conditions aim to assist people in honing self-management skills, there exists a need for apps targeting SCI due to its distinct pathophysiology [17]. For example, self-management for bladder impairments mainly involves managing incontinence in prostate cancer, Parkinson disease, and stroke, compared to bladder voiding dysfunction, urinary tract infections, urinary stones, and renal impairment in SCI [18].

Therefore, identifying available self-management support apps for SCI is important for achieving a more complete overview of mHealth self-management support tools for SCI that complements related findings from the literature. This overview can also be used as a basis for the development of a convenient reference collection of self-management support apps for SCI to support the selection and improvement of existing apps and the development of new ones.

Objectives

The objective of this study was to identify and describe self-management support apps for SCI available on mobile app digital distribution platforms. This study aimed to (1) describe these apps in relation to their quantity and quality, coverage of self-management support activities and skills, and self-management areas targeted by self-management approaches; and (2) highlight associated strengths and weaknesses.

Methods

Overview

The study was conducted in 2 phases. In phase 1, a systematic search of app stores was conducted to identify and summarize self-management support apps for SCI. In phase 2, a systematic literature review was conducted to complement the work done in phase 1. This review aimed to identify publications that focused on designing, describing, evaluating, piloting, implementing, or improving apps previously identified in phase 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [19] and their extension for literature searches [20] were used to guide reporting in both phases. There were deviations from the study protocol [21] due to unforeseen resource constraints. The study's aims were narrowed in scope. When available in both stores, apps were reviewed based on device availability rather than prioritizing apps from a specific store. The IMS Institute for Healthcare Informatics app functionality scale [22] and the behavior change technique taxonomy (version 1) [23] were not used for app evaluation and synthesis, respectively.

Search Strategy

Phase 1

Similar to recent systematic searches of app stores [24-26], the Google Play Store and Apple App Store were systematically searched via an application programming interface provided by 42Matters [27] using keywords for SCI to find eligible apps across regional marketplaces (Multimedia Appendix 1). These digital distribution platforms host the largest number of publicly

available mobile apps globally for smartphones, tablets, and wearables [28]. Given the limited documentation for the application programming interface of 42Matters, researchers conducted preliminary searches and communicated with company representatives to enhance their understanding. To avoid missing relevant apps, the search was comprehensive, covering app titles, descriptions, and developer names. Additional apps were identified by looking at other apps by the same developers and through the "similar apps" and "you might also like" features on both app stores.

Phase 2

MEDLINE, CINAHL Complete, PsycINFO, IEEE Xplore Digital Library, ACM Digital Library, Embase, Scopus, Web of Science Core Collection, Academic Search Premier, LISTA, and Business Source Premier were searched to find eligible literature (Multimedia Appendix 1). The search terms used identified app titles and developer names from phase 1. The reference lists of the included articles were planned to be hand searched.

Eligibility Criteria

Phase 1

To be eligible for inclusion, apps should target individual users with SCI for use primarily outside a clinical setting; be supportive of self-management in SCI; be available to all users within the corresponding regional marketplace; be accessible via a smartphone, tablet, or wearable (eg, smartwatch); be available in English; and be last updated after July 2017 and available up to July 2022. The fully featured version of the app was preferred over the limited version when priced at ≤US $10. In addition, the smartphone version was chosen over the tablet version, and the tablet was favored over the wearable version. Apps were excluded if a technical malfunction prevented access or use after 2 attempts. These criteria were selected as practical choices based on available resources to ensure the inclusion of apps that are relevant to individuals with SCI, accessible to a wide user base, up-to-date, and user-friendly across various device types, all while considering cost and technical functionality.

Phase 2

Publications were eligible for inclusion if they described an identified app from phase 1. Publications available in English were considered. Primary research studies, books, and gray literature (eg, conference proceedings, company websites, and professional publications) were also considered. Broad eligibility criteria were used to maximize the possibility of finding additional information to describe apps identified in phase 1.

Eligibility Assessment

Three researchers (AV, MD, and RMB), having expertise in health science, psychology, and health technology, were involved in the screening process. They attended training sessions to ensure consistency in screening during phases 1 and 2, using a web-based spreadsheet and the web-based service Rayyan [29], without using its artificial intelligence features. Screeners completed a training set of 20% of assigned apps and publications. For phase 1, screeners (AV and RMB) were randomly assigned a screening set of app titles, descriptions, and screenshots, as well as of apps to download and screen their content. For phase 2, screeners (MD and RMB) were randomly assigned a screening set of publication titles, abstracts or summaries, and full texts. A second screening of at least 20% was conducted as part of the training set for apps and publications. Screening was independently conducted to reduce the risk of reviewer bias [30]. Conflicting screening decisions (ie, *include*, *maybe*, or *exclude*) were resolved collaboratively.

Quality Assessment

Two reviewers (AV and MD), both health scientists, independently assessed the identified apps using the 23-item Mobile App Rating Scale (MARS) [31]. The MARS is a widely adopted and reliable tool for classifying and assessing mHealth app quality using 5 subscales: engagement (5 items), functionality (4 items), aesthetics (3 items), information quality (7 items), and a subjective app quality score (4 items) [32]. The review excluded the subjective quality dimension to ensure objectivity in the quality assessment process. Inconsistent ratings were resolved collaboratively. Interrater reliability was calculated for total and dimensional scores using the intraclass correlation coefficient [33]. A quality assessment was not planned for publications, as phase 2 aimed to provide supplementary descriptive information and not quality judgments.

Data Extraction and Synthesis

The same researchers who were involved in the screening process completed data extraction. These researchers attended a training session to help ensure consistency and reliability in data extraction using a web-based data extraction form. The form was discussed and modified for increased clarity. One researcher extracted data from the identified apps, corresponding app store pages, and developer websites, and then, another researcher reviewed and verified the extracted data. The extracted data were collated and summarized by AV and RMB. Any discrepancies in data extraction among researchers were resolved collaboratively.

A widely accepted framework or clinical guideline regarding the key components of a SCI self-management intervention could not be found. Therefore, data extraction and synthesis were guided by the self-management approaches for people with chronic conditions by Barlow et al [6], the self-management skills taxonomy by Lorig and Holman [34] (detailed in Textbox 1), and the Practical Reviews in Self-Management Support taxonomy of self-management support activities [5] to help organize its findings.

Textbox 1. Self-management task and skill frameworks.

Self-management tasks [6]

- Medical management: making health-related appointments, following treatment plans, tracking symptoms, and taking medication as directed
- Role management: organizing and coordinating the various everyday roles and responsibilities related to work, family, community, and self-care and adapting these roles as needed
- Emotional management: regulating and coping with emotions resulting from living with a condition in a healthy and effective manner

Self-management skills [34]

- Problem-solving: identifying problems and finding, implementing, and evaluating solutions
- Decision-making: weighing options and choosing the best course of action in response to changes in their condition
- Resource use: finding and effectively using resources
- Forming patient-provider partnerships: learning from and partnering with health care professionals to understand the patterns experienced with a condition, make informed decisions, and discuss related issues
- Action planning: developing a realistic action plan that can be confidently used to achieve a set goal
- Self-tailoring: developing and implementing personalized self-management strategies as needed

Results

Overview

A total of 13 apps were included in the final synthesis, and no publications describing them were identified. Figures 1 and 2 detail the corresponding methodological processes (see Multimedia Appendix 2 for the PRISMA checklist).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the app store search, selection, and inclusion process.

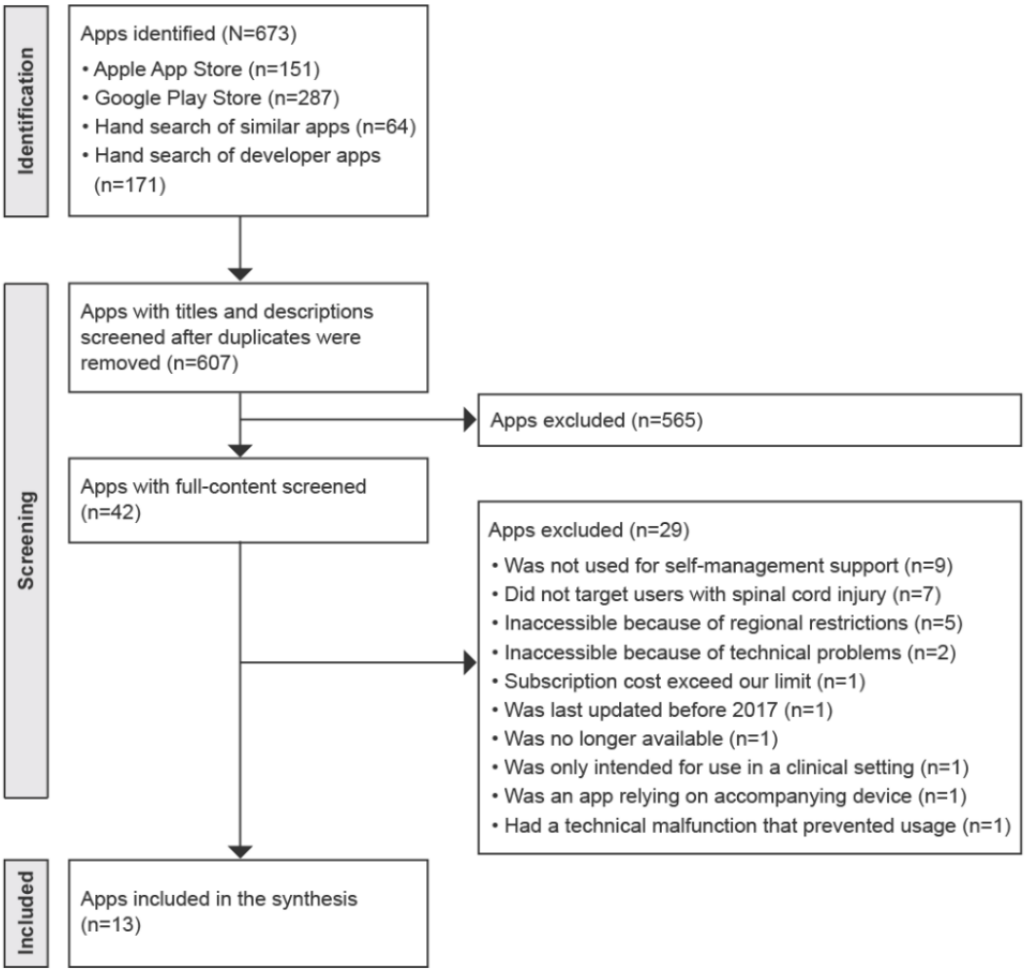

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the literature search, selection, and inclusion process.

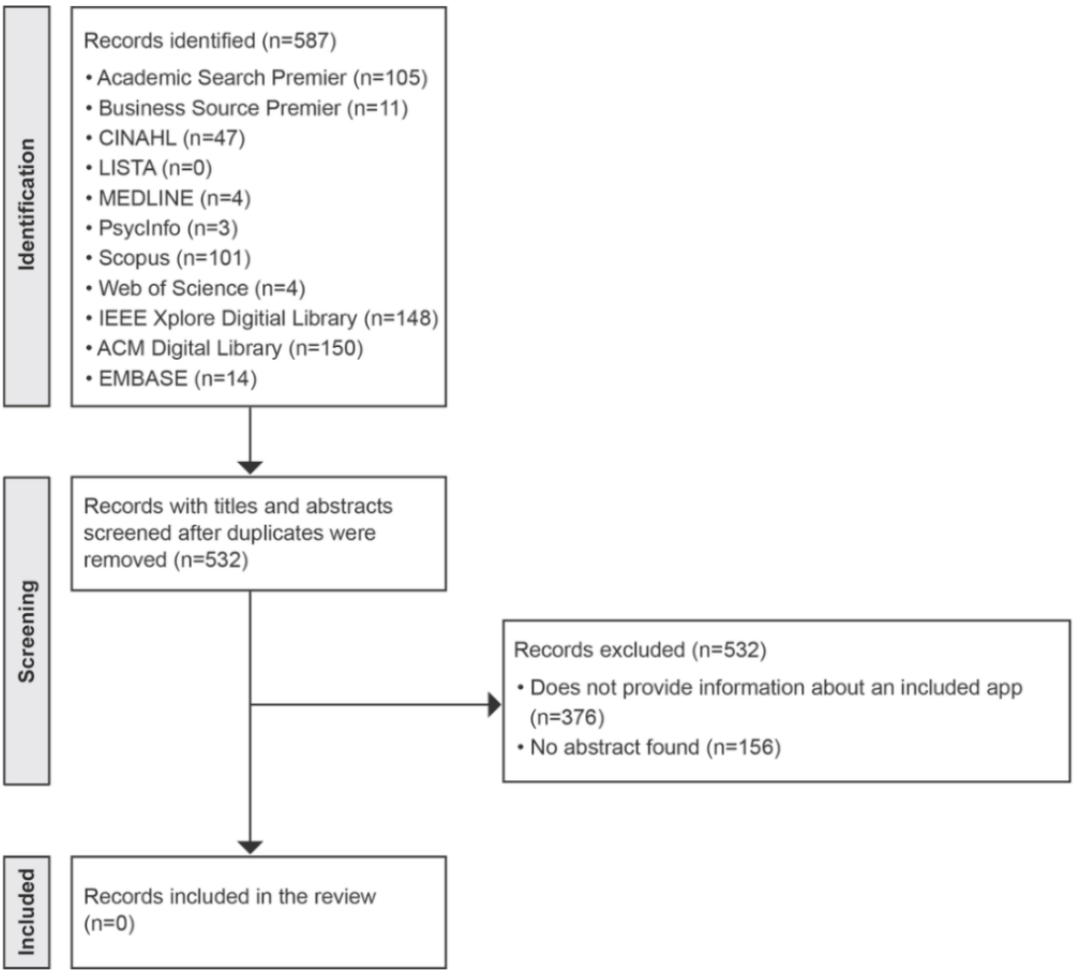

App Characteristics

Overview

The 13 identified apps are summarized in Multimedia Appendix 3. They were launched between 2013 and 2021, with the majority (9/13, 69%) released from 2019 onward [35-43] (Table 1). These apps mainly originated from the United States (8/13, 62%) [35,38-41,44-46], followed by Australia (2/13, 15%) [37,42] and 1 (1/13, 8%) each from Belarus [47], France [36], and Italy [43]. They were mainly published under the Health category (8/13, 62%) [37-40,42,43,46,47], followed by 1 (1/13, 8%) app each under the Tools [35], News and magazines [44], Sports [45], Communication [36], and Lifestyle [41] categories across both app stores. The identified apps supported 14 languages, with English having full support due to the language eligibility requirement, followed by French (4/13, 31%); German and Italian (3/13, 23%); Spanish and Portuguese (2/13, 15%); and several other European languages, Turkish, and Japanese (1/13, 8%). The identified apps were available in 72 countries, covering all 6 major world regions and 16 (73%) of the 22 subregions globally [48]. They were unavailable in countries in central Asia, middle Africa, eastern Africa, Melanesia, Polynesia, and Micronesia. Where reported (8/13, 62%) [35-39,44,45,47], 15% (2/13) of the identified apps had between 500,001 and 1,000,000 [35,47], 1001 and 5000 [36,44], 101 and 1000 [37,45], and 6 and 50 [38,39] downloads each. The number of downloads for the 5 Apple App Store apps was not reported. Target user ages were not reported, but most apps had content deemed appropriate for all ages (9/13, 69%) [35-40,44,45,47] and a few for adults only (4/13, 31%) [41-43,46].

Platforms and Functionality

Of the 13 apps included in this study, 10 (77%) used the Android operating system [49-56] and 4 (31%) used iOS [57-59]. Of the 13 apps, 2 (15%) used the Android operating system only [49,54], 3 (23%) used iOS only [57-59], and 6 (46%) used both Android and iOS [50-53,55,56,60-65]. The earliest operating system versions supported by the identified apps were Android version 4 (5/13, 38%) [38,39,44,45,47] and iOS version 9 (1/13, 8%) [40]. The identified apps had a file size ranging from 3 MB to 117 MB, with the average size being 31 (SD 35.18) MB for Android and 47 (SD 28.15) MB for iOS. Of the identified apps, half (7/13, 54%) had a tablet version [35,37,39,40,44-46]. Most of the identified apps (9/13, 69%) were functional without an internet connection [35-40,42,43,47]. The identified apps had no discernible way for users to access their data and freely export their data. Of the 13 apps, 1 (8%) incorporated gamification [42], 2 (15%) included assistive videos [42,47], and 3 (23%) provided music or audio [39,42,47].

Very few of the included apps (3/13, 23%) had a wide range of features. Of the 13 apps, only 2 (15%) offered tracking functionality for physical activity [37,42], and 1 (8%) app had features to support mindfulness and deep breathing exercises as a form of sleep therapy [39]. None of the apps provided a platform for peer support, though 1 (8%) of the 13 apps did provide a connection to a support professional [37]. No apps provided features for psychoeducation, journaling, goal setting, habits, or chatbot interactions.

Privacy and Support

Most of the identified apps (8/13, 62%) provided accessible privacy policies [35-41,43]. The remaining apps either had broken web page links to the privacy policies [42,44-46] or provided none [47]. When provided, privacy policies were accessible from the app store and app (4/13, 31%) [37,39-41] and app store alone (8/13, 62%) [35-41,43]. No clarification on personal data processing and data security measures was provided. Of the 13 apps, 1 (8%) [37] was identified as sharing personal health information as it connected users to health care providers. No deidentified, anonymized, or aggregated data were seemingly shared by the identified apps, and they did not claim to meet any regulation targeting data privacy or security such as the Health Insurance Portability and Accountability Act of 1996 in the United States. Data collection was mandatory for the identified apps. However, it was difficult to distinguish between optional and mandatory data collection. As a result, this distinction was not included in the synthesis. See Table 2 for more information.

Table 2. User data collected by the 13 identified self-management apps for spinal cord injury by purpose.

Data collected	Purpose	Apps, n (%)
Network connections	Analytics [35] and unknown [36-39,44,45,47]	8 (62)
Email address	Analytics [35-37,39], app functionality [36-39,41], developer communications [36,37,39], security and compliance [36,37,39], personalization [36,39], and account management [36,39]	6 (46)
App interactions	Analytics [35,36], app functionality [36], developer communications [36], and unknown [38,41]	4 (31)
Contact list	App functionality [37,41] and personalization [37]	4 (31)
Device ID	Analytics [35,37,38] and security and compliance [36-38]	4 (31)
IP address	Analytics [37-40] and security and compliance [38]	4 (31)

Age	Analytics [37], app functionality [37,38], and personalization [37,38]	2 (15)
Crash logs	Analytics [35,36], app functionality [36], and developer communications [36]	2 (15)
Date of birth	Analytics [37,41], app functionality [37], and personalization [37,41]	2 (15)
Device type	Analytics [37,41] and security and compliance [37,41]	2 (15)
Diagnostics	Analytics [35,36], app functionality [36], and developer communications [36]	2 (15)
Postal address	Analytics [37], app functionality [37], developer communications [37], and personalization [41]	2 (15)
User ID	Analytics [35,36], app functionality [36], developer communications [36], security and compliance [36], personalization [36], and account management [36]	2 (15)
Gender	Analytics [41] and personalization [41]	1 (8)
In-app search history	Analytics [35]	1 (8)
Other user-generated content	Analytics [35] and app functionality [35]	1 (8)
Statistics on page views	Analytics [37]	1 (8)

Most apps provided support options (12/13, 92%) and used email (6/13, 46%) [35,36,39,41,42,47]; website-based information (6/13, 46%) [36,37,40,42,44,45]; tutorials, guides, or manuals (6/13, 46%) [36,37,40,44-46]; frequently asked

questions (3/13, 23%) [36,37,41]; phone (2/13, 15%) [35,42]; web chat (1/13, 8%) [35]; contact forms (1/13, 8%) [42]; and social media platforms (1/13, 8%) [37] for this purpose. Of the 13 apps, 4 (31%) provided 2 options [40,41,44,45], 3 (23%) provided 4 options [36,37,42] and 1 option [39,46,47], and 1 (8%) provided 3 options [35].

Cost

Of the 13 apps, 5 (38%) did not request payment [35,37,41-43] and the remaining 8 (62%) accepted payment [36,38-40,44-47] to download [36,38-40,44,45,47], while 4 (31%) accepted payment for one-time or recurring in-app purchases to access full features [36,44-46]. The cost to download ranged from US $1.99 to US $19.99.

Developers

Developers were mainly for-profit companies (10/11, 91%) [49,50,52-60,62-65] except for 1 (9%) nonprofit company [51,61]. Developers published 246 apps across both app stores [49-65], with most of them being published in Google Play Store (137/246, 55.7%) [49-56] and the remainder in the Apple App Store (109/246, 44.3%) [57-65] (Table 3). Half of the developers focused on publishing health-related apps (6/11, 55%) [49,53-55,57,59,63,64], and the others published apps across a wide range of categories in the app store [50-52,56,58,60-62,65]. The Paralyzed Veterans of America [51,61] published 3 (23%) of the 13 identified apps [44-46]; other developers (10/11, 91%) published 1 each [35-43,47].

Characteristics of Approaches Providing mHealth Self-Management Support for SCI

All self-management tasks were supported by the identified apps (Table 4). Role management received the most support (11/13, 85%) [35-38,40-42,44-47], followed by medical (7/13, 54%) [37,38,40,42,43,45,47] and emotional (4/13, 31%) [39,42,44,45] management (Table 5). Support for a single task was most common (6/13, 46%) [35,36,39,41,43,46], followed by 2 (5/13, 38%) [37,38,40,44,47] and 3 (2/13, 15%) [42,45] tasks. When combined, role and medical management were most often supported together (4/13, 31%) [37,38,40,47], followed by role and emotional management (1/13, 8%) [44].

Table 4. Identified self-management apps for spinal cord injury by self-management approach (N=13).

App name and citation	Self-management focus area	Relevant self-management tasks	Relevant self-management skills	Relevant self-management support components
Pilates [47]	Physical activity promotion	Role management and medical management	Action planning	Training and rehearsal for practical self-management activities
Action Blocks [35]	Activities of daily living	Role management	Resource use	Training and rehearsal for practical self-management activities, training and rehearsal for everyday activities, and lifestyle advice and support
PN–Paraplegia News [44]	Health literacy and activities of daily living	Role management and emotional management	Problem-solving, action planning, and resource use	Information about the condition and or its management, information about available resources, and lifestyle advice and support
SNS Digital [45]	Physical activity promotion, health literacy, and activities of daily living	Role management, emotional management, and medical management	Problem-solving, action planning, and resource use	Information about available resources and lifestyle advice and support
JIB CALLS [36]	Activities of daily living	Role management	Resource use	Training and rehearsal for everyday activities
Disability Care App [37]	Therapeutic exercise and activities of daily living	Role management and medical management	Action planning, maintaining patient-provider partnership, and problem-solving	Practical support with adherence (medication or behavioral), training and rehearsal for practical self-management activities, and training and rehearsal to communicate with health care professionals
Dietitian's Tools [38]	Medicating and dieting	Role management and medical management	Action planning	Training and rehearsal for practical self-management activities and training and rehearsal to communicate with health care professionals

Neuro Therapy [42]	Therapeutic exercise and physical activity promotion	Role management, emotional management, and medical management	Action planning and maintaining patient-provider partnership	Training and rehearsal for practical self-management activities, practical support with adherence (medication or behavioral), provision of easy access to advice or support when needed, and social support

App name and citation	Self-management focus area	Relevant self-management tasks	Relevant self-management skills	Relevant self-management support components
Spine Fine [43]	Therapeutic exercise and physical activity promotion	Medical management	Action planning	Training and rehearsal for practical self-management activities, monitoring of the condition with feedback, and provision of easy access to advice or support when needed

Table 5. Characteristics of approaches to self-management support for spinal cord injury by frequency (N=13).

Characteristic	Apps, n (%)
Supported self-management tasks	
Role management [35-38,40-42,44-47]	11 (85)
Emotional management [39,42,44,45]	4 (31)
Medical management [37,38,40,42,43,45,47]	7 (54)
Supported self-management skills	
Action planning [37,38,40-47]	10 (77)
Resource use [35,36,41,44-46]	6 (46)
Problem-solving [37,39,40,44,45]	5 (38)
Maintaining patient-provider partnership [37,42]	2 (15)
Incorporated self-management support components	
Training and rehearsal for practical self-management activities [35,37,38,40,42,43,47]	7 (54)
Lifestyle advice and support [35,41,44-46]	5 (38)
Information about available resources [41,44-46]	4 (31)
Social support [41,42]	2 (15)
Practical support with adherence (medication or behavioral) [37,42]	2 (15)
Provision of easy access to advice or support when needed [42,43]	2 (15)
Training and rehearsal for everyday activities [35,36]	2 (15)
Training and rehearsal to communicate with health care professionals [37,38]	2 (15)
Monitoring of the condition with feedback [43]	1 (8)
Training and rehearsal for psychological strategies [39]	1 (8)
Targeted self-management focus areas	
Activities of daily living [35-37,44-46]	6 (46)
Physical activity promotion [40,42,43,45,47]	5 (38)
Health literacy [44-46]	3 (23)
Therapeutic exercise [37,42,43]	3 (23)
Mobility [41]	1 (8)
Medicating and dieting [38]	1 (8)
Pain management [39]	1 (8)

Most self-management skills were supported by the identified apps (4/6, 67%; Table 5). *Action planning* received support from most of the identified apps (10/13, 77%) [37,38,40-47], whereas *maintaining patient-provider partnership* received the least support (2/13, 15%) [37,42]. Support for a single skill was most common (6/13, 46%) [35,36,38,39,43,47], followed by 2 (4/13, 31%) [40-42,46] and 3 (3/13, 23%) [37,44,45] skills.

Incorporated self-management support components included 71% (10/14) of the Practical Reviews in Self-Management Support components (Table 5). The top 3 components were

incorporated more than the average number of times and accounted for 85% (11/13) of the identified apps. Information regarding the condition and its management, including equipment details, specific clinical action plans, rescue medications, and regular clinical reviews, was not included. Of the 13 apps, 6 (46%) incorporated 1 component [35,36,38,39,43,47], 4 (31%) incorporated 2 components [40-42,46], and 3 (23%) incorporated 3 components [37,44,45].

The adopted approaches to providing self-management support mainly focused on activities of daily living, physical activity promotion, health literacy, and therapeutic exercise (Table 5). Mobility, medicating and dieting, and pain management were targeted to a lesser extent.

MARS Evaluation

The mean MARS score for the 13 identified apps was 3.86 (SD 0.54), with a maximum of 4.52 for Action Blocks [35] and a minimum of 2.72 for AccessiRep [40], indicating good overall quality (Table 6). On average, the best-rated section was functionality (mean 4.56, SD 0.33), followed by information quality (mean 3.71, SD 0.78), aesthetics (mean 3.62, SD 0.91), engagement (mean 3.54, SD 0.61), app subjective quality (mean 3.39, SD 0.98), and app specific quality (mean 2.73, SD 0.97). The mean MARS score for the apps from Google Play and Apple App Store were 3.84 (SD 0.47; 8/13, 61%) and 3.88 (SD 0.71; 5/13, 39%), respectively. The interrater reliability as assessed by the intraclass correlation coefficient was 0.80 (95% CI 0.49-0.94), indicating a good level of agreement in the scoring between the 2 raters (AV and MD) [66].

Table 6. Mobile App Rating Scale scores (overall score and 4 subscales) of the 13 identified self-management apps for spinal cord injury.

App name and citation; developer and citation	Overall score	Engagement score	Functionality score	Aesthetics score	Information quality score

Dietitian's Tools [38]; Kinnereth LLC App Dev [54]	3.46	2.80	4.88	2.67	3.50
Pilates [47]; DSN Inc [49]	2.96	3.10	4.25	2.17	2.33
AccessiRep [40]; Cordilac LC [57]	2.72	2.20	3.75	2.33	2.58

Regarding *engagement*, most of the identified apps were deemed sufficiently customizable, interactive, and focused on the targeted audience [35-38,41,42,47], as indicated by the minimum acceptability score of 3.0 established by the MARS. Nonetheless, several apps were rated lower due to lacking sufficient settings for customization [39,40,43-47]. In terms of *functionality*, the identified apps were generally easy to use and had good navigation and gestural design. Similarly, the identified apps received high scores for aesthetics, as they featured appealing graphic designs, color schemes, and layouts that were consistent throughout. Concerning *information quality*, most apps had accurate descriptions and presented enough information of good quality. However, low or no scores were noted regarding the presence of specific, measurable, and achievable goals as well as an evidence base supported by scientific research or expert-reviewed guidelines for the app's content and functionality.

Discussion

Principal Findings and Comparison With Prior Work

This study identified 13 self-management support apps for SCI available on the Google Play Store and Apple App Store that meet this study's inclusion criteria. No scientific literature was found that focused on designing, describing, evaluating, piloting, implementing, or improving them. This emphasizes the critical

shortage of evidential support in literature for these apps and underscores the uncertainty around their quality and effectiveness. Consequently, it becomes challenging to confidently recommend any of them or identify which aspects require improvement. Unsurprisingly, none of the apps were identified by an earlier systematic literature review with similar inclusion criteria [67]. This highlights the need for greater collaboration between researchers and developers to improve the dissemination and availability of theory- and evidence-based self-management support apps for SCI.

Self-Management Support Apps for SCI

This study identified 11 self-management support apps launched on the Google Play Store and Apple App Store between 2017 and 2021, similar in number to the 11 apps identified by the earlier systematic literature review [67]. As all apps were unique, a total of 22 self-management support apps for SCI were available during this period. The United States continues to contribute most of the apps identified, which may result in a potential bias toward the cultural, social, and demographic context of the country and may not fully capture the diverse needs and preferences of users from other regions. Although apps from Canada, the Netherlands, Switzerland, and Thailand were discussed in the literature, no similar apps from these countries were found on app distribution platforms. According to this review, Australia, Belarus, and France were also represented for the first time. The number of downloads for Apple App Store apps was not reported, limiting our understanding of the popularity and reach of these apps. It was noted that most apps did not require an internet connection, which is beneficial for areas with poor or no internet connectivity.

mHealth Self-Management Support Approaches in SCI

This study identified self-management focus areas that align with those found in the earlier systematic literature review [67]. These included physical activity promotion, pain management, therapeutic exercise, medication, and dieting. The identified apps in this review also supported all self-management tasks; emotional management received the least amount of support, albeit more than in the earlier review. While the support for role management was slightly less but almost equal to medical management in the earlier review, the identified apps in this review provided more resources in support of role management. The general trend in the coverage of support for self-management tasks remains consistent with the earlier review. However, the apps identified in this study provide more comprehensive support for these tasks compared to the previous review. Unlike in the earlier review, *decision-making* and *self-tailoring* self-management skills were unsupported by apps identified in this study. They were also 2 (50%) of the top 4 skills supported by mHealth covered in literature. The trend in the coverage of support for self-management skills and support activities remains consistent with the earlier review, but the identified apps provide less coverage for these skills and activities.

Quality of Self-Management Support Apps for SCI

Similar to findings from this study, recent reviews on self-management support apps for food allergies or intolerances [68], depression [69], rare diseases [70], and diabetes (3.42) [71] also report that the overall quality of self-management support apps assessed are generally acceptable. App *functionality* also received the highest ratings across these studies, which suggests that self-management support apps tend to be user-friendly. A higher *engagement* score was reported by this study compared to the other aforementioned studies, suggesting that self-management support apps for SCI are more engaging on average. *Aesthetics* received high mean scores across the studies as well, suggesting that self-management support apps across varying health conditions had appealing graphic designs, color schemes, and layouts. *Information quality* scores were also similar among these studies.

Implications for Future Practice and Research

More apps that provide comprehensive self-management support for SCI are needed. Adopting new development methods could help reduce barriers to development, such as time, cost, and securing scarce expertise. For example, low-code development platforms provide prebuilt templates and drag-and-drop interfaces, allowing apps to be created with minimal hand-coding. In addition, customizing white-label solutions can further streamline the development process. Adopting an iterative co-design approach involving key stakeholders, such as persons with SCI, health professionals, app developers, carers, and researchers, would also be key for app success. This approach could also incorporate validation studies with health professionals, efficacy and effectiveness studies through collaborations with researchers, and quality evaluations with a wide range of key stakeholders using tools such as MARS [72].

Complying with best practices should also be considered. App store categorization should be more consistent to improve the discoverability and accessibility for potential users. Privacy notices must be accessible via app stores so users can make an informed decision at the point of download and in the app. Providing information about the required device permissions is also useful.

It is critical for future research to provide a supportive evidence base for the development of high-quality self-management support apps for SCI, as none appears to exist. Investigations using app use data are needed to adequately determine their feasibility. App download counts are insufficient as they only indicate awareness of the app and potentially the initial willingness to use it. Further investigation into the data collection practices of these apps is warranted due to the challenges in distinguishing between optional and mandatory data collection and the associated concerns about the potential data privacy risks and implications. Given the high turnover of available apps on these platforms, future systematic searches in app stores need to continuously monitor and capture this information to increase the awareness of available high-quality self-management support apps that could benefit people with SCI. Persons with SCI, their carers, and related health professionals should be asked to recommend self-management support apps for consideration. Searching a wider range of

mobile app digital distribution platforms could also be beneficial for identifying more self-management support apps. Furthermore, it could be beneficial to validate the reported findings with datasets from these other platforms. Research should also consider supplementing the MARS with other instruments for a more comprehensive assessment and description of apps, such as the app evaluation model by the American Psychiatric Association [73], behavior change technique taxonomy [23], and IMS Institute for Healthcare Informatics app functionality scale [22].

Limitations

Although the most popular by a wide margin, only 2 of the many mobile app digital distribution platforms (eg, Microsoft Store, BlackBerry World, Huawei, and AppGallery) were searched, and some eligible apps could have been overlooked. The app store search keywords were broad but also limited to ensure that screening was feasible for the small team, and it cannot be guaranteed that all eligible apps were retrieved. Using a proprietary application programming interface potentially imposes limitations in terms of transparency relating to search accuracy, comprehensiveness, and documentation, which could affect the reproducibility of this study. Although unlikely, it is acknowledged that some eligible apps might have been missed due to the English language restriction. Not considering all app versions across both platforms could have biased the results, but this was unlikely in this synthesis as the identified apps were identical versions and were almost indistinguishable beyond differences imposed by the platform. Assessing identified apps in the English language could have also biased the results as other translations might not provide a similar user experience. While the inclusion of privacy policies was noted, analyzing their content and drawing conclusions about their conciseness, transparency, intelligibility, and accessibility was beyond the scope of this synthesis. The MARS neglects important aspects of app quality, such as data privacy, security, and accessibility, but provides sufficient scope with its 5 dimensions for the purposes of this initial overview of self-management support apps for SCI. Due to the exclusion of several inapplicable items from the mean score of the *information* dimension, comparisons between apps with and without complete data, especially for this dimension, should be cautiously interpreted. As mobile app digital distribution platforms constantly undergo swift changes, it is acknowledged that these findings provide a snapshot. The identified apps may have been updated or no longer available, their content may have been modified, or new mobile apps may have been developed since this systematic search was conducted, and this can limit the generalizability of this study's findings. Furthermore, these findings may not be generalizable to all self-management support apps for SCI, as the inclusion criteria were specific to certain types of apps, including those available in English and in certain app stores, such as Google Play Store and Apple App Store.

Conclusions

This study contributes to a broader understanding of mHealth self-management support tools for SCI by identifying and evaluating 13 self-management support apps for SCI. While these apps had good overall quality as measured by the MARS assessment, greater collaboration between developers and researchers is needed to improve the dissemination and availability of theory- and evidence-based self-management support apps for SCI. Failure to adopt this approach could limit the potential impact of these apps and result in missed opportunities to improve self-management support for people living with SCI. Furthermore, exploring new app development methods, such as using low-code platforms, could help promote stakeholder inclusivity in the development process and reduce barriers to app development, including time, cost, and expertise.

Acknowledgments

We dedicate this work to the memory of our dear Renaldo M Bernard, who passed away before the final publication of this study, which he spearheaded. His death is a great loss to the scientific community and to all those who knew him as a kind, joyful, and bright researcher.

The authors thank Dr Ana Ona Macías for her generous contribution to the Mobile App Rating Scale analyses.

Abstract

Background: Preexposure prophylaxis (PrEP) is an effective strategy to reduce the risk of HIV infection. However, the efficacy of PrEP is highly dependent on adherence. Meanwhile, adherence changes over time, making it difficult to manage effectively.

Objective: Our study aimed to explore and predict the patterns of change in PrEP adherence among men who have sex with men (MSM) and evaluate the impact of the WeChat-based reminder intervention on adherence, thus providing more information for PrEP implementation strategies.

Methods: From November 2019 to June 2023, in a randomized controlled longitudinal study of the PrEP demonstration project in Western China (Chongqing, Sichuan, and Xinjiang) based on a mobile health (mHealth) reminder intervention, participants were randomly divided into reminder and no-reminder groups, with those in the reminder group receiving daily reminders based on the WeChat app. Participants were followed up and self-reported their medication adherence every 12 weeks for a total of 5 follow-up visits. We used the growth mixture model (GMM) to explore potential categories and longitudinal trajectories of adherence among MSM, and patterns of change in PrEP adherence were predicted and evaluated based on the decision tree.

Results: A total of 446 MSM were included in the analysis. The GMM identified 3 trajectories of adherence: intermediate adherence group (n=34, 7.62%), low adherence ascending group (n=126, 28.25%), and high adherence decline group (n=286, 64.13%). We included 8 variables that were significant in the univariate analysis in the decision tree prediction model. We found 4 factors and 8 prediction rules, and the results showed that HIV knowledge score, education attainment, mHealth intervention, and HIV testing were key nodes in the patterns of change in adherence. After 10-fold cross-validation, the final prediction model had an accuracy of 75%, and the classification accuracy of low and intermediate adherence was 78.12%.

Conclusions: The WeChat-based reminder intervention was beneficial for adherence. A short set of questions and prediction rules, which can be applied in future large-scale validation studies, aimed at developing and validating a short adherence assessment tool and implementing it in PrEP practices among MSM.

KEYWORDS

preexposure prophylaxis; adherence; trajectory analysis; men who have sex with men; mHealth; mobile health; mHealth intervention; decision tree

Introduction

In China, men who have sex with men (MSM) are the high-risk population for HIV infection. Previous studies have estimated the overall national HIV prevalence among MSM in China to be 5.7% from 2001 to 2018 [1]. The annual number of newly diagnosed HIV infections through homosexual transmission in China increased from 2.5% in 2006 to 25.6% in 2022 [2]. To reduce the persistently high incidence of new infections among high-risk populations, we need to focus on HIV prevention. Preexposure prophylaxis (PrEP) is a biomedical HIV prevention intervention that consists primarily of the prophylactic daily use of antiretroviral medications to reduce the risk of infection

in the event of HIV exposure [3]. Effective PrEP services for at-risk populations, including MSM, are key to reducing new HIV infections [4].

However, a growing number of studies have shown that the efficacy of PrEP is highly dependent on medication adherence [5,6]. PrEP adherence is defined as the users taking the medication as prescribed by the clinician, occurring behaviors consistent with the clinician's orders, and vice versa, known as nonadherence. A previous systematic review and meta-analysis study showed that the PrEP strategy was highly effective among MSM. Meanwhile, PrEP efficacy was strongly correlated with adherence, with the RR decreasing by 0.13 as adherence increased from 50% to 60%. It was shown that, on average, a 10% decrease in adherence would correspond to a 13% decrease in PrEP efficacy [7]. In summary, achieving a high level of adherence is necessary for PrEP to be completely effective. This highlights the need for good adherence in ensuring the efficacy of PrEP among the MSM population.

Moreover, earlier studies have acknowledged the time-varying nature of adherence, both within and between individuals over time [8]. Exploring and elucidating patterns of change in adherence can contribute to understanding the reasons for users' behavioral changes and enhance the capacity to recognize individuals who are more susceptible to nonadherence. Studies assessing long-term behavioral patterns of PrEP adherence have been conducted in many countries, including Australia [9], America [10], and South Africa [11]. However, at present, few studies in China have assessed patterns of change in adherence. Taken together, several previous empirical studies have shown that adherence is critical for PrEP efficacy in high-risk populations and deserves further attention. Future PrEP strategies will be more effective if we are able to accurately recognize patterns of change in adherence and develop predictive models that reliably identify individuals who engage in nonadherent behavior. Therefore, our study aimed to explore and predict the patterns of change in PrEP adherence based on the decision tree model, thus providing more information for PrEP implementation strategies. Our study was a preliminary application of decision tree prediction modeling to PrEP adherence among the MSM population in Western China. More importantly, recent simulation studies have shown that machine learning techniques, for example, decision tree modeling, can be reliably applied to relatively small samples and are more applicable to our particular study population [12,13].

In addition, mobile health (mHealth) has emerged as a promising tool for improving health care access and delivery globally [14]. Previous studies have shown that mHealth could reach and engage MSM in HIV prevention and care, which suggested that mHealth interventions have the potential to improve HIV prevention efforts [15]. At the same time, willingness to use mHealth intervention for HIV prevention was high among the MSM population [16]. Although research on adherence interventions for PrEP was in its early stages, some mHealth intervention methods showed promise. The WeChat app (Tencent Holdings Ltd) is the most popular social media platform in China, with 1.27 billion monthly active users [17]. Thus, a WeChat-based medication reminder service is a low-cost and scalable intervention.

In summary, based on the randomized controlled longitudinal study of the PrEP demonstration project through the mHealth intervention, the aims of our study were to (1) identify patterns of change in PrEP adherence among the MSM population; (2) provide an initial basis for identifying a set of questions and decision rules that can accurately predict individuals at high risk for low PrEP adherence behaviors among the MSM population based on the decision tree prediction model; and (3) evaluate the impact of the mHealth intervention on adherence. Validation in larger samples in the future could contribute to the creation of a comprehensive, brief adherence screening tool based on the results of our study. In the long term, our study will help administrators target individuals with low adherence to preventive interventions and, at the same time, provide a direct basis for policy development and service planning for the implementation of PrEP among MSM in China, which is of great practical significance.

Methods

Participants and Procedure

From November 2019 to June 2023, our study was conducted among the MSM population in Western China (Chongqing, Sichuan, and Xinjiang). The randomized controlled longitudinal study of the PrEP demonstration project was based on a mobile phone intervention, accompanied by the Chinese 13th Five-Year Plan for AIDS Prevention and Control carried out by the Ministry of Science and Technology (Chinese Clinical Trial Registration Number: ChiCTR1900026414).

The participants were HIV-negative MSM individuals at higher risk of HIV infection. We recruited eligible MSM individuals through collaboration with local nongovernmental organizations and peer referrals. The inclusion criteria included (1) assigned male sex at birth; (2) age 18 - 65 years; (3) negative HIV antigen antibody test; (4) self-reported high-risk sexual activity with a male partner (both temporary and regular) in the last 6 months; (5) no serious heart, liver, or kidney disease or hematopoietic dysfunction, bleeding tendency, and bleeding disease; (6) willing to use the experimental drug under guidance and comply with follow-up arrangements; and (7) signed informed consent.

After completing the baseline questionnaire, participants who met the inclusion criteria were randomly divided into a reminder group and a no-reminder group. Participants in the reminder group received daily mobile phone–based reminder messages and took lamivudine-tenofovir (PrEP drug) orally daily. The reminder information relies on the internet and an intelligent medication information tracking management system using cloud computing, big data, intelligent hardware, and other new-generation IT products to collect medication plans, medication reminders, medication logs, electronic instructions for medicines, adverse reactions, health knowledge, and other process information, and through the collection of information, it provides information for the administrator to provide the user with effective medication management to achieve the expected preventive effect. The reminder messages were sent at regular times daily through the WeChat app to remind users to take PrEP. At the same time, in order to protect the user's privacy, the content of the messages we sent were "processed." For

example, when users received "You need to learn," it meant that they were reminded to take medication; "Time for examination" meant that it was time for the next follow-up visit. The presentation of the reminder messages on WeChat is shown in Figures S1 and S2 in Multimedia Appendix 1. Participants in the no-reminder group who took PrEP daily did not receive reminder messages. Participants were followed up and self-reported their medication adherence every 12 weeks for a total of 5 follow-up visits.

Measurement

Demographic variables of MSM included age, place of residence, ethnicity, education attainment, employment status, marital status, and monthly disposable income.

The HIV Knowledge Scale (Cronbach α=.672) was used to measure knowledge mastery in the MSM population. The scale consisted of 13 questions and was based on the revised Universal Scale of the International HIV Knowledge Survey [18]. The answers included "correct," "wrong," and "I don't know." One point was awarded for a correct answer and zero points for an incorrect or unknown answer. A higher score indicated a higher level of knowledge about HIV. We believed that a score ≥11 indicates a high level of knowledge [19,20].

Meanwhile, we also measured the level of risk perception of the participants. They were asked, "How likely do you think you are to contract HIV? How serious do you think AIDS is? How much of a threat do you think AIDS poses to you?" These 3 items were used to measure their perceived risk. Participants rated their perceived risk on a scale of 1 - 5, with 1 - 2 representing a low level of perception, 3 representing a moderate level of perception, and 4 - 5 representing a high level of perception.

Previous literature mentioned that MSM may show different preferences and willingness to use PrEP and other biomedical prevention strategies based on the role of anal sex [21]. Therefore, our study included the variable "sexual role" to explore whether differences in sexual roles might lead to differences in adherence to PrEP in the MSM population. Sexual role was the way of performing sexual behavior with a male sexual partner, such as inserter (like "top") and receiver (like "bottom").

We also collected information about HIV testing, HIV counseling, the number of sexual partners, condom use, internet searches for sexual partners, sexually transmitted diseases history, commercial sex, recreational drug use, attitudes, and potential effects of PrEP use among male sexual partners among the participants.

Adherence

During the follow-up, participants self-reported the number of days they missed taking their medication in the previous 2 weeks, and adherence was equal to the proportion of days medication was taken.

Growth Mixture Model

The growth mixture model (GMM) was used in our study to determine potential class trajectories for adherence. The model used Akaike information criteria (AIC), Bayesian information criteria (BIC), sample size–adjusted BIC (aBIC), and entropy to explore the optimal trajectory of internalization and externalization problems. The AIC, BIC, and aBIC statistics were all used to determine how well the model fits by comparing the difference between the expected and actual values, with lower values indicating a good model fit. The entropy took values in the range 0 - 1, with closer to 1 indicating a clearer group classification. The Vuong-Lo-Mendell-Rubin likelihood ratio test and bootstrapped likelihood ratio test were used to compare the differences in fit between the k-1 and k-category models. When the *P* value was significant, the model was considered well fitted for the k-category.

Decision Tree

The decision tree is based on the known probability of the occurrence of various situations, through the composition of the decision rule to determine the probability and evaluate and judge the risk decision analysis method, which is the intuitive use of probability analysis using a graphical method. This decision branching is drawn graphically, much like the branches of a tree. The top decision node in the tree is called the root node; it corresponds to the best predictor. The final nodes are called terminal nodes or leaves. The numbers on the terminal nodes indicate the probability of each class and are what determine the final classification. In our study, the Gini index was used as a criterion for selecting features. The magnitude of the Gini index indicated the complexity of the data, and when the Gini index was less than a threshold, it indicated that the purity of the data was greater and the nodes of the tree stopped splitting. The decision tree model was pruned according to the complexity parameter (Cp) value, and the Cp value corresponding to the smallest error was selected to obtain the optimal decision tree model.

Statistical Analysis

Longitudinal data collected on repeated measures of PrEP adherence among the MSM population were analyzed using the GMM to explore potential categories and longitudinal trajectories of adherence, and statistical metrics were used to measure the degree of model fit. Based on the different potential categories of adherence, relevant information was compared using univariate analysis, and predictors with a *P* value ≤.05 were screened and included in the decision tree prediction model. The SMOTE algorithm in the "smotefamily" package of the R program was used to balance the adherence classification data; the "rpart" package was used to construct the decision tree prediction model. The predictive power of the final model was assessed by three criteria: (1) "accuracy" indicates the overall percentage of correct classifications; (2) "positive classification accuracy" refers to the percentage of predictions that the model accurately classifies as positive; and (3) "negative classification accuracy" refers to the percentage of predictions that the model accurately classifies as negative. For each of the 3 evaluation criteria, 10-fold cross-validation was used, and their estimates were computed as the average of the 10 test samples. At the same time, missing values were considered to be informative indicators, and therefore were considered as potential predictors in modeling [22]. *P* value

≤.05 represented a statistical difference. All analyses were completed using Mplus (Muthén & Muthén) and R software (R Foundation for Statistical Computing).

Ethical Considerations

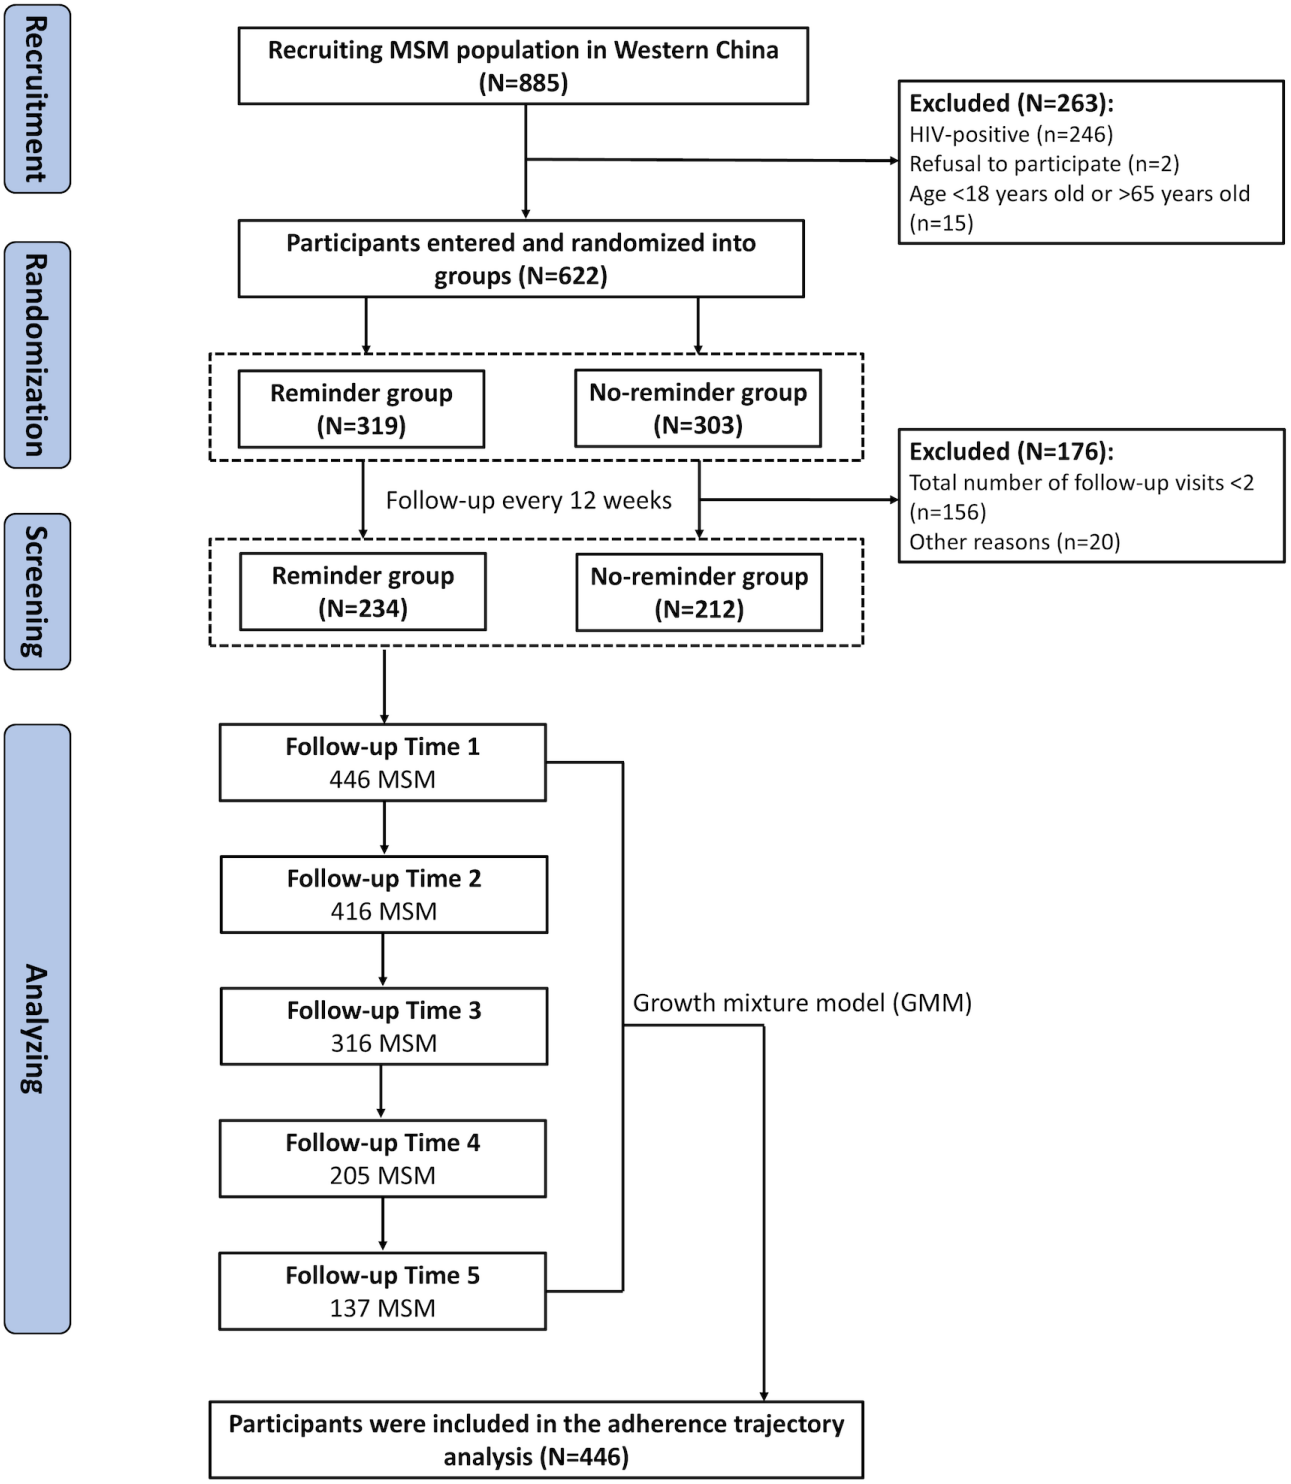
The study was approved by the Ethics Committee of Chongqing Medical University (reference number: 2019001). Before participating in this research, the participants were fully informed about the purpose, significance, voluntary participation, and confidentiality of the research. Each participant signed an informed consent form.

Results

Basic Demographic Information

A total of 885 MSM were recruited in Western China. Of these, 263 MSM were excluded because they did not meet the requirements for inclusion in the cohort. A total of 622 MSM were enrolled in the longitudinal study and were randomized into a reminder group (n=319) and a no-reminder group (n=303). Due to the need to model longitudinal trajectories of adherence, we excluded a subset of participants with less than 2 follow-up visits. A total of 446 MSM were eventually included in the statistical analysis, with 234 and 212 MSM in the reminder and no-reminder groups, respectively. The detailed screening process is shown in Figure 1. We compared basic demographic information between the reminder and no-reminder groups (Table S1 in Multimedia Appendix 1). According to the results of the univariate analysis, none of the variables differed statistically in both groups. We performed descriptive analyses of the number of MSM and adherence in each follow-up period (Table S2 in Multimedia Appendix 1).

Figure 1. Flowchart for the screening of study participants. MSM: men who have sex with men; GMM: growth mixture model.



Exploring Patterns of Change in Adherence

Based on the GMM, we explored 1, 2, 3, and 4 potential categories of adherence (Table 1). Considering the parameters, the scheme for category 4 is reasonable. However, Class 2 accounted for 3.81% (n=17) of the scheme for category 4, which is too small a number to carry out subsequent analyses, and the trajectories of Class 1 and Class 2 were partially close to overlapping. Therefore, we chose the scheme with class probability and trajectory distribution, which was more reasonable for category 3. The parameters of the model also showed good model fit. The adherence trajectories for each categorical scheme were plotted in Figure 2.

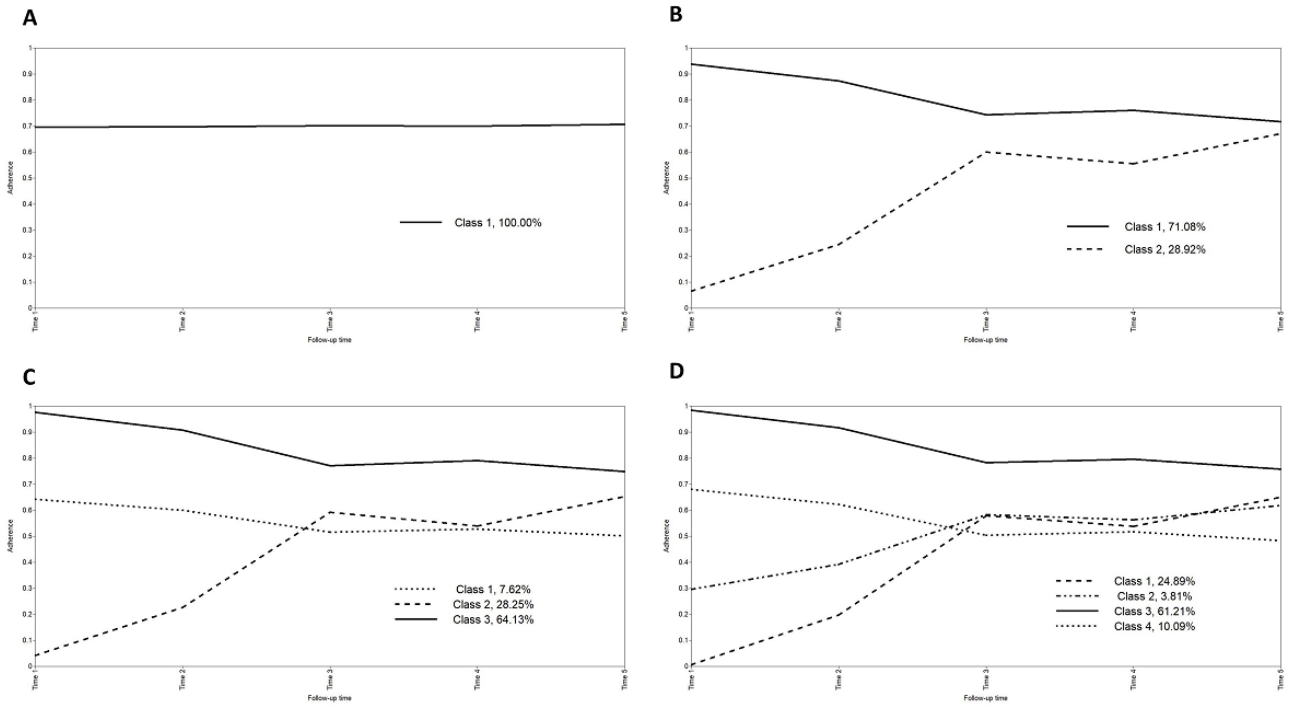
Figure 2. Trajectory of PrEP adherence potential categories in the MSM population. A, B, C, and D correspond to schemes with 1, 2, 3, and 4 adherence potential categories, respectively. PrEP: preexposure prophylaxis; MSM: men who have sex with men.



Based on the descriptions of the 3 latent categories of adherence (Table 2), Class 1 (n=34, 7.62%) had mean values of intercept (I) and slope (S) of 0.642 (P<.001) and –0.042 (P=.35), respectively, and was named "Intermediate adherence group." Class 2 (n=126, 28.25%) had mean values of intercept (I) and slope (S) of 0.042 (P<.001) and 0.183 (P<.001), respectively, and was named "Low adherence ascending group." Class 3 (n=286, 64.13%) had mean values of intercept (I) and slope (S) of 0.976 (P<.001) and –0.068 (P<.001), respectively, and was named "High adherence decline group."

Table . Description of GMM[a] parameters for 3 potential categories of PrEP[b] adherence among MSM[c] population.

Differences Between Adherence Potential Categories

We performed a univariate analysis of the relevant variables (Table 3). According to the results of the χ^2 test, educational attainment (*P*=.007), HIV knowledge score (*P*<.001), HIV testing (*P*=.05), HIV counseling (*P*=.02), number of male sexual partners (*P*=.003), attitudes of male sexual partners (*P*=.04), PrEP use (*P*=.05), and groups (reminder and no-reminder groups, *P*=.01) showed significant variability between patterns of change in adherence.

Predicting the Patterns of Change in Adherence

In general, only levels of adherence ≥80% are recognized as having a preventive effect [23,24]. For the "intermediate adherence group" and the "low adherence ascending group," both groups had adherence rates less than 80% and were considered to be at high risk for inadequate prevention. In our modeling, we prioritized these 2 groups together for prediction. We included all 8 variables that were significant in the univariate analysis in the data-balanced decision tree prediction model. The results of the decision tree analysis are shown in Figure 3.

In the final model, HIV knowledge score, education attainment, reminder interventions, and HIV testing were key nodes in the patterns of change in adherence. We extracted a total of 4 questions and 8 prediction rules. For example, we selected 2 of these rules for elaboration (Figure 4). If the MSM's HIV knowledge score (NODE 0) was ≥11, education level (NODE 1) was "Junior high; College or University degree or above," the MSM belonged to the reminder group (NODE 3), and the MSM had not been tested for HIV (NODE 4), the MSM had a 0.636 probability of belonging to the "low and intermediate adherence" groups. For the second prediction rule, if the MSM's HIV knowledge score (NODE 0) was <11, education level (NODE 10) was "Junior high; College or University degree or above," and the MSM did not receive mobile phone–based daily reminders (NODE 12), there was a 0.684 probability that the MSM would belong to the "low and intermediate adherence" groups.

After 10-fold cross-validation, the final prediction model had an accuracy of 75%; the classification accuracy of "low and intermediate adherence" was 78.12%, and that of "high adherence decline group" was 71.43%.

Discussion

Principal Findings

Our study was one of the few in China to assess and predict patterns of change in PrEP adherence among the MSM population. The results of the decision tree prediction model showed good and stable prediction results, identifying individuals at risk for low levels of adherence. At the same time, our research results also indirectly demonstrated the role of mHealth in PrEP adherence interventions. It revealed the great potential of digital health tools (for example, mobile phone apps or web-based) and interventions for HIV prevention and overall well-being in the MSM community.

Three Adherence Potential Categories Among MSM

We selected a 3-category scheme, in which the class probability and trajectory distribution were the most reasonable. The results

of the study showed that MSM in the "high adherence decline group" had a higher overall adherence level (mean adherence >80%) and accounted for the largest proportion (64.13%), which indicated that this PrEP strategy had a high acceptability among MSM in Western China and that most MSM could successfully adhere to PrEP. Several previous studies have also explored patterns of change in adherence. For example, in the CROPrEP project conducted in China (Beijing, Shenyang, Shenzhen, and Chongqing), the researchers identified 2 types of adherence trajectories based on a group-based trajectory model, which were named "High adherence" and "Low adherence" [25]. In a randomized controlled study based on an MSM population in the United States, the authors identified subgroups of individuals with similar adherence trajectories, also based on growth mixture modeling [8]. At the same time, the trajectory for this initial state at a high level and subsequent decline in adherence have been seen in previous studies [10,11]. Previous studies have conducted qualitative interviews with this subset of the population and found that the most consistent topic of declining adherence was about the frequency of visits [11]. Users felt unsupported and overwhelmed during the long visit intervals, thus failing to adhere to their daily medication. These findings were consistent with evidence from previous studies, which suggested that visit frequency may be associated with medication adherence [26,27]. It is suggested that appropriately increasing the frequency of visits (follow-up) and giving encouragement and support to users will help to improve adherence and avoid a decline. In summary, our study used a person-centered approach based on the GMM that took into account individual differences and presented trajectories based on individual characteristics. Identifying these subgroups of discrete individuals who follow similar adherence trajectories can help identify those at risk for nonadherence who may require increased intervention support. We extended the literature on PrEP adherence by assessing patterns of change in PrEP adherence.

Decision Tree to Predict Patterns of Change in Adherence

Over the past few years, machine learning methods have been increasingly used in a variety of fields and are equally feasible in small samples [28,29]. The MSM population is a sexual minority group and attaches greater importance to privacy issues, and we were unable to conduct a large-scale survey to get a large sample of data. Therefore, decision tree-based machine learning prediction method was more suitable for our study population. In addition, we combined the "intermediate adherence group" and "low adherence ascending group" identified by the GMM for prediction and prioritized the classification accuracy of this group. This decision was made to avoid incorrect negative categorization, which could result in MSM individuals with low adherence not receiving targeted interventions and guidance, increasing the risk of HIV infection. Indeed, many researchers advocated prioritizing sensitivity (classification accuracy for low and intermediate adherence groups) over specificity to ensure that the largest possible proportion of at-risk individuals were classified [30]. However, it should be noted that in our study, the classification accuracy of the "high adherence decline group" was 71.43%, which is acceptable in terms of specificity in addition to good sensitivity. Our study constructed a predictive model for PrEP adherence among the MSM population based on the decision tree and achieved good predictive results. We identified short questions and prediction rules that will facilitate the identification of individuals at risk for low adherence among PrEP users and targeted interventions that will be beneficial in improving adherence levels in high-risk populations.

Factors Influencing Patterns of Change in Adherence Among MSM

At the same time, decision tree also provided insight and understanding of the predictor variables of the data. The variable in the root node was the most influential variable in the categorization of observations, while the other nodes contained variables that have influence on a subset of the data [31]. In the final model of the decision tree, we found that the HIV knowledge score (root node) was the most influential predictor variable, followed by educational attainment, group (reminder and nonreminder groups), and HIV testing. The results showed a significant correlation between HIV knowledge and adherence among the MSM population. According to the Information-Motivation-Behavioral Skills Model, knowledge had a significant impact on individual behavior change and guided HIV risk reduction interventions [32], which provided a theoretical explanation for our findings.

Our findings suggested that the mHealth intervention would be beneficial in improving PrEP medication adherence in the MSM population, which was also consistent with previous studies [33]. A daily mobile phone–based reminder is a promising intervention based on the actual needs and wishes of MSM. The importance of serving the unique needs and preferences of this marginalized population based on mHealth technology was also highlighted in a study in Nepal MSM [16]. In future studies, more multifaceted features and more reliable data collection approaches should be considered for mobile phone–based interventions. mHealth interventions should prioritize privacy and confidentiality, be intuitive, be user-friendly, and be tailored to the specific needs and preferences of MSM, thereby optimizing the functionality and acceptability of these mHealth care interventions.

Furthermore, Mujugira et al [34] mentioned in their study that HIV self-testing and PrEP are supplementary tools that can empower individuals to take control of their HIV protection. Regular HIV testing was recommended as part of the PrEP implementation guidelines. Our findings also suggested that HIV testing could provide an opportunity to promote PrEP adherence in the Chinese MSM population. Based on the results of the decision tree model, interventions targeting knowledge, medication reminders, and HIV testing would be beneficial in improving adherence in the MSM population.

Limitations

Our study was a preliminary application of decision tree prediction modeling to PrEP adherence among MSM population in Western China. However, there are some limitations in our study. First, we measured adherence through participants' self-reports, which may have been influenced by their recall

bias, social desirability bias, and thus overestimation of adherence. However, a significant correlation between self-reported adherence and medication levels was found in a study of the PrEP program in a clinical setting, suggesting that self-reporting can be used to predict PrEP adherence [35]. Second, participants in our mHealth trial were rarely blinded, as they may have interacted with other participants in the survey field, thereby learning about the intervention, which is a typical shortcoming in mHealth trials. Although the results of our additional analyses indicated that there were no statistically significant differences between the intervention and control groups (Table S1 in Multimedia Appendix 1), the unblinded categorization of the 2 groups could have led to a potential impact on the results of the study. Future mHealth-based studies should fully consider the issue of blinding of interventions so as to ensure the accuracy of the findings. Meanwhile, there were the significant differences in baseline characteristics between included and excluded participants (Table S3 in Multimedia Appendix 1). According to the results of our analysis, age, place of residence, and employment status were statistically different in the inclusion and exclusion groups. The same shortcomings have been mentioned in previous studies [36]. The sample selected in their study was predominantly white and highly educated, which may have led to high estimates of self-reported adherence. However, we and previous researchers likewise agreed that such a bias was acceptable because these significantly different baseline characteristics were not the most significant factor influencing adherence. Meanwhile, for the evaluation metrics of the prediction model, we only selected 3 standard metrics and did not further adopt more metrics for assessment. However, the 10-fold cross-validation results had demonstrated the stability of the prediction results, and for small-sample machine learning predictions, we believed that the current metrics were sufficiently persuasive, and previous studies had used such an evaluation [22]. Since the MSM population is sensitive and concealed, this made our investigation process very difficult. Therefore, we did not have enough time to conduct external validation in this study. In future studies, we will validate the model more fully if the opportunity is available. Finally, further future research should be applied to larger samples while inputting more different variables so as to explore the accuracy of the predictive model.

Conclusions

Awareness and utilization of PrEP are increasing in China, and information to support improved PrEP adherence is becoming more important. Our study modeled the longitudinal trajectory of adherence among the MSM population in Western China and predicted patterns of change in adherence. Accurately identifying patterns of change in adherence based on the decision tree and its predictive pathways can help administrators increase their focus on individuals who need preventive interventions that are conducive to improving PrEP adherence. This study was an important first step in implementing predictors of adherence among the MSM population using PrEP. More specifically, we proposed a short set of questions and prediction rules that could hopefully be assessed in future large-scale validation studies to prospectively predict patterns of change in adherence in high-risk populations. Meanwhile, interventions targeting knowledge, mHealth reminders, and HIV testing will also be beneficial in improving adherence among the MSM population. Future studies should continue to investigate the dynamic trajectories of adherence, assess patterns of change more frequently, and develop more accurate predictive models to better understand PrEP adherence in high-risk populations in the current environmental context.

Acknowledgments

This work was supported by the National Key Project for Infectious Diseases of the Ministry of Science and Technology of China (2018ZX10721102-005).

Authors' Contributions

BL was responsible for the analysis of the data, interpretation of the results, and the draft and revision of the manuscript. XZ, J Li, and J Liu advised on the analysis approach, interpretation of the results, and the revision of the manuscript. BL, WH, and HP were responsible for data collection and data cleaning. XZ was responsible for funding acquisition and project administration and participated in the study conceptualization and supervision.

Conflicts of Interest

None declared.

Abstract

Background: A digital health technology's success or failure depends on how it is received by users.

Objectives: We conducted a user experience (UX) evaluation among persons who used the Food and Drug Administration–approved Digital Health Feedback System incorporating ingestible sensors (ISs) to capture medication adherence, after they were prescribed oral pre-exposure prophylaxis (PrEP) to prevent HIV infection. We performed an association analysis with baseline participant characteristics, to see if "personas" associated with positive or negative UX emerged.

Methods: UX data were collected upon exit from a prospective intervention study of adults who were HIV negative, prescribed oral PrEP, and used the Digital Health Feedback System with IS-enabled tenofovir disoproxil fumarate plus emtricitabine (IS-Truvada). Baseline demographics; urine toxicology; and self-report questionnaires evaluating sleep (Pittsburgh Sleep Quality Index), self-efficacy, habitual self-control, HIV risk perception (Perceived Risk of HIV Scale 8-item), and depressive symptoms (Patient Health Questionnaire–8) were collected. Participants with ≥28 days in the study completed a Likert-scale UX questionnaire of 27 questions grouped into 4 domain categories: overall experience, ease of use, intention of future use, and perceived utility. Means and IQRs were computed for participant total and domain subscores, and linear regressions modeled baseline participant characteristics associated with UX responses. Demographic characteristics of responders versus nonresponders were compared using the Fisher exact and Wilcoxon rank-sum tests.

Results: Overall, 71 participants were enrolled (age: mean 37.6, range 18-69 years; n=64, 90% male; n=55, 77% White; n=24, 34% Hispanic; n=68, 96% housed; and n=53, 75% employed). No demographic differences were observed in the 63 participants who used the intervention for ≥28 days. Participants who completed the questionnaire were more likely to be housed (52/53, 98% vs 8/10, 80%; *P*=.06) and less likely to have a positive urine toxicology (18/51, 35% vs 7/10, 70%; *P*=.08), particularly methamphetamine (4/51, 8% vs 4/10, 40%; *P*=.02), than noncompleters. Based on IQR values, ≥75% of participants had a favorable UX based on the total score (median 3.78, IQR 3.17-4.20), overall experience (median 4.00, IQR 3.50-4.50), ease of use (median 3.72, IQR 3.33-4.22), and perceived utility (median 3.72, IQR 3.22-4.25), and ≥50% had favorable intention of future use (median 3.80, IQR 2.80-4.40). Following multipredictor modeling, self-efficacy was significantly associated with the total score (0.822, 95% CI 0.405-1.240; *P*<.001) and all subscores (all *P*<.05). Persons with more depressive symptoms reported better perceived utility (*P*=.01). Poor sleep was associated with a worse overall experience (−0.07, 95% CI −0.133 to −0.006; *P*=.03).

Conclusions: The UX among persons using IS-enabled PrEP (IS-Truvada) to prevent HIV infection was positive. Association analysis of baseline participant characteristics linked higher self-efficacy with positive UX, more depressive symptoms with higher perceived utility, and poor sleep with negative UX.

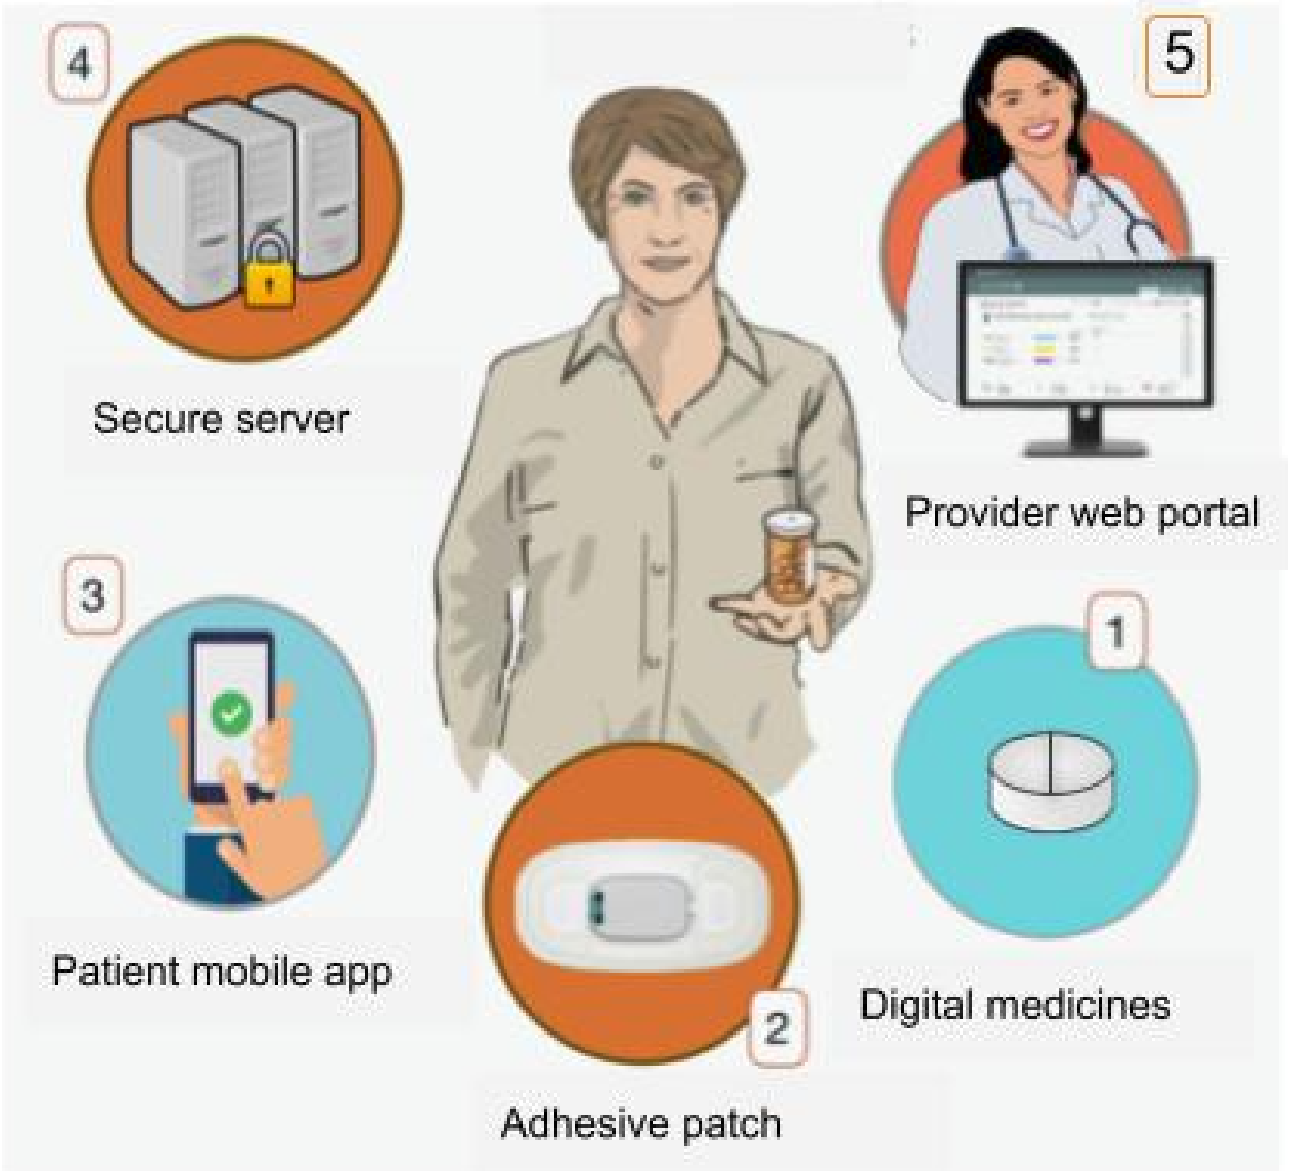
Introduction

The first ingestible sensor (IS) technology to capture oral medication adherence was approved by the Food and Drug Administration (FDA) in 2015 [1], followed by the approval of a second sensor variety in 2019 [2]. The major advancement associated with these medical devices is their capture of remote real-time data on actual drug ingestion, in some cases with simultaneous physiological data [3]. These novel digital technologies, in addition to accurate oral dose ingestion confirmation, may also allow bidirectional treatment adherence support [4-6]. The FDA-approved Digital Health Feedback System (DHFS) consists of an IS, external wearable patch, and paired mobile device [1]. It detects and records the timing of ingestion events and physiologic measures [3], which are then automatically uploaded to a secure internet server, allowing patients and health care providers to follow medication taking in real time and facilitate patient-provider communication (see Figure 1) [1,3-6].

Figure 1. Depiction of the components of the Digital Health Feedback System (DHFS). (1) At home, the patient takes the digitized medicine. The ingestible sensor activates in the stomach, and its serial number is captured and stored by the patch. (2) Patch data are transferred by Bluetooth to an app on the patient's paired mobile device. (3) Patients can follow their own medication taking (the DHFS has the capacity to send patients tailored automated reminder messages). (4) Data are transferred to secure servers. (5) Patient-approved health care workers can remotely receive real-time treatment adherence data and follow large cohorts of patients using the secure web-based dashboard.



IS-enabled tenofovir disoproxil fumarate plus emtricitabine (IS-Truvada) with the DHFS has recently been deployed to capture medication adherence behavior in persons starting oral pre-exposure prophylaxis (PrEP) [7]. This study confirmed that the DHFS is highly accurate, providing valid measures of ingestion with 99.3% (95% CI 97.2%-100%) reliability versus direct observation, similar to findings in a population of patients with tuberculosis (TB) [6,7]. Clinical trials evaluating DHFS

use in TB and hepatitis C treatments have demonstrated persistence use, efficacy, and even superiority versus direct observation [5,6]. Adverse events were few and mild, involving skin reactions to the patch, similar to reports from studies in chronic cardiometabolic disease management [3,8].

In the arena of HIV prevention, both providers and patients have described concerns with oral PrEP medication adherence as a barrier to successful implementation [9,10]. However, there are still no highly accurate real-time adherence measurement tools used in clinical practice to guide patient and physician discussions around these concerns. Providers continue to depend principally on self-reported adherence, which is subject to recall bias [11-13] and patient's efforts to avoid potential negative interactions with their physicians when disclosing nonadherence [14,15], or pharmacy refills, which indicate what a patient has on hand but provide no information on if and when medications are taken [16]. Directly observed therapy, which is primarily used in TB treatment, where a person is observed taking their medication, is highly reliable but personnel and resource intensive, time-consuming, costly [6,17,18], and impractical in chronic management for HIV prevention.

Multiple earlier technologies that supply data on oral medication adherence are available. Medication event monitoring system devices use openings of electronic containers and lids but have well-documented inaccuracies based on mismatches between openings and actual pill taking [19-24]. Smartphone apps incorporating SMS text messaging are based on self-report [25] or send videos [26] for later viewing and assessment. In contrast to these surrogate technologies, ISs signal when medication reaches the gastric track and are able to capture individual daily behavior patterns in real time, providing insight into variations in daily medication adherence. This capacity even has advantages over cumulative metabolite-based adherence measures developed and evaluated in the HIV prevention arena, such as dried blood spots and hair analysis [27,28], which do not allow real-time intervention or capture pattern variations in medication ingestion over time [7]. Such patterns are of importance based on the postdose durations of the therapeutic drug [29,30], which alters the risk of acquiring HIV infection, for example, a week where PrEP is taken once, followed by a week where it is taken daily [31-33].

Regardless of the superior capacities of the DHFS, the success or failure of any digital health innovation often depends on how it is received by the user [34]. Limited medical research exists on the user experience (UX) of persons using IS-based digital technology. UX is considered crucial to product design [34]. Classical consumer research ranks products according to levels of utility to consumers, which are subjective individual tastes; however, individuals change over time, and effort is devoted to developing an understanding of current and future user "personas" [35]. In contrast, traditional medical research, particularly in the infectious disease arena, historically looks for programmatic implementation of adherence technology, with the implicit assumption that "one size" should or could "fit all." The development of technology acceptance models has underscored the importance of understanding how personal attitudes contribute to behavioral intention on technology use [36-41], particularly how perceived ease of use and utility influences individuals' willingness to adopt and continue to use a given technology [39]. Research on the contribution of personal attitudes and characteristics is now expanding into health care technology use [42] but is entirely novel in the arena of digital adherence technology.

We conducted a detailed UX evaluation among persons prescribed PrEP to prevent HIV infection who used the DHFS with IS-Truvada. Our study evaluated the overall experience, ease of use, perceived utility, and intention of future use. We captured baseline demographics and urine toxicology screening (UTOX). In addition, we collected detailed self-report questionnaires to evaluate depressive symptoms, HIV risk perception, sleep, and individual self-efficacy in the context of medication taking [43]. Self-efficacy is defined as a person's belief in their capability to succeed and achieve a given level of performance [44] and is considered to be connected to motivation, achievement, and self-regulation [45,46]. We then conducted an association analysis of our UX findings with individual participant characteristics captured at baseline, to see if current and future user "personas" emerged.

Methods

Overview

UX data were collected upon exit from a prospective, single-arm, open-label intervention study of participants using the DHFS (manufacturers: Proteus Digital Health and Otsuka Pharma) with IS-enabled tenofovir disoproxil fumarate plus emtricitabine for up to 12 weeks. The parent intervention study evaluated DHFS adherence measurements, ability to capture patterns of adherence behavior, and the association of predictors with adherence behavior among persons starting PrEP [7].

Ethical Considerations

The study protocol was approved by the University of California San Diego (UCSD) Institutional Review Board (#161618), was conducted in accordance with Good Clinical Practice principles, and was registered on ClinicalTrials.gov (NCT03693040). Participants signed an informed consent. All data derived from this study were deidentified. Participants were compensated with a gift card equivalent in value to US $50 on the completion of all activities associated with the baseline and study exit visits, which included survey completion.

Participants

Eligible participants were HIV and hepatitis B seronegative, aged ≥18 years old, were at risk for HIV, and desired oral PrEP. Participants were recruited from the UCSD AntiViral Research Center, UCSD Owen Clinic, or other primary care clinics in San Diego. Participant procedures were as follows. Baseline laboratory evaluations were required within the defined parameters; participants needed to be able to use mobile devices (these were provided by the study if they did not have them), be willing to use the DHFS, and have no known skin adhesive hypersensitivity. Baseline demographics, UTOX, and self-reported questionnaires were collected. Participants were instructed on DHFS use at baseline; this instruction comprised how to place and change the patch, how to pair the patch with the mobile device, and how to connect the mobile device to

Wi-Fi. During the trial, participants changed the monitor patch themselves as needed and could view the medication ingestion log on their mobile device. Study staff counseled participants on wearing the patch and keeping their paired mobile device consistently charged. After the intervention, participants underwent repeat HIV testing and continued on PrEP as prescribed by their practitioner. Participants with ≥28 days in study (DHFS with IS-Truvada) completed the detailed exit questionnaire and formed the cohort analyzed.

Measures

Baseline self-report questionnaires evaluated habitual self-control [47], self-efficacy beliefs [43], depression (Patient Health Questionnaire–8 [PHQ-8]) [48], sleep (Pittsburgh Sleep Quality Index [PSQI]) [49], and HIV risk perception (Perceived Risk of HIV Scale [PRHS] 8-item) [50]. On study exit, the detailed UX questionnaire was completed. The UX questionnaire consisted of 27 questions with responses coded from 1 to 5 and included reverse scored and related questions to ensure validity [51]. Of the items scored on the Likert scale, 2 questions assessed satisfaction, from 1=extremely unsatisfied to 5=extremely satisfied; 5 questions asked participants to rate various aspects of the system, from 1=extremely unhelpful to 5=extremely helpful; and the responses to the remaining questions ranged from 1=strongly disagree to 5=strongly agree. The UX questions were grouped into 4 domain categories: overall experience, ease of use, intention of future use, and perceived utility. Textbox 1 shows the questions, domains, and the number of questions per domain.

Textbox 1. User experience questionnaire items for the Digital Health Feedback System (DHFS). Domain categories are shown, with questions grouped by category, not in the originally administered order.

Overall experience

1. How would you rate your overall experience with participating in this mediation adherence study?
2. How would you rate your overall satisfaction with the DHFS (the iPad and patch system)?
3. Overall, this experience using the DHFS was positive.
4. Overall, this experience using the DHFS was challenging. (reverse scored)

Ease of use

5. When you started the study, how helpful was the Patient Information Booklet?
6. How helpful were the Proteus app instructions?
7. I was very comfortable changing the patch on my own.
8. The instructions for changing the patch were easy to follow.
9. The patch is comfortable to wear.
10. Wearing the patch interfered with my daily activities. (reverse scored)
11. The Proteus app was difficult to navigate. (reverse scored)
12. Accessing my medication ingestion report was difficult. (reverse scored)
13. Technical difficulties were easily resolved.

Intention of future use

14. I would use the DHFS in the future.
15. I would use the DHFS in the future to keep track of my treatment.
16. I would use the DHFS in the future if I had problems following my treatment.
17. I would recommend that others use the DHFS.
18. I would recommend use of the DHFS to others if they are having problems following their treatment.

Perceived utility

19. How helpful was participating in the study for your medication adherence?
20. How helpful was the DHFS in helping you follow your medication adherence?
21. I used the DHFS app frequently to follow my medication taking.
22. I used the DHFS app frequently to follow my activity and rest.
23. The DHFS was useful.
24. The DHFS made taking my medication easier for me.
25. Using the DHFS interfered with how I typically manage my medications. (reverse scored)
26. Referring to the Proteus app during the study helped me track my medication adherence.
27. The DHFS improved my medication adherence.

Statistical Analysis

A total of 27 UX questionnaire item responses were scored (using reverse scoring where necessary), so that higher scores mean higher levels of satisfaction. The questions' average values were used for the total summary score and each of the 4 domain summary subscores. Demographic characteristics of participants who completed the UX questionnaire were compared to those of nonresponders using the Wilcoxon rank-sum test and Fisher exact test as appropriate.

Single- and multipredictor linear models were used to analyze the 5 summary scores for their association with demographic and other baseline characteristics, including age, gender, race and ethnicity (non-Hispanic White, Asian, Black, or Hispanic), UTOX results (positive or negative), number of substances detected in UTOX, sleep (PSQI), self-efficacy, habitual self-control, HIV risk perception (PRHS 8-item), and depression (PHQ-8). Prior to regression analyses, the multiple imputation by chained equations method with 10 imputations was used to impute missing values in the predictors. All model estimates were based on pooled results, using the rules from Rubin [52]. Predictors with *P* values <.20 in the univariable analyses were included for consideration into multivariable analyses. Backward model selection with a .20 threshold for predictor significance was used to select the final multivariable models. The *Result*s section reports model coefficients, their 95% CIs, and the relevant *P* values. The CIs for effects of ethnicity were Bonferroni-adjusted for multiple comparisons. PHQ-8 exhibited nonlinear association with the summary total score and subscores. Natural cubic splines, with the number of knots determined by minimizing the Akaike information criterion, were used to model these associations. Analyses and figures were done using R (version 4.0.3; R Foundation for Statistical Computing) [53]. The R package *mice* was used for multiple imputation analyses [54].

Results

Study Cohort Description

Study Enrollment, Demographics, and Cohort Description

Overall, 71 persons were enrolled in the intervention using the DHFS with IS-Truvada. Participants had a mean age of 37.6 (range 18-69) years and were mostly male (n=64, 90%), White (n=55, 77%; n=24, 34% were Hispanic), housed (n=68, 96%), and employed (n=53, 75%). Baseline toxicology was positive in 41% (n=28) of participants, with marijuana (n=17, 25%), amphetamines (n=10, 14%), and methamphetamines (n=8, 12%). A total of 63 participants used the DHFS with IS-Truvada for ≥28 days, and there were no significant differences in baseline demographics compared to enrolled participants who dropped out early (n=8) [7]. Of the 63 participants, 53 (84%) fully or partially completed the comprehensive UX exit questionnaire. Table 1 shows the demographic characteristics of participants at baseline and includes the comparison of participants who completed the UX questionnaire and those that did not. Questionnaire respondents did not differ statistically from nonrespondents on age (37.5 vs 33.9 y; *P*=.34), sex (48/53, 91% vs 9/10, 90% male; *P*>.99), employment status (39/53, 74% vs 7/10, 70% employed; *P*>.99), or race and ethnicity (30/53, 57% vs 5/10, 50% non-Hispanic White; *P*=.43). However, questionnaire respondents were more likely to have stable housing (52/53, 98% vs 8/10, 80%; *P*=.06) and less likely to test positive on UTOX (18/51, 35% vs 7/10, 70%; *P*=.08), particularly for methamphetamine (4/51, 8% vs 4/10, 40%; *P*=.02). No significant difference was observed in self-report questionnaire scores between respondents and nonrespondents (all *P*>.05).

Table . Baseline cohort characteristics and comparison between completers and noncompleters of the user experience questionnaire. *P* values are based on Wilcoxon rank-sum test (numeric variables) and Fisher exact test (categorical variables).

UX Questionnaire Summary Scores

Table 2 lists the summary statistics, including mean and range, for the total summary score and the 4 themed subscores. On average, participants expressed an overall satisfaction with the DHFS system (total summary score: mean 3.74, SD 0.70). On average, the participants had the highest summary score for overall experience (mean 3.89, SD 0.87), followed by ease of use (mean 3.74, SD 0.65), perceived utility (mean 3.73, SD 0.76), and intention of future use (mean 3.58, SD 1.08). Based on IQR values, at least 75% of participants provided favorable feedback for the total score (IQR 3.17-4.20), overall experience (IQR 3.50-4.50), ease of use (IQR 3.33-4.22), and perceived

utility (IQR 3.22-4.25), and at least 50% of participants expressed favorable feedback on intention of future use (IQR 2.80-4.40).

Table . Summary scores from the user experience questionnaire.

Summary score	Participants, n	Value, mean (SD)	Value, median (IQR)	Value, range
Overall experience	53	3.89 (0.87)	4.00 (3.50-4.50)	2.25-5.00
Ease of use	52	3.74 (0.65)	3.72 (3.33-4.22)	2.33-5.00
Intention of future use	53	3.58 (1.08)	3.80 (2.80-4.40)	1.00-5.00
Perceived utility	48	3.73 (0.76)	3.72 (3.22-4.25)	1.44-5.00
Total	47	3.74 (0.70)	3.78 (3.17-4.20)	2.00-4.96

Participant Characteristics as Predictors of UX Score

Total Summary Score

The single-predictor analyses showed that higher total summary scores were associated with better self-efficacy rating (0.822 per point, 95% CI 0.405-1.240; *P*<.001) and PHQ-8 score with a nonlinear trend (natural cubic spline with 1 knot). Only self-efficacy remained in the model after multipredictor model selection. Regression analyses for predictors of total summary score are shown in Table 3.

Table . Single- and multipredictor linear regression associations of demographics and baseline characteristics with the total user experience score.

Variable		Single-predictor model		Multipredictor model	
		Coefficient (95% CI)	*P* value	Coefficient (95% CI)	*P* value
Age (per year)		0.008 (−0.011 to 0.027)	.38	—[a]	—
Gender			.60		—
	Male	Reference		—	
	Female or transgender	−0.197 (−0.944 to 0.549)		—	
Race and ethnicity			.71		—
	Asian, non-Hispanic	−0.122 (−0.944 to 0.701)		—	
	Black, non-Hispanic	0.320 (−0.705 to 1.344)		—	
	Hispanic	0.209 (−0.377 to 0.796)		—	
	White, non-Hispanic	Reference		—	
Positive drug screen (any drugs)		0.214 (−0.239 to 0.666)	.35	—	—
Number of drugs (per drug)		0.103 (−0.139 to 0.346)	.39	—	—
Global PSQI[b] score (per point)		−0.018 (−0.082 to 0.047)	.58	—	—
Self-efficacy (per point)		0.822 (0.405 to 1.240)	<.001	0.822 (0.405 to 1.240)	<.001
Habitual self-control (per point)		0.224 (−0.134 to 0.581)	.21	—	—
HIV risk perception (PRHS[c] 8-item; per point)		−0.015 (−0.055 to 0.025)	.45	—	—

Overall Experience Score

In the univariable analyses, associations were found at the .20 significance level between a higher overall experience score and male gender (mean difference 0.543, 95% CI −0.274 to 1.360; *P*=.19 vs female or transgender), Hispanic ethnicity (mean difference 0.654, 95% CI 0.026-1.282 vs non-Hispanic White), better PSQI score (−0.080 per point, 95% CI −0.152 to −0.007; *P*=.03), better self-efficacy rating (0.688 per point, 95% CI 0.146-1.230; *P*=.01), stronger habitual self-control (0.384

per point, 95% CI −0.008 to 0.776; *P*=.06), and PHQ-8 score with a nonlinear trend (natural cubic spline with 1 knot; *P*=.09). In the multivariable analyses, incorporating the above univariable associations of .20 significance and higher, the overall experience score was associated with race and ethnicity (*P*=.02), lower PSQI score indicating better sleep (−0.070 per point, 95% CI −0.133 to −0.006; *P*=.03), and higher self-efficacy rating (0.771 per point, 95% CI 0.292-1.250; *P*=.002; see Table 4).

Table . Multipredictor linear regression associations of demographic, baseline characteristics, and percentage of confirmed doses with subscores. See Figure 2 for the perceived utility model.

Variable		Overall experience		Ease of use		Intent of future use		Perceived utility	
		Coefficient (95% CI)	*P* value	Coefficient (95% CI)	*P* value	Coefficient (95% CI)	*P* value	Coefficient (95% CI)	*P* value
Race and ethnicity			.02		—[a]		—		—
	Asian, non-Hispanic	−0.195 (−1.094 to 0.704)		—		—		—	
	Black, non-Hispanic	0.937 (−0.209 to 2.083)		—		—		—	
	Hispanic	0.606 (0.002 to 1.210)		—		—		—	
	White, non-Hispanic	Reference		—		—		—	
Global PSQI[b] score (per point)		−0.070 (−0.133 to −0.006)	.03	—	—	—	—	—	—
Self-efficacy (per point)		0.771 (0.292 to 1.250)	.002	0.750 (0.375 to 1.126)	<.001	0.885 (0.213 to 1.557)	.01	0.901 (0.411 to 1.391)	<.001
PHQ-8[c] total (per point)		—	—	—	—	—	—	—[d]	.01

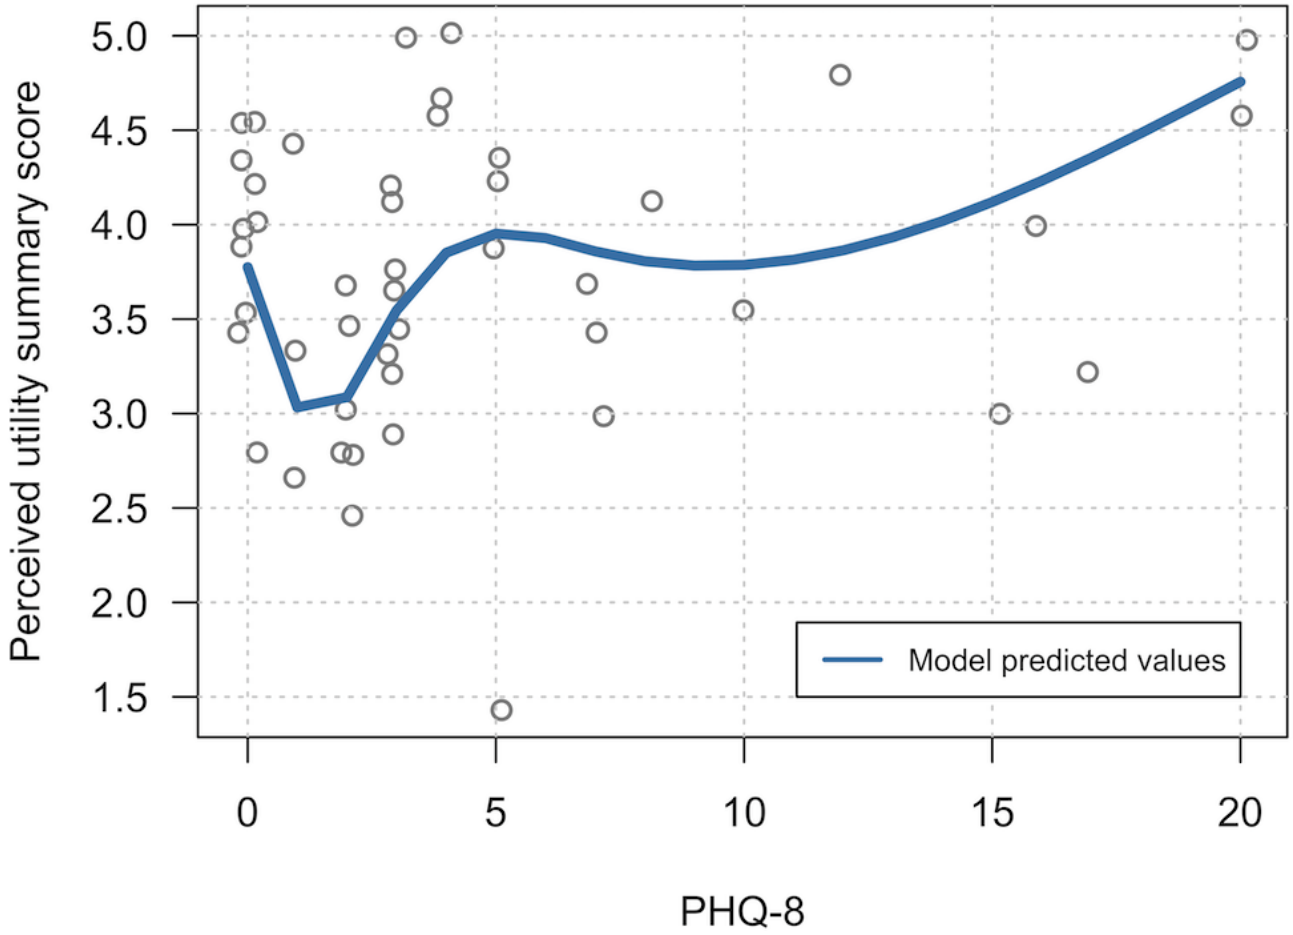
[a]Not applicable.

[b]PSQI: Pittsburgh Sleep Quality Index.

[c]PHQ-8: Patient Health Questionnaire–8.

[d]Nonlinear terms using cubic spline curves.

Figure 2. Observed values (points) and the predicted spline (line) showing association between PHQ-8 and perceived utility summary score, adjusted for self-efficacy. PHQ-8: Patient Health Questionnaire–8.



Ease of Use Score

The ease of use score showed correlation with better self-efficacy rating (0.750 per point, 95% CI 0.375-1.126; *P*<.001) and PHQ-8 score with a nonlinear trend (natural cubic spline with 1 knot; *P*=.16). The multipredictor model on the ease of use score retained only self-efficacy as a predictor (see Table 4).

Intention of Future Use Score

Only the self-efficacy rating was associated with the intention of future use score (0.885 per point, 95% CI 0.213-1.557; *P*=.01; see Table 4)

Perceived Utility Score

The single-predictor analyses showed association between the perceived utility score and self-efficacy rating (0.672 per point, 95% CI 0.187-1.157; *P*=.008), as well as PHQ-8 score (natural cubic spline with 3 knots; *P*=.10). The multipredictor model retained both predictors and showed that better perceived utility score was associated with better self-efficacy rating (0.901 per point, 95% CI 0.411-1.391; *P*<.001) and worse PHQ-8 score (natural cubic spline with 3 knots; overall *P*=.01; see Table 4).

Discussion

Principal Findings

The detailed UX analysis indicated that greater than 75% of participants who used the DHFS with IS-Truvada reported positive experiences, based on the total score and the subscore analyses (overall experience, ease of use, and perceived utility analyses); 70% of participants responded positively toward the intention of future use. Multivariable linear regression analyses of participant characteristics found that having a higher baseline self-efficacy concept score was associated with more positive UX in the total score and across all subscores. In addition, Hispanic ethnicity and more depressive symptoms were associated with reporting positive overall experience and higher DHFS utility, respectively. Poor sleep (captured by the global PSQI score) was associated with a worse overall experience.

UX research is central to the process of developing user-centric technology integration into clinical arenas serving different patient populations [34]. Our research indicates that among participants prescribed PrEP, the DHFS with IS-Truvada was well received. Meta-analysis of UX with mobile health technology repeatedly finds the following themes as being critical to the end user: functionality (related to experiences supporting self-management); acceptance (related to usability and feasibility); perceptions of benefit (related to self-efficacy and empowerment); and importance of co-design [55]. From

this perspective, our findings indicate that the DHFS met critical end-user needs of functionality, acceptance, and perception of benefit in the population using PrEP in this study.

Our data currently represent one of the largest and most detailed study available on UX in persons with any medical diagnosis who have experience using an IS medication adherence system. Our findings are in line with those of Chai et al [56], who reported from qualitative interviews that 15 out of 90 persons using a digital pill system (DPS) [2] for PrEP adherence measurement perceived the device as acceptable, novel, and valuable. Interestingly, men who have sex with men (MSM) taking PrEP who reported substance use were also found to have positive perceptions toward using the DPS in the future [57]. Notably, the PrEP cohort we studied had significantly higher levels of UX satisfaction with the DHFS than that reported in participants in a psychiatric study population (greater than 75% vs 53%, respectively) [58]. The authors noted that their study population included participants with acute psychotic illness; in contrast, participants on stable antipsychotic doses without psychotic symptoms in a prior study [59] reported 70% satisfaction and 78% utility in response to single-question item. The findings from a stable psychiatric study population are close to those found by our detailed UX analysis in persons starting PrEP.

At the outset, we investigated whether baseline demographics and self-report questionnaires could be used to inform current and future use "personas" among our study population, following the expectation that with technology use, "one size may not fit all." A significant association with positive UX for the total score and all subscores was the participants' sense of self-efficacy. Self-efficacy is defined as a person's belief in their capability to succeed and achieve a given level of performance [44]. Self-efficacy is considered to be connected to motivation, achievement, and self-regulation [45,46]. We used an established scale for capturing self-efficacy in the context of medication taking [43] and found an association between the self-efficacy concept and experience of DHFS technology functionality, acceptance, and perception of benefit. Our findings indicate that the self-efficacy concept is directly related to the use of the health care technology tested, and our findings are in line with prior reports showing that self-efficacy beliefs can affect perceived usefulness and perceived ease of use of technology in general, and health informatics and digital health social media applications in particular [60,61].

Persons having lower sleep quality at baseline reported a worse overall experience with the DHFS, which may be related to the requirement of a patch worn on the torso in the system tested and suggests that sleep quality should be evaluated before using the DHFS in a clinical study or practice. The role of depressive symptoms on the UX with the DHFS needs more evaluation. Current evidence indicates that persons with depressive symptoms have significantly higher use of health information technology than persons with other chronic diseases [62], and a plethora of research exists on both digital data-gathering and web-based intervention tools for depression [63]. No published literature appears to be available on what persons with depressive symptoms or a diagnosis of depression *want* from digital health technology. It is likely such data are collected during technology "co-design" efforts, but these data may be analyzed as chronic disease comorbidities or general mental health associations. Our findings suggest that specific criteria for digital health technology may be important to persons with depressive symptoms and support separate analysis of user requirements and experience for these persons.

Clinical Implications

As with any long-term therapy, successful provision of PrEP to prevent HIV infection requires a compassionate mindset, involving a highly individualized series of investigations into how each patient and their disease risk intertwine over time, with trust and honesty between both patients and physicians [64]. Patients need and have choices on PrEP delivery. Based on our UX evaluation of the DHFS with IS-Truvada, this technology is acceptable to patients prescribed PrEP and may be useful to provide insights for both patients and providers on optimal PrEP treatment modalities for individuals over time [7].

Limitations

The study sample was almost exclusively comprised of MSM, and the findings are not generalizable to other populations of patients using PrEP. The study duration was limited to 3 months, and our analysis included only those who persisted with the technology for at least 1 month, 84% (53/63) of whom completed the detailed UX questionnaire. As is expected with a detailed questionnaire, some participants omitted answers to some questions. However, the use of reverse scored and related questions, while primarily designed to ensure questionnaire validity, also served to expand the capture of concepts where questions were left unanswered. Significant differences were observed between questionnaire nonrespondents and respondents, limiting the generalizability of our findings to persons taking PrEP who are homeless or use methamphetamine. In the latter regard, it is notable that Chai et al [56,57] report positive UX and attitude findings regarding DPS technology in MSM taking PrEP who use substances. Despite being one of the largest detailed study available on UX in persons who used an IS medication adherence system, our sample size was limited, and as the probability of reporting a positive experience was observed in >75% of the study population, the likelihood of identifying "current and future use personas" across our study was restricted by our sample size.

Conclusions

The evaluated IS technology met critical end-user needs of functionality, acceptance, and perception of benefit in the population using PrEP in this study. These findings support the continued evaluation of IS adherence technologies in this patient population. Oral medication adherence is a complex behavior. Increased focus on understanding and matching the needs of individual patients to available digital adherence technology options may improve the impact of these technologies on adherence monitoring and support, as well as inform optimal PrEP treatment modalities for individual patients over time.

Abstract

Background: The World Health Organization has called for addressing the growing burden of noncommunicable diseases (NCDs) by promoting healthy lifestyles among the population. Regarding patient health, primary care professionals (PCPs) are the first line of care who can positively influence patients' behavior and lifestyle habits. However, a significant percentage of PCPs do not lead a healthy lifestyle. Therefore, addressing their health behaviors may be the key to substantially increasing health promotion advice in general practice. The Mediterranean diet has been extensively studied, and there is strong evidence of it being a dietary pattern for the prevention of NCDs, in addition to its significant environmental, sociocultural, and local economics benefits.

Objective: This study focused only on the dietary aspect of the PCPs' lifestyle. The primary objective was to evaluate the effect of using the Electronic 12-Hour Dietary Recall (e-12HR) smartphone app to improve diet, specifically to promote adherence to the Mediterranean diet (AMD), among PCPs. The secondary objectives were to establish the usability of the e-12HR app and to determine AMD among PCPs.

Methods: An individual-level randomized, controlled, and single-blind clinical trial was conducted with 2 parallel groups: a control group (CG), using the nonfeedback version of the e-12HR app, and an intervention group (IG), using the feedback version of the e-12HR app. The level of human involvement was fully automated through the use of the app. There was a 28-day follow-up period. Participants were PCPs (medicine or nursing) recruited offline at one of the selected primary care centers (Andalusia, Spain, Southern Europe), of both sexes, over 18 years old, possessing a smartphone, and having smartphone literacy.

Results: The study response rate was 73% (71 of 97 PCPs), with 27 (38%) women and 44 (62%) men: 40 (56%) PCPs in the CG and 31 (44%) in the IG. At baseline, AMD was medium (mean Mediterranean Diet Serving Score [MDSS] index 9.45, range 0-24), with 47 (66%) PCPs with a medium/high MDSS index. There were significant statistical improvements (CG vs IG, in favor of the IG) at week 4 (no significant statistical differences at baseline): +25.6% for the MDSS index (P=.002) and +213.1% for the percentage with a medium/high MDSS index (P=.001). In relation to specific food groups, there were significant statistical improvements for fruits (+33.8%, P=.02), vegetables (+352%, P=.001), nuts (+184%, P=.02), and legumes (+75.1%, P=.03). The responses to the usability rating questionnaire were satisfactory.

Conclusions: The results support recommending the use of the e-12HR app as a tool to contribute to improving diet and preventing NCDs among PCPs, while positively influencing patient dietary behavior and preventing diet-related NCDs among patients.

Introduction

Major chronic noncommunicable diseases (NCDs; eg, cardiovascular diseases, cancer, chronic respiratory diseases, and diabetes) are responsible for 74% of deaths worldwide, making them the leading cause of preventable mortality [1]; they also reduce patients' well-being and activity, which contributes to a poor quality of life, disability, and reduced productivity [1]. Notably, these NCDs share common risk factors, such as an unhealthy diet, smoking, harmful alcohol consumption, and physical inactivity [1], all of which are behavioral or lifestyle-related factors that are potentially modifiable [2]. For this reason, the World Health Organization has called for addressing the growing burden of NCDs by promoting healthy lifestyles [1,3].

Health care workers are a subgroup of the population where lifestyle promotion is essential for 3 main reasons. The first reason is their own health: although health care professionals do their best to provide exceptional patient care, they often fail to prioritize their own self-care [4], resulting in unhealthy behaviors associated with a high risk of NCDs. Studies of health care workers' lifestyles in hospitals, for example, showed high rates of overweight/obesity [5-7], low fruit and vegetable consumption [6,7], low physical activity [5-8], tobacco [5,7] and alcohol consumption [6,7], and high levels of stress and insufficient rest [4-6]. In addition, almost half had more than 2 of these risk factors [5,6].

The second reason is the success of health care organizations: health care workers with better and healthier habits have been shown to have higher personal and job satisfaction and fewer sickness-related absences from work [9]. The third reason is patient health: several studies have described that health care professionals who practice healthy behaviors offer more advice on healthy habits to patients who come to their practice, that they have more assertive attitudes when counselling patients, and they provide more comprehensive and aggressive counselling, which can positively influence patients' health [10-14].

Regarding patient health, primary care is the cornerstone for preventing NCDs through health education and plays an essential role in the success of therapeutic medicine [11]. Primary care professionals (PCPs) are the first line of care who can positively influence patient behavior and lifestyle habits [15], and indeed, patients perceive PCPs (doctors and nurses) as the most trusted source of health information and advice on healthy lifestyles [13]. However, a significant percentage of PCPs, as with hospital health care professionals, do not lead a healthy lifestyle: there is a high prevalence of NCD risk factors, such as smoking [10,16], alcohol abuse [10,16], overweight/obesity [17], physical inactivity [5,10,17], inadequate fruit and vegetable intake [10,11,17], added salt intake [17], and high consumption of ultraprocessed foods [18], sugars, and fats [10]. Therefore, addressing PCPs' health behaviors may be the key to substantially increasing health promotion advice in general practice [12].

As the evidence shows, PCPs are exposed to several risk factors of NCDs; this study focused only on the dietary aspect of the PCPs' lifestyle. As a starting point, the research team posed the following question: How can the dietary habits of PCPs be improved?

The research team has previously evaluated the effectiveness of a smartphone app called the Electronic 12-Hour Dietary Recall (e-12HR) in improving diet in Spanish university students (health science [19,20] and non–health science [20]). The main hypothesis of this study was that the use of this app among PCPs can have an influence on improving their diet, as has already been evidenced in previous research among university students [19,20], the null hypothesis being that the use of the app has no influence on improving the diet of PCPs.

To the best of our knowledge, this study is the first to evaluate the use of a smartphone app to improve diet among PCPs. The primary study objective was to evaluate the effect of using the e-12HR app on improving diet among PCPs, specifically to promote adherence to the Mediterranean diet (AMD). The Mediterranean diet has been extensively studied, and there is strong evidence of it being a dietary pattern for the prevention of NCDs [21-25], in addition to its significant environmental, sociocultural, and local economics benefits [26-28]. In addition, secondary objectives were to establish the usability of the e-12HR app and determine AMD among PCPs.

Methods

Overview of the Study

The study was an individual-level randomized, controlled, and single-blind clinical trial with 2 parallel groups: a control group (CG) and an intervention group (IG). All participants used an app called the e-12HR app, with different versions for the CG and the IG. In the CG, participants used the nonfeedback version of the e-12HR app, and in the IG, participants used the feedback version of the e-12HR app (see the *Intervention* section). The

level of human involvement was fully automated through the use of the app.

All research was carried out in 3 basic health zones of the Andalusian Health Service (Andalusia, Spain, South of Europe): Camas, Coria del Río, and San Juan de Aznalfarache. Several primary care centers were selected in the 3 zones: the Camas, Santiponce, Valencina de la Concepción, Castilleja de Guzmán, Coca de la Piñera, Carambolo, and Pañoleta health centers in Camas; the Coria del Río health center in Coria del Río; and the San Juan de Aznalfarache and Gelves health centers in San Juan de Aznalfarache. The study ran for 28 days, and participant recruitment took place offline from September to October 2022.

Inclusion criteria for the study were both sexes, age over 18 years, possession of a smartphone (iOS or Android operating system), smartphone literacy, and a PCP (medicine or nursing) at one of the selected primary care centers. Exclusion criteria included food intolerance, chronic disease, or pregnancy (due to the possibility of requiring specific dietary recommendations).

Ethical Considerations

The study was conducted according to the guidelines laid down in the Declaration of Helsinki, and all procedures involving study participants were approved by the Andalusian Biomedical Research Ethics Portal (PEIBA) on March 30, 2022 (identifier: 2813-N-21). The trial was registered at ClinicalTrials (identifier: NCT05532137). Written informed consent was obtained from all participants.

Participant Enrollment

The project was publicized in the selected primary care centers by a member of the research team, and individual talks were scheduled with interested health care professionals. In each of the individual talks, the study protocol was explained, including the objectives, risks, and benefits of the research, and an email address for the study was provided.

To participate in the study, it was necessary for interested health care professionals to send an email to the designated address, indicating their “interest in participating in the study” and the primary care center where they worked. After receiving the email, a member of the research group sent candidates a series of documents necessary to be able to participate in the study: (1) an informed consent form; (2) a form with personal information (sex, date of birth, primary care center, weight, height, and smoking status), with documents 1 and 2 to be completed, signed, and returned to the same email address; (3) instructions for downloading the e-12HR app (free to download from the App Store or the Play Store); (4) an image of the Mediterranean diet pyramid (with recommendations for consumption by food group); (5) a personal alphanumeric code; and (6) a user’s guide with detailed information for using the app. Document 6 was the only one that differed depending on whether it was intended for participants in the CG (nonfeedback e-12HR version) or the IG (feedback e-12HR version), and obviously, document 5, which contained the personal code, was unique for each participant.

Throughout the study, participants could contact the research team by email with any questions, including questions to reduce the likelihood of harm.

Participant Allocation

In each basic health zone, the recruited participants were randomized into 1 of 2 groups (CG or IG) in a ratio of 1:1 as follows: the participant who sent the first email was assigned to the CG, the participant who sent the second email was assigned to the IG, and so on.

This study was single-blind because, due to the nature of the intervention, the PCPs could not be blinded. However, the investigator who performed the statistical analysis of the data was blinded throughout the study. In addition, each participant only had access to 1 version of the app: the personal codes of the participants assigned to the CG activated only the nonfeedback e-12HR version, while the personal codes of the participants assigned to the IG activated only the feedback e-12HR version.

Intervention

The structure and functions of the e-12HR app (nonfeedback and feedback versions) have been described in detail by Béjar et al [19]. In this study, we used e-12HR version 3.0. The e-12HR app did not undergo changes throughout the study. In brief, the nonfeedback e-12HR version allows the user to collect food consumption data; however, this version does not provide any feedback to users to promote the Mediterranean diet (ie, this version of the app presents a single function: diet determination). The feedback e-12HR version allows for the collection of food consumption data, and as an additional automatic function, every 7 days the app issues personalized feedback on how to improve AMD (ie, this version of the app has 2 functions: determining the diet and providing feedback to improve AMD). The feedback provided came in 3 parts: (1) the AMD index score: specifically, the Mediterranean Diet Serving Score (MDSS) index [29] (range 0-24); (2) the image of a traffic light: the MDSS index score was divided into 1 of 3 levels (low: score 0-8, red light; medium: score 9-15, orange light; high: score 16-24, green light) [30]; and (3) recommendations for consumption by food group [19]. The nonfeedback e-12HR version did not provide any of the 3 parts of the feedback, as they were exclusive to the e-12HR feedback version. See Multimedia Appendix 1 for real images of the e-12HR app (nonfeedback and feedback versions).

Follow-up and Outcome Measures

To analyze the effect of the intervention (CG nonfeedback e-12HR vs IG feedback e-12HR), 4 follow-up points were established: week 1 (baseline), week 2, week 3, and week 4. At each follow-up point, the research team manually calculated the MDSS index for each of the 2 groups from the data provided by the e-12HR app. The method for calculating the MDSS index has been described in detail elsewhere [19].

The main result variable was the change in the total MDSS index at weeks 2, 3, and 4 of monitoring, while the secondary result variables were the personal information variables, the MDSS index at week 1 (baseline), and the answers to the

usability rating questionnaire for the e-12HR app (see the *Usability Rating Questionnaire for the e-12HR* section).

The MDSS index at week 1 (baseline) was used to determine AMD among the PCPs (a secondary objective of the study). To relativize the data, the MDSS index of the PCPs was compared to the MDSS index of health sciences students. For a proper comparison, the MDSS index was obtained using the same app (e-12HR) and during the same follow-up period (recruitment period: September-October 2022) for both students and health care professionals.

Usability Rating Questionnaire for the e-12HR

After the 4-week study period, a member of the research team sent a new email to each PCP who had completed the follow-up; this new email contained a usability rating questionnaire for the e-12HR app [19] (see Multimedia Appendix 2).

Statistical Analysis

The sample size was estimated for the main result variable. Assuming SD=2.7 points, dropout rate=20.6% (from a previous study on use of the e-12HR app among health science university students [19]), α=.05, and β=.20 (bilateral test), 82 participants (n=41, 50%, per group) were needed to detect an increase of 2 points in the MDSS index (CG versus IG). The sample size was calculated using nQuery Advisor Release 7.0 (Statsols).

Quantitative variables were expressed as means (SD), and qualitative variables were displayed as numbers (percentages). The nonparametric Kolmogorov-Smirnov test was used for the test for normality.

For unpaired samples and quantitative variables, the Student *t* test or the nonparametric Mann-Whitney *U* test was used, and the chi-square test (or Fisher exact test) was used for the comparison of proportions.

For paired samples, quantitative variables, and two groups, the Student *t* test or the nonparametric Wilcoxon test was used, penalizing *P* values with Bonferroni adjustment for multiple comparisons. For 3 or more groups, the ANOVA test or the nonparametric Friedman test was used.

P<.05 was considered significant, except for multiple comparisons using Bonferroni penalization: *P*<.02 (.05/3).

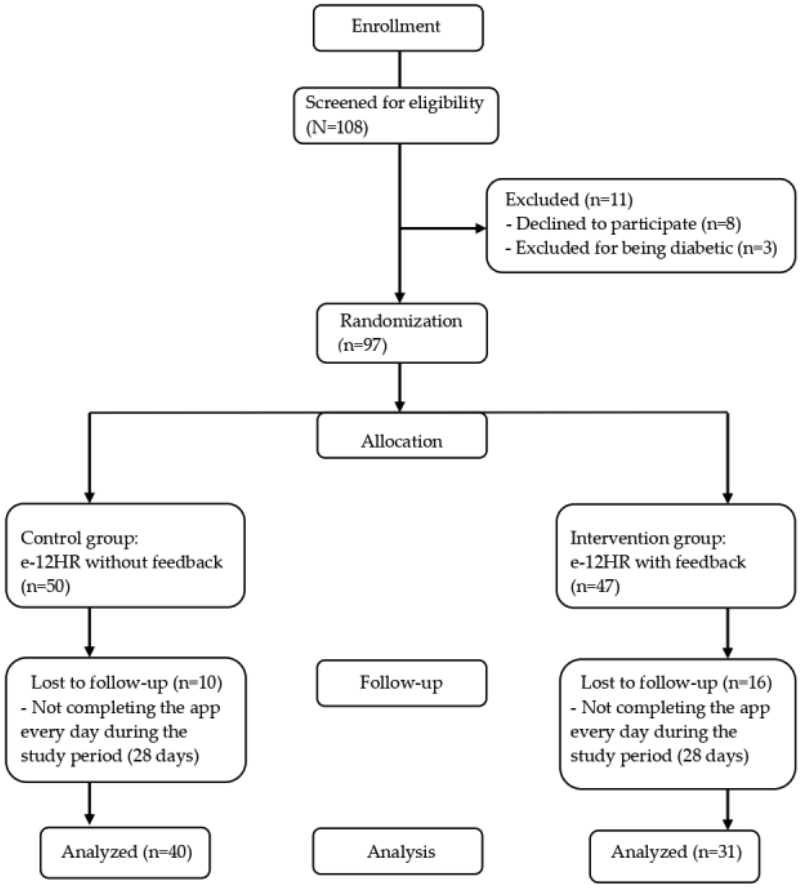
All statistical analyses were performed using the SPSS statistical software package version 26.0 (SPSS Inc).

Results

Sample and Adherence to the Study

The sequence of allocating participants to the 2 study groups is detailed in Figure 1. In total, 97 PCPs signed the informed consent form (n=50, 52%, in the CG and n=47, 48%, in the IG). Of them, 26 (27%; n=10, 38%, in the CG and n=16, 62%, in the IG) were considered nonresponsive because they did not complete the study's 4-week follow-up period (Figure 1). The nonresponsive individuals were not included in the later statistical analysis (ie, in this study, per protocol analysis was applied).

Figure 1. Flowchart of the study. e-12HR: Electronic 12-Hour Dietary Recall.



The study response rate was 73% (71 of 97 participants), with 40 of 50 (80%) participants in the CG and 31 of 47 (66%) participants in the IG (Figure 1). Participants did not report any harm or unintended effects throughout the study.

Personal Information of the Participants

Table 1 shows the personal information of the PCPs who completed the study (CG and IG).

Table 1. Characteristics of participants who completed the study on the short-term effects of a health promotion intervention based on the e-12HR[a] smartphone app on AMD[b] among Spanish PCPs[c].

Characteristics	All participants (N=71)	CG[d] (n=40)	IG[e] (n=31)	*P* value[f]

[a]e-12HR: Electronic 12-Hour Dietary Recall.

[b]AMD: adherence to the Mediterranean diet.

[c]PCP: primary care professional.

[d]CG: control group.

[e]IG: intervention group.

[f]*P*<.05 considered significant.

[g]Evaluated with the Mann-Whitney *U* test.

[h]Evaluated with the chi-square test.

[i]Not applicable.

No significant statistical differences were observed in the personal variables studied between the CG and the IG (Table 1). PCPs (n=47, 66%, doctors and n=24, 34%, nurses) recorded their daily consumption using the e-12HR app for a total of 1988 days (N=71 participants × 28 recording days). The app differentiated 19 food groups. Thus, a total of 37,772 daily food group consumption data points were collected during the study.

There were no significant statistical differences in the personal variables between responsive (those who completed the study) and nonresponsive (those who did not complete the study) participants.

MDSS Index

As previously mentioned, the MDSS index was calculated manually by the research team (CG and IG, weeks 1, 2, 3, and 4) [19]. During the process, the research team corrected obvious errors made by the PCPs: for example, when the app asked for the number of standard servings of a certain food group consumed on the current day, if the participant entered a value of 150, it was considered that the data referred to milliliters or grams (instead of standard servings). In any case, only 0.2% (91 of 37,772) of the recorded data were corrected.

At week 1 of the monitoring period (baseline), that is, before the IG received the first feedback from the e-12HR app (only week 1 was considered because the feedback for IG in weeks 2, 3, and 4 could affect the alteration of the usual dietary intake),

the PCPs had a mean MDSS index of 9.45 (SD 2.32), which corresponds to a medium level of adherence [30]; moreover, two-thirds of them (n=47, 66%) had a medium/high MDSS value (≥9) at baseline (week 1) [30].

Effect of the Intervention With the e-12HR App in Terms of Variation in the MDSS Index and Number of Participants With Medium/High (≥12) MDSS Index

Tables 2 and 3 show the MDSS index, and Table 2 also shows the number of participants with a medium/high MDSS index (≥12) in the CG and the IG throughout the 4 weeks of follow-up. We decided to use the value of 12 (instead of 9) [30] due to the high percentage of PCPs (n=47, 66%) who at baseline (week 1) already had an MDSS index≥9; therefore, using the value of 9 would have made it difficult to observe statistically significant differences between the CG and the IG.

Table 2. MDSS[a] index for the CG[b] and the IG[c] and number of participants with a medium/high (≥12) MDSS index throughout the 4 weeks of follow-up.

Variables and week number	CG (n=40)	IG (n=31)	*P* value[d]

[a]MDSS: Mediterranean Diet Serving Score.

[b]CG: control group.

[c]IG: intervention group.

[d]Intragroup differences (CG and IG) in week 1 versus weeks 2, 3, and 4. $P<.02$ (.05/3) was considered significant (penalizing *P* values with Bonferroni adjustment for multiple comparisons).

[e]Evaluated with the Wilcoxon test.

[f]Evaluated with the Student *t* test.

Regarding intragroup modifications, there were no significant statistical differences in the MDSS index in the CG, either throughout the 4 weeks of study, ranging from mean 9.30 (SD 2.59) in weeks 1 and 4 to mean 8.98 (SD 2.84) in week 2 (Table 2) or in weeks 2, 3, and 4 when compared to week 1 (baseline; Table 3). In the IG, there were significant statistical differences in the MDSS index throughout the 4 weeks of study, ranging from mean 9.65 (2.23) in week 1 to mean 11.68 (SD 3.61) in week 4 (Table 2). Compared to week 1 (baseline), the differences were statistically significant from week 2 onward: with 1.16, 1.29, and 2.03 points of improvement at weeks 2, 3, and 4, respectively (Table 3). There were no significant statistical differences in the number of participants with a medium/high (≥12) MDSS index (week 1 vs week 4) in either the CG or the IG.

Regarding intergroup modifications, there were significant statistical differences for both the MDSS index and the number of participants with a medium/high (≥12) MDSS index in the CG versus the IG (in favor of the IG) from week 2 onward (no significant differences in week 1). For the MDSS index, we found 1.83, 1.86, and 2.38 points of improvement at weeks 2, 3, and 4, respectively; for the number of participants with a medium/high (≥12) MDSS index, we found 24.4, 29.4, and 37.3 percentage points of improvement at weeks 2, 3, and 4, respectively (Table 2).

Effect of the Intervention With the e-12HR App in Terms of Variation in Food Groups

Table 4 shows the number of participants who met the consumption criteria for each food group [19] in the CG and the IG throughout the 4 weeks of follow-up.

Table 4. Number of participants who met the consumption criteria of the MDSS[a] index for each food group throughout the 4 weeks of follow-up (CG[b] n=40, IG[c] n=31).

[e]Evaluated with the chi-square test.

[f]*P* value in rows: intragroup differences (CG versus IG) in week 1 versus week 4. *P*<.05 was considered significant.

[g]Evaluated with the chi-square test.

[h]Not applicable.

[i,j]Evaluated with the Fisher exact test.

Regarding intergroup modifications, statistically significant differences (CG vs GI) were observed throughout the study period in 4 food groups: fruits (weeks 3 and 4), vegetables (weeks 2, 3, and 4), nuts (week 4), and legumes (weeks 2, 3, and 4). In these 4 food groups, at week 4, the number of participants meeting the recommendations was higher in the IG compared to the CG, with 22.8% for fruits, 35.2% for vegetables, 23.0% for nuts, and, finally, 26.3% for legumes (Table 4).

Regarding intragroup modifications, statistically significant differences (week 1 vs week 4) were observed in the CG for white meat and in the IG for vegetables and nuts.

Usability Rating Questionnaire for the e-12HR App

Of 71 participants, 45 (63%) returned the completed questionnaire: 25 (63%) of 40 from the CG and 20 (65%) of 31 from the IG. The responses of the 45 PCPs are shown in Table 5.

Table 5. Responses to the usability rating questionnaire for the e-12HR[a] app (CG[b] n=25, IG[c] n=20).

Questions and groups	Answers
1. Easy to complete (strongly agree + agree)	
CG, n (%)	25 (100)
IG, n (%)	20 (100)

[a]e-12HR: Electronic 12-Hour Dietary Recall.

[b]CG: control group.

[c]IG: intervention group.

[d]Differences between subgroups. $P<.05$ was considered significant.

[e]Not applicable.

[f]Evaluated with the Fisher exact test.

[g]Evaluated with the chi-square test.

No statistically significant differences were observed for any of the questions on the questionnaire (CG vs IG). All PCPs indicated that the e-12HR app was easy to complete, and most of them responded that the app contained questions that were understandable (CG n=24, 96%; IG n=20, 100%) and that feedback was understandable (only for the IG, n=18, 90%). Furthermore, a large percentage were willing to use the app again (CG n=20, 80; IG n=12, 60%). Completion of the app could be considered to have taken 3 minutes or less (CG n=19, 76%; IG n=15, 75%).

Discussion

Principal Findings

In relation to the main objective, there were significant statistical differences between the 2 groups in this study. At week 4 (no significant differences in week 1, baseline), the values were higher in the IG compared to the CG by 25.6% for the MDSS index (Table 2); by 213.1 for the number of participants with a medium/high (≥12) MDSS index (Table 2); and by 33.8% for fruits, 352.0% for vegetables, 184.0% for nuts, and 75.1% for legumes for the number of participants meeting the recommendations for specific food groups (Table 4).

Regarding the secondary objectives, first, the answers to the questions of the usability rating questionnaire for the e-12HR app were satisfactory. According to the questionnaire, the daily use time of the app was about 3 minutes or less per day for most respondents (Table 5). When working with smartphone apps, usability is an important aspect to consider. According to health care professionals, there are 3 principal criteria for selecting a "nutrition and diet" app for clients/patients, which are [31] ease of use (satisfactory data were obtained in this study), free of charge, and validation (the e-12HR app is free to download and has been previously validated [32-36]). Second, at baseline (week 1), AMD for PCPs was medium (mean MDSS index 9.45, SD 2.32) and 66% of participants had a medium/high MDSS index (≥9).

Overview

To begin with, workplace interventions are an excellent strategy to promote a healthy diet, considering that health care professionals spend long hours in their professional activity and often have 1 or more meals during their working day. At the hospital level, interventions have been implemented to facilitate access to and choice of healthy foods during the working day, such as modifying the availability of foods served in the canteen, subsidizing the cost of fresh fruits and vegetables (which are often more expensive than less healthy alternatives) [37], or implementing traffic light labeling (green: healthy; yellow: less healthy; red: unhealthy) [37,38]. In a study by Thorndike et al. [38] (in a hospital in Boston, Massachusetts, USA), their intervention also included personalized automated messages using a platform that automatically generated 2 weekly emails with feedback on previous purchases in the hospital cafeteria and lifestyle advice. Significant statistical increases were observed in green-labeled food purchases and decreases in red-labeled food purchases among the IG compared to the CG in the hospital cafeteria throughout the study period.

Thorndike et al's [38] intervention was based on information about food eaten only in the hospital cafeteria (without considering other food consumed outside the hospital), so its scope was limited. However, to date, no interventions to promote a healthy diet among PCPs have been implemented; for example, the workplace intervention strategies discussed before would be difficult to implement in Spain because health centers are widely distributed throughout the territory and do not usually have a cafeteria or restaurant. Considering these difficulties as a possible alternative strategy, this study was the first to assess the ability of a smartphone app to improve the dietary habits among health care professionals (specifically, PCPs). Several randomized controlled clinical trials have used an app to improve AMD in Spanish adults, such as patients of health care centers (the EVIDENT II app [39,40] and the SalBi Educa Nutrition app [41]) and patients with type 2 diabetes mellitus (the EVIDENT II app [42]), but not in health care professionals.

Comparison With Prior Work

As previously mentioned, the e-12HR app has also been evaluated among Spanish university students (health sciences and non–health sciences) [19,20]. In relation to the main objective, the results obtained by the e-12HR app among PCPs compared to university students were (1) similar for the MDSS index (the increase among PCPs was 25.6% for the MDSS index, as shown in Table 2, and among university students was 17.4% [19] or 25.7% [20]), (2) more positive for the number of participants with a medium/high MDSS index (the increase among PCPs was 213.1%, as shown in Table 2, and among university student was 61.9% [19] or 74.5% [20]), and (3) less positive regarding the number of participants meeting the recommendations for specific food groups (improvements in 4 food group among PCPs, as shown in Table 4, and in 7 food groups among Spanish university students).

Regarding the secondary objectives, first, similar results were obtained among Spanish university students for the answers to the questions of the usability rating questionnaire for the e-12HR app. Second, at baseline (week 1), the mean MDSS index of 9.45 (SD 2.32) and the number of participants with a medium/high MDSS index (66%) among PCPs (Table 1) were higher compared with the data from health sciences students [20] during the same follow-up period (mean MDSS index 7.59, SD 2.72; percentage of participants with a medium/high MDSS index=33.4%). Significant statistical differences were found (P<.05) for both the MDSS index, which was evaluated with the Mann-Whitney U test, and the number of participants with a medium/high MDSS index, which was evaluated with the chi-square test: PCPs showed an improvement of 24.5% for the MDSS index and 98.2% for the number of participants with a moderate/high MDSS index (PCPs vs health science university students). This comparison must be made with caution, since the sample of PCPs was made up of doctors and nurses and the sample of health sciences university students was made up of students from the faculties of medicine and pharmacy. In addition, in a previous study by Sentenach-Carbo et al [43] among Spanish PCPs, the number of participants with medium/high AMD was lower: 55% versus 66.2%. It should, however, be considered that the adherence index used by both studies was different: the MDSS index was used in this study, and the validated 14-point Mediterranean diet adhesion screener was used in the Prevention with Mediterranean Diet (PREDIMED) study.

Limitations

This study presents several limitations, and the first is internal validation. This included the fact that the e-12HR app is a self-reporting method and presents the limitations inherent in this type of tool, which have been amply described [44-50]. Due to the nature of the intervention, on the one hand, only the investigator who performed the statistical analysis of the data was blinded (but not the PCPs) and, on the other hand, it was not possible to guarantee that the participants were not using another nutrition app during the study period.

Regarding external validation, the dietary program was short (4 weeks), and the long-term evolution of the study variables is unknown. In addition, the evaluation of the usability of the app was based on the responses of those participants who completed the study; however, there could be differences in the perception of usability between responsive (those who completed the study) and nonresponsive (those who did not) participants.

Future Research

According to Recio-Rodríguez et al [40], future research related to the effectiveness of apps to improve diet should clarify the possible effects of certain factors (eg, age, gender, or educational level). Therefore, in future studies, the research team intends to evaluate the effectiveness of the e-12HR app in increasing the MDSS index in different strata of PCPs—for example, examining results according to gender, age, occupational category, and the BMI as possible moderating variables and according to technological perception and technological familiarity as possible mediating variables.

Conclusion

At baseline, Spanish PCPs presented medium AMD (measured as the MDSS index and the number of participants with a

medium/high MDSS index). Throughout the study period, in the short term, the use of the e-12HR app (an easy-to-implement and low-cost intervention) showed moderate improvements in the MDSS index and remarkable improvements in the number of participants with a medium/high MDSS index; in addition, PCPs responded positively to questions about the usability of the app. These results support recommending the use of the e-12HR app as a tool to contribute to improving diet and preventing NCDs among PCPS, which, at the same time, could positively influence patient dietary behavior and prevent diet-related NCDs among the patients. From the point of view of health care organizations, the prevention of NCDs among PCPs could, in addition, lead to higher personal and job satisfaction and fewer sickness-related absences from work; for this reason, health organizations themselves should be more involved in the recommendations to use tools such as the one analyzed in this study among their own workers.

Acknowledgments

This work was supported in part by the SAMFyC Foundation (grant number TD180/21). The SAMFyC Foundation had no role in the design, analysis or writing of this article. The research team would like to thank the PCPs who participated in this study.

Authors' Contributions

LMB performed the conception and design of the study, developed the app, analyzed and interpreted data, and wrote the paper. PMR and MDGP were involved in data collection and interpretation of the data and contributed to drafting the manuscript. The authors/evaluators are the owners and developers of the e-12HR app.

Abstract

Background: Adherence to medication is estimated to be around 50% for chronically ill patients in high-income countries. Improving the effectiveness of adherence interventions could have a far greater impact on population health than any improvement in specific medical treatments. Mobile health (mHealth) is one of the most effective solutions for helping patients improve their medication intake, notably through the use of mobile apps with reminder systems. With more than 327,000 apps available in the mHealth field, it is difficult for health care professionals and patients alike to choose which apps to recommend and use.

Objective: We aim to carry out a systematic search of medication management smartphone apps available in France that send reminders to patients and assess their quality using a validated scale.

Methods: Mobile apps were identified in October and November 2022 after a systematic keyword search on the 2 main app download platforms: App Store (Apple Inc) and Google Play Store. Inclusion criteria were free availability, date of last update, and availability in French. Next, 2 health care professionals independently evaluated the included apps using the French version of the Mobile App Rating Scale (MARS-F), an objective scoring system validated for assessing the overall quality of apps in the mHealth field. An intraclass correlation coefficient was calculated to determine interrater reliability.

Results: In total, 960 apps were identified and 49 were selected (25 from the App Store and 24 from the Google Play Store). Interrater reliability was excellent (intraclass correlation coefficient 0.92; 95% CI 0.87-0.95; P<.001). The average MARS-F score was 3.56 (SD 0.49) for apps on the App Store and 3.51 (SD 0.46) for those on the Google Play Store, with 10 apps scoring above 4 out of 5. Further, 2 apps were tested in at least one randomized controlled trial and showed positive results. The 2 apps with the highest ratings were *Mediteo rappel de médicaments* (Mediteo GmbH) and *TOM rappel medicaments, pilule* (Innovation6 GmbH), available on both platforms. Each app's MARS-F score was weakly correlated with user ratings on the App Store and moderately correlated on the Google Play Store.

Conclusions: To our knowledge, this is the first study that used a validated scoring system to evaluate medication management apps that send medication reminders. The quality of the apps was heterogeneous, with only 2 having been studied in a randomized controlled trial with positive results. The evaluation of apps in real-life conditions by patients is necessary to determine their acceptability and effectiveness. Certification of apps is also essential to help health care professionals and patients identify validated apps.

Introduction

Therapeutic adherence is defined by the World Health Organization as "the extent to which the behaviors of a person required to take medication, follow a diet and/or change lifestyle correspond to the recommendations agreed with a healthcare professional" [1]. It is estimated to be around 50% for people with chronic diseases in high-income countries [1]. The result is an increased risk of complications, hospitalization, and mortality for these patients, as well as consequently higher health care costs [2-5]. Improving the effectiveness of adherence interventions could potentially have a far greater impact on population health than any improvement in specific medical treatments [1].

Mobile health (mHealth) is a promising strategy to optimize therapeutic adherence [6]. mHealth covers medical and public health practices based on mobile devices such as cell phones, patient monitoring systems, personal digital assistants, and other wireless devices [7]. It is dominated by the use of health and wellness smartphone apps, the number of which continues to grow yearly [8]. In 2021, over 327,000 mHealth apps were listed in digital stores [8].

In France, almost 90% of French people aged older than 12 years owned a smartphone in 2022 and 72% of them had downloaded apps [9]. For their part, French general practitioners seem to be in favor of mHealth apps or devices and ready to prescribe these in their practice, but at the same time stress the importance of validating the use of these apps through randomized clinical trials and certification by health care professionals [10].

Several studies have confirmed that the use of a medication management app improves adherence to therapy, notably by sending reminders, even in older patients with no experience of using new technologies [11-14]. However, no study evaluating the quality of medication management apps via a validated score has been published to date.

The main objective of this study was to identify medication management apps to improve patient adherence and assess their quality, using a validated scale. The secondary objective of this study was to identify high-quality medication reminder apps and to provide recommendations to any patient needing to take one or more medications, regardless of pathology.

Methods

Overview

This involved a systematic search of smartphone apps with content evaluation, carried out between October 1, 2022, and June 20, 2023. It was reported in line with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist for reporting a systematic review (items not pertinent to a systematic search of apps were considered not applicable) [15].

App Selection

Apps were searched from October 1 to November 30, 2022, on the App Store and Google Play Store. These 2 platforms were used by over 99% of mobile users to download apps in 2022 [16].

The keywords searched on the download platforms were "medication reminder" ("rappel de médicament"), "medication monitoring" ("suivi de médicament"), "treatment reminder" ("rappel de traitement"), "treatment monitoring" ("suivi de traitement"), and "pillbox" ("pilulier"). The selection of search terms was based on existing studies, which were adapted after several prior search attempts on digital download platforms [17]. We also included native health apps, automatically present on iOS and Android phones without the need to download them. Being preinstalled on smartphones, they cannot be identified by our search equations on app stores. However, they are available and easily accessible to users. Android currently has no native health app.

Inclusion criteria were as follows: (1) medication reminder app; (2) availability in the French language; (3) free (apps free for only a trial period were not selected); (4) updated within the last 2 years (since 2022, Google Play Store removes apps without updates for more than 2 years [18], and for the App Store, this period is 3 years for apps with few downloads in the last 12 months [19]); and (5) not specific to a single treatment (eg, the contraceptive pill) or to the treatment of a particular pathology. Inclusion criteria were based on the data available on the apps' presentation page, that is, the title, description, images, and general information about the app. Apps were excluded after download in the event of (1) or (2) unavailability on download platforms at the time of evaluation by one of the evaluators.

The decision to assess exclusively free apps was grounded in the primary target audience of patients encountering diverse and, at times, multiple impediments to consistent medication adherence. The high cost of an app is one of the main reasons why it is not downloaded [20]. In addition, users frequently report hidden costs as the main reason for discontinuation [20]. So, considering the price as a dissuading factor for the adoption of health apps, proposing a paid app to this population appeared inadequate [21].

Evaluation via the French Version of the Mobile App Rating Scale App

The Mobile App Rating Scale (MARS) was used to evaluate the apps. This score was previously validated for the overall quality assessment of an app in the field of mHealth [22]. The French version of this score, MARS-F, has also been validated for use with French-language apps [23].

MARS-F is a 19-item questionnaire divided into 4 objective evaluation sections (A to D): engagement (5 items: entertainment, interest, personalization, interactivity, and adaptation to target group), functionality (4 items: app performance, ease of use, navigation, and app gesture design), aesthetics (3 items: layout, graphic design, and overall visual appeal), and information (7 items: accuracy of app description, precise app objectives, quality of information, quantity of information, visual information, credibility of information, and scientific evidence; Multimedia Appendix 1). Each item is rated with a Likert scale from 1 (“inadequate”) to 5 (“excellent”). When specific objectives (item 14) were not delineated, and pertinent information (items 15, 16, and 17) or scientific evidence (item 19) was lacking, the respective items were rated as “not applicable.” Consequently, these items were excluded from consideration in the overall scoring process. In total, MARS-F is a score out of 5, corresponding to the average of these 4 sections. Section E, not included in the overall MARS-F calculation, evaluates the apps’ subjective quality via 4 items and is described separately. The MARS-F also includes a preliminary descriptive section on the apps’ characteristics, including users’ ratings on the platforms, the apps’ target objectives, the strategies used, its affiliation (commercial, governmental, and academic), as well as the technical aspect (password protection, possible sharing, and internet access required).

In total, 2 family medicine residents evaluated each app independently. Before starting, they assisted with a training video on the use of MARS-F and trained in real-life conditions by evaluating 3 apps not selected for this study. The scores for each item were then discussed one by one to ensure a similar understanding on the part of the 2 evaluators.

Apps available on the 2 platforms were evaluated independently on iOS and Android. Each app was tested and used for at least 15 minutes. Evaluations took place from February to June 2023.

Statistical Analysis

App characteristics were described using frequencies and proportions. To determine interrater reliability, a 2-way mixed-effects model intraclass correlation coefficient (ICC) was calculated for the mean of the raters. An ICC below 0.5 was considered poor, moderate between 0.5 and 0.75, good between 0.75 and 0.90, and excellent if above 0.90 [24].

The average of the scores given by the 2 raters or evaluators was used for the final rating of each app. Apps were compared according to their respective MARS-F quality score. The results were presented as mean (SD) and median and quartiles.

The correlation between the average rating of app users on download platforms and the MARS-F obtained was measured by Spearman correlation after a normality test. Regarding the correlation between MARS-F and user ratings, we excluded apps with a limited number of ratings on platforms, as they may not be highly representative of users. The choice of the threshold was determined following a sensitivity analysis, wherein the correlation was computed for various thresholds: five ratings on platforms, 10, 20, 30, 50, and so on. The selected threshold was the lowest one for which both the lower and upper thresholds yielded similar results. The threshold of 20 user ratings was finally selected. The correlation between reviewers’ subjective assessment of the apps via item 23 (“What is your overall star rating for the application?”) and the MARS-F obtained for each app was also calculated by Pearson correlation after a normality test. The correlation was judged as very strong from 1 to 0.9, strong from 0.9 to 0.7, moderate from 0.7 to 0.5, weak from 0.5 to 0.3, and very weak from 0.3 to 0.

All statistical analyses were performed with EasyMedStat (version 3.29; EasyMedStat).

Ethical Considerations

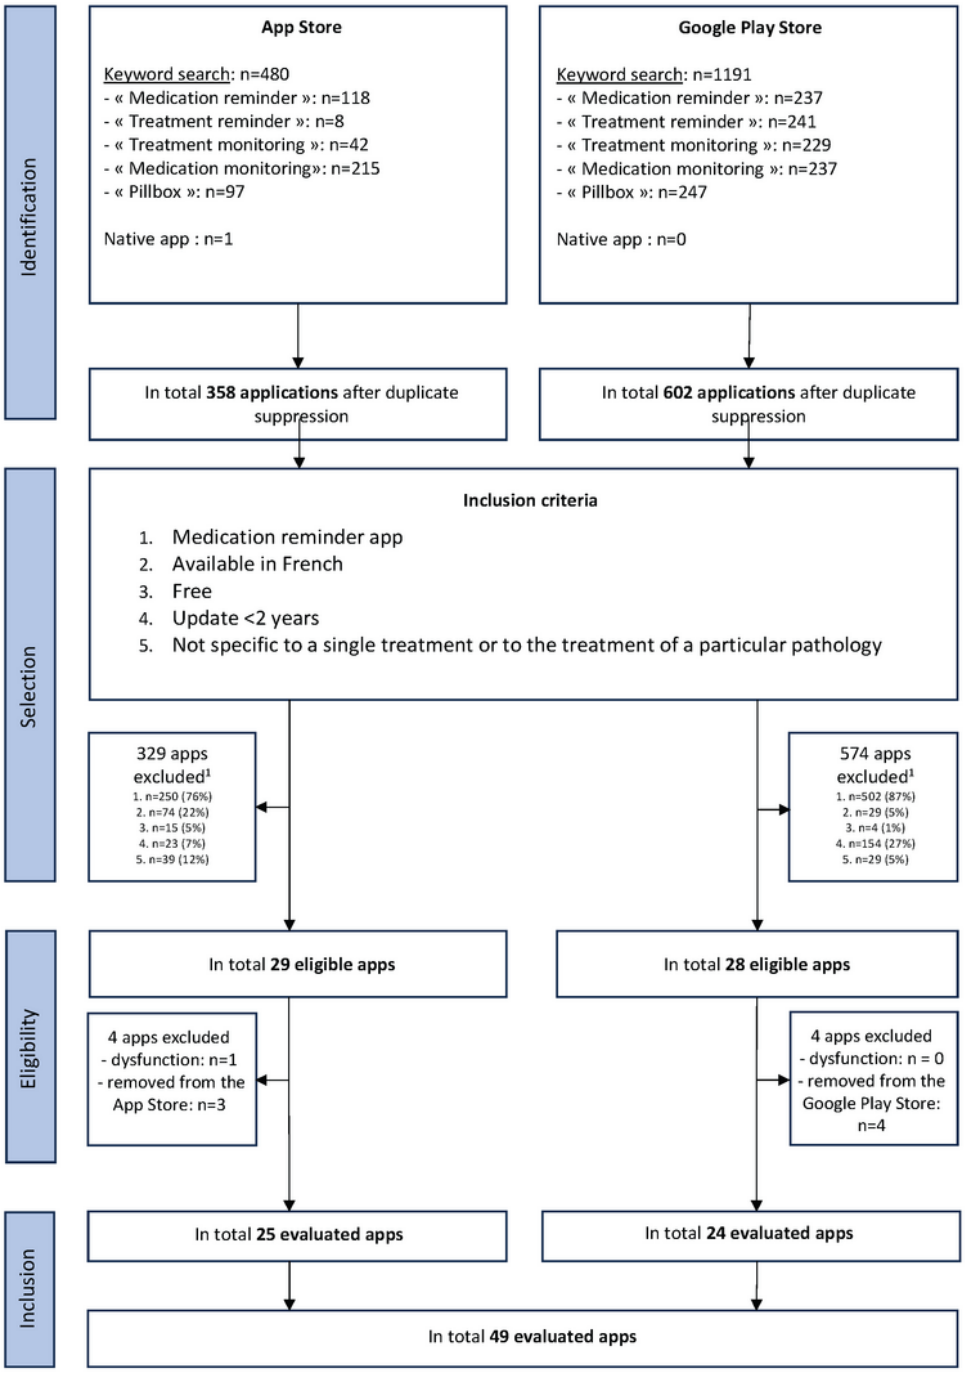
The Research Ethics Committee of the University of Montpellier approved this research project (UM 2022-006bis; Multimedia Appendix 2). This study was not funded.

Results

App Selection

After a keyword search and the addition of native apps, 480 apps were identified on the App Store and 1191 on the Google Play Store. A total of 25 apps meeting the inclusion and exclusion criteria were selected from the App Store and 24 from the Google Play Store (Figure 1).

Figure 1. Flowchart showing app selection. The numbers under "selection" refer to the inclusion criteria. The sum of the percentages exceeds 100% because a single app may not meet different inclusion criteria.



Description of the Apps

In total, 51% (n=25) of the apps evaluated were available on the App Store and 49% (n=24) on the Google Play Store, 10 of which were common and available on both platforms. Further, 40 had been rated by users on both platforms (23 on the App Store and 17 on the Google Play Store).

Although all the apps were available free of charge, some had a paid version, as in the case of 15 (60%) App Store apps and 12 (50%) Google Play Store apps. The affiliation of the developers was not always known, but the majority were commercial (24/25, 96% on the App Store; 21/24, 87.5% on the Google Play Store).

Technical aspects according to the download platform are summarized in Table 1.

Table 1. Technical aspects of apps according to platform.

	App Store (n=25), n (%)	Google Play (n=24), n (%)
Allows sharing	12 (48)	10 (42)
Has an app-linked community	3 (12)	1 (4)
Has the ability to password-protect	10 (40)	3 (12.5)
Requires a login ID	4 (16)	2 (8)
Sends reminders	25 (100)	24 (100)
Needs internet access to work	10 (40)	8 (33)

Evaluation Reliability

MARS-F interrater reliability for all apps was excellent (ICC 0.92; 95% CI 0.87-0.95; *P*<.001).

For each section, interrater reliability was excellent for engagement (ICC 0.92; 95% CI 0.88-0.95; *P*<.001) and for subjective app quality (ICC 0.95; 95% CI 0.92-0.97; *P*<.001). It was good for aesthetics (ICC 0.81; 95% CI 0.70-0.89; *P*<.001) and the information section (ICC 0.86; 95% CI 0.78-0.92; *P*<.001). Finally, interrater reliability was only moderate for the functionality part (ICC 0.70; 95% CI 0.52-0.82; *P*<.001).

Quality of Apps Based on MARS-F

The mean MARS-F score was 3.56 (SD 0.49) for iOS apps and 3.51 (SD 0.46) for Android apps (Table 2). The full set of scores by the app is presented in Multimedia Appendix 3.

Table 2. Average score, range, and median per section.

Variable	iOS (n=25)		Android (n=24)	
	Score, mean (SD)	Score, median (Q1[a]-Q3)	Score, mean (SD)	Score, median (Q1-Q3)
Section A: engagement	3.19 (0.616)	3.3 (2.8-3.6)	3.15 (0.628)	3.15 (2.8-3.52)
Section B: functionality	4.26 (0.448)	4.38 (4-4.62)	4.17 (0.431)	4.25 (3.84-4.53)
Section C: aesthetics	3.5(0.555)	3.67 (3.17-4)	3.38 (0.599)	3.5 (3-3.83)
Section D: information	3.29 (0.708)	3.3 (2.83-3.8)	3.33 (0.561)	3.17 (2.83-3.81)
MARS-F[b]: global quality	3.56 (0.485)	3.6 (3.21-3.98)	3.51 (0.455)	3.48 (3.29-3.88)
Section E: subjective quality	2.52 (1.12)	2.38 (1.5-3.62)	2.55 (1.19)	2.25 (1.72-3.22)

[a]Q: quartile.

[b]MARS-F: Mobile App Rating Scale, French version.

General App Features

The iOS apps with the highest MARS-F scores were *TOM rappel medicament, Pilule* (MARS-F score: 4.37; Innovation6 GmbH), then *Mediteo rappels de médicaments* from (MARS-F score: 4.34; Mediteo GmbH), followed by *Rappels de médicaments* from (MARS-F at 4.13; smartpatient GmbH). The Android apps with the highest MARS-F scores were *Mediteo rappels de médicaments* (MARS-F score: 4.32), followed by *TOM Rappel medicaments, pilule* (MARS-F score: 4.24) and *Rappel de pilule et medicament* (MARS-F score: 4.09; Medisafe). The MARS-F ranking of apps by platform is available in Multimedia Appendix 4.

In total, 84% (n=21) of the apps available on the App Store had a MARS-F score above 3, with 5 (20%) scoring above 4. On Google Play Store, 79% (n=19) of apps had a MARS-F score higher than 3, including 5 (21%) with a score higher than 4.

The "scientific evidence" item was completed for 4 (16%) apps on the App Store and 2 (8%) apps on the Google Play Store, 2 of which were common to both platforms.

Correlation Between MARS-F and User Ratings

In total, 23 (92%) apps were rated by users on the App Store, with an average rating of 4.38/5 (range 2.9-5.0) and an average number of ratings of 475 (range 1-3900; Multimedia Appendix 5). On Google Play Store, 17 (71%) apps were rated by users, with an average score of 4.17/5 (range 3.3-4.8) and an average number of ratings of 25,062 (range 24-223,000).

After performing sensitivity analyses, tests looking for a correlation between a given app's MARS-F and average user rating were carried out on apps with at least 20 reviews on the platforms. The correlation was weak on the App Store (ρ=0.46; *P*=.12) and moderate on the Google Play Store (ρ=0.55; *P*=.02).

Correlation Between MARS-F and Reviewers' Subjective Evaluation

The correlation between MARS-F and item 23 ("What is your overall star rating of the app?") was considered very strong for iOS apps (ρ=0.93; *P*<.001) and strong for Android apps (ρ=0.88; *P*<.001).

The mean score for this item was 2.90 and 2.98 on iOS and Android, respectively, which is below the respective mean MARS-F.

Discussion

Principal Results

The main objective of our study was to identify medication management apps to improve patient adherence. In total, 960 apps were identified: 358 (37.3%) on App Store and 602 (62.7%) on Google Play Store. This imbalance in favor of the Google Play Store has already been observed in several studies [25,26]. However, after selection, the number of apps was balanced 51% (n=25) on the App Store and 49% (n=24) on the Google Play Store, so it seems that the Google Play Store search engine offers more apps for the same keyword. This balanced proportion is consistent with a 2019 medication management app evaluation study in which 328 apps available in English were studied [17]. In this study, 53.4% and 46.6% of apps were retrieved from the Google Play Store and the App Store, respectively [17]. Our study evaluated the content of these apps according to the information available on app download stores without downloading them.

Our study highlighted a cybersecurity issue: only 40% (n=10) of apps identified on iOS had password-protected access, and 4% (n=1) required a login ID. These figures were even lower for Android apps, at 12.5% (n=3) and 8.3% (n=2), respectively. This was also the case for pain management apps, with 39% of apps evaluated allowing password protection and 44% requiring login [27].

The overall quality of the medication reminder apps evaluated is considered acceptable to moderate, with 84% (n=21) of apps on the App Store achieving a MARS-F higher than 3/5 with an average of 3.56 (SD 0.49) and 79% (n=19) on Google Play Store with an average MARS-F of 3.51 (SD 0.46). We have no point of comparison in the absence of any previous French-speaking or English-speaking study evaluating medication reminder apps by a validated score. Nevertheless, these results were expected, as they are consistent with other French studies on health apps for smoking cessation (mean MARS-F of 3.49, SD 0.57) for 14 apps [28], nutrition (mean MARS-F of 3.26, SD 0.43) for 15 apps [29], mental health (mean MARS-F of 3.16, SD 0.43) for 12 apps [30], or oral hygiene (mean MARS-F of 3.20, SD 0.38) for 9 apps [31].

All the other studies reported that the functionality section of the MARS scale had the highest ratings, which was also the case in our study, with an average of 4.26 (SD 0.45) for the App Store and 4.17 (SD 0.43) for the Google Play Store for this section. This shows that most apps are functional, which also coincides with the fact that only 1 app was excluded for malfunction in our study. In contrast, the section with the lowest average score was the engagement section (average of 3.19, SD 0.62, on the App Store and 3.15, SD 0.63, on the Google Play Store), followed by the information section (average of 3.29, SD 0.71, and 3.33, SD 0.56, on the App Store and Google Play Store, respectively), in line with the literature [32-37]. Several other studies have noted lower scores for the information section [25,27,30,31,38-41]. Nevertheless, these 2 sections are regularly cited as being those for which we find lower averages. Further, 1 exception is the study by Salehinejad et al [42], for which the highest-rated section was the information section. This is a special case, as the evaluation was concerned with COVID-19 management apps, which were probably created for information purposes in the first place.

About the information section, the lack of involvement from health care professionals, universities, or governmental organizations, may explain the observed low scores, thereby lowering the credibility of the apps. This point is assessed in the MARS-F by item 18 (“Does the application come from a legitimate source (specified in the application store description or in the application itself)?”). Often difficult to ascertain [16], most apps were affiliated with a commercial company, with only 14.6% of medication management apps and 15.2% of apps for patients with genitourinary tumors showing involvement by health care professionals [43]. Involvement by health care professionals was sometimes mentioned on the apps’ websites, but without explaining their precise role or degree of involvement. The “scientific evidence” item (item 19) was completed for 4 different apps out of the 49 evaluated in our study, 2 of which were common to both the App Store and Google Play Store. These 2 apps are the only ones to have been tested in at least one randomized controlled trial with positive results: smartpatient GmbH or MyTherapy’s *Rappels de médicaments* [44] and Medisafe’s *Rappel de pilule et medicament* [45]. They are ranked among the best apps on the 2 platforms according to their MARS-F obtained in this study. This lack of scientific validation of health care apps is a recurring theme [25,29,32,33,37].

In our study, user ratings of digital app stores were higher than MARS-F, as expected [27,29]. The absence or low correlation between user rating and MARS score has also been described previously [33,46]. To our knowledge, only the study by Chen et al [47] found a link between the quality of apps assessed by the MARS score and user rating for drug information apps. The average MARS score of apps with higher user star ratings was significantly higher than for apps with lower user star ratings (3.38, SD 0.64, vs 3.05, SD 0.64, $P<.001$) [47]. However, this may be explained by their study design: 3 out of 7 assessors were not health care professionals, which may be a bias.

The correlation between item 23 (“What is your overall star rating for the app?”) and the MARS-F was very strong for apps on iOS and strong for apps on Android. These results are consistent with other studies dealing with nutrition and mental health apps, respectively [29,30]. It is interesting to note that the subjective rating of the reviewers correlated with the overall quality of the app assessed by an objective scale, unlike the user rating. It is challenging to predict whether this is due to the evaluators’ experience or the fact that they have delved deeper into the evaluation of apps using the MARS score.

Strengths and Limitations

The main limitation of this study is the mobile app sector itself since this study is a reflection of the supply and quality of apps for a specific period. We note, for example, that 6 apps (3 on the App Store and 3 on the Google Play Store) were excluded because they were no longer available a few months after they were identified and downloaded for evaluation. This difficulty had already been highlighted in a study that aimed to evaluate apps for pregnant women at 2-year intervals, in 2017 and then

in 2019. One of the things that stood out was that the best app in 2017 was no longer available in 2019 at the time of the second evaluation [40]. The presence of new versions following updates is another element that can influence the quality of an app over time. App selection by only one of the evaluators is also a limitation, as it is possible that some eligible apps have not been identified. In terms of evaluation, the apps were assessed after they had been in use for a minimum of 15 minutes, so additional strengths or weaknesses of each app may not have been detected due to this limited duration.

Our choice to evaluate only free apps is also open to criticism. It could be argued that this choice is induced by a bias of the health care system in which the authors of this paper, who are French, operate. France has indeed the lowest share of out-of-pocket health expenditure among all EU countries [48]. Yet, medication nonadherence is a global problem. Costs attributed to "all causes" nonadherence range from US $5271 to US $52,341 [49]. The high cost of a paid app is dissuasive and hidden costs have been demonstrated as one of the main reasons for discontinuation of the use of an app [20,21]. To our knowledge, the superiority of a paid medication management app over a free one has yet to be demonstrated.

Finally, the MARS score was used because its use is simple, validated, and widespread in the evaluation of health care apps. However, it has several limitations. The first is the absence of data security and privacy evaluation criteria, although the presence of a password and login is indicated in the descriptive section. These points are nevertheless a concern for users of health care apps [50]. The second limitation is the absence of a threshold for judging app quality. We have described it here as moderate, as in several other studies, which found similar average scores, but this was not described when this tool was created [51].

To our knowledge, no other study has evaluated medication management apps using a validated scale. The identification method combined with the inclusion and exclusion criteria enabled an exhaustive analysis of free medication reminder apps available to French patients. These were not selected based on user ratings or the number of downloads from digital stores, which made it possible to evaluate apps that are not promoted on platforms but may nevertheless be relevant to patients. The weak correlation between app quality and user rating found in this study supports this approach. Apps available for iOS and Android devices were evaluated independently on each operating system, as there may be differences in terms of updating or functionality depending on the device used. Finally, the independent testing by 2 evaluators is a strong point, particularly with the observed excellent interevaluator reliability, enabling result confirmation.

Perspectives

This work is the first step toward facilitating more in-depth studies on top-rated and best-quality apps. App evaluation by patients with the user version of the MARS [52] would be relevant, even though there is currently no validated French version of this scale. The long-term use and benefits of these apps need to be studied in randomized clinical trials, to verify their acceptability and whether or not they improve therapeutic adherence and clinical outcomes in patients undergoing long-term treatment.

The results of this study, added to other studies on app evaluation in the health care field, show the possible ways to improve existing apps and give leads for the creation of new ones. Functionality is paramount, and this point already seems to have been achieved for the majority of apps currently available. The areas that need improvement relate above all to engagement and the information available, of which gamification is 1 avenue to be explored [53]. Data security and privacy protection are also important for patients and should not be neglected.

Currently, France is investing in the use of digital health, particularly for patients with chronic diseases. There is an ongoing project to list more than 50 apps offering exchanges with *Mon Espace Santé* by 2026. Therefore, it is vital to set up certification for existing apps to help doctors in their recommendations [10]. The creation of an app with the help of health care professionals and validated by the Agence du Numérique en Santé would also be a solution that would enable doctors to know which apps to recommend, thus facilitating its use by patients.

Abstract

Background: Medication nonadherence remains a significant health and economic burden in many high-income countries. Emerging smartphone interventions have started to use features such as gamification and financial incentives with varying degrees of effectiveness on medication adherence and health outcomes. A more consistent approach to applying these features, informed by patient perspectives, may result in more predictable and beneficial results from this type of intervention.

Objective: This qualitative study aims to identify patient perspectives on the use of gamification and financial incentives in mobile health (mHealth) apps for medication adherence in Australian patients taking medication for chronic conditions.

Methods: A total of 19 participants were included in iterative semistructured web-based focus groups conducted between May and December 2022. The facilitator used exploratory prompts relating to mHealth apps, gamification, and financial incentives, along with concepts raised from previous focus groups. Transcriptions were independently coded to develop a set of themes.

Results: Three themes were identified: purpose-driven design, trust-based standards, and personal choice. All participants acknowledged gamification and financial incentives as potentially effective features in mHealth apps for medication adherence. However, they also indicated that the effectiveness heavily depended on implementation and execution. Major concerns relating to gamification and financial incentives were perceived trivialization and potential for medication abuse, respectively.

Conclusions: The study's findings provide a foundation for developers seeking to apply these novel features in an app intervention for a general cohort of patients. However, the study highlights the need for standards for mHealth apps for medication adherence, with particular attention to the use of gamification and financial incentives. Future research with patients and stakeholders across the mHealth app ecosystem should be explored to formalize and validate a set of standards or framework.

Introduction

Background

Medication adherence is defined by the World Health Organization as the extent to which a person's behavior corresponds to their agreed health recommendations from a health care provider [1]. In high-income countries, such as Australia and the United States, the estimated average adherence rate has remained at approximately 50% over the last two decades [2]. Adherence rates have also been measured to be much lower in low-income countries [1]. The direct consequences of medication nonadherence are suboptimal clinical benefits leading to disease progression and

complications, which in turn has an impact on patients' quality of life. The impact of medication nonadherence on health is even more apparent in older or low-income people, with a substantial association between higher all-cause hospitalization and mortality [3,4].

Medication nonadherence also contributes to medication wastage and a substantial economic burden arising from the medical resources consumed to treat preventable health events, productivity loss, and loss of life. In Australia, medication nonadherence was estimated to have an economic burden of approximately Aus $10 billion (US $6.5 billion) annually in 2018 [5]. This economic burden is expected to be much higher since then, exacerbated by additional barriers to medication adherence, such as travel restrictions and medication shortages, from the recent COVID-19 pandemic [6] and financial stressors of a potential economic recession [7,8]. In light of the significant economic burden and health impact on patient lives, there is a pressing need to address medication nonadherence through health care–provided interventions [9].

More recently, mobile health (mHealth) apps have been used to support medication management and promote medication adherence [10]. Some mHealth apps use gamification to enhance user engagement and some also provide direct-to-patient financial incentives, which are funded by the government or third-party interest groups such as health insurers [11]. Gamification (ie, the use of game elements in nongame contexts) and financial incentives (ie, the provision of an item with real-world economic value in exchange for a completed task) have been applied across many health and nonhealth domains. Two notable examples of gamification and financial incentives are Duolingo (Duolingo, Inc) and the "Incentive to Quit" trial, respectively.

Duolingo is an educational technology company that has an app under the same name offering courses in multiple languages, music, and math. Currently, the app has over 21 million daily active users and has retained a high level of engagement over the last decade of operations attributed to its use of gamification such as point-based systems, social leaderboards, and interactive storytelling [12]. A meta-analysis on the gamification of learning [13] suggests that in addition to gamified storytelling, social interactions including competition and collaboration were particularly effective in facilitating behavioral and motivational learning outcomes. While it cannot be assumed that the competitive and collaborative aspects of gamification would foster behavioral or motivational outcomes for medication adherence, the meta-analysis [13] also notes that the self-determination theory by Ryan and Deci [14] can be used to explain the mechanistic effects of gamification in the context of learning. The self-determination theory has also been applied to health behavior change including medication adherence [15]. The theoretical framework outlines 3 psychological needs (ie, competence, autonomy, and relatedness) required for intrinsic motivation. This intrinsic motivation can subsequently result in volitional behavior such as improved medication adherence.

A Cochrane review [16] into incentives for smoking cessation found that not only the use of financial incentives, either monetary or vouchers, were accepted in multiple mixed-population settings but also there was sufficient evidence to indicate that incentives improved long-term smoking cessation rates. This outcome was also sustained after the withdrawal of the incentives. The result from the Cochrane review may have contributed to the inception of the "Incentive to Quit" trial, a government-funded program in Australia using supermarket vouchers for reaching smoking cessation milestones. The program will cost Aus $500,000 (US $324,255) with the aim to recoup the amount by reducing smoking-related public health costs that are estimated to be Aus $1.5 billion (US $972 million) nationally each year [17]. This signals a potential sustainable solution to funding concerns for financial incentive programs in countries providing universal health care.

In the domain of medication adherence, our scoping review [18] identified limited evidence for the benefit of gamification with incentives. We also highlighted a wide variation in app content, design, and development processes; the use of behavioral theories or frameworks; evaluation methods; and outcomes. The review also found that when there was no patient involvement, it was likely that design and implementation decisions were largely made by developers or researchers. This lack of patient involvement could lead to the misalignment of patients' goals and bias in the selection and use of gamified and incentivized app features.

Several qualitative studies [19-21] have explored patient perspectives on the use of technologies such as mHealth apps for medication adherence. The studies include a range of findings including observed benefits of a single location to manage their whole regimen, the value of personalization and utility, and an ambivalent feeling toward apps in health. A limitation of these study findings is that they were specifically designed to investigate a particular chronic condition and may not apply to an app for a generalized cohort. Gamification and incentive-containing apps were also not the focus of those studies, limiting the ability to draw conclusions about how patients feel about apps using these features [19-21].

As there is insufficient knowledge in the existing literature pertaining to patient perspectives on gamification or financial incentives in a generalized cohort for medication adherence, a study was conducted to address this gap and disseminate the findings through publication.

Objectives

This qualitative study aims to identify and understand patient perspectives of Australian patients taking medication for chronic conditions on the use of gamification and financial incentives in mHealth apps for medication adherence. The perspectives gained from this study will help identify barriers, identify potential opportunities, and provide a foundation for developers seeking to apply these novel features in an app intervention for a general cohort of patients.

Methods

The COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist was used to guide reporting [22]. A completed COREQ checklist applied to this study is available in Multimedia Appendix 1 [22].

Ethical Considerations

Research involving humans in Australia is reviewed by an independent group of people called a Human Research Ethics Committee. The ethical aspects of this study have been approved by the Human Research Ethics Committee of the University of Sydney (project number 2022/061).

Recruitment

Participants were passively recruited through study posters and flyers displayed by consenting pharmacies and medical practices and email newsletters distributed by patient advocacy groups (eg, organizations comprised of mostly patients or caregivers to represent and promote the needs and priorities of patients) to their members advertising the study. Participants who were interested self-enrolled via a QR code displayed on the recruitment materials, which directed them to a screening questionnaire. The screening questionnaire was based on the following inclusion criteria: aged ≥18 years, competent in English, taking ≥1 medication for an ongoing medical condition for ≥3 months, not being given end-of-life care or in palliative care, and not being a health care professional. Eligible participants were then contacted via phone by the first author (ST). The first author introduced himself by explaining his own professional background and personal motivations for conducting the study including that the research would contribute to a higher degree. The first author explained the purpose of the study and potential impact before confirming enrollment and availabilities for focus group sessions. Participants were assigned to groups based on their availability when at least 3 participants were available to attend a common session. An email was subsequently sent to the participant containing the link to the web-based focus group (Zoom; Zoom Video Communications Inc) and a link to a web-based survey (REDCap [Research Electronic Data Capture]; Vanderbilt University) to capture consent to record and the baseline characteristic questions.

Focus Groups

In line with the COREQ checklist, the first author (ST), having worked in community pharmacies for 6 years, facilitated all the focus groups after undertaking formal training and orientation by the research team. Apart from the first author and participants, there were no other parties in any of the focus groups. All focus groups commenced with an introduction of the study topic and rules and guidelines for the focus group before the recordings were initiated. An ice breaker “1-fun fact” question was asked for all participants starting with the facilitator followed by a list of open-ended questions covering topics across medication adherence, gamification, and financial incentives. All focus groups were limited to a duration of 1 hour. Participants who attended the web-based focus group was compensated with an Aus $50 (US $32) e-gift card.

The semistructured focus group guide was created and reviewed by all authors to reduce assumptions and potential bias of the first author. The semistructured focus group guide is available in Multimedia Appendix 2. Using the constant comparative method, concepts raised in a focus group were used as additional prompts in the subsequent focus groups if it was not identified before moving on to the next topic. The additional prompts were neutrally phrased and open ended to limit bias. An example of an additional prompt is as follows: “In a previous focus group data management and privacy was mentioned, what are your thoughts on data management and privacy in an app like this?” The facilitator also actively aimed to explore positive and negative perspectives equally.

Data Collection and Analysis

The web-based focus group sessions were audio and video recorded using Zoom and stored on a secured university-licensed cloud service (OneDrive; Microsoft Corp). Each recording was auto-transcribed (Adobe Premiere Pro; Adobe, Inc) before undergoing manual transcription by the first author for familiarization. Notes made by the first author during the focus groups were also annotated in the transcripts. A senior author (SC) reviewed the audio record and transcripts of the first 2 focus groups. Before conducting the remainder of the focus groups, the team discussed the conduct of the focus groups, discussed the preliminary findings, and provided advice to the first author regarding the use of prompts and pauses. The transcripts from 2 focus groups were independently reviewed and iteratively coded using NVivo (Release 1.7.1; Lumivero) into concepts by 2 of the authors (ST and SC). The research team then compared and discussed the concepts to generate a list of themes and subthemes. The subthemes and themes were evaluated and revised 3 times before being applied to the transcripts again for validation. Having decided on an agreed coding framework, this framework was applied to the remaining transcripts. Additional subthemes were added as required; however, the recruitment of the focus groups was discontinued when the last transcript did not generate any unique concepts indicating that the study was approaching data saturation. The last focus group, after recruitment ended, further indicated this as it also did not generate any unique concepts. The coding mapping tree is illustrated in Multimedia Appendix 3. Participants were informed of the preliminary findings, themes, and subthemes as a study summary and were invited to review the transcripts for commentary and correction. One participant concurred with our findings, and no other participant provided any feedback.

Results

Overview

Of the 20 participants who showed interest in participating in the study, 1 participant was excluded due to the contact being unreachable or unresponsiveness. A total of 19 participants were included in the 5 web-based focus groups (via Zoom) conducted between May 2022 and December 2022. The mean age of the participants was 40 (SD 17; range 19-71) years. All participants reported that they used their smartphone daily, while more than half reported playing games (13/19, 69%) and using loyalty rewards (12/19, 63%) on a weekly or daily basis. More than a third of the participants (7/19, 37%) were taking ≥3 medications. Further details on participant characteristics (Table 1) where collected and tabulated, such as self-reported clinical characteristics.

In total, 3 main themes were identified, along with 8 subthemes. Many of the concepts derived in the subthemes were interconnected and overlapped across the 3 main themes. Additional quotes from the participants corresponding to the subthemes are available in Multimedia Appendix 4.

Theme 1: Novelty of Gamification and Incentives Require a Purpose-Driven Design

Overview

Game features designed to improve medication and health knowledge, the process of goal setting, and a sense of empowerment were recognized as potentially beneficial. The use of incentives arising from game features to drive medication adherence was a novel concept that was acceptable to some but not universally embraced. Given the novelty, participants expected apps with these features to have excellent functionality and reliability. They noted that potentially complex language, inaccessible terminology, and complicated medication use processes require that the digital usability of apps be optimized.

Gamification for Knowledge, Empowerment, and Goal Setting

Participants' views about the use of gamification to drive medication adherence in apps were formulated from their knowledge and experience of using health apps in general. Participants' expectations about apps for medication management centered on having reminders and features to help with the organization of supply. Some also had prior experience with medication apps that included resources to help them improve their medication knowledge. Those with no prior experience rationalized that this was a benefit for some but not necessarily for themselves. Participants believed that gamification could allow users to "test your knowledge before and after" use. One participant predicted that game features designed to educate about drug interactions could empower consumers to check, understand, and respond to drug interactions:

> *...to check the medications and the side effects and everything and whether if there's any food or medicine interaction.* [Participant 12]

However, another participant doubted their capacity to benefit from this:

> *My chemist is frequently telling me don't take this tablet with that tablet because they interact...If I had a more educational interactive session, I'm not sure the message might get through to an old head like this.* [Participant 11]

Participants expected game elements to ideally elicit and respond to the individuals' specific health-related goals and personalized needs. In the following example, a participant shares how gamification had helped them to engage with yoga:

> *I think that gamification really was a selling point for me because to be honest. I...I wanted to be in the top batch (of users) and to do that I can't be missing my exercise.* [Participant 12]

Failing to support or empower the user in response to individualized and time-sensitive goals would result in a lack of motivation to engage with gamification as expressed by Participant 2 in one focus group, which was endorsed by Participant 1 and 4:

> *I think when the goal goes away, I don't feel the need to use the app anymore, I just stop using it completely.* [Participant 2]

The use of gamification to promote adherence seemed foreign to some; the following participant explained their concerns:

> *I have to say that it wouldn't put me off, but I could see that some people would see it [gamification] as a trivialization of the process. And you know, on that, I don't think it would encourage me either.* [Participant 9]

Incentives or Rewards for Driving Medication Adherence Is Novel

Most participants had experience with accruing and redeeming incentives in apps and understood that incentives create motivation to drive goals:

> *We are incentive driven as a race or as a people.* [Participant 14]

Participants expected incentivization to be facilitated by the accrual of points to culminate in a "tangible kind of incentive," such as non–cash-purchasing power or other reward. There were mixed views about the notion of receiving monetary rewards for adherent behavior. Some embraced the notion, as can be seen in the following statement:

> *Something like that, that's not cash or monetary appeals to me because it's something I do to get a reward.* [Participant 14]

However, some explained that incentives were simply not needed:

> *And the only incentive for me is, it's my health, it's the motivating factor.* [Participant 13]

There was some innate hesitancy toward the concept of people receiving personal benefit for good medication adherence behavior:

> *I have a suspicion that I'm probably more adverse to having anything monetary related on apps, I think I suspect that I probably have a stronger aversion. So if you're asking me if there was one, I probably would not use it. However, I don't think the average population would have an issue if you combined financial incentive with nonfinancial incentive [features] or you could switch the feature on and off.* [Participant 17]

Some felt that simply rewarding the quantity of drugs dispensed could lead to perverse incentives:

> *...abuse of medications by people taking medications, you know, two or three times today when they're only prescribed to take it once a day to reach a financial incentive.* [Participant 14]

Furthermore, participants expressed the notion that receiving rewards for medication adherence could be problematic for people with gambling problems:

> *I guess one of my worries is that it can become a bit like gambling at some point, especially for people that are addiction prone, that's the main thing that's a worry for me when it comes to this sort of concept for medication adherence.* [Participant 6]

Regarding how the points were to be redeemed, some participants expressed that the accrual of points could be turned into financial rewards, redeemable in the pharmacy:

> *Maybe you get to 10% discount on your next to medication script.* [Participant 12]

Other participants wanted accrued points to turn into a notification that provides rewards at other vendors:

> *I'd much prefer to see a nonfinancial incentive something like your app flushes up a barcode for free coffee or a donut or whatever it is, you know, rather than a dollar value.* [Participant 14]

Some others wanted points to be converted to financial benefits for charitable organizations:

> *I would rather that I contributed to something that was part of a bigger pool of money to help people in need.* [Participant 13]

Functionality and Reliability

The participants also highlighted the importance of having a reliable and functional mHealth app to support medication adherence. This meant the need for an app to provide accurate information about their medication schedule and dosage, accurately keep track of their repeats, and keep reminding them when it was time to take their medication or when to fill their repeats. Apps that were slow and clunky also impacted their perception of its effectiveness to keep track of their medication. Overall, the participants were clear that a reliable and functional app was critical to their ability to successfully manage their medication adherence:

> *My scripts are different quantities, some of them fall due in like three weeks and some of them fall due in four weeks...the app wasn't able to manage that [different frequencies of script repeat reminders], and it was easier for me to have the scripts (and manage it) myself.* [Participant 14]

The importance of reliability and consistency seemed particularly poignant when applied to the collation of rewards and incentives:

> *If there was like a problem with the app but their points whatever weren't going through or they also had lots of the rewards got sold out and they couldn't get what they wanted. I think those sorts of things could make people pretty unhappy and then they might just not use the app at all.* [Participant 18]

Digital Usability

It was considered imperative for an app to use simple, lay language to help break down complex medical topics or terminology. In addition, the app needs a simple user interface and intuitive features. Participants who identified as technology avoiders, due to a desire to be a digital minimalist or having concerns about their ability to use an app effectively, suggested that they would consider an app if the content was easy to understand and if it was not difficult to use. This can be further supported externally by a health care professional or care provider to guide the user or provide a tutorial or introduction to the app:

> *I've never used an app. I'm not very tech savvy. I'm probably tech phobic. I'm 60 and I've only had a mobile phone for the last two years... I would probably just need to someone to show me the benefits. How to make it [medication management] easy for me, how to use it [the app]. Probably they're the main things for me.* [Participant 13]

Participants noted that digital usability can be enhanced using gamified graphical or visual representations to summarize complex topics and medication adherence numbers into easy-to-understand tallies and metrics:

> *...a good way to visualize a lot of like statistics and stuff rather than having it in words. And it's all just this simple and easy to read, you know, you don't have to have like a stats background.* [Participant 19]

Theme 2: Trust-Based Standards

Participants expressed that their attitudes toward using gamification or financial incentives for medication adherence was highly influenced by their thoughts about whether the app was created and curated with trust-based standards. These standards related to the perceived credibility of the app and its ecosystem and the policies and governance relating to the user's data.

Credibility of the App Ecosystem

An app ecosystem refers to the intricate network of connections among the app, devices, databases, and various stakeholders such as end users, developers, and app owners. Participants expressed that the credibility of an app's ecosystem was determined by multiple factors such as brand image, mission statement, and history.

For example, some participants seemed reluctant or skeptical about the transfer of rewards being managed between commercial entities:

> *...the chemist to interact with the coffee vendor. And I can't see that...business managing to cooperate appropriately.* [Participant 11]

Some expressed concerns that a transfer to charitable organizations is potentially problematic:

> *Really concerns me that the money wouldn't get to where it's supposed to go, that you're adding more and more middlemen to it and everybody takes their cut.* [Participant 14]

Credibility was noticeably different when financial incentives were provided by a for-profit versus a not-for-profit organization:

> *If it had some sort of backing from a site like GP's or was from the government or from medical institutions or from medical groups, I would be more comfortable with it. And if it was just a private initiative, I wouldn't feel as comfortable around it, to be honest.* [Participant 17]

Generally, financial incentives provided by not-for-profit organizations were found to be more credible with most participants likely to engage with an app if it was managed by a not-for-profit organization. In contrast, participants were conflicted by for-profit organizations offering financial incentives as the app health benefits, enhanced by rewards, can be compromised and exploited. This was attributed to the lack of transparency over the economic sustainability of financial incentives. Credibility was also valuable in apps that did not offer financial incentives as it informed participants on the

trustworthiness of educational medical content provided via gamified features.

Governance Over One's Data

The notion of having to share one's health data to engage with gamification and incentives was seen as highly sensitive. Most participants reported being somewhat comfortable with sharing some personal health data on the mHealth apps they had used. Moreover, when the practicalities of sharing private data to redeem rewards were discussed, participants expressed some skepticism:

> *When you try to fill in the forms [for financial incentives] and they ask you a lot of questions like your demographic, your age group and all. Even if they ask for my email and my name, that should be fine. But sometimes they've asked too many questions, and that won't appeal to me anymore because of data privacy concerns.* [Participant 12]

> *I would be averse to the model you proposed there. I don't like the concept. It's morally repugnant and that it comes to the measure of how much information do they wish me to provide at the point of redemption.* [Participant 11]

It was also noted that access to social game elements, including financial incentives or rewards, should not be dependent on the user's decision to provide specific personal data. Having the ability for the app user to selectively choose what data are shared, including how far they are shared and for what purpose, was also suggested as a best practice by some participants. Participants wanted to be informed of what data would be shared before "consent to share" was requested.

Theme 3: Personal Choice

The last theme was related to participants' views about personal choice, that is, having the option to decide whether they should use an app and then how and when they would like to use the app with games and incentives.

Choice to Use the App

Many participants felt there was the potential for mHealth apps with gamification to effectively support medication adherence. Some would choose to engage with incentives. Participants also expected that medication management apps with gamification and incentives would come at no financial cost to them. Participants wanted the researchers to know that consumers did not want to feel forced or coerced into using these apps, especially by their treating health care provider or insurance provider:

> *I think it should be an option for everyone to use an app. So, whether they like it, I don't think it should be forced upon anyone.* [Participant 19]

Ability to Customize and Choose What Features to Use in the App

There was significant variability among the participants on the extent to which they were required to engage with gamification and the accrual of incentives. It was evident that participants wanted the flexibility to decide how and when they wanted to use the app.

The participants noted that they wanted the option to toggle on and off features that they want to use or hide, respectively. An example of a specific feature customization is being able to change the esthetics and cosmetic features of the app to the user's personal preference:

> *I mean you don't want bright colors and childish kind of images for like a seventy-year-old. I feel like they want something more mellow and relaxed and I don't know, I guess also like a customization of the actual theme. You know how sometimes like you can customize how you want something to look and make you feel that if you put it in the hands of the consumer, it can customize it. They'll be more like your feel, more personal and they'll enjoy using the app more.* [Participant 19]

While a high level of customizability was desired, it was acknowledged that this could increase complexity and potentially reduce digital usability. A balanced approach to customizability was suggested where the user would be provided with default "recommended" or standard features based on some characteristics of the user. For example, it was mentioned that it could be possible to provide a relatively younger person with a high degree of flexibility on first use. Whereas for an older person, the initial level of customization could be limited, while allowing options for further customization once the user was familiar with the basic functionality:

> *What puts me off is probably if it takes a long time to set up any customization or, you know, Avatar, that sort of stuff. And it took a long time for me, again, being very time poor, I think that would put me off. So maybe something very easy to navigate and stuff like that.* [Participant 7]

Discussion

Principal Findings

The themes synthesized in this study provide a preliminary understanding of patient perspectives on the use of gamification and financial incentives in mHealth apps to promote medication adherence. To summarize, participants expressed that apps that allow users access to game features, which are designed to promote knowledge about medicines, and allow the self-monitoring of medication taking were broadly accepted and even desirable. However, the notion that a user's behavior would be monitored by a third party and that users may accrue financial or nonfinancial benefits as rewards for adherent behavior created some skepticism. An app would need to be underpinned by good governance that is built on trust in the sponsor for it to be adopted by the public. Participants believed that the adoption of apps with game features and incentives will require that users maintain a high level of personal choice in the selection of app features, desired engagement levels, and ways to redeem rewards.

In the focus groups, participants predicted that medication apps could be helpful for individuals taking multiple medications,

for example, to help them overcome problems with forgetfulness or disarray, using reminders and scheduling. Participants in the focus groups tended to support the option of patients self-recording their medication consumption using a medication app. Previous research [15] suggests behavior change can be achieved with interventions based on the Self-Regulation Theory [23], for example, by optimizing attributes such as competence and autonomy. This could be explored through the self-monitoring of medication consumption using an app. With regard to gamification, participants saw potential to improve medication knowledge through engagement with gamified learning modules, which in turn could help patients to remain adherent to medicines for chronic diseases.

When the concept of potentially rewarding good medication adherence with financial or nonfinancial benefits was considered, participants discussed that to trigger and realize the incentives, their behavior would be observed by a third party that may or may not be their help providers. In research settings, the monitoring of adherence to provide incentives is achieved by directly observing consumption (ie, watching actual consumption in a community pharmacy), conducting pill counts of returned containers, and using electronic monitoring devices such as MEMS Caps. While those methods are accepted as accurate methods of measuring adherence [24], they are resource intensive, relatively intrusive, and unsuited for widespread adoption for the management of most chronic diseases. Therefore, while medications apps could be designed to monitor and incentivize adherence by communicating with an app, to the participants in this study, the notion of having their medication taking being monitored and receiving incentives for interacting with such an app was novel and generated several controversial discussions about appropriateness and ethicality of providing rewards for a health behavior. Much of the skepticism expressed was related to concerns about trust in third-party app providers.

The theme of trust-based standards aligns with existing and burgeoning concerns about data privacy and security across all mHealth apps; specifically with regard to inconsistencies in the way data privacy is applied [25]. In addition, Schroeder et al [26] found that the major concerns patients had on data privacy within mHealth apps were related to the potential risk of misuse of their personal health data and the fear of receiving personalized advertisements. In this study, participants actively vocalized a fear regarding which actors would have access to their health data and how private companies could monetize and gain from access to personal data. Commercial advertising and exploitation in an mHealth app setting raises substantial concerns on an ethical level, and revisions to consumer law are urgently needed to protect the user [27]. It is essential that apps adhere to established and emerging data privacy standards to establish a level of trust. While most health care apps do comply with the existing compliance standards [25,28], such as the General Data Protection Regulation and the Health Insurance Portability and Accountability Act, this is generally unbeknown to the public and considered inadequate by individuals when personally exposed to or made aware of events relating to security data breaches. This was particularly emphasized in our findings due to the recency of several major data breaches in Australia from a telecom company, Optus, and a health insurance company, Medibank, during the study period [29]. While this concern may have been inflated by recency bias, studies have reported increases in data breaches globally, indicating that these concerns may be warranted [30,31].

Further improvements in transparency and stronger preventive and remedial processes relating to data breach events or unauthorized access of data may alleviate this concern for the individual. Being data-privacy compliant and transparent adds to the security for an individual to carry out health activities within the app by mitigating the risk of damage to their identity and dignity [32]. When data privacy and security is applied and communicated effectively, the collection, analysis, use, and evaluation of personal health information have potential to generate new preventive and curative therapies, diagnostics, and the optimized delivery of health care. The well-managed use of app data when well managed can be fed back to the individuals as a form of digitally assisted precision medicine [33]. The concept of securely sharing data for the personal benefit of one's medical treatment and no other uninformed purpose has been identified by our participants as an acceptable approach if it is provided as an opt-in option instead of a mandate of the app.

The likely success of mHealth apps with gamification and incentives largely depends on their ability to engage with their intended users and align with their needs and preferences. A SWOT (strengths, weaknesses, opportunities, and threats) analysis in the study by Hein et al [34] reported that while digital solutions add complexity to health regimens, they also have the potential to provide high-quality medication management, enable additional services, and drive innovation in health care. The added complexity of digital solutions can be contributed by potential issues with regard to functionality and reliability or poor digital usability. Ensuring the functionality, reliability, and digital usability of apps is paramount to all mHealth and IT solutions and is not exclusive to integrating gamification and financial incentives into mHealth apps for medication adherence. The findings of this study provide some anecdotal evidence of poor experiences with apps used in health and other areas. While general IT standards such as SQuaRE (System and Software Quality Requirements and Evaluation) exist, there are no gold standards to qualitatively evaluate software apps with regard to digital usability specifically for health [35-37]. The development of a framework to include and contextualize existing IT standards for health may provide further guidance when developing such interventions. This may include recommendations such as more rigorous testing, user feedback loops, and mechanisms to allow developers to identify and address any technical issues or usability challenges promptly. Furthermore, involving health care professionals and patients in the app's design process can provide valuable insights into specific needs and preferences, ultimately enhancing engagement and adherence [38].

This study shows that potential users will want to maintain a high level of personal choice over how they opt in, configure, use, share their personal data, and opt out of mHealth apps with gamification and incentives. This finding highlights the critical role of ensuring that patients have a sense of autonomy over

their health behavior [39]. As such, mHealth apps should be designed to empower patients to become active partners in their health care while ethically informing health care providers of patient-specific data. People who use mHealth apps have been shown to have increased satisfaction with their overall care and have reported improved interactions with their health care provider [40]. In addition, health care providers feel that the use of an mHealth app ensures better clinical decision-making and patient outcomes [41-43]. During clinical practice, the benefits of using an mHealth app should be outlined and promoted alongside their medical treatment. A holistic approach removes coercion and respects the patient's autonomy over the app and their medical treatment. Sax et al [27] similarly argue that patients should have autonomy over their health care decisions and that more attention should be provided to mHealth apps due to the increasingly persuasive methods the apps use to influence the behavior of users potentially for economic gains. To analyze the ethical impact of an app on autonomy, Sax et al [27] further suggested a framework that considers 3 requirements: independence, authenticity, and options. Considering the role of the health care provider in mHealth, further research into best clinical practices on how to support mHealth adoption through these 3 requirements is needed.

In addition, personal choice is closely related to the self-determination theory by Deci and Ryan [23], which emphasizes the importance of autonomy, competence, and relatedness in motivation and behavior change. In the context of mHealth apps for medication adherence, this theory suggests that patients should be given a sense of control over their health care decisions and that the use of financial incentives and gamification should be aligned with their personal values and goals. From our scoping review [18], we analyzed various underpinning theories or frameworks used for app development and found that the self-determination theory was used among the included studies. This indicates that the self-determination theory could be a useful framework for bolstering an mHealth app designed to address medication adherence. Such an app might incorporate gamification and financial incentives, where participants noted that social features foster a sense of community, encouraging connection and relatedness. A further analysis of patient perspectives on the various gamified and incentivized features in the context of this framework may help generate the default "recommended" or standard features of an app. Research into best practices specifically for financial incentives in medication adherence would also help address the concerns of exploitation and abuse, which have been identified in our findings and the literature, to undermine intrinsic motivation [44].

Government agencies are making efforts to manage the challenges and facilitate the opportunities associated with mHealth apps in general, which will be important to the application of gamification and financial incentives to promote medication adherence. For example, during the study and analysis, the Australian Digital Health Agency published an assessment framework for mHealth apps [45] in December 2022. The Australian Digital Health Agency is a statutory agency of the Australian government aimed at accelerating the adoption and innovation of digital technologies for health. The framework is intended to be used as a reference tool for app developers working on health apps in Australia. While not specific to medication adherence, gamification, or financial incentives, we found that there were similarities between the derived themes and subthemes in this study and the assessment domains (namely acceptability, safety and trust, ease of use, privacy and security, and technical quality assurance).

Contribution to Research

Overall, this study builds upon existing literature across medical modalities and conditions in mHealth apps to explore consumer perceptions of gamification or financial incentives for medication adherence. While some consumers appear ready to embrace the concept, it was surprising that participants ascribed such high importance to the notion that the widespread uptake of these features will require excellent governance and oversight. The themes have practical implications as a foundation for providing guidance to aspiring app developers. Further consultation with consumers, the industry, the government, and health providers will be required to ensure that apps using gamification and financial incentives are created and curated with clear guidelines and standards. It is also recommended that as the industry adopts these standards to create a specific app or app features, consumers are consulted throughout the design process, from conceptualization through early adoption and delivery to quality assurance. Future research is still warranted to discuss and evaluate the implementation of standards or frameworks in app development such as that provided by the Australian Digital Health Agency by consulting with more patients and industry stakeholders. This will ensure that the apps are acceptable and remain relevant and motivational to improve uptake.

Limitations

Two main limitations were identified in the design and analysis of this study that may have affected the interpretation of reported results. The first limitation source comes from the recruitment strategy. The need to scan a QR code to self-register interest in the study may have excluded certain participant groups such as those who identify as digital minimalists or technology adverse despite meeting the inclusion criteria. While the QR code ensures we recruited appropriately skilled participants to the study, there is a risk of unintentionally excluding certain participants resulting in the loss of some opinions on this topic. In addition, our recruitment strategy was not specifically designed to support a demographically diverse set of participants, with regard to language or the cultural background. The small sample size may have further impacted the lack of diversity. The use of focus groups, while benefiting from fruitful discussions among participants, also inherently includes limitations in the form of conformity bias as there may be disproportionate contributions by the participants and heterogeneity in character personalities.

The second limitation arose because the facilitator, analysts, and authors were from health care backgrounds, which potentially introduces bias in study findings through moderating the focus groups and analysis of the data. While all authors were also health care consumers, future studies could include a

stronger focus on personal reflexivity and involve a non–health professional and consumer in the research team.

Ultimately, while recruitment stopped because of signals indicating data saturation, the findings of this study are not intended to be taken as a final, comprehensive, and conclusive report on patient perspectives. As technology advances and changes, so do the public and individual perceptions of it. Since this study did not present participants with a working or beta model of a particular app, the findings are mainly limited to perspectives of the concepts of gamification and incentives in general, rather than any specific app.

Conclusions

Our findings provide an introductory understanding of patient perspectives on mHealth apps including gamification or financial incentives for medication adherence. Developers seeking to apply gamification and incentives in a general cohort of patients should strive to involve patients and their perspectives in all stages to inform design and development. This is critical, given the variation in consumer attitudes to the way incentives could be operationalized and concerns about sharing their personal data.

In addition, trust-based standards and personal choice and autonomy should be respected to support optimal app development in this modality. These considerations can effectively be summarized by using a comprehensive and validated framework. This field would gain from further research in the discussion and evaluation of such frameworks and share best practices with further patients and industry stakeholders.

Acknowledgments

The participants did not have a professional or personal relationship with the authors before the study.

Authors' Contributions

ST, a male industry professional, designed the study, collected data, and performed coding and analysis and drafting of the manuscript. SC, a male senior lecturer, designed the study, performed coding and analysis, and performed a review of the manuscript. LS, a female professor, designed the study, adjudicated the coding and analysis, and performed a review of the manuscript.

Abstract

Background: There are no recent studies comparing the compliance rates of both patients and observers in tuberculosis treatment between the video-observed therapy (VOT) and directly observed therapy (DOT) programs.

Objective: This study aims to compare the average number of days that patients with pulmonary tuberculosis and their observers were compliant under VOT and DOT. In addition, this study aims to compare the sputum conversion rate of patients under VOT with that of patients under DOT.

Methods: Patient and observer compliance with tuberculosis treatment between the VOT and DOT programs were compared based on the average number of VOT and DOT compliance days and sputum conversion rates in a 60-day cluster randomized controlled trial with patients with pulmonary tuberculosis (VOT: n=63 and DOT: n=65) with positive sputum acid-fast bacilli smears and 38 observers equally randomized into the VOT and DOT groups (19 observers per group and n=1-5 patients per observer). The VOT group submitted videos to observers via smartphones; the DOT group followed standard procedures. An intention-to-treat analysis assessed the compliance of both the patients and the observers.

Results: The VOT group had higher average compliance than the DOT group (patients: mean difference 15.2 days, 95% CI 4.8-25.6; *P*=.005 and observers: mean difference 21.2 days, 95% CI 13.5-28.9; *P*<.001). The sputum conversion rates in the VOT and DOT groups were 73% and 61.5%, respectively (*P*=.17).

Conclusions: Smartphone-based VOT significantly outperformed community-based DOT in ensuring compliance with tuberculosis treatment among observers. However, the study was underpowered to confirm improved compliance among patients with pulmonary tuberculosis and to detect differences in sputum conversion rates.

Introduction

Video-observed therapy (VOT) facilitates remote monitoring of patients with tuberculosis [1] and constitutes an alternative program to directly observed therapy (DOT) [2]. VOT has 2 forms: synchronous VOT (S-VOT) and asynchronous VOT (A-VOT) [1]. In S-VOT, observers video call their patients for real-time observation of drug administration, whereas with A-VOT, observers can review the video sent by the patients at any time. Globally, A-VOT is preferred over S-VOT because

it allows patients the flexibility to record drug administration sessions, and the video can be reviewed multiple times [3].

In Thailand, approximately 80,000 tuberculosis cases are reported annually [4]. Since 1996, the country has implemented DOT to ensure treatment adherence [5]. Despite evidence from 2 previous studies indicating the poor sustainability of DOT, no changes have been made due to the lack of alternative strategies and resources [6,7]. The National Tuberculosis Control Program Guideline recommends community-based DOT, observed by health personnel, as the preferred approach [8]. However, in 60% to 75% of tuberculosis cases, family-based DOT is used instead of health personnel observation, reflecting the complacency of the health care system [9,10]. Since 2015, VOT has been used in some areas, without, however, using an accountability system [11]. This system included irregular S-VOT using the LINE (Line Corporation) app or an offline A-VOT that could not be audited daily [11]. The Thai VOT (TH VOT) system, an A-VOT system, has been devised and implemented in Songkhla province, serving as a testing area for the A-VOT system [12,13]. Rather than visiting patient homes in the community as in traditional DOT or performing irregular VOT as previously done, observers can feasibly use the TH VOT system to reduce their travel expenses, and each VOT session performed can be audited daily [12,13]. The TH VOT system is usable and convenient for patients, especially for those who usually take medication late at night [13]. However, the system's effectiveness in improving medication adherence compared to the traditional community-based DOT remains unknown.

Prior research in Western countries has shown that A-VOT surpasses DOT in ensuring patient adherence, cost-effectiveness, and overall acceptance [14-19]. These investigations evaluated A-VOT based on observation counts. For comparison, counts under DOT, which follow strict regulations, such as those in the United Kingdom and the United States, were also examined [15,18]. In contrast, the observation counts reported from DOT in Thailand are irregular, owing to a low level of accountability among observers [6,7,12]. Therefore, to evaluate the effectiveness of VOT compared to DOT, it is important to consider compliance from both the patients' and the observers' perspectives, unlike what has been evaluated in the prior studies [15-18].

The primary objective of this trial was to compare the average number of days that patients with pulmonary tuberculosis and their observers were compliant under VOT and DOT. This was conducted during the intensive phase of treatment, which lasted 60 days, and followed the published protocol [20]. We assumed that medication adherence depended on the compliance of both patients and observers in both the VOT and DOT programs. The results of this study will help determine whether A-VOT can completely replace conventional DOT in Thailand. This is in line with the "Thailand Operation Plan To End TB (2023 to 2027)," which aims at using innovative technology to control tuberculosis [21].

The secondary objective of this trial was to compare the clinical outcomes between the VOT and DOT groups. The clinical outcomes were sputum conversion and reporting of adverse events. This is useful for the future planning of the A-VOT system and for conducting further studies on a larger scale. The eligibility criteria and outcomes were registered before the commencement of the study (TCTR20210624002) [22].

Methods

Study Design

We conducted a cluster randomized controlled trial (RCT) in which an observer was assigned to a cluster of patients with pulmonary tuberculosis living in the same jurisdiction, using either DOT or VOT. The trial was registered in the Thai Clinical Trials Registry (TCTR20210624002). The trial protocol followed the CONSORT (Consolidated Standards of Reporting Trials) 2010 statement [23] and is available online [20].

Study Setting

In Thailand, individuals diagnosed with tuberculosis receive definitive diagnostic evaluations at a hospital located within the jurisdiction of their place of residence. Subsequently, specialized nurses trained in tuberculosis care (tuberculosis nurse) at each hospital delegate a tuberculosis staff member (DOT observer) to administer DOT services to patients located within the corresponding primary care unit (PCU) that aligns with the pertinent jurisdiction.

This study was conducted in the Hat Yai and Meuang Songkhla districts of Songkhla province, Southern Thailand, where a robust internet network is available. Regarding telecommunications services in Thailand, both AIS and TrueMove H corporations offer 4G and 5G networks with speeds that are well above the minimum requirement of 10 Mbps bandwidth for uploading videos from mobile phones [24]. All tuberculosis staff who served as the observers of this study had worked as DOT observers for at least 2 years. All participants were regular smartphone users.

Background of the Existing A-VOT in Thailand

In Thailand, the TH VOT mobile web system was developed for remote monitoring of antituberculosis drug adherence [12]. This system is accessible through any mobile web browser and is available as an app on Google Play Store [25]. It uses user authentication via the widely used LINE app, with daily LINE notifications for setting the times agreed upon [26-28]. Patients upload videos of their medication intake to the server, which then alerts observers to review these videos. Our previous study, conducted in November 2021, found high patient compliance (approximately 70%) and moderate observer compliance (approximately 50%-65%), despite the challenges posed by the Delta variant of the novel SARS-CoV-2 [13,29]. The system, requiring approximately 1 minute for patient video recording and 1.5 minutes for observer review, proved effective and faced no technical issues in areas with robust internet. It was particularly beneficial for patients taking medication late at night, allowing observers to review videos the following morning [13]. More details on system functions and usability are available on the internet in our previous studies [12,13,20].

Sampling Method and Recruitment Procedures

In our study area, we randomly selected 53 PCUs using a computer-generated list of random invitations. From these, we invited 38 observers from 38 PCUs based on the list of invitations, leaving 15 PCUs uninvolved. The randomized allocation lists, used for assigning PCUs at a 1:1 ratio to either the VOT or DOT group, were also generated by a computer. Patients with tuberculosis under the jurisdiction of the selected 38 PCUs were assessed for eligibility and subsequently invited to provide informed consent to participate in the study.

Participants

Observers (Cluster Level)

All 38 observers from randomly selected 38 PCUs consented to participate in the study; 19 observers were allocated to the VOT group, and the remaining 19 observers were allocated to the DOT group.

Patients (Individual Level)

Patients were considered eligible if they had newly active pulmonary tuberculosis with a positive acid-fast bacilli (AFB) sputum smear, were aged >18 years, owned a smartphone, could use the LINE app, and resided in the same jurisdiction as the observer. Participants were excluded if they had a condition that required specialist intervention, which precluded the 60-day follow-up in intensive phase, rifampicin-resistant tuberculosis evaluated by a cartridge-based nucleic acid amplification test (Xpert MTB and RIF, Cepheid), were unable to continue the treatment for 60 days, or had alcohol dependence.

Cointerventions

The patients were provided zipped bags daily for 60 days, each with a daily dose of their HRZE (isoniazid, rifampicin, pyrazinamide, and ethambutol) drug regimen [12]. Patients whose consent was registered in the database by a tuberculosis nurse were scheduled to take their medication (HRZE regimen) once daily. After each patient registration, the observer in the jurisdiction where the patient resided was notified through an autonotification of the official LINE (either DOT or VOT).

For monetary compensation, the patients received 300 baht (US $8.68) immediately after registration to cover the cellular internet cost for the first month. Further compensation was paid once the patients completed their 60-day intensive treatment without discontinuing the assigned intervention. They received 300 baht (US $8.68) as a reimbursement for cellular internet cost in the second month and 400 baht (US $11.57) for transportation of the sputum specimen on 3 consecutive days.

The observers who observed medication administration among patients for at least 15 daily sessions out of 60 sessions were compensated with 600 baht (US $17.36). They were also compensated for the cost of travel to visit their patients (4 baht [US $0.12] per km).

Assigned Interventions

Cluster Level

VOT for Observers

To avoid a learning curve on the VOT side, the observers performed real or simulated activities for 1 month before the trial [13].

After being notified of patient recruitment, the observers visited the patients at home on the first day. The observer would instruct the patient to redemonstrate the learned procedures [12] as a means of verifying their correct understanding of how to record and upload the video. This training and validation process for independent execution typically required approximately 30 minutes. The observer and patient set a time range for taking the medication, after which the system would send reminder notifications to both the patient and the observer via LINE. Next, the patient maintained a daily record of the drug-taking session, noted any adverse events, and sent a video to the observer through the TH VOT system. The observer reviewed the video, approved the session, and provided necessary advice through the LINE chat box. The observer followed up with a phone call if the patient failed to send the video within 30 minutes of the appointment. If the observers detected any mistakes performed by the patients, they would conduct a video call via LINE to correct the process; these video calls would take approximately 15 minutes.

DOT for Observers

Each patient and observer received a session booklet (more details in the protocol by Kumwichar et al [20]). After being notified by the automatic system, the observer conducted a home-visit DOT as a routine service. To validate the observers' recorded information, the patient and observer were requested to take a photo of the most recent page of the booklet and send it to the auditor through the official TH VOT LINE system every weekend. The auditor reviewed and recorded the number of daily compliance sessions in the database. Note that the observer was independently responsible for managing appointment times with their patients. There was no system support for scheduling appointments to mimic a conventional DOT.

Individual Level

VOT for Patients

After registration, patients in the VOT group were trained by their observer to record and upload a drug-taking video session according to the standard operating procedure [12]. Briefly, the patients had to set their video frame so that their face was clearly visible. All tablets and capsules should also be clearly visible. They then had to click the "record video" button to start video recording, noting that there is a warning below the button to complain of any nonserious adverse events that may have occurred during the video recording before taking the medication. Patients had to then pick up the pills and place them on their tongue. Next, they swallowed the pills using clear water from a (clear) glass, raised their tongue to show the sublingual area, and stuck out their tongue to show the palatal area. After the drug-taking process was completed, they had to click the

"end recording" button to upload the video. After uploading the video to the TH VOT system, the patients could watch an instructional video to remind themselves of the serious adverse effects, which, should they experience, they must stop the medication and call the observer immediately.

DOT for Patients

For patients in the DOT group, the tuberculosis nurse provided a booklet to record their daily drug intake and whether the intake was observed by the assigned observer. The tuberculosis nurse requested the patients to return the booklet and all zipped bags on the follow-up day to claim compensation. Each weekend, the auditor notified the patients to capture and send a recent booklet page to the official LINE chat, to which the observers did not have access. All daily reports from patients were recorded without verification, treating them as self-administered treatment.

Procedures for the Auditor to Review Each Video or Picture Session

Sessions in the VOT Group

"Day" was used as the time unit for judging compliance, and local times (GMT +7 hours) were recorded. The *morning* began at midnight, and the evening ended at 11:59 PM. However, daily compliance was judged as "achieved within the cut-off time" if the patients took their medication and submitted their videos before 6 AM on the following day. The auditor assessed the daily video sessions for both the patients and the observers based on the protocol [20].

Sessions in the DOT Group

The auditor scored daily compliance weekly based on booklet photos sent by patients with tuberculosis and their observers. The patients were considered to have daily compliance as reported (no audit). The auditor would make a phone call to patients with tuberculosis to confirm whether they were observed as reported by their observer and to remind them to safely store the booklet and all zipped bags received from the tuberculosis clinic, as per the protocol [20].

Follow-Ups

Each patient was scheduled to return to the tuberculosis clinic for follow-up on day 61. One day before the scheduled visit, the tuberculosis nurse reminded the patients in the DOT group to return the booklet and zipped bags. A deep cough specimen was collected early in the morning for 3 consecutive days (from days 61 to 63). The sputum specimens were subjected to the AFB test. The patients were requested to notify their physicians about all adverse events that occurred at the start of treatment. Physicians recorded the reported adverse events from history using the electronic health record (EHR) system and suggested appropriate treatment. If a patient missed their follow-up appointment, the responsible tuberculosis nurse contacted them and recorded their reasons in the EHR.

Data Collection

Data regarding observational activities were recorded in the database, and data regarding clinical outcomes were documented in the EHR system of the participating hospitals. The records were retrieved for analysis at the end of the follow-up period.

Outcomes

Primary Outcomes

The data recorded by the auditor were compiled to understand patient and observer compliance in each arm. For the compliance of individual patients, the daily compliance scores rated by the auditor were summed. The mean number of compliance days was calculated for all patients.

Similarly, for compliance of individual observers, daily compliance scores rated by the auditor were calculated. A higher number of patient doses observed increased the mean number of compliance days for the entire group of observers (VOT or DOT).

Secondary Outcomes

The clinical outcomes retrieved from the EHR, the conversion of the AFB smear (3 negative sputum smears), the reporting of adverse events, missing follow-up visits, and death during the 60-day follow-up period were compared between the 2 groups.

The information retrieved from the EHR system was used to compare the reporting of adverse events by observers in the VOT and DOT groups.

Sample Size

Each jurisdictional area comprised 1000 to 5000 individuals. With an approximate annual tuberculosis incidence of 130 per 100,000 individuals in the Songkhla province [30], the sample size estimate was based on the assumption that each cluster could recruit approximately 1 to 5 (mean 3) patients with tuberculosis within 9 months.

The sample size was calculated using the group RCT calculator [31]. The parameters are shown in the protocol [20]. The required number of clusters for each arm was 19. Thus, the number of patients with tuberculosis in each group was 57 (19×3). Using a sample size inflation factor of 20% to compensate for the uncertainty of the tuberculosis incidence in each jurisdictional area, a sample size of 70 patients with tuberculosis was estimated for each arm.

Cluster Randomized Allocation

Observers who consented to participate were randomly allocated to either the VOT or DOT groups using a file generated using the R software (R Foundation for Statistical Computing). The sequences were stored on a study server. Following the trial protocol, the participating observers registered themselves in the LINE system. After they pressed the "accept" button, the observers were informed about their allocated intervention group through the study LINE system.

Implementation of the Trial and Patient Information

The new patients with pulmonary tuberculosis were recruited to the VOT or DOT group by a tuberculosis nurse, depending on the jurisdiction of the observer's residence. Relevant information regarding the study was provided to the potential patients before the start of the trial, including highlighting who could observe them taking medication (their observer and

auditor) along with possible assigned interventions (VOT or DOT). The observers' intervention group was excluded before they consented to participate. If the patients consented to participate, they were assigned to the same intervention group as the observer in their jurisdiction. The participants were free to refuse the intervention at any point after receiving instructions from the tuberculosis nurse. Those who refused to participate or withdrew from the study continued the traditional DOT without data collection compliance. However, clinical data were collected as permitted in accordance with the Thai Personal Data Protection Act, 2019.

Blinding

The observers disclosed their assigned interventions to auditors, tuberculosis nurses, and researchers. Next, the researchers trained the VOT observers to familiarize themselves with the TH VOT system [13]; the DOT observers were requested to perform traditional DOT as routine care. Therefore, none of the researchers or staff involved in the study were blinded to the assigned interventions.

Statistical Analysis

Patient and observer background information was summarized using descriptive statistics. An intention-to-treat analysis was conducted according to a randomized allocation. Thus, the participants were classified according to the intervention group to which they were assigned, regardless of whether they changed observation modality. We compared the mean number of compliance days between the 2 groups 60 days after treatment initiation. For a straightforward discussion, we also calculated the compliance rate (%) of each group using the following formula: sum of compliant days for each group×100/(number of patients in each group×60)

Our study was a cluster RCT; thus, the number of compliance days of patients and observers was nested in clusters. We analyzed the 60-day compliance, considering that the same observer may monitor >1 patient. The intervention effect was based on a linear mixed effects model [32]. According to our study design, the intervention was a fixed effect, whereas the cluster level was a random effect. The estimated mean numbers of compliance days along with their SEs for 4 groups of patients under VOT and those under DOT were derived from the model that accounted for the cluster effect.

The number of compliance days for each individual, adjusted for clustering effects, would be calculated based on the specified model. Subsequently, a quantile-quantile (Q-Q) plot would assess the normality of the estimated numbers for each group. If data points predominantly align with a reference line, suggesting normality, a 2-tailed *t* test would be justified for comparing the estimated numbers under VOT versus DOT. Before conducting the *t* test, the Breusch-Pagan test would evaluate homoscedasticity [33]; a *P* value <.05 indicating heteroscedasticity necessitates the use of the Welch *t* test, whereas homoscedastic conditions would permit the application of the Student *t* test. In cases where data markedly deviate from the reference line, indicating non-normality, nonparametric methods would be applied. Data visualization for this study was conducted as outlined in the protocol [20].

Only descriptive statistical methods were used for the secondary outcomes because we did not have sufficient statistical power to detect small differences. The chi-square test was used for comparison; nevertheless, when the expected counts were <5, the Fisher exact test was used.

We also conducted a power analysis using the methodology proposed by Rutterford et al [34] to assess the robustness of our findings. For this analysis, the mean number of patients per cluster was used, and an estimated intraclass correlation coefficient of 0.2 was used to calculate the statistical power, expressed as a percentage. Power calculations were not performed for rare outcomes in which no events occurred in either the DOT or VOT groups.

All analyses were performed using the *epiDisplay* (version 3.5.0.2) [35], *tidyverse* (version 1.3.1) [36], *lmerTest* (version 3.1.3) [37], and *car* (version 3.1-2) [38] packages in R language and environment (version 4.1.1; R Core Team). Statistical significance was established at a 2-sided *P* value of <.05.

Deviation From the Registered Protocol

In this study, we added calculations for the compliance rate to provide more detail and readability than provided in the statistical analysis outlined in the registered protocol.

Ethical Considerations

The Human Research Ethics Committee of the Faculty of Medicine, Prince of the Songkla University, approved the trial on February 19, 2021 (REC 64-036-18-9). All participants consented to participate in the trial, allowed access to their data in the EHRs for this research, and consented to the reporting of results in a format in which individuals cannot be identified.

Results

Participants

Between January 2022 and May 2023, a total of 38 observers from 38 PCUs participated in cluster randomization, with 19 (50%) assigned to the VOT group and 19 (50%) to the control group. The trial ended in July 2023 because of a limited budget. A flow diagram of the observers and patients is shown in Figure 1. Eventually, 62.6% (92/147) of the eligible patients in the VOT group and 82.8% (106/128) of the patients in the DOT group consented. Exclusion of patients who consented occurred mainly because they required hospitalization and were transferred to the internal medicine department, which precluded participation in the 60-day intensive phase of VOT or DOT. Of the rest, 63 and 65 patients were recruited in the VOT and DOT groups, respectively. None of the patients changed the modality of observation. However, 21% (13/63) of the patients in the VOT group refused to record videos because of miscommunication with the observers and lack of training with respect to video recording. In the DOT group, 2% (1/65) of the patients refused the intervention after receiving a tutorial on the procedure because of personal concerns. One patient died of severe superimposed pneumonia.

Finally, 87% (55/63) of the individuals in the VOT group returned for a follow-up visit, compared with 74% (48/65) of the individuals in the DOT group. The number of missing

follow-up cases was not significantly different between the 2 groups.

All patients assigned to the allocations (63 in the VOT group and 65 in the DOT group) were followed up until the end of the trial. Data from all patients, including those who refused the intervention or died, were analyzed using an intention-to-treat approach.

Table 1 compares the baseline characteristics of the observers and patients in the VOT and DOT groups. The observers in both groups supervised a median of 4 patients each. None of the characteristics showed significant differences in distribution.

Figure 1. Study flow. Condition that requires specialist: all patients required hospitalization and were transferred to the internal medicine department; follow-up visit: sputum collection and clinical evaluation by a physician. DOT: directly observed therapy; VOT: video-observed therapy.

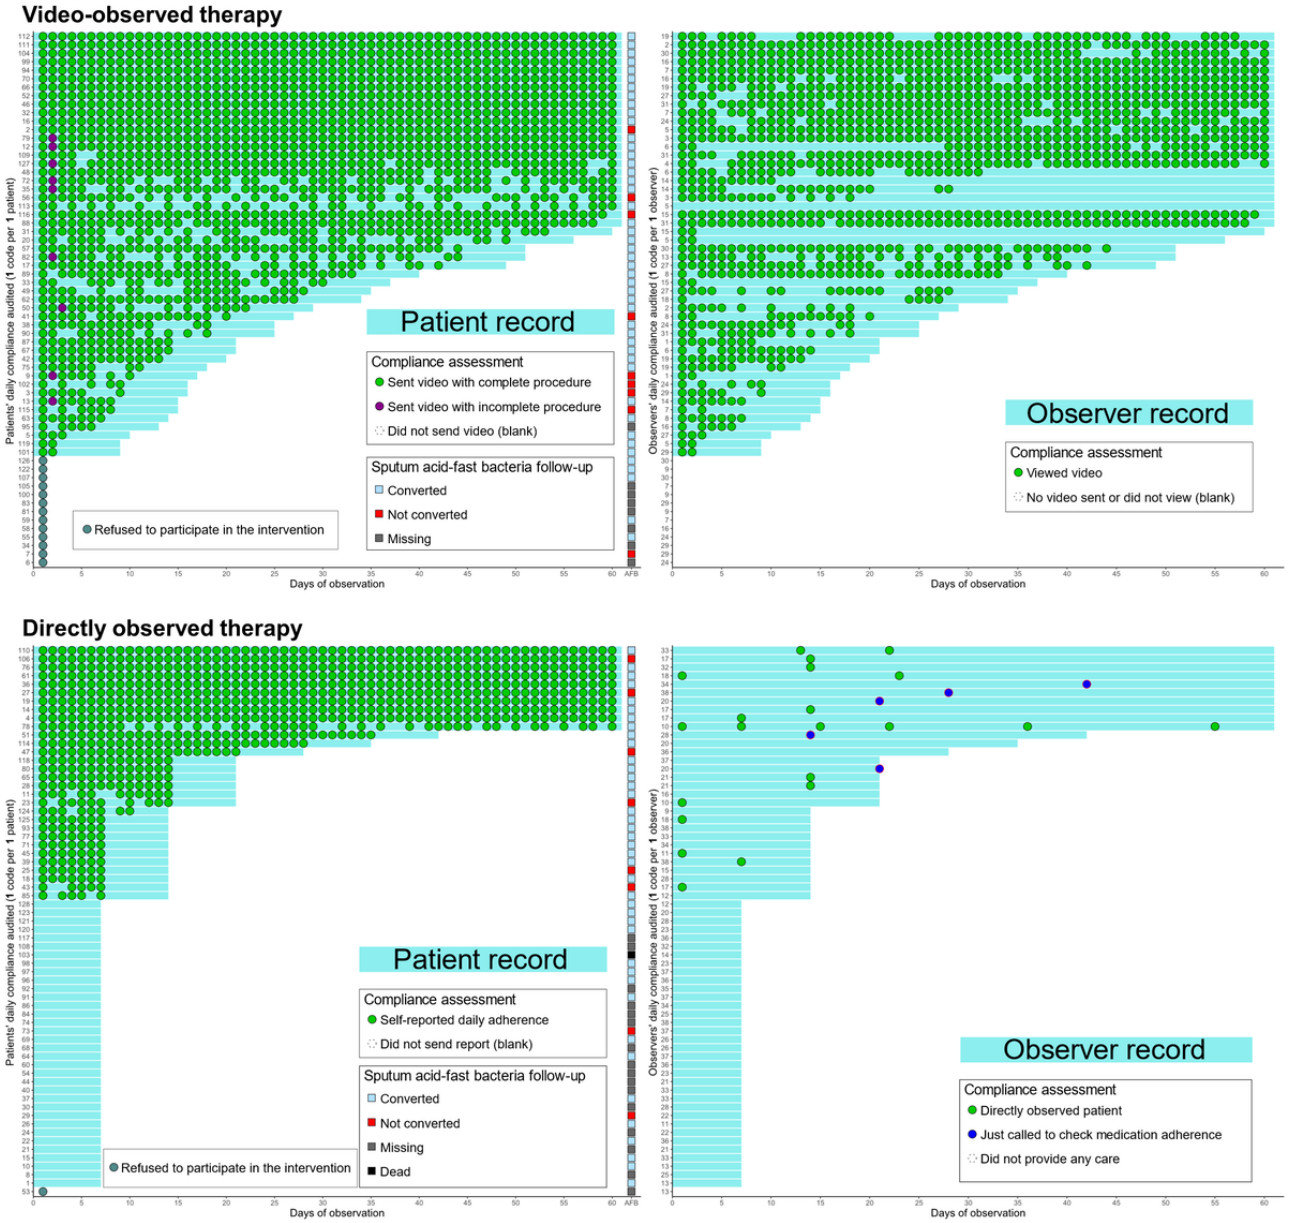
[b]DOT: directly observed therapy.

[c]COPD: chronic obstructive pulmonary disease.

Overall Patient and Observer Compliance

Figure 2 shows the 60-day treatment compliance of the patients (left column) and their observers (right column) in the time series of green dots along the x-axis. The y-axis indicates individual records. On the patient side, the last point of the individual time series represents the follow-up AFB smear. Overall, patient compliance correlated with observer compliance. More than half of the patients were unavailable to answer phone calls twice, at which point, they and their observers were discontinued from the compliance assessment.

Figure 2. Schematic depicting the 60-day treatment compliance of the patients and their observers in the video-observed therapy and directly observed therapy groups as well as the sputum follow-up results. The blue dots (representing only making a call and not conducting a home visit) were not counted as a compliance day.



Within the VOT group, no patient deviated from the recording protocol on day 1 of the compliance assessment because of the oversight provided by their at-home observer. Subsequently, 9 patients failed to comply with the recording protocol but were promptly corrected by their observers. Thereafter, the patients made no further mistakes. Remarkably, without considering the cluster effect, patient compliance rate in the VOT group approached 45.13% (1706/3780) over the 60-day period. In contrast, observer compliance rate was 35.19% (1330/3780).

In contrast, patient compliance rate in the DOT group was 20.9% (815/3900) over the 60-day period. However, the compliance rate of their observers (not including the blue dots in Figure 2) was only 0.54% (21/3900). More than half of the patients (59/65, 91%) initially received no attention. Only 21% (14/65) of the patients were observed at least once. Within 60 days, the number of compliance days for the observers ranged from 0 to 6. Furthermore, some observers simply made a call to check whether their patients had taken their medication without conducting a home visit but reported that the observation was complete (blue dots).

Outcomes

The cluster-adjusted number of compliance days for each group, as evidenced by the Q-Q plots in Multimedia Appendix 1, is assumed to follow a normal distribution. For VOT versus DOT group comparison, there was evidence of heteroscedasticity by the Breusch-Pagan test as $P<.001$ for patient and observer comparisons. The Welch t test was used for comparison of the primary outcomes. Table 2 presents a comparison of the primary and secondary outcomes of the VOT and DOT groups. When comparing the primary outcomes, the average compliance days adjusted for clustering for patients in the VOT group were significantly higher than for those in the DOT group, with a

mean difference of 15.2 (95% CI 4.8-25.6). Similarly, VOT observers reported significantly higher average compliance days compared with almost none for DOT observers, with a mean difference of 21.2 (95% CI 13.5-28.9). With the mean number of patients per cluster equal to 3, our study demonstrated sufficient statistical power (>80%) for detecting differences in compliance among observers.

Assessment of the follow-up secondary outcomes showed that 73% (46/63) of the patients in the VOT group achieved sputum AFB smear conversion, compared with 62% (40/65) of the patients in the DOT group (Table 2). The percentage of missed follow-up appointments was notably higher in the DOT cohort, at 25% (16/65), compared with the VOT cohort, at 13% (8/63). The number of adverse events reported by attending physicians was higher than that reported by observers. Overall, in the VOT group, 17% (5/29) of the adverse events recorded by physicians were detected by observers. Conversely, all the adverse events in the DOT group were overlooked by the observers. No statistical significance was detected for comparisons of all secondary outcomes.

Table 2. Primary and secondary outcomes evaluated in this study.

Outcomes	VOT[a] (n=63)	DOT[b] (n=65)	*P* value	Power (%)
Primary outcomes				
Estimated mean compliance days per person, mean (SE)[c]

Discussion

Principal Findings

This study assessed medication adherence by evaluating compliance with the experimental intervention in both patients and their observers, using this as a surrogate outcome measure. We assumed that the higher compliance rates among both patients and observers would indicate greater medication adherence in patients. Overall, patients in the VOT group had a notably higher average number of compliance days than those in the DOT group, consistent with the compliance of the observers. However, this study was underpowered to detect improved compliance among the patients. The consent rate in the VOT group (92/147, 62.6%) was lower than that in the DOT group (106/128, 82.8%). This, combined with the fact that 13 patients in the VOT group refused the intervention after consenting due to a lack of support from their observers, implies a need for increased effort from the tuberculosis nurse at the tuberculosis clinic and the observers to enhance patient acceptability of the A-VOT system.

The TH VOT system includes an onscreen reminder before the "record video" button is clicked, prompting patients to report any adverse events in the video before taking their medication. This reminder process was absent in the DOT group. As shown in Table 2, none of the reported adverse events were serious; most patients could endure them. However, without active inquiry about these events by their observers, the patients did not report them. The failure of patients to communicate their adverse events to the observers could be an important factor related to low treatment compliance. Without this care from the observers, patients were less likely to engage in observation therapy, as it would not differ from self-administered therapy (SAT). This issue could be partially mitigated by the reminder interface in the TH VOT system, which prompts users to record a daily video. However, the observers were able to detect only 17% (5/29) of the adverse events retrospectively identified by physicians.

In this RCT, the patient characteristics were well balanced between the VOT and DOT groups. In addition, compliance in both patients and their observers was assessed within clusters, which is more practical than assessing individual effects in a community-based DOT setting [39]. In the VOT group, better compliance was observed and a higher percentage of patients achieved positive AFB smear conversion compared with the DOT group. However, this difference was not significant, potentially due to the limited sample size. The results also suggest a correlation between the compliance of patients and observers. This may indicate the influence of observers on patients in persuading them to adhere to the observation process. Observers in the VOT group reported approximately one-fifth of the adverse events recorded by physicians. In contrast, all these events were completely ignored by the observers in the DOT group. Therefore, training for both VOT and DOT as well as quality control of the observers are of utmost importance.

Previous studies in the United Kingdom and the United States have shown that more than half of the patients received successful observations in the intensive phase at a rate of ≥80% [15,18]. However, our results are less than half of those reported. The possible reasons for this discrepancy include that in Thailand, compulsory observations are required only for patients with extensively drug-resistant tuberculosis [40]. The treatment efficacy of DOT in Thailand has shown no significant difference compared with that of SAT, particularly in nonclinic-based DOT, which often transitions into SAT [5-7]. Given this context, more suitable comparative studies for the findings with the intended-but-failed DOT would have been those exploring the differences in treatment outcomes between VOT and SAT. However, our literature search did not yield any published studies presenting this comparison. Consequently, we referred to data from the United States, indicating that DOT, compared with SAT, resulted in a 40% increase in complete treatment (estimated as odds ratio−1) for individuals with latent tuberculosis infection [41]. Assuming that VOT would be as effective as DOT (as VOT in the United States has been shown to be equivalent to DOT [18,19]), we anticipated that VOT would similarly result in a 40% improvement in complete treatment over SAT in the US context. For our 2-month follow-up, which evaluated sputum conversion rates as a surrogate outcome for complete treatment, we hypothesized that these outcomes would parallel those in the complete treatment observed in the US study. However, the TH VOT system demonstrated only an 18.7% improvement in successful treatment (calculated as [73−61.5]/61.5×100). Compared with those in the United States, this finding underscores the need for more concerted efforts and regulation to enhance treatment success rates in Thailand.

In addition, this study was conducted during the COVID-19 pandemic. Observers might have used the pandemic as a pretext for poor compliance on observation [29]. However, the COVID-19 pandemic was not the main cause of poor compliance among observers, as we noted the poor compliance in our pilot study even before the pandemic began [12]. In addition, there has been evidence of poor compliance with DOT services among observers for >20 years [6,7].

Limitations

The main limitation of this study was that the trial period was restricted to the first 2 months of tuberculosis treatment (intensive phase). However, although sputum conversion is an uncertain surrogate for successful treatment, many studies have shown that this rate correlates well with treatment success [42-46]. Moreover, blinding was not possible. Nevertheless, both groups were monitored by the same auditor; consequently, the Hawthorne effect should be balanced [47]. In addition, we could not differentiate between the daily doses that were not observed and those that were not taken. Finally, we inferred that the higher compliance of both patients and observers with the assigned intervention indicated better medication adherence. The difference in sputum conversion rate and reporting of adverse events should be interpreted with caution due to inadequate sample size.

The compliance of patients in the VOT group was directly recorded on video to ensure accuracy. In contrast, compliance in the DOT group was based solely on patient reports, which could not be verified. The statistics based on potential

overreporting in the DOT group may have biased our results toward the underestimation of the superiority of the A-VOT system over DOT. This disparity in compliance quality limited the comparison of the 2 groups. Even so, the reported compliance in the DOT group may have been overestimated; however, it was still lower than that in the VOT group. This might be because the VOT system is more feasible than the traditional DOT and its notification system can enhance observer compliance [13]. Consequently, it may indirectly improve patient compliance through increased encouragement and response from observers [48].

Staff time and effort to train and supervise drug intake should be considered during the implementation of the A-VOT system. The A-VOT could reduce the travel time of the observers substantially. On the contrary, effort to train patients to use the A-VOT system, especially patients who are from a low socioeconomic background, and session recording supervision by S-VOT may be necessary for the first few days, when patients are still unfamiliar with the system.

Conclusions

In Thailand, although A-VOT requires more initial effort and has lower acceptability, it was superior to traditional community-based DOT in ensuring treatment compliance among observers. Nonetheless, the study lacked the statistical power to validate enhanced adherence to treatment among patients with pulmonary tuberculosis and to detect differences in sputum conversion rates. In community-based DOT settings with robust internet availability, replacing the DOT program with the A-VOT system may improve medication adherence among patients with tuberculosis, although a more accountable system for the observers is needed.

Acknowledgments

The authors would like to sincerely thank all the tuberculosis staff in the Hat Yai and Mueang Songkhla districts for their engagement in the implementation of the Thai video-observed therapy system. Development of the mobile app was supported by the Health Systems Research Institute, Thailand. This study was funded by the Fogarty International Center and the US National Institute of Allergy and Infectious Diseases of the US National Institutes of Health under award number D43 TW009522. The content of the manuscript is solely the responsibility of the authors, and it does not necessarily represent the official views of the US National Institutes of Health. In addition, the authors would like to express gratitude to Kannarin Bunmee and Asawin Sarabae from Hat Yai Hospital for their excellent coordination of the research project.

Data Availability

The data used in this study were deidentified to ensure patient confidentiality in accordance with the Personal Data Protection Act BE 2562 of Thailand. Therefore, the data could not be used to indirectly identify a person; however, they were sufficiently detailed to enable analysis and yield results consistent with the original data. The research data have been shared on GitHub [49].

Authors' Contributions

PK defined the conceptual framework of the study, led the development of video-observed therapy, and handled data analysis. PK and VC, who were responsible for obtaining the necessary data permissions, also played key roles in interpreting the results of the analysis. The process of data specification and curation involved collaboration between PK and TP. The first draft of the manuscript was created by PK, whereas VC played an essential role by contributing to the academic discourse and offering critical evaluations of subsequent drafts. Final approval of the manuscript was obtained from all authors.

Conflicts of Interest

None declared.

Abstract

Background: The COVID-19 pandemic accelerated telemedicine and mobile app use, potentially changing our historic model of maternity care. MyChart is a widely adopted mobile app used in health care settings specifically for its role in facilitating communication between health care providers and patients with its messaging function in a secure patient portal. However, previous studies analyzing portal use in obstetric populations have demonstrated significant sociodemographic disparities in portal enrollment and messaging, specifically showing that patients who have a low income and are non-Hispanic Black, Hispanic, and uninsured are less likely to use patient portals.

Objective: The study aimed to estimate changes in patient portal use and intensity in prenatal care before and during the pandemic period and to identify sociodemographic and clinical disparities that continued during the pandemic.

Methods: This retrospective cohort study used electronic medical record (EMR) and administrative data from our health system's Enterprise Data Warehouse. Records were obtained for the first pregnancy episode of all patients who received antenatal care at 8 academically affiliated practices and delivered at a large urban academic medical center from January 1, 2018, to July 22, 2021, in Chicago, Illinois. All patients were aged 18 years or older and attended ≥3 clinical encounters during pregnancy at the practices that used the EMR portal. Patients were categorized by the number of secure messages sent during pregnancy as nonusers or as infrequent (≤5 messages), moderate (6-14 messages), or frequent (≥15 messages) users. Monthly portal use and intensity rates were computed over 43 months from 2018 to 2021 before, during, and after the COVID-19 pandemic shutdown. A logistic regression model was estimated to identify patient sociodemographic and clinical subgroups with the highest portal nonuse.

Results: Among 12,380 patients, 2681 (21.7%) never used the portal, and 2680 (21.6%), 3754 (30.3%), and 3265 (26.4%) were infrequent, moderate, and frequent users, respectively. Portal use and intensity increased significantly over the study period, particularly after the pandemic. The number of nonusing patients decreased between 2018 and 2021, from 996 of 3522 (28.3%) in 2018 to only 227 of 1743 (13%) in the first 7 months of 2021. Conversely, the number of patients with 15 or more messages doubled, from 642 of 3522 (18.2%) in 2018 to 654 of 1743 (37.5%) in 2021. The youngest patients, non-Hispanic Black and Hispanic patients, and, particularly, non–English-speaking patients had significantly higher odds of continued nonuse. Patients with preexisting comorbidities, hypertensive disorders of pregnancy, diabetes, and a history of mental health conditions were all significantly associated with higher portal use and intensity.

Conclusions: Reducing disparities in messaging use will require outreach and assistance to low-use patient groups, including education addressing health literacy and encouraging appropriate and effective use of messaging.

Introduction

As health systems have adopted electronic health records, patient portal platforms, including widely used mobile apps such as MyChart, have proliferated in both primary care and medical specialties, including obstetrics [1,2]. A patient portal is a secure web-based interface connected to the personal electronic health record. Through the patient portal, individuals are able to review their health record, schedule appointments, refill prescriptions, and conduct secure direct messaging with health care providers [3]. The advent of mobile apps such as MyChart, recognized as the number-one medical app in terms of downloads on the Apple App Store and amassing more than 10 million downloads on Google Play, underscores the portability of these features, facilitating secure communication between patients and health care providers. Patient portals, augmented by mobile apps such as MyChart, provide patients with a resource where they can readily communicate with providers and actively participate in their health care [4]. The COVID-19 pandemic has accelerated the use of telemedicine and eHealth, potentially changing our historic model of maternity care [5].

Patient portal use has been steadily increasing since the 2009 Health Information Technology for Economic and Clinical Health (HITECH) Act and government financial incentives motivating adoption of required technology such as electronic patient portals [6]. Since patient portals have become more common in medical care, several studies have analyzed the effects of patient portals on clinical outcomes. In outpatient, primary care practices, the nonobstetrics literature has provided evidence that electronic portal use is associated with improved patient satisfaction and patient-provider communication [6-9]. Secure messaging within electronic patient portals has also been associated with positive clinical outcomes; for instance, diabetes management patients who used a secure messaging feature were found to have lower hemoglobin A_{1c} values [6,8-15]. Additionally, pilot studies analyzing portal use in obstetric populations have suggested that portals can be a useful tool for management of complex medical comorbidities. A study evaluating portal use and glucose control in an obstetric population found that patients who were active portal users were less likely to have within-goal glycemic control, suggesting that pregnant patients with suboptimal glycemic control may have been more readily engaged in secure messaging with providers [16]. However, previous studies analyzing portal use in obstetric populations have demonstrated significant sociodemographic disparities in portal enrollment and messaging, specifically showing that patients who are non-Hispanic Black, Hispanic, uninsured, and have low income were less likely to enroll in and use patient portals [15]. The rapid expansion of patient portals raises concern that disparities in health outcomes and health care access may be further exacerbated by disparities in technology access and electronic health literacy, which has been demonstrated in prior research [5,6]. Because of findings from previous studies that have suggested associations between patient portal use and improved clinical outcomes, there is a need to gain a deeper understanding of use patterns and the factors influencing the use of patient portals during pregnancy [6-16].

It was therefore of interest to evaluate our health system's use of an obstetric patient portal in the context of the rapid expansion of telemedicine since the start of the COVID-19 pandemic in 2020. This study aimed to estimate changes in patient portal use and intensity in prenatal care before and during the pandemic period and to identify sociodemographic and clinical disparities that continued during the pandemic.

Methods

Overview

This was a retrospective cohort study using electronic medical record (EMR) and administrative data from our health system's Enterprise Data Warehouse. Records were obtained for the first pregnancy episode of all patients who received antenatal care at 8 academically affiliated practices and delivered at a large urban academic medical center from January 1, 2018, to July 22, 2021, in Chicago, Illinois. The study included all patients aged 18 years or older who attended at least 3 clinical encounters during pregnancy at the practices that used the EMR portal.

Ethical Considerations

The study was approved by the Institutional Review Board of Northwestern University with waiver of informed consent (STU00202847). This study follows the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines for reporting observational research.

Trends in Patient Portal Use and Message Frequency

Our health system faculty practices use the EpicCare EMR and MyChart, the associated commercial patient portal. Patients can view records, review laboratory and imaging results, send messages to providers, schedule appointments, and request medication refills via MyChart. During a clinical encounter, a provider can generate an individualized access code designated for portal enrollment, or patients can self-enroll in the portal via email without a prior access code. To gain access to portal use and functions, patients must activate their MyChart account through the portal website. The patient can then access MyChart through web-based interfaces or mobile apps. A formal mechanism for declining the MyChart invitation is unavailable, and all patients are considered to be enrolled in the portal; thus, we were unable to analyze patients who were provided with a MyChart invitation but chose not to use the portal.

Only patient portal use for communication with obstetric providers (physicians, nurse practitioners, certified nurse midwives, or nurses within the Department of Obstetrics and Gynecology) was considered active use for this study. Communication with nonprenatal care providers was excluded from this analysis, as we solely analyzed messaging use within the patients' prenatal practice. Patients were considered enrolled in the portal if they had an account at the time of delivery. Portal enrollment was not specifically analyzed in this study. Patients were considered portal users if they sent at least 1 secure message during pregnancy. Portal users were further categorized by intensity, which was classified by the number of secure messages sent during pregnancy as infrequent (≤5 messages), moderate (6-14 messages), or frequent (≥15 messages). The categorization of portal use into infrequent, moderate, or

frequent categories was determined by assessing patient portal use patterns within our clinic's prenatal practices. Patients sending fewer than 5 secure messages were classified as infrequent users, signifying limited engagement with the portal. Those sending between 6 and 14 messages were categorized as moderate users, indicating a moderate level of portal interaction. Patients sending more than 15 secure messages were considered frequent users, reflecting active and regular portal engagement. These specific cutoff points were chosen to distinguish between different levels of patient portal engagement. Our data did not permit identification of "threads" across messages involving multiple messages on the same issue, as this would require natural language processing of message texts that could identify specific issue content and the duration of threads across a given prenatal time interval.

Patient Portal Use by Patient Sociodemographic and Clinical Characteristics

Patient sociodemographic and clinical data were categorized using hospital administrative data and *International Classification of Diseases, Tenth Revision* (*ICD-10*) diagnosis and procedure codes, as well as prenatal visits, characterized as <9, 9-12 or >12 visits. Maternal age was categorized as <20, 20-24, 25-29, 30-34, 35-39, and ≥40 years at the time of prenatal care enrollment. Race and ethnicity were categorized as Hispanic, non-Hispanic Black, non-Hispanic White, Asian, and other/unknown. Additional sociodemographic characteristics that were collected included preference for a non-English language, antenatal care insurance status (Medicaid versus private or other), and residential zip code. Maternal residential zip codes in Illinois were matched to census zip code tabulation areas (ZCTAs) using the 2020 American Community Survey for the percentage of households living at or below the poverty level. Individuals were categorized as living in ZCTAs with <5%, 5%-9.99%, 10%-19.99%, or >20% of households living at or below the poverty level, or being non–Illinois residents [17].

In addition to multifetal gestation and prior cesarean delivery, parity was categorized as either nulliparous, 1 pregnancy, or 2 or more pregnancies. Maternal BMI at birth was categorized as normal weight (≤24 kg/m^2), overweight (25-29 kg/m^2), or obese (≥30 kg/m^2). We used *ICD-10* data from the delivery admission to characterize the prevalence of any of a number of chronic conditions, including cardiac disease, bleeding disorder, pulmonary hypertension, chronic renal disease, gastrointestinal disease, HIV/AIDS, bariatric surgery, asthma, connective tissue or autoimmune disease, neuromuscular disease, and thyrotoxicosis. We also categorized patients as having a history of depression or severe mental illness (schizophrenia, bipolar disorder, or psychosis) or substance use. We found that hospital *ICD-10* coders had incorrectly coded *both* gestational and preexisting diabetes and hypertension for a substantial number of delivery admissions. We therefore characterized diabetes and hypertension codes as either uniquely preexisting only, gestational only, or coded for both.

Statistical Analysis

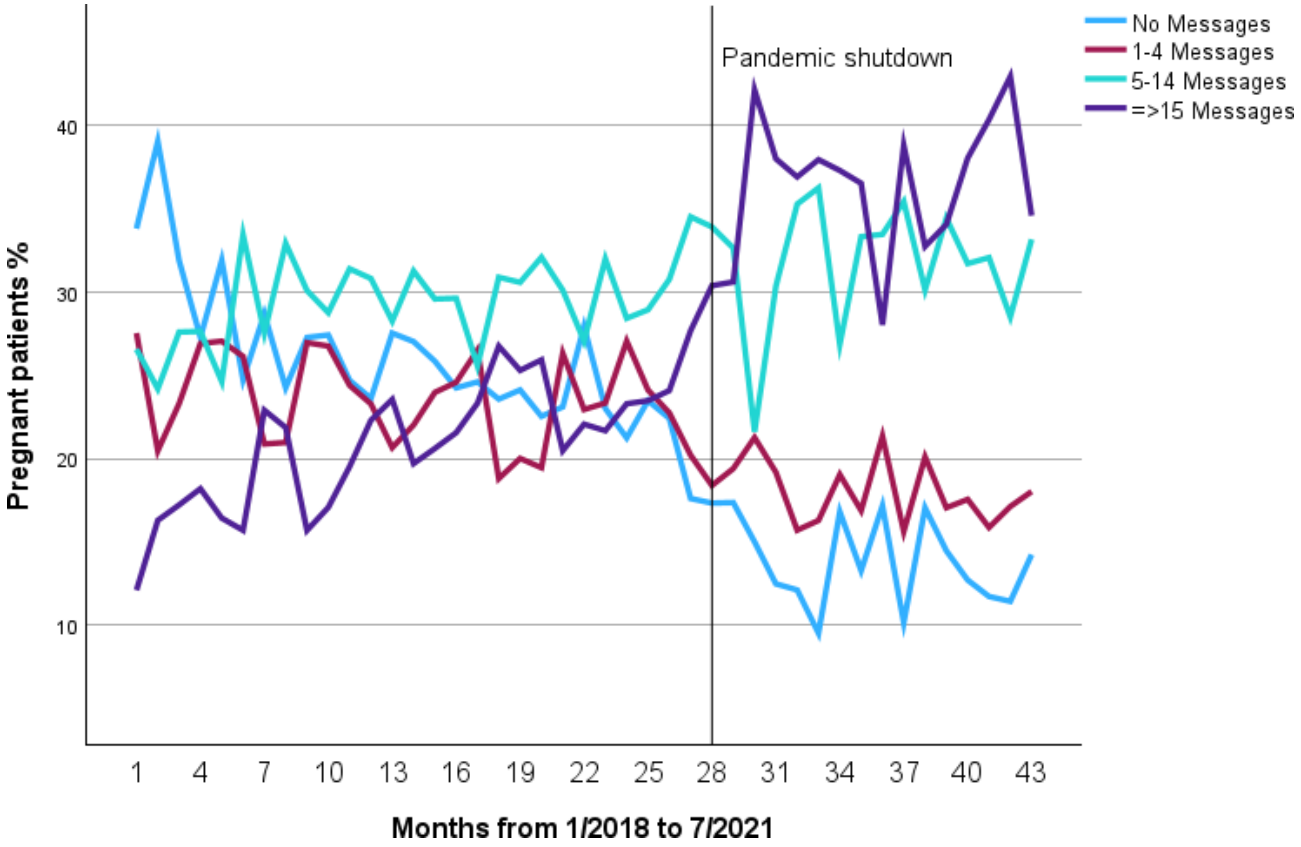
Monthly messaging intensity rates were computed to assess changes before and after the March 2020 pandemic. We determined the significance of bivariate differences in messaging frequency using χ^2 tests. We estimated a logistic regression model of the likelihood of zero portal use for patients who delivered from April 2020 during the 15 months after the end of the pandemic in March 2022. Analyses were performed using SPSS Statistics (version 28; IBM Corp).

Results

Trends in Portal Use and Message Frequency

A total of 12,380 patients were eligible for inclusion. In the total study period, 2681 (21.7%) of patients were nonusers of the portal, 2680 (21.6%) were infrequent users, 3754 (30.3%) were moderate users, and 3265 (26.4%) were frequent users. Figure 1 displays portal use rates by delivery date over the 43-month study period, denoting April 2020 (month 28) as the full onset of the COVID-19 pandemic. There was a modest trend toward increased use in the first study years, followed by a rapid increase in use and a correspondingly dramatic reduction in nonuse after the onset of the COVID-19 pandemic. The number of patients who were nonusers decreased between 2018 and 2021, from 996 of 3522 (28.3%) in 2018 to only 227 of 1743 (13%) in the first 7 months of 2021. Conversely, the number of patients with 15 or more messages doubled, from 642 of 3522 (18.2%) in 2018 to 654 of 1743 (37.5%) in 2021.

Figure 1. Pregnant patient portal messaging intensity. There were 12,380 patients with at least 3 prenatal visits with deliveries between January 1, 2018, and July 22, 2021.



Patient Portal Use by Sociodemographic and Clinical Characteristics

Table 1 displays patient characteristics by messaging intensity. The proportion of those with no portal use was correlated with the number of prenatal visits. Of the 2430 of 12,380 (19.6%) study patients with 8 or fewer visits, 1123 (46.2%) were nonusers overall, as compared to only 488 (10.8%) nonusers among 4520 patients (36.5%) in the sample with 13 or more visits. Those with the most prenatal visits had over 3 times the proportion of frequent messaging than those with the fewest visits. Higher parity was similarly correlated with lower message intensity.

Table . Obstetric patient electronic medical record portal use by number of messages sent during pregnancy among patients with at least 3 prenatal visits. There were 12,380 patients with deliveries from January 1, 2018, to July 22, 2021. All comparison were at *P*<.001 except preeclampsia (*P*=.03).

			Total, n (%)	No messages, n (%)[a]	≤5 messages, n (%)[a]	6-14 messages, n (%)[a]	≥15 messages, n (%)[a]
Overall			12,380 (100)	2681 (21.7)	2680 (21.6)	3754 (30.3)	3265 (26.4)
Delivery year							
	2019-2020		3522 (28.4)	996 (28.3)	863 (24.5)	1021 (29)	642 (18.2)

Substance use		312 (2.5)	113 (36.2)	55 (17.6)	69 (22.1)	75 (24)

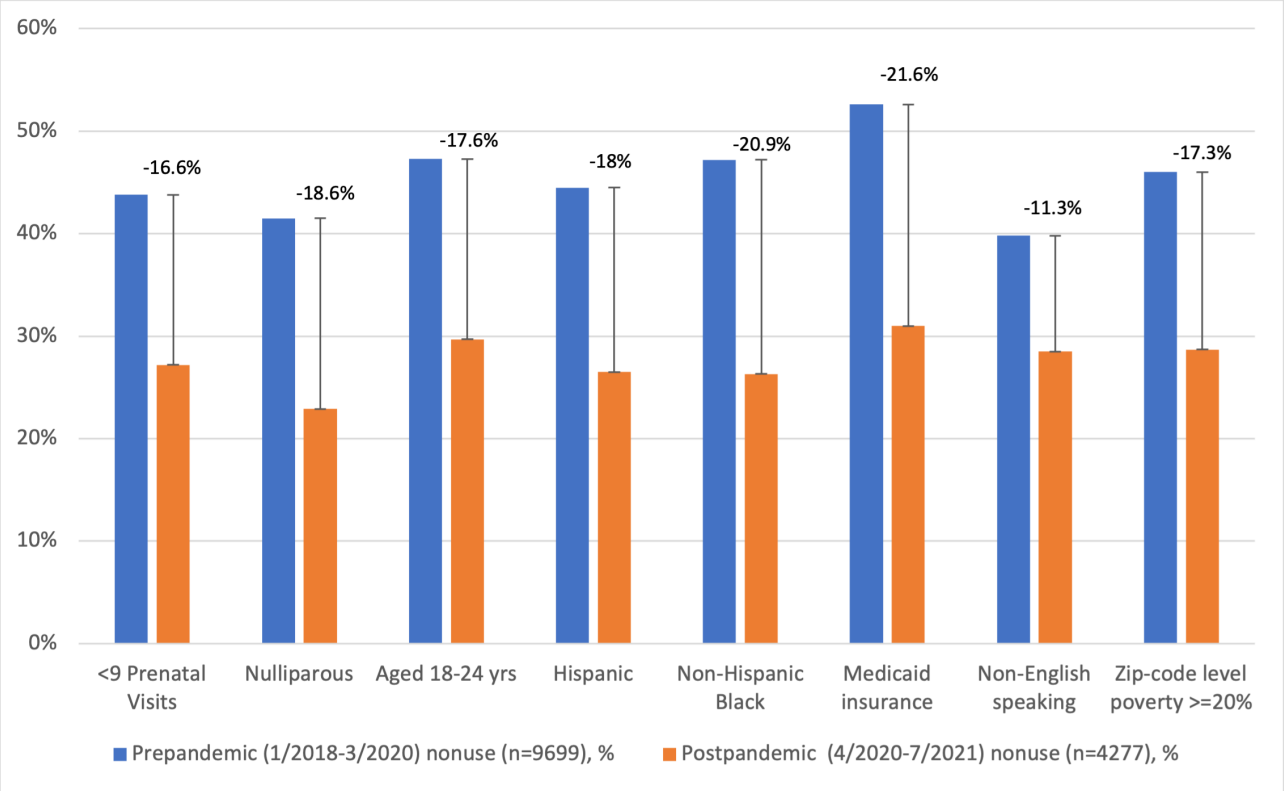
[a]Percentage calculated against the total for each characteristic.

[b]Preexisting comorbidities included cardiac disease, bleeding disorder, pulmonary hypertension, chronic renal disease, gastrointestinal disease, HIV/AIDS, bariatric surgery, asthma, connective tissue or autoimmune disease, neuromuscular disease, thyrotoxicosis, history of depression or severe mental illness (schizophrenia, bipolar disorder, or psychosis), or substance use.

Portal use was more frequent among those who were older, with the lowest messaging intensity among the youngest patients (younger than 25 years), who represented only 675 (5.5%) of all births. The highest messaging intensity was among patients older than 30 years. Non-Hispanic Black patients had the highest proportion of nonuse at 783 of 1784 (44%), followed by Hispanic patients at 581 of 1629 (35.4%) and non–English-speaking patients at 180 of 401 (44.8%). While patients with Medicaid comprised only 14% of the patient population, they had the highest proportion of nonuse among all patient subgroups at 1095 of 1730 (63.3%), and there was a clear poverty-level gradient in messaging intensity across ZCTAs.

Figure 2 presents change in portal use over time for patients with sociodemographic and clinical characteristics associated with high rates of portal nonuse who delivered after April 2020. Patients with Medicaid births had a 21.6% reduction in their nonuse rate after the pandemic. Similar large increases in use occurred among all the groups profiled, including those with fewer prenatal visits, as well as younger, minority, and lower-income patients.

Figure 2. Change in the proportion of patients with highest portal nonuse after the April 2020 pandemic shutdown.



Odds of Pandemic Portal Nonuse

Our logistic model of nonuse, based on the 4277 patients with postpandemic deliveries, showed that the number of visits and parity remained strongly correlated with the likelihood of portal nonuse (Table 2). Those with <8 visits were 97% more likely to have been nonusers than those with >12 prenatal visits, and patients with ≥2 parity were over 3 times more likely to be nonusers than nulliparous patients. Confirming bivariate results for the whole period, the youngest patients, non-Hispanic Black patients, and Hispanic patients, particularly non–English speaking patients, had the highest odds of continued nonuse. Patients with gestational diabetes were significantly more likely to be portal users, while patients with other comorbid conditions and those with preexisting mental health conditions were also more likely to use the portal.

Table . Logistic regression results for postpandemic obstetric patient nonuse of electronic medical record portal messaging among patients (n=4277) with deliveries from April, 2020, to July 22, 2021.

[a]Preexisting comorbidities included cardiac disease, bleeding disorder, pulmonary hypertension, chronic renal disease, gastrointestinal disease, HIV/AIDS, bariatric surgery, asthma, connective tissue or autoimmune disease, neuromuscular disease, thyrotoxicosis, history of depression or severe mental illness (schizophrenia, bipolar disorder, or psychosis), or substance use.

Discussion

Principal Findings

This study was undertaken to guide efforts to improve prenatal portal use by addressing what were already known to be significant socioeconomic disparities in use. We found that messaging frequency significantly increased over the 43-month study period. Most notably, there was a decline in nonuse in the immediate postpandemic period, approximately cutting in half the previous nonuser population from 25.8% to 13.9%. However, pandemic nonuse remained concentrated among patients with fewer prenatal visits, higher parity, and public insurance, as well as those who were younger, were not English speakers, had lower income, and identified as non-Hispanic Black or Hispanic. As hypothesized, patients with high-risk clinical conditions, such as history of depression or severe mental illness, preexisting comorbidities, or gestational or preexisting diabetes, were more likely to use the portal and to be frequent messengers.

The socioeconomic disparities found in this cohort are consistent with prior literature analyzing patient portal use and messaging in obstetric and nonobstetric populations. It has been suggested in several studies that those who identify as non-White, have low income, and are publicly insured are less likely to use portals than their counterparts [5,15,18-22]. Numerous studies have demonstrated that non-Hispanic Black, Hispanic, low-income, and publicly insured or uninsured patients were less likely to activate and use portal messaging. A study of more than 1700 primary care patients receiving care at Kaiser Permanente Georgia showed that compared to non-Hispanic White participants, non-Hispanic Black patients were less likely to register for electronic patient portals, even after controlling for differences in education, income, or internet access, which were also associated with portal registration [4,15]. Previous studies have shown conflicting conclusions regarding the associations of high-risk clinical characteristics and portal use intensity [10,23-25]. For example, 2 studies in a primary care setting found that patients with chronic conditions and conditions associated with increased morbidity used the portal more often than healthier patients [4,24]. However, another study in a similar primary care setting conversely found that patients with fewer medical problems used the portal more often than patients with chronic conditions [25].

Potential Value of Increasing Patient Portal Use in Obstetrics

During the COVID-19 pandemic, health care providers increasingly relied on telehealth and electronic communication methods for health care delivery and patient care [5,19,20]. Telehealth and electronic patient communication were especially important for obstetrics, due to the necessity to continue scheduled prenatal care visits and screenings. The findings in this study demonstrate that messaging may have become a more important care function in the postpandemic period, despite the return to in-person visits.

The antenatal period represents a critical time, when health care engagement may influence both maternal and infant outcomes; however, disparities in antenatal portal use have been identified. Several studies that analyzed portal use in the setting of obstetrics demonstrate greater portal use in antenatal patients who have chronic conditions and are at higher risk for pregnancy complications; however, other studies suggest that medically high-risk obstetric patients were less likely to enroll and use portals [15,16,26]. This cohort's findings align with the former, demonstrating that participants with high-risk clinical conditions, including preexisting comorbidities, preexisting mental illness, and gestational diabetes, were more likely to use the portal and use the portal frequently.

Implications for Improving Patient Communication With Providers in Obstetrics

With secure messaging, patients can discuss a variety of topics, such as a change in condition, a new condition, laboratory results, and prescription concerns. A clinical example of the impact of secure messaging is the management of gestational diabetes mellitus. In this patient population, secure messaging serves as a platform for health care providers to stimulate patient engagement and self-management during a very disruptive obstetric complication.

Upon diagnosis of gestational diabetes mellitus, patients are bewildered as to how to alter lifestyle habits, shop, and prepare for meals, let alone monitor blood glucose to keep their child safe. Unlike an office visit, secure messaging allows health care providers to instantly explain the diagnosis and send patient-education tools, guides, and even YouTube instructions so the patient can immediately launch into self-care management action. This patient action empowers patients to use secure messaging to maintain close communication with the health care providers. Secure messaging solidifies diabetes self-management for weekly review of blood glucose in order to determine the need for insulin therapy. Another challenge in pregnancy if insulin therapy is necessary is for patients to continue to engage in health restoration for themselves and their child. Patient education on insulin administration can be provided via telemedicine or office visits, with weekly glucose review for any insulin adjustment—all through secure messaging for the remainder of the pregnancy. Though the literature has demonstrated telemedicine and mobile health as modalities to improve diabetes control, evidence for the significance of clinical metrics for patient satisfaction with secure messaging is scant, although it has been shown to cause no harm. There is need for more research in this area.

It is clear that patient portals provide an additional avenue for patient-provider communication; however, the disparities found in this paper show that the portal is not equally accessible to several sociodemographic groups.

An early obstetrics encounter is the best time to introduce patients to the value and usefulness of the patient portal. Often, patients need assistance with setting up the patient portal. A

mixed methods study analyzing factors affecting patient portal use among pregnant women with low income demonstrated that 33% of participants did not use the portal because they were unsure how to use it [26]. A practice message is always good to send while in the obstetrics office so the patient is comfortable with the EMR messaging application. Discussion of what will be available to the patient, such as lab results and appointment reminders, can lead to discussing the benefits of sharing blood glucose readings on a weekly basis. This can be crucial for medication and nutrition adjustment to improve diabetes self-care during pregnancy.

It is apparent that there is a need for innovative strategies and interventions aimed at enrolling Medicaid beneficiaries, those in poverty, young patients, and racial/ethnic minorities. With increased mobile phone use rates among women with low income, there is potential to increase portal use through interventions aimed at portal use via mobile apps.

Limitations

Given that this is a retrospective study, the associations made in this study can not be assumed to be causal, and there is potential for unmeasured confounding. For example, this study did not have direct measures for health literacy, internet access, education level, or self-care behaviors, which may play a role in portal use. Additionally, although this sample was large and diverse, patients in this study received care at a large academic tertiary care center and findings may not be fully generalizable to other health settings. Furthermore, portal enrollment was not specifically studied with this data set, which is a parameter that has potential to highlight further sociodemographic and clinical disparities in portal use. As stated in the Methods section, our data did not permit identification of “threads” across multiple messages on the same issue, which would require natural language processing. This could be an important next step in messaging research.

Conclusion

Portal use has major implications for redesigning obstetric delivery systems. This study documents that portal use and messaging frequency at our center have significantly increased in recent years, especially after the COVID-19 pandemic. Obstetric patients with high-risk chronic conditions are now more likely to use patient portals and to message frequently after the pandemic. However, sociodemographic disparities continue to exist fo portal use and intensity. Patient portals have the ability to encourage patient engagement and improve patient-provider communication and shared decision-making. Inclusive health literacy strategies developed for obstetric patients, such as training for and encouragement of portal use, may be a strategy to reduce disparities and improve outcomes. Future studies should focus on evaluating health and digital literacy interventions to address disparities in portal use.

Abstract

Background: Physical inactivity and a poor diet are modifiable behaviors that contribute to obesity. Obesity is a well-recognized risk factor for chronic diseases, including diabetes. Mobile health (mHealth) apps can play an important adjuvant role in preventing and treating chronic diseases and promoting positive health behavior change among people with obesity, and eHealth literacy skills have the potential to impact mHealth app use.

Objective: The purpose of this study was to explore the associations between the 2 dimensions, access and application, of eHealth literacy skills and mHealth app use among US adults (≥18 years of age) with obesity (BMI ≥30 kg/m^2).

Methods: Data were obtained from February to June 2020 using the Health Information National Trends Survey 5. A total of 1079 respondents met the inclusion criteria of adults with obesity and owners of smartphones. Individual associations between mHealth app use and sociodemographic variables were explored using weighted chi-square and 2-tailed *t* tests. A multivariable weighted logistic regression model was fitted, and adjusted odds ratios (ORs) of using mHealth apps with corresponding 95% CIs were reported across multiple sociodemographic variables. An Ising model-weighted network visualization was produced. A receiver operating characteristic curve was calculated, and the area under the curve was reported with the corresponding Delong 95% CI.

Results: A majority of respondents were female (550/923, 59.6%) or non-Hispanic White (543/923, 58.8%). Individuals in households earning less than US $50,000 comprised 41.4% (382/923) of the sample. All sociodemographic variables were found to be univariately significant at the 5% level, except employment and region. Results from the multivariable weighted logistic regression model showed that the adjusted odds of using an mHealth app are 3.13 (95% CI 1.69-5.80) and 2.99 (95% CI 1.67-5.37) times higher among those with an access eHealth literacy skill of using an electronic device to look for health or medical information for themselves and an application eHealth literacy skill of using electronic communications with a doctor or doctor's office, respectively. Several sociodemographic variables were found to be significant, such as education, where adjusted ORs comparing subgroups to the lowest educational attainment were substantial (ORs ≥7.77). The network visualization demonstrated that all eHealth literacy skills and the mHealth app use variable were positively associated to varying degrees.

Conclusions: This work provides an initial understanding of mHealth app use and eHealth literacy skills among people with obesity, identifying people with obesity subpopulations who are at risk of a digital health divide. Future studies should identify equitable solutions for people with obesity (as well as other groups) and their use of mHealth apps.

accessibility; eHealth literacy; mHealth; multivariable logistic regression; obesity; smartphones

Introduction

Overview

Physical inactivity and poor dietary behaviors are modifiable behaviors that contribute to obesity [1,2]. Recent studies show that obesity affects nearly 42% of the US population aged 20 years or older [3], with an associated excess annual estimated medical cost of upwards of US $170 billion in 2019 [4]. Obesity is a well-recognized risk factor for chronic diseases, including diabetes, cardiovascular diseases, and cancer, and a significant cause of premature morbidity and mortality [2,5]. Wang et al [6] demonstrated the importance of reducing the weight of patients classified as obese, which is a major contributor to the increased incidence of type 2 diabetes mellitus. Obesity is a complex and multifaceted disease, extending far beyond the realm of individual behavior or mere lifestyle choices. Genetic, environmental, and socioeconomic factors in the development of obesity [7]. However, mobile health (mHealth) apps can play an important adjuvant role in preventing and treating chronic diseases and promoting positive health behavior change among individuals with obesity [8,9], with several factors influencing users' acceptance of and engagement with mHealth apps [10-12]. Previous intervention studies have used mHealth apps to promote health behavior change among individuals with obesity [13,14]. Participants from the reference studies found that the use of mHealth made the intervention helpful and benefited weight loss when used in conjunction with other weight loss intervention methods. mHealth apps provide access to health information and can extend this access to underserved groups, particularly those at higher risk of chronic diseases [15]. However, many individuals with chronic diseases like obesity fail to engage in mHealth app use [16].

mHealth and eHealth Literacy

Istepanian et al [17] defined mHealth as mobile computing, medical sensors, or communication technologies designed for health care. Recent interventions involving mHealth apps provide evidence of improvement in participants' self-care and disease self-management [18,19]. It is estimated that more than 350,000 mHealth apps are available on the market [20]. Despite the number of digital health interventions targeting weight management, the level to which users actively and regularly engage with those apps entails user engagement early in the intervention design process [21]. While health literacy is a broader concept associated with the ability of individuals to obtain and understand health information to make rational health decisions, eHealth literacy comprises the complex navigation of health care information from internet sources [22,23]. Kontos et al [24] showed that people with lower levels of education were less likely to use the internet to communicate with a doctor or use health information on their mobile devices. Moreover, national and international studies have shown that weight-management apps are beneficial for improving weight loss [25,26]. Previous studies have recommended focusing on understanding the level of health literacy of recipients who may use these apps, particularly those interested in weight loss interventions. Understanding eHealth literacy skills is critical when evaluating health information from mHealth apps and the subsequent application of the knowledge gained [27,28].

eHealth literacy is defined as seeking, finding, understanding, and appraising health information from electronic sources and applying the knowledge acquired to address or solve a health-related problem [29,30]. More recently, eHealth literacy has been conceptualized in dimensions including access to digital services and the application of services and information that satisfy users [31]. People lacking or with a low level of health literacy or eHealth literacy skills benefit less from digital health information and health informatics interventions [32,33], as low eHealth literacy skills were found to impact mHealth app use when mediated through mHealth app efficacy [23]. By contrast, those with higher levels of health literacy and eHealth literacy skills report a positive connection between mHealth app use and health outcomes [34].

mHealth apps are operated across a diverse group of users. This includes individuals with varying incomes, ages, races, ethnicities, and educations [35]. Curating data that include this and other defining personal characteristics require a significant number of resources. Few studies of eHealth literacy and mHealth app use have included a diverse group of participants. Through a national data set of noninstitutionalized adults, this study uses a diverse national data set. The purpose of this study is to explore the potential associations between the 2 dimensions, access and application, of eHealth literacy skills and mHealth app use among a diverse group of US adults (aged ≥18 years) with obesity (BMI ≥30 kg/m^2).

Theoretical Underpinning

Seeking health information has become a typical behavior among people of all ages and health conditions [36]. The information obtained when factoring in a person's eHealth literacy skills, has the potential to influence health outcomes. This is particularly important for people with obesity. People with obesity have lower self-confidence in managing their health. However, people with obesity view communication with their physician as helpful with self-care weight management [37]. Therefore, people with obesity may improve their confidence over time in managing their weight if they have the eHealth literacy skills to seek information from their physician electronically. There have been numerous information behavior theories and models developed to understand how individuals seek and use information [38]. For example, Zare-Farashbandi and Lalazaryan [39] designed their health information acquisition model based on 6 stages of information seeking. The model acknowledges that the information-seeking process can be iterative and that there is a need for a feedback loop in the search process. However, the model does not consider personal or contextual factors affecting information seeking.

Longo's model of health information considers the effects of personal and contextual factors on the information-seeking behavior of patients [40]. Focusing on patients with chronic diseases, the model was significant in depicting the output process of information-seeking for patients [39]. These theories and models have also considered various social contexts and population groups, such as older individuals, patients with cancer, prisoners, and diabetics [38,41-43]. However, this study is informed by Lenz's [41] Information Seeking Model, which is the foundation of many fundamental tenets of recent models and instruments aimed at measuring eHealth literacy skills.

According to this framework, in which information gathering is part of the decision-making process, individuals follow 6 stages to seek health information. First, they receive a stimulus from their previous disease experience or the environment. Second, they establish their informational goals, including sources, time available, and the type of information needed. Third, the person decides whether or not to actively access the information they want. The decision is based on the individual's previous knowledge, background, and the expected cost-benefit of the action. The fourth stage is of particular interest, characterized by the information-seeking action itself. This step is correlated to the eHealth literacy dimension of access, and it could be an in-depth search or superficial information gathering, depending on the person's need and previous attempts. The access dimension corresponds to having the availability of digital services that suit people's needs and work correctly [44]. The fifth stage corresponds to information achievement and interpretation. This step is related to the eHealth literacy dimension of application, in which the individual understands and appraises or applies the information obtained. In this final stage, people may have to decide on the adequacy of the acquired information [39]. Understanding health information seeking through the potential associations of eHealth literacy skills and mHealth app use may provide insights into how population groups with health disparities with chronic conditions such as obesity can access and apply the information they seek [45]. Using this framework, the objective of this study is to explore the potential associations between the 2 dimensions, access and application, of eHealth literacy skills and mHealth app use among a diverse group of US adults with obesity.

Methods

Data

The Health Information National Trends Survey (HINTS) was used to explore the potential association between mHealth app use and eHealth literacy skills. HINTS has been administered every few years by the National Cancer Institute since 2003, and the data sets that have been made publicly available are used for evaluating health information access and use among US adults [24,46,47]. HINTS collects representative data about noninstitutionalized US adults' knowledge, access, attitudes, and use of cancer- and health-related information. The survey uses a 2-stage stratified random sampling that selects households from residential addresses in the United States and then selects 1 adult within each household [24,46].

This study used the HINTS 5, Cycle 4 data set. The data were collected from February to June 2020 and comprised responses from 3865 participants. Despite the COVID-19 impact on society, the response rate for the survey remained high. The response rate (37%) for the survey remained relatively high and was even higher than prepandemic HINTS 5 surveys, which experienced response rates of at most 33% [48]. However, COVID-19 impacted the time frame in which the data are typically collected. Individuals included in this analysis were those who indicated ownership of a tablet, smartphone, or both and self-declared a BMI ≥30 kg/m^2 (obese). The dependent variable was based on respondents' answers to the following item: "In the past 12 months, have you used any of these health or wellness apps?" The binary variable derived was used to indicate those who reported using any health or wellness apps within the past 12 months and those who did not.

The main independent variables representing eHealth literacy skill's access and application dimensions were the following four items pertaining to eHealth information and services, connecting to the common stem of "In the past 12 months, have you used a computer, smartphone, or other electronic means to do any of the following: (1) looked for health or medical information for yourself; (2) used email or the internet to communicate with a doctor or doctor's office; (3) looked medical test results; and (4) made appointments with a health care provider?" Access within this context is the information-searching behavior involved in accessing information. Application within this context is defined as the interpretation and appraisal of information aimed at completing an action. Additional covariates extracted include age in years, health insurance status, sex at birth, employment status, marital status, education, annual household income (in ranges), race and ethnicity, and US Census region. These variables have been used in previous studies to evaluate mHealth app use or can be relevant confounders regarding the associations between eHealth literacy skills and mHealth app use [49,50].

Due to low counts, the following categories were combined: employment status of unemployed across lengths of unemployment; employment status of students and others; marital status of separated and divorced; marital status of married and those living as married or with a romantic partner; education categories below 11 years of education; and race and ethnicity categories of non-Hispanic Native Hawaiian or Other Pacific Islander and American Indian or Alaska Native.

Statistical Analysis

In order to investigate the research objective and hypothesis, a comprehensive statistical analysis was performed on the collected data using univariate and multiple logistic regression modeling. The weights provided by HINTS were used to perform all analyses and adjust for sampling biases [51]. A weighted complete case analysis was performed on the data. Characteristics were summarized using means, SDs, counts, and percentages as appropriate. Weighted chi-square and 2-tailed *t* tests were used to explore univariate associations between each of the covariates and mHealth app use, with test statistics and corresponding *P* values tabulated. Visualizations were created to explore associations, including (1) Ising model

network weighted analysis of the associations between the main independent variables (eHealth literacy skill's access and application covariates) and the outcome; (2) weighted box plot for the continuous covariate (age) and the dependent variable; and (3) multiple weighted 100% stacked bar charts across the main independent variables and the dependent variable. Additional weighted 100% stacked bar charts were constructed (Multimedia Appendix 1) to visualize the sociodemographic variables and the outcome.

The primary study aim is to assess associations between mHealth app use (binary outcome) and each of the eHealth literacy skills dimensions of access and application (main covariates). Univariate analysis is included to provide a comprehensive description of the individual variables in the study and establish a foundation for more complex multivariable analyses. These were further examined using a multivariable weighted logistic regression adjusted for the aforementioned sociodemographic factors. Adjusted odds ratios (ORs), corresponding 95% CIs, and *P* values were reported across eHealth literacy skills dimensions and sociodemographic variables. Results were tabulated and highlighted using a significance level of 5%. A pseudo-R^2 was calculated. The receiver operating characteristic (ROC) is a common approach used to measure the sensitivity versus specificity of logistic models. Additionally, the area under the curve (AUC) is a single metric for that trade-off, with AUC=1 meaning that the model perfectly fits the data and AUC=0.5 indicating there is a split chance that the model fits the data. Both of these approaches are used to evaluate the performance of logistic models. The ROC curve was estimated, and the corresponding AUC value and Delong 95% CI were reported. R software (version 4.0.3; R Foundation for Statistical Computing) was used for statistical analyses.

Ethical Considerations

This research was approved by the institutional review board (IRB) of the University of North Carolina at Charlotte (study #IRB-22-0585). This data set consisted of deidentified, aggregated data. The IRB approval process did not require additional consent from the respondents representing the data.

Results

A total of 1079 participants were identified as obese and owners of a smartphone, tablet, or both. Fewer than 15% (156/1079) of the responses were removed due to incomplete or incoherent data, resulting in 923 complete observations, with mHealth app use (dependent variable), eHealth literacy skills dimensions (main independent variable), and additional covariates summarized in Table 1. The average age was 53.51 (SD 14.91) years, and most participants were female (550/923, 59.6%) and non-Hispanic White (543/923, 58.8%). A college degree or above was the highest level of education for 43.3% (400/923) of study participants, and they were mainly employed (with a single or multiple employer; 594/923, 64.4%) and covered by health insurance (872/923, 94.5%). The South contained the largest percentage of participants (436/923, 46.7%), which also corresponds to the nation's most populous region [52]. Individuals in households earning less than US $50,000 comprised 41.4% (382/923) of the sample, and 18.9% (174/923) of participants had an annual household income that fell within the range, containing the median annual household income in the United States of US $67,521 in 2020 [53].

The majority of participants (482/923, 52.2%) did not use mHealth apps, resulting in a balanced outcome variable. Within the eHealth literacy skills access dimension, 77.5% (715/923) of respondents used an electronic device to look for health or medical information for themselves within the past 12 months, and approximately half (468/923, 50.7%) used electronic means to look up medical test results, also within the past 12 months. Within the eHealth literacy skills application dimension, 55.6% (513/923) of respondents used email or the internet to communicate with a doctor or doctor's office within the past 12 months, and 53.3% (429/923) made an appointment with a health care provider through electronic means in that same time period. We also examined the univariate association between mHealth app use, covariates, and main independent covariates.

Table 2 summarizes results from weighted chi-square and *t* tests for univariate associations between mHealth app use and each of the covariates. Most covariates and all the main covariates were found to be significant at the 5% level. All eHealth literacy skills dimensions were found to be significantly associated with mHealth app use based on univariate weighted chi-square tests ($P<.001$). Similarly, all demographic factors were found to be significantly associated with mHealth app use except for employment status ($P=.20$) and Census region ($P=.16$). Figure 1 displays pairwise weighted 100% stacked bar charts for each of the eHealth literacy skills dimensions versus mHealth app use. Figure 2 portrays a joint network representation of the weighted associations between the eHealth literacy skills dimensions and mHealth app use, which demonstrate strong positive associations both between the skills dimensions as well as between those and the outcome (mHealth app use). Figures S1-S9 in Multimedia Appendix 1 include a weighted box plot (age) and weighted 100% stacked bar charts visualizing the univariate associations with mHealth app use.

Table 3 presents the results of the multivariable weighted logistic regression model. The adjusted odds of using an mHealth app are 3.13 (95% CI 1.69-5.80) times higher among those who responded with an access eHealth literacy skill of using an electronic device to look for health or medical information for themselves within the past 12 months. Similarly, those with an application eHealth literacy skill of using email or the internet to communicate with a doctor or doctor's office within the past 12 months experience 2.99 (95% CI 1.67-5.37) times higher odds of using an mHealth app compared to those without this skill. Sociodemographic factors found to be significantly associated with mHealth app use include age, disabled or retired status, single or never married or widowed, education, and Hispanic ethnicity. Each additional year of age is associated with 4% lower odds of using mHealth apps (OR 0.96, 95% CI 0.94-0.98). Disabled and retired participants experienced 4.21 (95% CI 1.28-13.82) and 2.53 (95% CI 1.14-5.60) higher odds, respectively, of using mHealth apps compared to those who were employed. Single or never married and widowed participants experienced 49% and 81% lower odds of mHealth app use, respectively, than those who are married, living as married, or living with romantic partners. Previous work has

indicated that surrogate seekers, those who may seek health information on behalf of others, were more likely to be married or have someone close to them with a chronic illness [54]. Those who received more than 11 years of formal education experienced higher odds of mHealth app use than those with 11 years or less, with OR estimates ranging from 7.77 to 17.24, though with substantially wide CIs. Hispanic participants experienced higher odds of using mHealth apps than non-Hispanic White participants (OR 2.61, 95% CI 1.28-5.33). Insurance status, sex at birth, annual household income, and Census region were not found statistically significant upon adjusting for the other covariates, though there is some level of collinearity present among sociodemographic covariates, as demonstrated in the univariate significance of some of these variables. The multivariable weighted logistic regression adjusted for sociodemographic characteristics showed relatively strong explanatory power with a pseudo-R^2 of 0.32 and AUC of 0.7957 (95% CI 0.7671-0.8243). The corresponding ROC is included in Multimedia Appendix 1.

Table 1. Unweighted characteristics of study participants (n=923) using the 2020 Health Information National Trends Survey data set.

Sociodemographic variables	Values
Age (years), mean (SD)	53.51 (14.91)
Health insurance, n (%)	
Insured	872 (94.5)
Uninsured	51 (5.5)
Sex at birth, n (%)

Table 2. Weighted chi-square and 2-tailed *t* tests (test statistics and *P* values) for univariate associations between mHealth app use (dependent variable) and each of the covariates.

Variable	Chi-square (*df*)	*P* value
Sociodemographic factors		
Age (years)	3.77 (921)[a]	<.001
Health insurance	6.28 (1)	.01
Sex at birth	6.25 (1)	.01
Employment status	8.54 (6)	.20
Marital status	18.55 (3)	<.001
Education	78.02 (5)	<.001
Annual household income	34.38 (8)	<.001
Race and ethnicity	11.31 (5)	.046
Census region	5.18 (3)	.16
Main covariates		
eHealth literacy skills: access dimension		
eHealth information for self	95.60 (1)	<.001
Electronic test results	97.48 (1)	<.001
eHealth literacy skills: application dimension		
Electronic communication with doctor or doctor's office	127.87 (1)	<.001
Made provider appointments electronically	81.48 (1)	<.001

[a]*t* test was used for the univariate analysis.

Figure 1. Visualization of weighted 100% stacked bar charts for each of the eHealth literacy skills dimensions (main covariates) against mHealth app use (outcome). A: Electronic health information for self; B: Electronic test results; C: Electronic communication with doctor or doctor's office; D: Made appointments electronically.

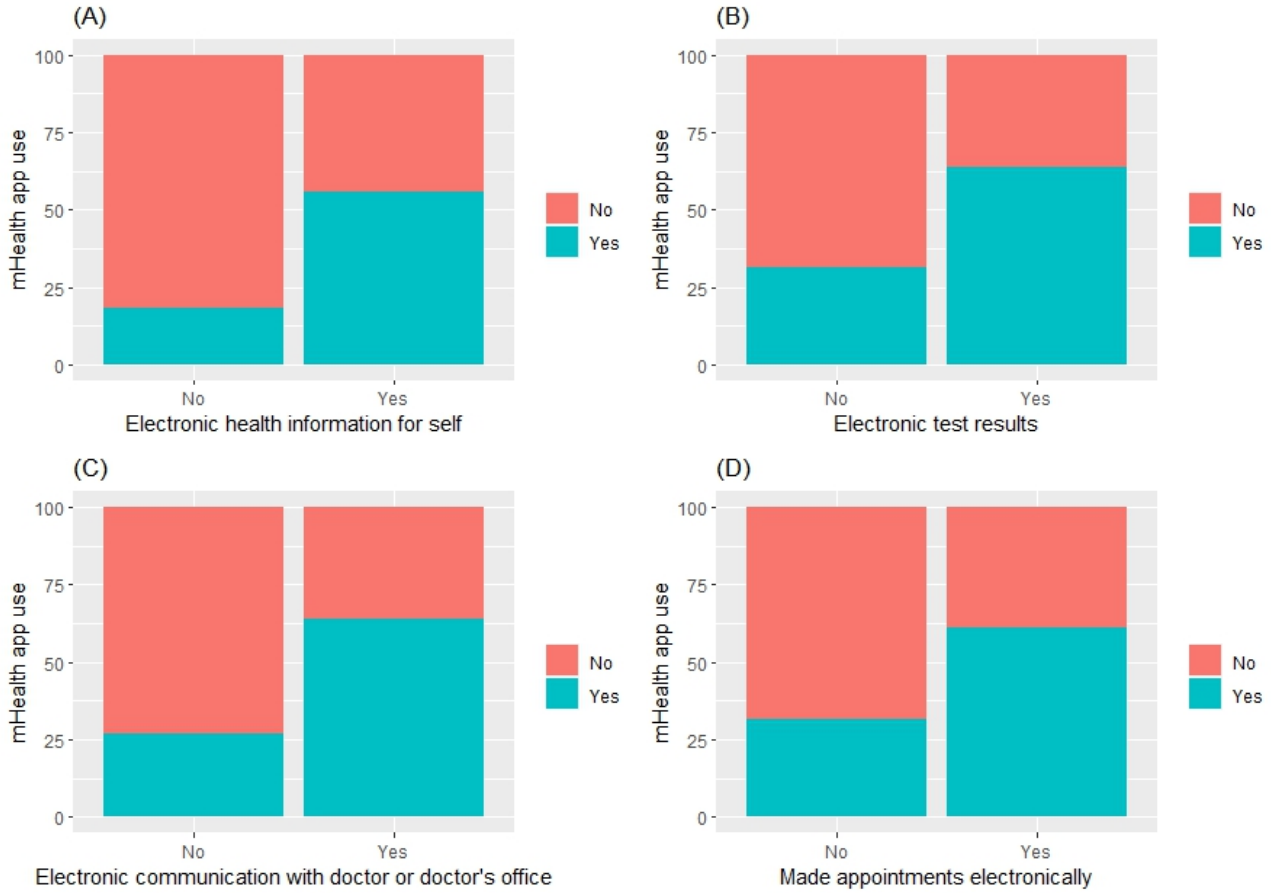

Figure 2. Ising model-weighted network visualization of eLASSO associations (unadjusted by other covariates and with 0.25 penalization factor) between the eHealth literacy skills dimensions (SHI: self-health information; TD: talk to a doctor or doctor's office; TR: test results; MA: made appointments; and mH: mHealth app use). Thicker edges (lines) between nodes (circles) represent stronger associations.

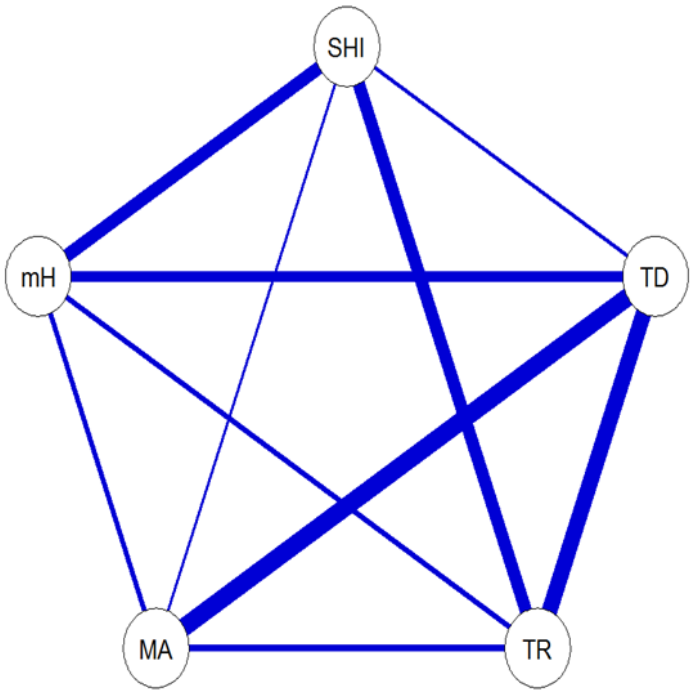

Table 3. Adjusted odds ratios (ORs), corresponding 95% CIs, and *P* values for the multivariable weighted logistic regression model assessing mHealth app use (n=923). The regression model included adjustments for eHealth literacy, age, insurance status, sex, employment and marital status, education, income, race and ethnicity, and census region.

Characteristics	OR (95% CI)	*P* value

Discussion

Overview

The purpose of this study was to explore the associations between the 2 dimensions, access and application, of eHealth literacy skills and mHealth app use among US adults with obesity. We used the HINTS 2020 data to explore this potential association with a sample of 923 respondents with complete information represented in the data set. We found that the majority of the respondents had health insurance, were female, and were non-Hispanic White, with an average age of 54 years. Also, more than half of the respondents had some level of college or were college graduates. This study highlights the association between eHealth literacy skills for accessing and the application of health information using mHealth apps among people with obesity.

The weighted univariate analyses demonstrated associations between all of the covariates and mHealth app use except employment status and census region. Socioeconomic factors of education and income have been found to be important in the general use of content within digital environments (ie, internet) [44]. However, more specifically to this study, these factors are important in showing the potential relationship they have with mHealth app use among people with obesity. When considering weight management or physical activity interventions using mHealth apps, future interventions should attempt to improve the eHealth literacy of participants by targeting segments of people with obesity identified to be more at risk, such as older individuals with obesity or those in lower income brackets. These initial metrics can be collected through a variety of eHealth literacy assessment tools. The eHealth Literacy Scale, for example, has been studied in diverse languages and populations, and it was designed to convey an estimate of people's eHealth-related skills. Other instruments, such as the eHealth Literacy Questionnaire, were established to support researchers, designers, and the government in evaluating, developing, and applying effective digital health interventions [54]. Previous research identified that patients with adequate eHealth literacy had more ability to seek health information on the internet and find reliable and high-quality information than patients with inadequate eHealth literacy [55,56].

Accessing health information requires active information-seeking skills. Additionally, context and behaviors to gain information are intertwined in this process. Respondents' access to web-based health information (seeking health information for themselves) can be informed by the Lenz search behavior stage. The respondents' access to information requires a search for information from impersonally related sources. There is no indication of the familiarity that respondents have with these resources based on the survey questions. People with obesity who use mHealth devices may exhibit multiple factors in their search for health information, and recent eHealth literacy work supports the nuances involved in seeking health information [57,58].

The information acquired through the information-seeking process impacts an information seeker's decision-making process. Electronic communication with the doctor's office can be the result of gathering enough information to move forward based on their original goal or a stop in the information acquisition process that prompts information seeking through a personal connection through digital communication. The results from this work are not intended to model these variables but demonstrate that Lenz's model, enhanced with recent theories, may help inform studies aimed at understanding active information seeking at the intersection of digital health devices such as mHealth and eHealth literacy skills. Recent models and theories commonly demonstrate that health information–seeking behavior involves the action of seeking out information, irrespective of how or why it is sought [36].

Consistent with Mahmood et al [59], education and age are important sociodemographic factors associated with mHealth app use among people with obesity. As access to health services

increases through the use of telehealth technology embedded within mHealth apps, it is imperative that this population group be able to benefit from this type of health service [60]. People with lower education levels and older individuals experience more limited eHealth literacy skills and lower mHealth app use, further widening the digital divide gap [18,24]. Additionally, when we examine other sociodemographic factors, marginalized ethnic groups such as Hispanic populations may have access to mHealth apps but experience digital divide issues [30,61].

Issues such as use and knowledge as they relate to using mHealth apps can also contribute to the digital divide [62]. Additional attention is needed to focus on these vulnerable populations. Interventions that can attempt to address this issue are the development of apps and health promotion campaigns that are designed to be culturally relevant [63]. Within the realm of health promotion and wellness, mHealth mindfulness approaches have been used for African American populations [64]. Moreover, studies have described the importance of mHealth interventions with phone features that are familiar to the target population group [62]. There should be consideration of acceptability and efficacy during the developmental phases to support the use of mHealth apps. When considering efficacy, simpler solutions in app design and use should be evaluated. For the older population, features such as 1-click access to a dashboard within health apps that are appropriately displayed in size may be appropriate. Future mHealth apps should also consider health education–related features to support users with low eHealth literacy skills [30,65]. The recent COVID-19 pandemic highlighted the continued digital divide and the disparity in health care services for those who lack sufficient digital literacy skills [66]. mHealth apps benefit people with various chronic conditions, including obesity. People with obesity are less likely to benefit from these mHealth apps if they have low eHealth literacy skills.

mHealth apps facilitate access to health information that has increasingly migrated to web-based spaces [67]. More importantly, mHealth devices assist individuals with seeking health information and decision-making regarding their health [68]. mHealth apps are also advantageous to improve access to health information for personal health data management [15,69]. Since we found that the eHealth literacy skills dimension of access for people with obesity is associated with higher odds of using mHealth apps for seeking health information for themselves, health services should reconsider how they disseminate health information to reach higher proportions of the population. Inevitably, the accessibility of web-based health information has changed the way people engage in health decision-making [70]. This is also evident from our network analysis results, which demonstrate the interconnectivity among all elements relating to eHealth literacy skills and mHealth app use among people with obesity, resulting in the need for holistic solutions to enhance mHealth app use and access to health information. Lenz's model primarily focuses on the search process and use of the information; however, future studies should consider the nuanced contextual factors for people with obesity and their use of mHealth-related devices.

Accessing health information through mHealth apps streamlines the application of health information for decision-making. Many people with obesity have additional chronic diseases that can benefit from timely communication with their health care provider [71]. Effective communication is important for reported satisfaction and perceived health management outcomes. Face-to-face communication has been the standard for communication among patients and health care providers. However, there are mixed results on the perceived effectiveness of face-to-face communication versus IT-aided communication such as mHealth devices [72]. Recent studies have found that mHealth apps are viewed as useful by patients for improving communication and the accessibility of health data [73]. Therefore, this constant communication creates the potential for a bidirectional channel of communication among people with obesity and their health care providers. An in-depth content analysis of vaccination apps showed that few apps provide the capability for bidirectional communication among users and health care providers [74]. The challenges of bidirectional communication can be attributed to barriers to data integration. Given the numerous mHealth apps available for download, this creates interoperability challenges for electronic health care record systems [75]. For mHealth apps that are designed to improve physician and consumer communication, transdisciplinary scholarship is necessary to overcome these barriers. More importantly, technical and networking policies must be developed to support and incentivize the ability to improve this type of communication.

This study benefits from the use of a nationally representative sample of noninstitutionalized US adults. This study provides an adjusted analysis of the associations between mHealth app use and eHealth literacy skills among people with obesity. New technologies that require eHealth literacy skills are transforming how we receive health care and access health information, but they also highlight new disparities as they relate to digital health services [30]. However, to address the rise of chronic conditions such as obesity, it is essential to empower patients to engage in their own health management. One promising strategy is using mHealth apps as a complementary tool to manage weight loss and track physical activity [26]. We provide evidence of several significant factors that can be informative when designing inclusive mHealth app-based health intervention studies. Our results also have implications for studies aimed at managing weight loss or tracking the physical activity of people with obesity to assist with mHealth app development and uptake.

Concerning limitations, first, there could be additional confounding variables that are not included in the study, which is limited by the survey design questionnaire. Some of these confounding variables may be related to self-care behaviors or use patterns with mHealth apps [25]. Furthermore, a bias in the survey design includes the assumption that apps are used only on tablets or smartphones, such that only individuals who indicated having a tablet or smartphone were asked within the survey about having or using health or wellness apps. Second, respondents were only asked about access to information within the previous 12 months. There is a possibility that users do not access or seek health information between visits with their doctors on a yearly basis. Nevertheless, many patients with low health literacy are often left dissatisfied and unsure of the information shared by their doctor and seek third-party sources

such as web-based health communities to fill those gaps [76,77]. Also, respondents who report ownership of a tablet, smartphone, or both may also use a computer, but they did not indicate that as part of their response. Third, results from the Ising model visualization show a strong relationship between respondents seeking health information for themselves and mHealth app use. As a result of seeking health information, this may also explain the strong relationship between mHealth app use and talking with one's doctor. Therefore, these correlations may exist because they are measuring the same events. Also, some sociodemographic variables used in this study are correlated (eg, age and retired status), so some multicollinearity may be present. Fourth, with a small sample of uninsured people represented in our sample, the statistical significance for health insurance in our model may have been different with a larger sample of uninsured people. Additionally, the data did not provide a distinction between private and public health insurance, though the information content of such a factor may already be embedded in the income variable. A study aimed at self-monitoring of diet, physical activity, and weight among patients who were underinsured or uninsured demonstrated higher adherence through the use of 2 mHealth-related apps in comparison to a paper group [6]. Also, the sample in this study covers the COVID-19 peak period in early 2020, which may have represented a crest (and potentially a permanent shift in behaviors) in electronic access to health information among people with obesity compared to previous time periods. Lastly, there is a limitation in the HINTS survey questions as they were not designed using a web-based health information–seeking behavior framework, though we were able to detect relevant associations even with this design limitation.

Future directions of this work should consider this model structure for people without obesity. A comparative analysis may identify whether eHealth literacy relevance differs between individuals with obesity and those without obesity. This work also considered mHealth app use, but it did not examine cognitive motivational factors for mHealth use. The identification of motivational barriers and facilitators can be analyzed within the context of psychological motivation frameworks to identify potential intervention targets to leverage in mHealth intervention–based studies. Also, since the COVID-19 pandemic may have brought behavioral changes in the overall population regarding eHealth literacy, a dynamic study that explores those changes over time could highlight whether segments of people with obesity may now experience heightened needs compared to prepandemic stages.

Conclusion

This study estimated the associations between mHealth app use and eHealth literacy skills. Our findings are consistent with previous literature, showing that eHealth literacy skills are associated with accessing digital health information and the application of digital health services. For example, age is negatively associated with mHealth app use among people with obesity, with other sociodemographic factors also showing strong associations. This highlights substantial uneven access to eHealth information among people with obesity, potentially leading to disparities in health outcomes among sociodemographic groups. It is imperative that this phenomenon be further investigated as digital health–related services that involve the use of mHealth apps become more integrated into health care services and aim to reach wider segments of the population. A continued challenge is to engage people with chronic conditions such as obesity to use mHealth apps, especially older individuals with obesity and those with lower educational backgrounds. Our work provides evidence of factors associated with mHealth app use in relation to access and application. This work provides an initial understanding of mHealth app use and eHealth literacy skills among people with obesity, and future studies should identify equitable solutions for people with obesity (as well as other groups) and their use of mHealth apps.

Abstract

Background: It is not known whether an intervention made mandatory as a physical education (PE) class assignment and aimed at promoting physical activity (PA) in adolescents can create a healthy walking habit, which would allow further improvements to be achieved after the mandatory and promoted intervention has been completed.

Objective: The aims of this study were to (1) investigate whether, after a period of using a step tracker mobile app made mandatory and promoted as a PE class assignment, adolescents continue to use it when its use is no longer mandatory and promoted; (2) determine whether there are changes in the PA level, body composition, and fitness of adolescents when the use of the app is mandatory and promoted and when it is neither mandatory nor promoted; and (3) analyze whether the covariates maturity status, gender, and specific app used can have an influence.

Methods: A total of 357 students in compulsory secondary education (age: mean 13.92, SD 1.91 y) participated in the study. A randomized controlled trial was conducted consisting of 2 consecutive 10-week interventions. Participants' PA level, body composition, and fitness were measured at baseline (T1), after 10 weeks of mandatory and promoted app use (T2), and after 10 weeks of nonmandatory and nonpromoted app use (T3). Each participant in the experimental group (EG) used 1 of 4 selected step tracker mobile apps after school hours.

Results: The results showed that when the use of the apps was neither mandatory nor promoted as a PE class assignment, only a few adolescents (18/216, 8.3%) continued the walking practice. After the mandatory and promoted intervention period (T1 vs T2), a decrease in the sum of 3 skinfolds (mean difference [MD] 1.679; *P*=.02) as well as improvements in the PA level (MD –0.170; *P*<.001), maximal oxygen uptake (MD –1.006; *P*<.001), countermovement jump test (MD –1.337; *P*=.04), curl-up test (MD –3.791; *P*<.001), and push-up test (MD –1.920; *P*<.001) in the EG were recorded. However, the changes between T1 and T2 were significantly greater in the EG than in the control group only in the PA level and curl-up test. Thus, when comparing the measurements taken between T1 and T3, no significant changes in body composition (*P*=.07) or fitness (*P*=.84) were observed between the EG and the control group. The covariates maturity status, gender, and specific app used showed a significant effect in most of the analyses performed.

Conclusions: A period of mandatory and promoted use of step tracker mobile apps benefited the variables of body composition and fitness in adolescents but did not create a healthy walking habit in this population; therefore, when the use of these apps ceased to be mandatory and promoted, the effects obtained disappeared.

Introduction

Background

In recent years, a growing significance has been placed on the engagement of adolescents in physical activity (PA), given the decrease in active time and the increase in sedentary activities and screen time [1]. These behaviors have negatively impacted the health of adolescents by increasing the risk of cardiovascular disease and other associated chronic diseases [2]. This situation has prompted the implementation of new practices that have been shown to be effective in increasing the level of sports practice in adolescents [3,4]. In this context, interventions that incorporate electronic devices have gained relevance [5], given their extensive use during the COVID-19 pandemic and their integration into the daily lives of adolescents [6].

Mobile sports apps have emerged as valuable resources in promoting PA among adolescents [7], and it has been observed that interventions with mobile devices have made it possible to increase moderate-intensity PA and daily step count among users [8]. This has also had a positive impact on the health of the adolescent population because the use of these mobile apps has improved their body composition and fitness levels [9,10], which are fundamental for their subsequent development [11,12]. This is because adolescents who are overweight or obese have a high probability of remaining so in adulthood [13], with the associated high health risk for cardiovascular and respiratory diseases [14]. On the contrary, adequate levels of body fat, within the limits considered healthy [15], as well as an adequate physical fitness level, especially good cardiorespiratory fitness, are indicators of adequate health and serve as preventive factors against various diseases in adulthood [16].

In this regard, mobile apps seem to be effective tools for improving the health status of adolescents and for preventing future health risks. It is crucial to emphasize that the effectiveness of increasing adolescents' PA level through mobile apps was evident only in studies in which the use of these apps was mandatory. Specifically, the promotion of app use as an assignment in physical education (PE) classes played a significant role in achieving positive outcomes [9,17]. Furthermore, it is worth noting that no major differences were found in the effects achieved by the intervention when comparing the different mobile apps used, as long as they were all step trackers [9]; however, the gender of the adolescents was shown to be a determinant factor in the benefits obtained because female adolescents used these apps more often than male adolescents during the mandatory and promoted intervention period, which led to significant differences in the benefits obtained in BMI, corrected calf girth, fat mass, and physical fitness [18]. Therefore, the mandatory use of apps seemed to be effective in this population, although it should be noted that a previous study showed that the first weeks of the intervention were the most effective in the adolescent population due to the novelty of the intervention, but as the intervention progressed, the effects were reduced [19]. This is a relevant aspect because there is a considerable loss of adherence after the first weeks of the intervention [8], which could negatively influence the overall benefits obtained.

In addition to the loss of adherence, there are also periods in the school calendar when PA decreases, such as holiday breaks. These are characterized by the absence of students from school, which makes it difficult to promote the use of this type of intervention as a PE class assignment. This has a particular significance because prior research has revealed a detraining effect, wherein the gains in body composition and fitness achieved during an aerobic intervention period were subsequently lost, leading to a regression to preintervention levels [20].

Therefore, it is essential to verify whether, after a period of mandatory and promoted use of step tracker mobile apps as a PE class assignment, which has shown beneficial effects on body composition and physical fitness in previous research [9], it is possible to create a healthy walking habit in adolescents and to have them continue using the apps when they are neither mandatory nor promoted to try to avoid detraining effects. This would allow us to define strategies to compensate for the loss of adherence and decrease in PA level observed during holiday periods, similar to previous research on flexibility in adolescents [21]. However, no previous research is known to have analyzed whether the effects achieved throughout a period of mandatory and promoted use of step tracker mobile apps are maintained over time when their use is neither mandatory nor promoted as a PE class assignment. Furthermore, previous studies in this area have not analyzed whether the effects of such interventions may depend on the maturity status of adolescents, although numerous studies have shown that the rate of maturation during adolescence varies between individuals [22]. Thus, this factor may condition the changes in body composition and fitness variables in adolescents [23].

Objectives

Therefore, considering the absence of previous research analyzing whether adolescents aged 12 to 16 years continue their walking practice with step tracker mobile apps when their use is no longer mandatory and promoted as a PE class

assignment, as well as the influence that covariates such as maturity status, gender, and specific app used may have on the results, the aims of this study were to (1) investigate whether, after a period of mandatory and promoted use of a step tracker mobile app as a PE class assignment, adolescents continue to use it when its use is no longer mandatory and promoted; (2) determine whether there are changes in PA level, body composition, and fitness of adolescents when the use of the app is mandatory and promoted as a PE class assignment, as well as whether maturity status, gender, and specific app used can have an influence on the results; and (3) analyze whether there are changes in PA level, body composition, and fitness of adolescents when the use of the app is neither mandatory nor promoted as a PE class assignment, as well as whether maturity status, gender, and specific app used can have an influence on the results.

Hypotheses

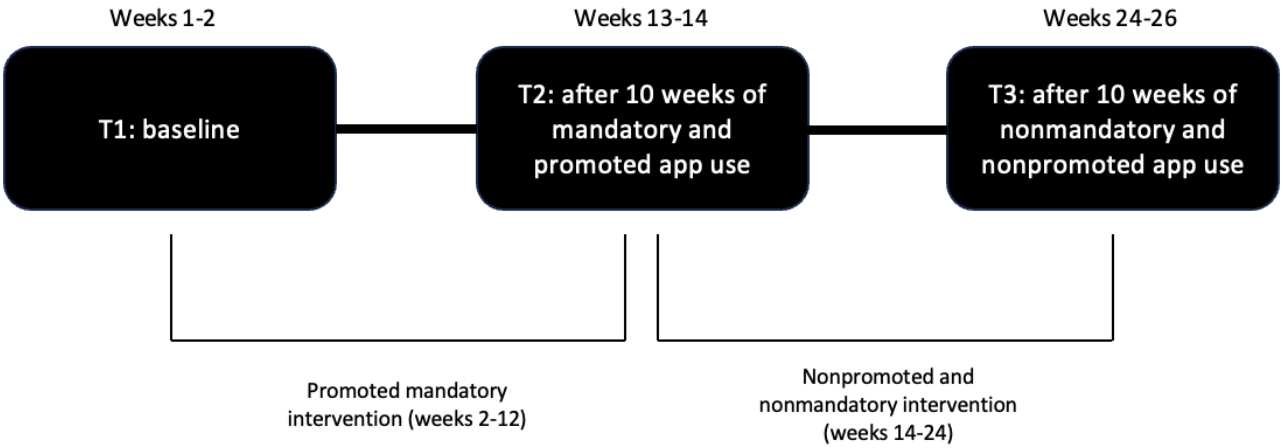
On the basis of the aims of the research and previous research involving technological devices (eg, wearables) or websites, it is hypothesized that adolescents will stop using the mobile app during the period of nonmandatory and nonpromoted use (H1); that there will be significant differences in PA level, body composition, and fitness of adolescents during the mandatory and promoted period, influenced by maturity status and gender but not by specific app used (H2); and that some of the benefits achieved by adolescents during the mandatory and promoted period will be lost after the mandatory and promoted intervention has been completed, with the results being influenced by maturity status and gender but not by specific app used (H3).

Methods

Design

The intervention in this study was carried out by replicating the methodology of previous research [9], the main difference being that this research analyzed what happens to the study variables when the mandatory intervention ends and becomes a nonmandatory, nonpromoted intervention. Our new research design comprised 3 data collection periods (T1: baseline, T2: after 10 weeks of mandatory and promoted app use, and T3: after 10 weeks of nonmandatory and nonpromoted app use) with a total duration of 26 weeks. T1 took place in the first 2 weeks (weeks 1-2); the mandatory intervention with the step tracker mobile apps promoted as a PE class assignment took place in the following 10 weeks (weeks 2-12); T2 took place in the next 2 weeks (weeks 13-14); the use of the step tracker mobile apps was neither mandatory nor promoted during the following 10 weeks (weeks 14-24); and T3 took place in the last 2 weeks of the study (weeks 24-26). Figure 1 shows the timeline of the study. The intervention began on January 9, 2023, and ended on June 23, 2023.

Figure 1. Timeline of the study.



This study was a randomized controlled trial. It followed the CONSORT (Consolidated Standards of Reporting Trials) guidelines [24] and was preregistered at ClinicalTrials.gov (NCT06164041). A convenience sampling method was used to recruit adolescents from accessible educational institutions.

The study used a specific research model (Table 1).

Table 1. Research model.

Variable type	Construct	Groups included	Variables included
Independent	Physical activity level	App use group and control group	Subjective assessment of the level of physical activity
Dependent	Kinanthropometric and body composition variables	App use group and control group	Body mass; height; BMI; sitting height; sum of 3 skinfolds; corrected arm, thigh, and calf girths; waist girth; hips girth; waist to hip ratio; muscle mass; and fat mass
Dependent	Physical fitness variables	App use group and control group	VO_{2max}[a], CMJ[b] test, curl-up test, and push-up test
Covariates	Variables	App use group and control group	Maturity status, gender, and specific app used

[a]VO_{2max}: maximal oxygen uptake.

[b]CMJ: countermovement jump.

Ethical Considerations

This study was approved by the institutional ethics committee of the Catholic University of Murcia (code CE022102) and adhered to the guidelines set forth by the World Medical Association and the Declaration of Helsinki. Adolescents who expressed willingness to participate in the study were required to sign an informed consent form, with both adolescents and their parents acknowledging their understanding of the study aims and procedures.

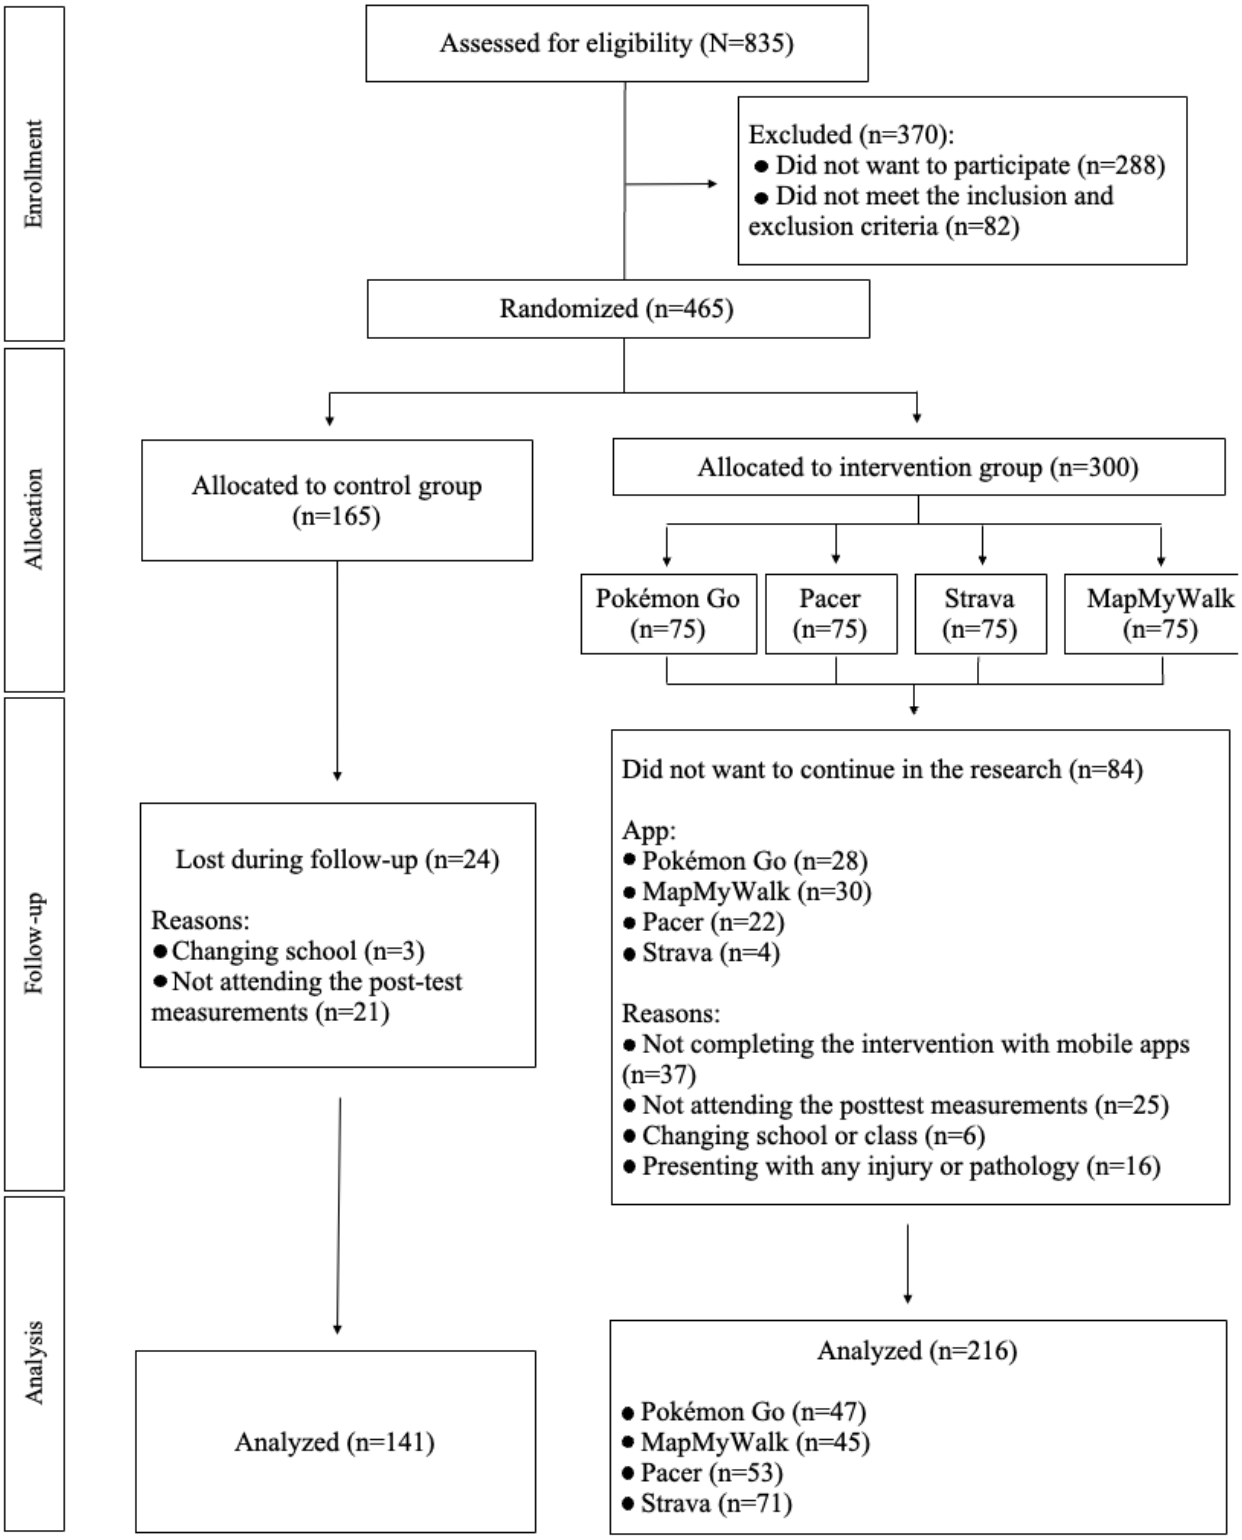
Participants

We recruited participants from 2 compulsory secondary schools located in Murcia. These schools were chosen because of their large student population in secondary education within their respective localities. Initially, the research team contacted the schools to provide a detailed explanation of the study's procedure and objectives. If a particular school declined to participate, the school with the next largest number of students in the locality was approached. Once the school's approval was obtained, the PE department heads were contacted. Subsequently, a face-to-face meeting was arranged with interested students and their parents to discuss the study further.

The minimum sample size necessary for the study was calculated using RStudio software (version 3.15.0; Posit Software PBC) and followed the methodology used in previous studies [25], in which the SD value (0.64) from previous studies that used a similar design with 3 data points to measure changes in PA among adolescents was used [26]. With an estimated error (d) of 0.067 and a CI of 95%, the required sample size was determined to be 350 adolescents.

Figure 2 illustrates the flowchart for the selection of the sample. The final sample comprised 357 adolescents aged between 12 and 16 years. The participants were assigned to the different groups using a cluster randomized design [27]. Group assignment was concealed from the researcher who analyzed each participant's compliance with the inclusion and exclusion criteria. The inclusion criteria for the study were as follows: (1) enrollment in 1 of the selected educational institutions, (2) aged between 12 and 16 years, (3) completion of all questionnaires and physical tests during the 3 measurement periods (T1, T2, and T3), (4) attending the kinanthropometric and body composition assessment sessions, and (5) absence of any pathology or injury that would hinder participation in the tests or measurements conducted. The exclusion criteria were as follows: (1) missing >20% of the mandatory PE sessions throughout the academic year, (2) lack of a mobile phone, (3) failure to meet the minimum mandatory weekly distance requirement in the experimental group (EG) when app use was mandatory and promoted, (4) changing schools or class group during the course of the intervention, (5) starting or ending any form of PA (for reasons unrelated to the study) during the intervention that could alter the PA level being assessed as part of the study, and (6) having presented with any illness during the follow-up period that would have prevented the participant from engaging in their usual PA.

Figure 2. Sample selection flowchart.



Randomization and Blinding

After the recruitment and selection of the adolescents, meetings were held with the teachers to provide them with a clear understanding of the trial's purpose and the randomization process. Parents or legal guardians of the potential participants at each school were notified through a letter that explained the study's objectives and procedures. The principal investigator, along with other uninvolved investigators, carried out the randomization process using a computer-generated random number table. The randomization assigned all students within the same class at each school to the same mobile app group. The classes were randomly assigned to participate as intervention or control classes. A total of 16 classes were finally randomized, of which 11 (69%) were included in the EG and 5 (31%) in the control group (CG). The ratio chosen for the randomized clusters was 2:1 (for every 2 classes included in the EG, 1 was included in the CG) because previous research

with mobile apps has highlighted the lack of adherence to mobile apps, and we wanted to ensure that we had enough participants in the EG to account for a possible high dropout rate (close to 35%) from hindering the extrapolation of the results [28]. The control classes were instructed to continue their regular PE classes, while the intervention was offered to them after the final data collection took place. Baseline measurements were taken before the randomization process. All measurers were blinded to the group to which each individual belonged during the second and third measurements, as well as to the individual's ratings in the previous measurements.

Instruments

The instruments used in this study were the same as those used in previous investigations [9] because these are valid and reliable in the adolescent population.

Questionnaire Measurement

A sociodemographic questionnaire developed ad hoc was administered to obtain data on the age and gender of the participants, their regular PA, and the occurrence of injury or illness, following the pattern of previous studies [23].

PA level was measured using the Physical Activity Questionnaire for Adolescents (PAQ-A) [29]. This questionnaire had been previously validated in Spanish and showed satisfactory reliability, with an intraclass correlation coefficient of 0.71 for the final score [30].

Kinanthropometric and Body Composition Measurement

The anthropometric measurement included 3 basic parameters (body mass, height, and sitting height), 3 skinfold measurements (triceps, thigh, and calf), and 5 girth measurements (arm relaxed, waist, hips, thigh, and calf) [31]. Measurements were performed by anthropometrists (level 3 and level 4) accredited by the International Society for the Advancement of Kinanthropometry [31].

The anthropometric instruments used were the same as those used in previous research [9]: a Harpenden skinfold caliper, a Lufkin W606PM anthropometric tape measure, a Tanita BC418-MA segmental scale, and a Seca 213 stadiometer. All instruments were calibrated before the beginning of each of the measurements (T1, T2, and T3).

The following derived variables were calculated from the anthropometric measurements: BMI, muscle mass [32], fat mass [33], sum of 3 skinfolds (triceps, thigh, and calf), waist to hip ratio (waist girth/hips girth), and corrected girths of the arm (arm relaxed girth – [π × triceps skinfold]), thigh (middle thigh girth – [π × thigh skinfold]), and calf (calf girth – [π × calf skinfold]) [34]. The body composition formulas have been used in previous research [35] and are the ones most often recommended for evaluation in this population [36].

The maturity offset was calculated according to the procedure established by Mirwald et al [37] and using gender-specific formulas: –9.37 + 0.0001882 × ((height – sitting height) × sitting height) – 0.0022 × (age × (height – sitting height)) + 0.005841 × (age × sitting height) – 0.002658 × (age × weight) + 0.07693 × (weight / height). The result of the maturity offset equation is expressed in years from the age at peak height velocity (PHV) when the result is positive and in years to the age at PHV when the result is negative.

The same anthropometrist performed the T1, T2, and T3 measurements on each participant to reduce interevaluator error. The intra- and interevaluator technical errors of measurement [34] were 0.02% and 0.04% for basic measurements, 1.09% and 1.87% for skinfolds, and 0.03% and 0.08% for girths. The correlation coefficients of the anthropometrists with respect to a level 4 expert anthropometrist were 0.96 for basic measurements, 0.91 for skinfolds, and 0.93 for girths.

Physical Fitness Measurements

Cardiorespiratory fitness was evaluated using the 20-meter shuttle run test. The test ends when the adolescent is unable to complete the required distance in the indicated time twice consecutively or when he or she reaches exhaustion. Upon completion of the test, the final speed at which the adolescent concluded the shuttle run was used to calculate their maximal oxygen uptake (VO_{2max}) [38]. This test has high validity and reliability for the determination of VO_{2max} [39].

Lower limb explosive strength was assessed by means of the countermovement jump (CMJ). Adolescents had to perform a 90-degree knee flexion at maximum speed, keeping the back fully straight with hands placed on the hips, followed by a maximal knee extension to jump [40]. The adolescents were required to execute a maximal jump while maintaining their hands on their hips throughout the test. The jump height was determined by measuring the flight height achieved during the jump [40].

For the measurement of abdominal strength and endurance, we used the curl-up test. For the execution to be valid, the adolescents had to keep their feet fully supported on the floor and their arms crossed on the chest, and the trunk flexion had to allow the upper back to be lifted off the floor [41]. The test ended when the time was up (1 min) or when the participant reached exhaustion.

The push-up test was used to evaluate upper body strength. The repetition was valid if the adolescents managed to fully extend their arms and return to the 90-degree position [42]. The adolescents had to perform as many push-ups as possible in 1 minute. The test ended when the time was up (1 min) or when the participant reached exhaustion.

Procedure

The procedure used was also similar to that used in previous research [9], but the difference was that in this study, the intention was to discover how adherence to the intervention changed when the intervention was no longer mandatory or promoted as a PE class assignment and how this affected the variables analyzed. Therefore, unlike previous studies [9], this study comprised 3 measurement periods (T1, T2, and T3), with 2 interventions carried out consecutively. The first one was mandatory and promoted as a PE class assignment, and the second one was neither promoted nor promoted as a PE class assignment.

The data collection process followed the same protocol as in previous research [9,43], with the sociodemographic and PAQ-A questionnaires completed first, followed by the anthropometric measurements. Once these were completed, the fitness tests were explained and performed randomly, twice each, with the 20-meter shuttle run test performed last and only once. The physical test protocol adhered to the guidelines set forth by the National Strength and Conditioning Association, with the aim of minimizing interference between tests and allowing sufficient recovery time from the exertion and metabolic demands of the assessments [44].

To minimize bias in the measurements, they were carried out under the same conditions for all students. The PE class hour was used for the measurements and the adolescents were always measured at the same time and on the same day of the week at T1-T2-T3. The questionnaires were completed in a reserved space in which the adolescents did not have any distractions that could have conditioned their answers. In addition, while the researchers resolved any possible doubts, in no case did they condition the adolescents' responses. For the anthropometric measurements, the air-conditioned locker rooms of the sports pavilion were used to minimize variability due to temperature and humidity fluctuations across the 3 measurement periods. To conduct the physical tests, the indoor sports pavilion at each school was used, which was specifically chosen to eliminate the influence of atmospheric variables that could potentially affect the results and introduce bias.

Mobile App Intervention

Before starting the intervention, 465 adolescents participated in pretest measurements (T1; Figure 2). The mandatory and promoted intervention lasted 10 weeks, during which the adolescents were required to use 1 of the 4 selected apps: Pokémon Go, Pacer, Strava, or MapMyWalk. These apps were selected based on their implementation of a substantial number of behavior change techniques [45] specifically designed to effectively enhance PA level among users. Moreover, they have already been used in previous research with adolescents, with participants demonstrating good adherence [9]. The assignment to each of the app groups was randomized by class group. Thus, initially, an equal number of adolescents was assigned to use each app (Pokémon Go: 75/300, 25%; MapMyWalk: 75/300, 25%; Pacer: 75/300, 25%; and Strava: 75/300, 25%). Of the 465 adolescents, 165 (35.5%) were assigned to the CG.

Before starting the mandatory and promoted intervention, the adolescents were provided with instructions on the proper use of step tracker mobile apps. The aim of the first phase was for students, after receiving instructions on the correct use of the apps, to use them in a manner guided by the PE teachers so that they could become familiar with their use and interface. For this purpose, after randomization, a meeting was held with each of the class groups that were assigned to the EG. In this meeting, the students installed the app corresponding to their class group, and an explanation on the functioning of each was provided to them. Any doubts were resolved by the researchers and the PE teachers. The researchers in charge of explaining how the apps worked were not involved in the measurements or subsequent analysis because they knew which student belonged to each app group and which student belonged to the CG. Once each app had been described and its use explained, a training plan was drawn up to be followed during the period of mandatory and promoted use. During the initial week, the adolescents were instructed to achieve a minimum of 5000 steps or cover a distance of at least 3.19 km each time they used the app. It was established that approximately 1565 steps equals 1 km [46]. This minimum distance was defined to ensure that the adolescents exceeded the sedentary threshold [47]. The initial distance was progressively increased weekly until reaching a distance of 15,520 steps or 8 km each time they used the app. In addition, the researchers followed up with the PE teachers to ensure that the distance was completed by the students every week.

The adolescents were motivated to use the app for a duration of 10 weeks, aiming for a minimum use of 3 times per week. This frequency aligned with the PA recommendations set forth by the World Health Organization [48]. The duration of 10 weeks was justified based on previous research with adolescents, in which a short or moderate duration (6-12 wk) was more effective for producing changes than a longer duration [19], and to be able to adjust it to the duration of the academic year. To encourage the use of the mobile apps during the period of mandatory and promoted use, PE teachers rewarded participation in the study with up to 1 point in the final PE grade for those who completed the study.

After the mandatory and promoted intervention with the mobile apps, posttest 1 measurements were carried out (T2). This was followed by a 10-week period in which the use of the apps was no longer promoted or mandatory as a PE class assignment, after which posttest 2 (T3) measurements were taken. During this period of nonmandatory and nonpromoted use, the adolescents could continue to use the mobile apps voluntarily, just as they would in their daily lives. The adolescents who continued to use the apps were recorded.

In both the mandatory and promoted and the nonmandatory and nonpromoted periods, a researcher who did not participate in the data collection process recorded the distance (in kilometers) and the number of steps taken by each participant after using the mobile apps daily.

A total of 357 adolescents participated in the final measurements (Pokémon Go: n=47, 13.2%; MapMyWalk: n=45, 12.6%; Pacer: n=53, 14.8%; Strava: n=71, 19.9%; and CG: n=141, 39.5%), while 108 adolescents dropped out of the program (Pokémon Go: n=28, 25.9%; MapMyWalk: n=30, 27.8%; Pacer: n=22, 20.4%; Strava: n=4, 3.7%; and CG: n=24, 22.2%; Figure 2). Adolescents who, despite the mandatory and promoted use, did not start using the mobile app were considered to have dropped out, as were those who did not complete at least 25% of the total training volume required because previous research has shown that this is the minimum volume needed to produce significant changes in body composition and fitness variables [43]. Adolescents who completed at least 25% of the training volume required were retained in their respective app groups, those who exceeded 25% of the required training volume but did not complete the entire intervention received up to half a point in the final PE grade, and those who dropped out or did

not complete at least 25% of the training volume did not receive any bonus point in the final PE grade.

Data Analysis

The normality of the data was assessed using the Kolmogorov-Smirnov test, alongside analyses of skewness, kurtosis, and variance. As the variables exhibited a normal distribution, parametric tests were used for their analysis. Three repeated measures ANOVAs were performed. On the first, the group factor was used as the grouping variable; on the second, the time point factor was used; and on the third, the differences in the changes between the CG and EG at the different time points were assessed. In this way, intra- and intergroup differences were determined for each of the study variables. A subsequent Bonferroni analysis made it possible to determine the statistical differences between each of the pairs compared. Three analyses of covariance were also performed to determine the influence of the covariates maturity status, gender, and specific app used on the results obtained for the study variables. Effect size was analyzed using partial eta-squared (η_p^2) and was defined as small (≥0.10), moderate (≥0.30), large (≥0.50), very large (≥0.70) or extremely large (≥0.90). These translate into 0.20, 0.60, 1.20, 2.0 and 4.0 for standardized differences in means [49]. A *P* value <.05 was used to establish statistical significance. The data analysis was performed using SPSS software (version 25.0; IBM Corp).

Results

Overview

Of the 357 adolescents, 186 (52.1%) were male, and 171 (47.9%) were female. Of the 186 male adolescents, 26 (14%) used Pokémon Go, 35 (18.8%) used Strava, 29 (15.6%) used Pacer, 25 (13.4%) used MapMyWalk, and 71 (19.9%) were in the CG. Of the 171 female adolescents, 21 (12.3%) used Pokémon Go, 36 (21.1%) used Strava, 24 (14%) used Pacer, 20 (11.7%) used MapMyWalk, and 70 (40.9%) were in the CG. The mean age of the male adolescents was 13.91 (SD 1.22) years, with a mean maturity offset of 0.20 (SD 1.39) years. Their mean body mass was 55.68 (SD 13.09) kg, and their mean height was 164.59 (SD 10.07) cm. The mean age of the female adolescents was 13.89 (SD 1.21) years, with a mean maturity offset of 1.50 (SD 0.90) years. Their mean body mass was 52.53 (SD 10.92) kg, and their mean height was 158.76 (SD 6.32) cm.

Of the 216 adolescents in the EG during the period of mandatory and promoted use of the app, only 18 (8.3%) continued to use the apps independently during the nonmandatory and nonpromoted period. The average distance walked by these adolescents was 47.69 (SD 23.80; range 5-200) km in the 10 weeks of nonpromoted and nonmandatory use.

Differences in the EG and CG at the Different Study Time Points

Table 2 shows the differences in the measurements taken in the EG and CG at the different study time points (T1, T2, and T3). Significant differences in the PA level were observed exclusively within the EG: it was higher at T2 than at T1 (*P*<.001) but lower at T3 than at T2 (*P*=.03). No differences were found between T1 and T3 (*P*=.47) either in the EG or in the CG in any of the comparisons. In terms of the anthropometric and body composition variables, body mass and height significantly increased in both EG and CG between T1 and T2 (*P*<.001) and T1 and T3 (*P*=.002-.008), but no differences were found between T2 and T3 (*P*=.23-.99). In the sum of 3 skinfolds, the EG showed a significant decrease between T1 and T2 (*P*=.02), but a significant increase was found between T2 and T3 (*P*=.03). All corrected girth (*P*<.001-.049) and muscle mass (*P*<.001-.007) measurements showed significant increases in both groups between the 3 time points, including hips girth (*P*<.001-.03). By contrast, BMI (*P*=.01-.99), sitting height (*P*=.11-.99), fat mass (*P*=.07-.99), and waist girth (*P*=.23-.99) did not show differences in any of the groups in any of the comparisons.

Table 2. Differences in the experimental group (EG) and the control group (CG) during the different study time points (intragroup differences).

[a]VO_{2max}: maximal oxygen uptake.

[b]CMJ: countermovement jump.

Regarding physical fitness, VO_{2max} significantly increased in the EG between T1 and T2 (*P*<.001), but it significantly decreased between T2 and T3 (*P*=.005). The CG exhibited no discernible differences. The CMJ score significantly increased at T2 compared to T1 (*P*=.04) and remained elevated at T3 compared to T1 (*P*=.03). In the CG, the adolescents showed a higher score at T3 than at T1 (*P*=.003) and T2 (*P*=.03). The curl-up test showed a significant increase in the EG between T1 and T2 (*P*<.001), which remained the same at T3 (*P*<.001), while in the CG, the increase was smaller and was only observed between T3 and T1 (*P*=.001). Finally, in the push-up test, an increase was observed in the score between T1 and T2 (*P*<.001), which remained, although it was less pronounced, at T3 (*P*=.01) only in the EG (Table 2).

As shown in Multimedia Appendix 1, the covariate maturity status was a determinant factor in the differences found in the EG for the variables PA level, body mass, height, sum of 3 skinfolds, corrected girths, hips girth, waist to hip ratio, muscle mass, VO_{2max}, CMJ test, curl-up test, and push-up test between T1 and T2 (*P*<.001-.04); for the variables PA level, sum of 3 skinfolds, corrected arm girth, hips girth, muscle mass, and VO_{2max} between T2 and T3 (*P*<.001-.03); and for the variables height, corrected girths, hips girth, waist to hip ratio, muscle mass, CMJ test, curl-up test, and push-up test between T1 and T3 (*P*<.001-.04). For the CG, significant differences were observed in body mass, height, BMI, corrected girth, hips girth, waist to hip ratio, and muscle mass between T1 and T2 (*P*<.001-.02); in corrected girths, hips girth, muscle mass, and CMJ test between T2 and T3 (*P*<.001-.03); and in height, corrected girths, hips girth, waist to hip ratio, muscle mass, CMJ test, and curl-up test between T1 and T3 (*P*<.001-.01).

The effect of the covariate gender on the study variables is shown in Multimedia Appendix 2. It was a determinant factor in the differences found in the EG in PA level, body mass, height, sum of 3 skinfolds, corrected girths, hips girth, waist to hip ratio, muscle mass, VO_{2max}, CMJ test, curl-up test, and push-up test between T1 and T2 (*P*<.001-.04); in PA level, sum of 3 skinfolds, corrected arm girth, and VO_{2max} between T2 and T3 (*P*<.001-.04); and in height, corrected girths, hips girth, waist to hip ratio, muscle mass, CMJ test, curl-up test, and push-up test between T1 and T3 (*P*<.001-.01). In the CG, this covariate was a determinant factor in the differences found in body mass, height, BMI, corrected girths, hips girth, waist to hip ratio, and muscle mass between T1 and T2 (*P*<.001-.047); in BMI, corrected girths, hips girth, and muscle mass between T2 and T3 (*P*<.001-.002); and in height, corrected girths, hips girth, waist to hip ratio, muscle mass, CMJ test, and curl-up test between T1 and T3 (*P*<.001-.02).

The covariate specific app used (Multimedia Appendix 3) was not shown to be influential either in the differences found in PA level or in anthropometry variables and body composition, although it was influential in the changes in VO_{2max} (T1-T2: *P*=.004; T2-T3: *P*=.007) and the curl-up test (T1-T2: *P*<.001; T1-T3: *P*<.001).

Differences Between the EG and CG in the Study Variables at the Same Time Point During the Research Period

Table 3 shows the differences between the EG and CG in the study variables at the 3 time points (T1, T2, and T3). The differences at the 3 time points were significant in the sum of 3 skinfolds (*P*=.01-.03), in hips girth (*P*=.003-.02), and fat mass (*P*=.02-.03), as well as in the curl-up test at T2 (*P*=.047). The rest of the variables showed no significant differences between the 2 groups at any of the time points.

Table 3. Differences between the experimental group (EG) and control group (CG) at the study time points (intergroup differences).

Variable and time point	EG, mean (SD)	CG, mean (SD)	Mean difference (EG–CG)	*P* value	*F* test (*df*)	η_p^2
Subjective level of physical activity						
T1	2.62 (0.68)	2.72 (0.64)	–0.100	.20	1.664 (1)	0.005
T2	2.79 (0.59)	2.72 (0.73)	0.074	.29	1.104 (1)	0.003

[b]CMJ: countermovement jump.

Regarding the intergroup differences, it is striking that the differences found in the sum of 3 skinfolds, hips girth, and fat mass were not influenced by the covariate maturity status. In the case of the covariate gender, it could be a determinant factor in the differences found at T1 in PA level, body mass, height, sitting height, corrected calf girth, hips girth, and muscle mass (*P*=.003-.04); at T2 in body mass, height, sitting height, corrected girths, hips girth, muscle mass, VO_{2max}, CMJ test, curl-up test, and push-up test (*P*<.001-.048); and at T3 in body mass, height, corrected calf girth, and muscle mass (*P*=.01-.03). Finally, the covariate specific app used seemed to influence the differences found in the sum of 3 skinfolds, hips girth, waist to hip ratio, and fat mass at T1, T2, and T3 (*P*=.002-.04), in the curl-up test at T2 (*P*=.04) and T3 (*P*=.02), and in VO_{2max} at T3 (*P*=.02; Multimedia Appendix 4).

Table 4 shows the differences in the changes produced between the EG and CG when comparing the different time points (T1–T2, T1–T3, and T2–T3). The results showed that the changes produced in PA level (*P*=.004) and the curl-up test (*P*=.02) were significantly higher in the EG than in the CG between T1 and T2. In addition, the changes in corrected thigh girth (*P*=.003) and muscle mass (*P*=.02) between T2 and T3 were greater in the CG than in the EG. In the rest of the variables, the changes between the EG and the CG at the different time points were not significant.

[a]VO_{2max}: maximal oxygen uptake.

[b]CMJ: countermovement jump.

Regarding the influence of the covariates on the changes found between the EG and CG at the different time points (Multimedia Appendix 5), it was observed that none of the covariates had any influence either on the changes found between T1 and T2 in PA level or on the changes in the muscle mass between T2 and T3. However, changes in the curl-up test were influenced by the covariate gender between T1 and T2 (*P*=.04), just as the changes in the corrected thigh girth were influenced by gender (*P*=.04) and specific app used (*P*=.01) between T2 and T3. The covariate maturity did not have a significant influence on any of the changes (*P*=.09-.97).

Discussion

Summary of the Main Results of the Study

The results of this research show that after the use of the step tracker mobile apps became voluntary and was no longer promoted as a PE class assignment, only a small percentage of adolescents (18/216, 8.3%) continued using them for PA, with minimal training volume. Comparing the changes in the study variables in the EG and CG (intragroup differences) before and after the mandatory and promoted period (T1 vs T2), the EG showed an increase in PA level and fitness variables, with a decrease in the sum of 3 skinfolds. However, at the end of the nonmandatory and nonpromoted period, there was a decrease in adolescents' PA level and VO_{2max}, accompanied by an increase in the sum of 3 skinfolds, compared to the values at the end of the mandatory and promoted period (T2 vs T3). Both EG and CG exhibited increases in corrected arm girth, hips girth, and muscle mass. Finally, when comparing the measurements taken before the start of the mandatory and promoted period and at the end of the nonmandatory and nonpromoted period (T1 vs T3), both groups showed significant increases in body mass, height, corrected girths, hips girth, waist to hip ratio, muscle mass, CMJ test, and curl-up test, as well as an increase in the push-up test only in the EG. These changes were influenced by the covariates maturity status and gender (both of which influenced most of the variables related to PA level, anthropometric measurements, body composition, and fitness in both groups) as well as by the covariate specific app used (which mainly influenced VO_{2max} and the curl-up test).

Regarding intergroup differences, significant differences were noted between the EG and CG at T1, T2, and T3 in sum of 3 skinfolds, hips girth, waist to hip ratio, and fat mass, and at T2 in the curl-up test. While maturity status did not affect intergroup differences, gender and specific app used did have an influence. Despite the intra- and intergroup differences found during both intervention periods, greater changes from T1 to T2 were seen in the EG, particularly in PA level and the curl-up test,

unaffected by the covariates, except for gender in the curl-up test. Conversely, from T2 to T3, the CG exhibited greater changes in corrected thigh girth, being influenced by gender and specific app used, and muscle mass, with no covariate influence. No significant changes were found between T1 and T3, with no influence of the covariates.

Purpose of This Study

The study addresses the challenge of promoting PA among adolescents due to limited school hours and motivation issues [50], which makes it impossible to meet the World Health Organization recommendations [48]. Previous research suggested that mandatory app use promoted as a PE class assignment could enhance PA, body composition, and fitness during the first week of use due to the apps' novelty [9,51]. However, it is unclear whether these effects persist when app use becomes nonmandatory and nonpromoted. For this reason, the study aims to assess whether step tracker mobile apps could encourage PA outside of school hours and establish walking as a healthy habit.

Use of Apps by Adolescents During Mandatory and Promoted and Nonmandatory and Nonpromoted Use Periods

As the results show, during the nonmandatory and nonpromoted intervention period, only a small percentage of adolescents (18/216, 8.3%) used the mobile apps; therefore, the changes achieved during the mandatory and promoted intervention period faded away. These results are similar to those of the study by Slootmaker et al [52], in which the use of wearable devices and websites led to improvements in PA after 3 months of the intervention, although the effects disappeared after 8 months when participants did not use the devices for 5 months. One possible explanation for these results is that PA during adolescence is strongly influenced by intrinsic motivation [53,54] and enjoyment experienced during PA [55]. Knowing this, it is possible that walking with an electronic device is not the most satisfying activity for adolescents; therefore, once the extrinsic component, such as the incentive of a bonus point in the PE grade, is removed, all interest shown initially in the intervention is lost. Thus, if the intention is for this population to use these apps due to the benefits they provide on PA level, body composition, and fitness [9,18,43], their use can be made mandatory and promoted by the school, at least as far as walking for exercise is concerned.

These findings suggest that interventions using step tracker mobile apps, when mandatory and promoted as a PE class assignment, may not establish an independent walking habit among adolescents. The primary goal should be to promote lasting habits because short-term increases in PA, while beneficial for fitness and body composition, lack long-term impact. Perhaps 1 of the main drawbacks that prevents adolescents from adhering to the use of these apps is their mandatory implementation by educational institutions; when their use is not promoted or rewarded, they cease to be effective [56]. This indicates that students are participating in the intervention for the reward (ego orientation), rather than for the benefits it might have on their present and future health (task orientation). Furthermore, it would be necessary to consider whether this type of intervention is less effective because it focuses only on cardiorespiratory improvement, and whether the inclusion of other types of training, such as strength or flexibility, would increase adherence [56] because they are more novel or closer to adolescents' interests.

Considering the results obtained in this study, the first research hypothesis (H1), which proposed that adolescents will stop using the step tracker mobile apps during the period of nonmandatory and nonpromoted use, can be accepted. During the period of nonpromoted and nonmandatory use, only a few of the adolescents (18/216, 8.3%) continued to use the apps, and the distance walked was minimal. This suggests that the return to baseline levels after the period of nonmandatory and nonpromoted use is due to the fact that the adolescents did not continue walking for exercise, which is why the increase in energy expenditure and improvement in physical fitness achieved during the period of mandatory and promoted use was lost during this period.

Effects of Interventions on PA Level Among Adolescents

The EG demonstrated an increase in PA level during the mandatory and promoted intervention, surpassing the CG. However, these benefits were not sustained over time. The findings align with previous research, which demonstrated that the use of mobile apps led to a notable rise in adolescents' PA level [9,17]. Notably, this study adds a new perspective, indicating that the effectiveness of step tracker mobile apps diminishes once their use is nonmandatory and nonpromoted as a PE class assignment. This highlights the importance of enforcing app use for enhancing adolescent PA. Future interventions should consider this because effectiveness may hinge on mandatory use. Future research is needed to promote the nonmandatory use of step tracker mobile apps in adolescents who have not previously used such apps because this would allow us to demonstrate whether it is the lack of mandatory use or the loss of interest in the use of the apps that leads to nonuse.

Effects of Interventions on the Kinanthropometric and Body Composition Variables Among Adolescents

Regarding the kinanthropometric and body composition variables, height and body mass increased significantly in all groups throughout the study, consistent with typical growth patterns during puberty [57]. During PHV, which typically occurs between the age of 11.4 and 12.2 years in female individuals and 13.8 and 14.4 years in male individuals, the height of female individuals and male individuals increases steadily [58,59]. Regarding body mass, previous research has shown similar results [9], and 1 possible explanation for this finding is that the body mass variable does not allow discriminating whether the change produced was due to an improvement in muscle mass or fat mass [60]. In this study, corrected girths and muscle mass also increased significantly in both groups, suggesting potential impacts of maturation rather than app-specific exercises. If the apps used had included strength exercises, it could be speculated that these exercises were the cause of the improvements in girths and muscle mass, as observed in previous research [61]. However, the exclusive use of apps meant for aerobic training makes us consider that

the changes were the consequence of the maturation process of these adolescents, characterized by hormonal changes related to increases in muscle mass [62,63]. These results are corroborated with the inclusion of the covariates maturity status and gender. The maturational state had an influence on the intragroup differences in muscle mass variables but did not influence the intergroup differences at the different time points (EG vs CG at T1, T2, or T3), which establishes the importance of the maturational state in the changes found and also agrees with previous research, which showed that limb girths increase during the maturational process [64]. In addition, it should be noted that the covariate gender also influenced the changes in muscle mass during the different time points, which could be due to the fact that during puberty, muscle development is greater in male individuals than in female individuals due to the higher production of steroid hormones in male individuals, with clear differences between both genders [62].

With respect to the fat variables, the EG experienced a significant decrease in the sum of 3 skinfolds between T1 and T2, but this change reverted to baseline levels at T3. This aligns with previous findings suggesting that the use of step tracker mobile apps can reduce fat mass in adolescents [9]. Increased PA during the mandatory and promoted period likely contributed to this reduction, increasing energy expenditure, as seen in other 10-week aerobic exercise programs in the adolescent population [65], which could have influenced the decrease in fat mass. The main novelty of this study is that when app promotion ceased, fat mass returned to initial levels, echoing findings of detraining studies [20]. This could be because the increase in PA achieved during the period of mandatory and promoted use of the app was lost when the use became nonmandatory and nonpromoted, which could have prevented the adolescents from maintaining their increased energy expenditure. In addition, maturity status and gender did not impact fat mass changes, suggesting the intervention's influence. Nevertheless, the small effect sizes and nonsignificant differences between the groups hint at inconsistency in app-induced changes, possibly explaining the return to baseline values after the intervention. Therefore, future research with the use of step tracker mobile apps for a longer period, which also considers other relevant variables for aerobic training to be effective, such as duration or intensity [66,67], is needed to elucidate their true effect on adolescent body composition.

In hips girth, a significant increase was found in both groups between T1 and T2, as well as T1 and T3. A possible explanation for these results is that hips girth steadily increases during adolescence, ending with a plateau at age 16 years [68], which could explain the increase in this variable in the 2 groups. It would be important for future research to analyze these differences according to the age or ethnicity of the adolescents because these variables significantly influence hips girth [69].

Effects of Interventions on the Physical Fitness Variables Among Adolescents

As for the physical fitness tests, a significant increase in VO_{2max} was only found in the EG between T1 and T2, with a significant decrease observed between T2 and T3. These results are similar to previous research, in which VO_{2max} increased and performance in the 20-meter shuttle run test improved after the period of mobile app use compared to the CG [9,10]. A possible explanation for these results could be that the use of the apps during the mandatory and promoted period, in which an incentive was offered, favored the improvement in the adolescents' physical fitness. However, when its use became nonmandatory and nonpromoted as a PE class assignment, and it was no longer incentivized, it is possible that the adolescents did not walk a sufficient distance or at the intensity necessary to maintain the significant improvements achieved in physical fitness, with these variables significantly influencing VO_{2max} [70]. However, future research analyzing the intensity and volume of adolescents' walks while using step tracker mobile apps is needed to provide more information in this area and to discover whether the maintenance of the benefits obtained is also dependent on these factors.

In the CMJ, curl-up, and push-up tests, it was observed that in the EG, performance improved between T1 and T2 and remained high at T3, while in the CG, the adolescents showed an improvement at T3 compared to T1, with no differences found in the push-up test. These results are similar to previous research in which improvements in the curl-up and push-up tests were found after the mandatory and promoted period of use of mobile apps [9], as well as in specific 6-week aerobic walking programs [71]. Walking has been shown to improve trunk muscle strength [72], which, together with the increases found in this study in muscle mass and corrected girths, could be the reason why the EG showed significant improvements in these fitness tests. However, maturity status, gender, and specific app used should be considered when analyzing changes in physical fitness because they seem to be relevant in the differences found, and future research is needed to learn about the differences in the benefits obtained with the mobile apps as a function of these factors.

In addition, the improvements in the curl-up test in the CG exclusively occurred at T3 compared to T1; this may be solely due to changes in muscle mass caused by the maturation process [62,63], which would be slower in the adolescents in the CG than in the adolescents in the EG who used the app and would favor the improvement in trunk musculature, explaining the absence of differences between T1 and T2 and between T2 and T3 in this group. This was observed with the inclusion of the covariate maturity status because it was shown to influence the differences in the curl-up test of the adolescents in the CG between T1 and T3. In addition, it should be noted that the changes between T1 and T2, when comparing the EG and CG, were significantly greater in the EG, which could be consistent with the fact that walking improves trunk muscle strength [72] because the covariate maturity status did not influence the differences in the changes between the 2 groups. Therefore, the use of step tracker mobile apps could be of interest for improving performance in fitness tests that require trunk strength, allowing for improvements that are superior to those achieved solely due to the maturation process.

One of the unexpected aspects of this study is that the covariate specific app used influenced the results obtained on the adolescents' body composition and fitness. In 1 of the first

studies on the subject, it was found that the step tracker specific app used had almost no influence on the benefits obtained with a compulsory PE class intervention [9]. However, this study has shown that the covariate specific app used can be a determining factor in the changes obtained; therefore, future research should analyze the causes of these differences to try to find the reasons why they occur and whether this could depend on whether adolescents feel more comfortable with a particular app and prefer using this app over another, which would open the door to research that could delve deeper into the specific components included in each app and how they are valued by adolescents.

The second research hypothesis (H2), which proposed that there will be significant differences in adolescents' PA level, body composition, and physical fitness during the mandatory and promoted period, influenced by maturity status and gender but not by specific app used, can be partially accepted. This is because the results showed benefits in the PA level, cardiorespiratory fitness, and fat variables after the mandatory and promoted intervention, although the only significant changes observed between the EG and CG were in abdominal strength and PA level between T1 and T2. Furthermore, as expected, the covariates maturity status and gender influenced the results observed in body composition and fitness, although specific app used also had an influence.

The third research hypothesis (H3), which stated that some of the benefits achieved by the adolescents during the mandatory and promoted period will be lost after the nonmandatory and nonpromoted period, with the results being influenced by maturity status and gender but not by specific app used, can be partially accepted. The benefits obtained during the mandatory and promoted period were lost when adolescents stopped using the apps during the nonmandatory and nonpromoted period. Only the benefits in muscle mass and fitness variables (CMJ, curl-up, and push-up tests) were maintained at T3 compared to T1 in the EG. However, the changes between T1 and T3, when comparing the EG and CG, were not significant in any of the variables analyzed. Again, the covariates maturity status, gender, and specific app used influenced the results.

Limitations of This Study

This study is not without limitations. First, the measurement of PA using a questionnaire has limitations; for example, although some studies show that the PAQ-A can be valid for measuring changes in PA performed by the same group in 2 different time periods [30], others indicate that its validity and reliability are questionable because it does not measure aspects such as frequency or intensity of activity, and nor does it allow for comparisons of changes in PA between 2 groups [73]. Therefore, although the PAQ-A is sometimes the best choice for measuring PA due to its favorable cost-benefit ratio [74,75], its use could affect the results of the study. Future research should include accelerometry, which would also make it possible to differentiate the intensities and the time spent in each activity level, which would make it possible to analyze whether these factors are modulators of change. Second, in future research, it would be appropriate to consider aspects such as the volume and intensity of training performed with step tracker mobile apps because these aspects can influence changes in body composition and fitness, as well as the length of time for which the changes achieved are maintained [76,77]. Third, the nutritional intake of adolescents was not considered in this study, and although previous research has shown that aspects of nutrition, such as adherence to the Mediterranean diet, are not modified with the use of step tracker mobile apps [9], it would be important to consider the amount and type of nutritional intake because these variables can influence changes in body composition [78]. Fourth, only those students who completed at least 25% of the training volume were included in the analyses. This is because previous research has shown that this is the minimum volume needed for differences in adolescent body composition and fitness to begin to occur [43]. In this study, when trying to analyze whether adolescents continued to use the app when it was neither mandatory nor promoted, it was assumed that those who did not use the apps during the mandatory and promoted period would not use them in the nonmandatory and nonpromoted period either. Therefore, this may be a bias because adolescents who did not even start the intervention were eliminated from the analysis, but this was not the aim of the research. Finally, another noteworthy aspect to be considered could be that this type of intervention does not consider the context or the environment of the adolescents; while it places the adolescent at the center of the intervention, it does not consider that other agents in their close environment (family and friends) could be of great relevance for the acquisition of healthy habits [79,80]. Furthermore, another unexplored aspect that should be considered is that at these ages (12-16 y), adolescents practice physical sports activities mainly for their competitive and recreational component [53-55], not for their health benefits, and walking may not be the most motivating and fun activity for this population, which may hinder the establishment of this healthy habit when the performance of these tasks is optional for students, although improvements in health are evident.

Practical Applications

Considering the limitations of this research, a practical application derived from it is that if step tracker mobile apps are intended to be used to increase daily steps and PA level of the adolescent population and are promoted as a PE class assignment, their use must be maintained over time or accompanied by other types of complementary programs that promote the establishment of healthy lifestyle habits [81] that allow the improvements obtained to be maintained. In this regard, previous research has shown that the use of step tracker mobile apps, combined with nutritional programs or training sessions on healthy habits, has a significant effect on improving the health status of adolescents by facilitating their continued use [81,82]. On the contrary, the occasional use of these apps is ineffective; once the period of mandatory and promoted use ends, adolescents who used the apps will return to baseline levels that are similar to those of adolescents who did not use them as a result of detraining, as observed in previous PA promotion programs where young people who undertook aerobic training showed losses in the benefits obtained after a period of detraining [20].

Conclusions

This study is the first to analyze the losses that occur in the positive changes achieved in PA level, body composition, and fitness variables by adolescents aged 12 to 16 years after a period of mandatory and promoted use of step tracker mobile apps when their use becomes nonmandatory and nonpromoted. Our findings suggest that adolescents stop using step tracker mobile apps when their use is neither mandatory nor promoted as a PE class assignment. During the mandatory and promoted period, adolescents in the EG increased their PA level and cardiorespiratory fitness and reduced their fat mass. However, when participation in the step increase program with the apps was neither mandatory nor promoted, adolescents stopped using the apps and discontinued their walking practice; as a consequence, the gains achieved were lost, leading to a regression to baseline levels. The change in the EG compared to the CG was only significant in the curl-up test at the end of the mandatory and promoted intervention but not in the rest of the variables or in the comparison between the other time points. Therefore, this study shows that the use of mobile apps by adolescents aged 12 to 16 years in their free time, promoted as a PE class assignment, did not manage to create a healthy walking habit in this population, which could be a determining factor in fostering independent walking practice in adolescents, which could yield significant health benefits. These results are of relevance for the use of step tracker mobile apps in education because when their use is mandated and promoted as a PE class assignment, they seem effective in reducing fat mass and increasing PA level in adolescents. Special attention should be paid to the covariates maturity status, gender, and specific app used because they might influence the changes achieved during the intervention. Future research along these lines should also analyze the most influential aspects to be considered to achieve independent use and greater adherence of adolescents to step tracker mobile apps, including analyses of their immediate environment and the factors that could be most relevant, to ensure that use is continued after they have already become familiar with the step tracker mobile app, and its use is neither mandatory nor promoted as a PE class assignment.

Acknowledgments

The authors would like to thank the schools, management teams, teachers, students, and research assistants who made it possible to carry out the measurements for this project. This work is part of the doctoral thesis of AMO. AMO's participation in this research is funded by Séneca Foundation – 21409/FPI/20. Fundación Séneca. Región de Murcia (Spain). This manuscript was developed during AMO's international stay at the CIAFEL research group of the Faculdade de Desporto da Universidade de Porto. This research has been financed by grants for knowledge generation projects (Title: fomento de la actividad física diaria recomendada para la salud en adolescentes mediante apps móviles, wearables y una tac gamificada / Call: 2022 / Reference code: PID2022-140245OA-I00).

Abstract

Background: Some common modified vascular risk factors remain poorly controlled among stroke survivors, and educational programs may help improve these conditions.

Objective: This study aimed to evaluate the effect of a planned web-based educational intervention based on the health belief model (HBM) in promoting secondary prevention among patients with ischemic stroke.

Methods: An evaluation-blinded quasi-experimental trial with a historical control group was conducted. Patients admitted from March to June 2020 were assigned to the historical control group, and patients admitted from July to October 2020 were assigned to the intervention group. The control group received routine health management. The intervention group received 6 additional sessions based on the HBM via Tencent Meeting, an audio and video conferencing application, within 3 months after discharge. Sessions were held every 2 weeks, with each session lasting approximately 40 minutes. These sessions were conducted in small groups, with about 8 to 10 people in each group. The primary outcomes were changes in blood pressure (BP), low-density lipoprotein cholesterol (LDL-C), hemoglobin A_{1c} (HbA_{1c}), and the proportion of patients achieving the treatment target. The secondary outcomes were medication adherence, assessed with the Morisky Medicine Adherence Scale (MMAS), and disability, assessed with the modified Rankin scale.

Results: In total, 315 patients experiencing their first-ever stroke were analyzed. More patients in the intervention group had controlled BP (41.9% vs 28.4%; adjusted odds ratio [aOR] 1.93; *P*=.01), LDL-C (83.1% vs 67.7%; aOR 2.66; *P*=.001), and HbA_{1c} (91.9% vs 83.9%; aOR: 3.37; *P*=.04) levels as well as a significant postintervention decrease in the systolic BP (adjusted β −3.94; *P*=.02), LDL-C (adjusted β −0.21; *P*=.008), and HbA_{1c} (adjusted β −0.27; *P*<.001), compared with control groups. Significant between-group differences were observed in medication adherence (79.4% vs 63.2%; aOR 2.31; *P*=.002) but not in favorable functional outcomes.

Conclusions: A web-based education program based on the HBM may be more effective than current methods used to educate patients having strokes on optimal vascular risk factors and medication adherence.

Introduction

According to the Global Burden of Disease Study 2019, stroke is the second leading cause of death worldwide [1]. It also presents a substantial challenge to the Chinese population, as it is the leading cause of mortality, long-term disability, and severe disease burden in China. Ischemic stroke accounts for the largest proportion of these cases [2,3]. Meanwhile, the mortality of ischemic stroke is lower than that of hemorrhagic stroke in middle-income countries; therefore, more attention needs to be directed toward patients who experienced ischemic stroke [4]. Data based on the China National Stroke Registries revealed that the stroke recurrence rate was approximately 12.5% within 12 months, which may lead to the deterioration of functional outcomes, decreased quality of life, and even increased mortality [5]. Therefore, it is necessary to achieve secondary prevention of ischemic stroke through lifestyle changes and medication intervention. A qualitative study found that stroke survivors perceived that using preventive medications was more important than modifying lifestyle behaviors [6]. It was previously reported that rational use of these drugs may reduce the risk of recurrent stroke and improve survival [7,8]. However, a systematic review of 22 studies showed that the pooled prevalence of medication nonadherence was 29% [9], and the risk factors remain poorly controlled among stroke survivors [10].

The health belief model (HBM) is widely used to guide health education, aiming to help participants develop, adopt, and practice healthy behaviors [11,12]. It emphasizes the subjective psychological process of individuals, suggesting that individuals with beliefs related to disease and health are more willing to adopt healthy behaviors. This theoretical model guides the health education for secondary prevention of stroke from six aspects: (1) helping patients identify their own risk factors for strokes (perceived susceptibility), (2) understanding the possible adverse consequences of stroke recurrence (perceived severity), (3) becoming aware of barriers (perceived barriers) and (4) benefits of secondary prevention(perceived benefits), (5) receiving information and encouragement through social media (cues to action), and (6) establishing confidence in their ability to engage in disease prevention (self-efficacy). When individuals are provided with these factors, they are more likely to adopt the recommended behaviors for secondary prevention.

In particular, the COVID-19 pandemic has had a negative impact on post–acute stroke care [13]. Care pathways focused on secondary prevention of cardiovascular disease may be disrupted, stroke follow-up may be delayed or reduced, and survivors may have difficulty accessing rehabilitation services [14,15]. China has implemented strict national policies to reduce the risk of exposure to the virus [16]. Staff shortages caused by a large number of medical staff supporting high-risk areas, quarantine efforts, and pathogen testing have led to a reduction in outpatient clinics and medical services available to patients having strokes [17]. Therefore, theory-based and implementable secondary prevention measures become particularly important to improve medication adherence and control of vascular risk factors, such as blood pressure (BP), hemoglobin A_{1c} (HbA_{1c}), and low-density lipoprotein cholesterol (LDL-C) levels, within a reasonable range, for stroke survivors during lockdown.

This study aimed to investigate the effects of planned health education based on the HBM, compared to general health management, on improving medication adherence and controlling vascular risk factors in patients ischemic stroke 3 months after admission during the COVID-19 lockdown.

Methods

Study Design

This study was an assessor-blinded quasi-experimental trial with a historical control group. Consecutive participants admitted to the stroke center of the First Hospital of Jilin University were recruited. The hospital is located in the central part of Jilin Province, northeast China, with a population of 27 million and the highest age-standardized prevalence and incidence rate of stroke [5]. It also has the first province-wide stroke emergency map in China, named the Jilin Province Stroke Emergency Maps [18]. The transportation of patients between cities ensured the diversity of participants in our center. Patients admitted from March to June 2020 were assigned to the historical control group, and patients admitted from July to October 2020 were assigned to the intervention group.

Ethical Considerations

This study was conducted in compliance with the principles of the Declaration of Helsinki. The study protocol was reviewed and approved by the ethical committee of the First Hospital of Jilin University (20K055-001) and was registered in the Chinese Clinical Trial Registry (ChiCTR2000040804). All participants signed an informed consent form.

Participants

Patients diagnosed with a first-ever ischemic stroke [19], confirmed by head computed tomography scanning or magnetic resonance imaging; aged≥18 years; able to understand instructions; and able to use mobile phones proficiently were included. Patients diagnosed with primary mental disorders or other serious organ dysfunction, such as liver and kidney dysfunction, were excluded.

Interventions

Patients in the control group were provided with a health management manual with explanations and discharge advice during hospitalization; they conducted out-of-hospital follow-ups through an online WeChat public group and received monthly telephonic coaching sessions of approximately 15 minutes each, provided mainly by a qualified stroke health manager, as previously published [20]. In response to national policies, we canceled the health education courses held in our center during hospitalization to avoid social gatherings according to hospital rules.

Patients in the intervention group received 6 additional web-based educational sessions based on the HBM via Tencent Meeting, which is an audio and video conferencing application. The sessions were held every 2 weeks between 9 AM and 10 AM, with each session lasting approximately 40 minutes. The

intervention was conducted in small groups, with about 8 to 10 people in each group. A qualified stroke health manager, skilled in health education, facilitated all the sessions. The first session was focused on perceived susceptibility. Approximately 20 minutes were allocated for free discussion to encourage participants to identify and express their own risk factors. The second session focused on perceived severity on the basis of the model. The third session focused on perceived benefits. Participants could ask questions and discuss the possible benefits of their behaviors. The fourth and fifth sessions mainly supplemented cues to actions. Participants were encouraged to put forward questions that they did not fully understand and received prompt explanations. The last session aimed to address patients' perceived barriers to secondary prevention behaviors. Participants worked with others to correct incorrect beliefs and provide strategies to overcome these barriers (Table 1).

Participants received a notification on their mobile phones 1 hour before each session. We also implemented online reminders before each session and ensured that all participants attended the meetings on time. Patients who completed all sessions and participated in 3 or more discussions during the sessions were awarded an electronic version of the "Learning Star" honorary certificate to encourage them to continue to adhere to healthy behaviors.

Table . The education session structure based on the health belief model.

Intervention theme	Intervention targets	Procedure of sessions
Perceived susceptibility	Aware of the severity of the disease, current bad behaviors, and risk factors	Through the "Screen Image Sharing" technology of the Tencent Meeting, the PowerPoint was presented to the patients at the same time as the lecture, describing stroke-related statistics and common risk factors (eg, hypertension, diabetes, and dyslipemia).
Perceived severity	Recognize the possibility and risk of stroke recurrence	Describing the possible physical and psychological impact and economic burden of stroke recurrence through several cases that failed to engage in secondary preventive strategies and encouraging participants to share some feelings of distress, when they experienced their first stroke.
Perceived benefits	Aware of the benefits of changing daily lifestyle and following secondary prevention measures	A patient who had been followed up for 1 year without stroke recurrence and had a better prognosis was invited to share his experiences, particularly some lifestyle changes and daily disease monitoring behaviors after discharge.
Cues to actions	Master the specific ways to change the bad lifestyle	Explaining the specific methods of smoking cessation, weight control, reasonable diet, as well as daily monitoring of blood pressure and glucose, and giving medication guidance.
Cues to actions	Recognize the importance of proper use of drugs	Following the medication regimens and not stopping the medicine on their own. Highlighting the strong correlation between dyslipidemia and recurrence during the course of treatment to correct patients' misconceptions.
Perceived barriers	Address the barriers to perform secondary prevention behaviors	Participants were asked to come up with and discuss beliefs, attitudes, or facts that may prevent them from engaging in behaviors correctly.

Outcome Indicators

The outcome assessor was a full-time physician who was professionally engaged in the follow-up of cerebrovascular disease and was not involved in any of the program implementations. Data on patients' sociodemographic characteristics, complications, and stroke severity as well as BP, HbA_{1c}, and LDL-C results were retrieved from electronic medical records. The above physiological and biochemical indicators were collected twice: within 48 hours of admission and during the face-to-face outpatient clinic follow-up 3 months after stroke onset.

The primary outcomes were control of BP, HbA_{1c}, and LDL-C levels according to the recommendations for treatment targets in the Chinese Stroke Association guidelines [21]. The reference treatment targets for patients with ischemic stroke were as follows: BP<140/90 mmHg, LDL-C<2.6 mmol/L, and HbA_{1c}≤7%. BP of the nonhemiplegic side was measured after the patient rested for 5 minutes in a sitting position using a digital sphygmomanometer (Omron HBP-9020). The mean value of 3 consecutive measurements with 1-minute intervals was taken as the final result. LDL-C concentration and blood levels of HbA_{1c} were measured in fresh venous blood samples.

The outcome of self-reported medication adherence was measured by the Chinese version of the 8-item Morisky Medicine Adherence Scale (MMAS) [22,23,24]. The total score ranges from 0 to 8, with a score ≥6 classified as adherent [25]. We also used the modified Rankin Scale (mRS) to evaluate

clinical outcomes in patients with stroke. mRS is a 7-level scale, ranging from 0 (no symptoms) to 6 (death), for assessing the recovery state of neurological function. Patients with an mRS score of 0-1 were defined as having favorable outcomes.

Statistical Analyses

An a priori sample size calculation was performed for this study based on the outcome "the difference in BP at 3 months after discharge in patients with hypertensive ischemic stroke receiving a comprehensive reminder system intervention [26]." Assuming a 20% drop-out rate, at least 170 patients in each group were included to achieve a power of 0.90 with a 2-sided significance level of 5%. Baseline characteristics were reported as means (SDs), median (IQRs), and proportions, as appropriate. Means or probability and 95% CIs were used to report the differences between groups and were examined using the chi-square test for categorical variables and student 2-tailed *t* test or Mann-Whitney *U* test for continuous variables, respectively. Binary logistic regression was used to adjust for confounding variables and compare the proportion of vascular risk factors that reached the target value between the intervention and control groups. Differences in the levels of vascular risk factors between the 2 groups were compared using multiple linear regression, and clinical baseline parameters were considered as covariates. Two-sided *P* values less than .05 were regarded as statistically significant. Data analysis was performed using IBM SPSS Statistics (version 22.0; IBM Corp).

Results

In total, 340 consecutive patients were included in this study. Figure 1 illustrates the study flow chart; 315 patients were finally analyzed, with 155 in the historical control group and 160 in the intervention group. Table 2 presents the demographic and clinical characteristics of the participants. The mean age of participants was 59.2 (SD 10.5) years (the maximum age was 88 years, and the minimum age was 25 years). There were no significant differences in participants' age, gender, educational level, household income, and health insurance between the 2 groups. Slightly more patients in the control group had comorbidities and were smokers, but this difference was not statistically significant. There were no significant differences between the 2 groups in BP, LDL-C, and HBA_{1c} levels or in the proportion of patients who met treatment targets within 48 hours of admission (Table 3).

Figure 1. Study flow chart.

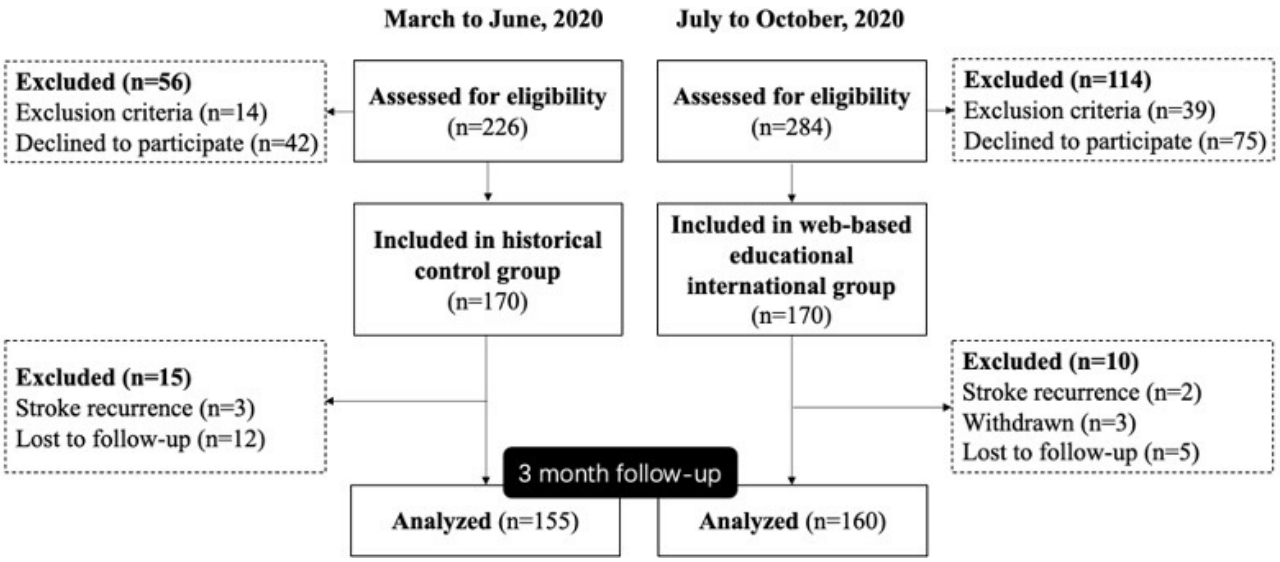

Table . Sociodemographic and clinical characteristics of participants (N=315).

Characteristics		Control group (n=155)	Intervention group (n=160)	*P* value
Age (years), mean (SD)		58.9 (10.3)	59.5 (10.6)	.61

[g]Adjusted for age, sex, cormorbidities, educational level, income, and insurance.

[h]Adjusted for age, sex, cormorbidities, smoking, alcohol use, and the National Institutes of Health Stroke Scale at baseline.

Systolic BP showed a significant reduction at 3 months (adjusted β −3.94, 95% CI −7.18 to −0.60; *P*=.02; Table 5) for the HBM-based planned web-based educational intervention program, but there was no effect on diastolic BP level (adjusted β −2.45, 95% CI −5.06 to 0.17; *P*=.07). There was also a significant postintervention reduction in the mean level of LDL-C (adjusted β −0.21, 95% CI −0.37 to −0.06; *P*=.008) and HbA_{1c} (adjusted β −0.27, 95% CI −0.37 to −0.16; *P*<.001) among the patients in the intervention group compared to those in the comparison group.

Self-reported adherence scores for the intervention and control groups at 3 months were 6.7 (SD 1.5) and 6.2 (SD 1.7), respectively (*P*=.009). The proportion of patients reporting adherence to their medication was 79.4% (127/160) in the

intervention group compared to 63.2% (98/155) in the control group (aOR 2.31, 95% CI 1.37-3.87; *P*=.002). However, there was no significant difference in the favorable functional outcomes between the two groups at 90 days.

Table . Differences of vascular risk factors parameter values between the two groups at 3 months.

Parameter	Control group (n=155)	Intervention group (n=160)	Adjusted β (95% CI)[a]	*P* value
SBP[b] (mmHg), mean (SD)	144.5 (16.7)	140.1 (16.8)	−3.94 (−7.28 to −0.60)	.02
DBP[c] (mmHg), mean (SD)	85.3 (9.9)	82.1 (10.5)	−2.45 (−5.06 to 0.17)	.07
LDL-C[d] (mmol/L), mean (SD)	2.2 (0.8)	2.1 (0.6)	−0.21 (−0.37 to −0.06)	.008
HbA_{1c}[e] (%), mean (SD)	6.2 (1.2)	5.9 (1.0)	−0.27 (−0.37 to −0.16)	<.001

[a]Adjusted for age, sex, cormorbidities, smoking, alcohol use, and baseline value.

[b]SBP: systolic blood pressure.

[c]DBP: diastolic blood pressure.

[d]LDL-C: low-density lipoprotein cholesterol.

[e]HbA_{1c}: hemoglobin A_{1c}.

Discussion

Principal Findings

Our study demonstrated that a planned web-based education program based on the HBM model positively impacted the control of vascular risk factors in patients who had ischemic stroke and improved medication adherence. The theory-guided practice may help enhance the effectiveness of health management. A comprehensive reminder system based on the HBM also improved medication adherence and reduced BP of patients who had a stroke [26]. However, in the SMS4Stroke study, guided by the HBM with behavior change theory, BP did not show a significant change between the 2 groups [27]. A possible reason is that the intervention duration was relatively short at 2 months. The HBM predicts the impact on human behavior from 6 aspects, and participants may change their behavior through health education related to these themes.

Hypertension control is a cornerstone of secondary stroke prevention. Health education based on the HBM increased the BP control compliance rate of participants by 2 times at 3 months, but the level was still suboptimal compared with other studies [26,28]. One of the reasons may be that the cold weather in the northeast and the residents' preference for pickles led to a BP level of 149/87 mmHg at baseline, which was significantly higher than that of patients from Southern and Northern China [29,30]. However, our data are almost consistent with those of the China National Stroke Registry, a multicenter database covering the whole country [31]. Therefore, there is room for improvement in the next period.

Higher LDL-C levels have been associated with stroke recurrence over the past 10 years. Unlike hypertension and hyperglycemia, dyslipidemia may not cause significant physical discomfort for patients. In addition, a lack of knowledge about statins also makes patients likely to ignore adherence to long-term use of this medicine [32,33]. After the web-based education intervention, LDL-C levels decreased to 0.6 mmol/L (95% CI −0.7 to −0.4), which was double the 0.3 mmol/L reported in a 12-week exercise and education program for nondisabling stroke at 6 months follow-up [34]. HbA_{1c} can objectively reflect the average glycemic control over the last 3 months. With the cues to actions we provided, through lifestyle changes and adherence to hypoglycemic agents, the mean HbA_{1c} of patients with diabetes in the intervention group fell within the normal range, and 148/160 (92.5%) patients achieved control goals, which was better than the results of a 3-month poststroke education delivered via 5-minute movies to stroke survivor and caregiver dyads in Pakistan [35]. This is likely because only a quarter of the patients in this study had diabetes, and the patients had better glycemic control at baseline.

The 3-months medication adherence in these 2 groups was higher than that of previous studies [9,36]. However, it is still lower than the 89.0% medication adherence reported in a study of 600 patients conducted in 3 stroke centers across Korea [37]. Only patients who continued to take all prescribed medications were further evaluated for adherence, resulting in the exclusion of patients who reported discontinuing all or some medications, which may explain this difference. A study conducted in 2020 found that the imposed COVID-19 lockdown is unlikely to affect the medication behavior of patients with high preestablished adherence [38]. Therefore, we purposefully established the medication beliefs of patients based on the HBM model, which helps to ensure patients' medication adherence under the normalization of the pandemic.

Although statistically significant improvements were found in both vascular risk factor control and medication adherence in the intervention group compared with the control group, the functional outcomes were not statistically different. This is probably because the neurological condition was not severe in our participants. Multicenters with large samples and multifaceted efforts are required to prove the efficacy of our web-based health education program.

Our study has several limitations. Due to the shortage of medical staff and researchers during the lockdown, this study used a historical control method, which provides less quality evidence compared to randomized controlled trials. Outcomes after intervention were evaluated for 3 months, and long-term effects

need to be further assessed. The study was conducted in a single center, and the included patients may have regional characteristics, having a certain impact on the results. We only investigated overall medication adherence, and the persistence of a specific medication was unknown. The assessment methods of self-report may have led to recall bias; a more objective measure of adherence would be preferable to confirm our findings. However, this study design allowed us to realize the potential benefits of web-based health education under real-life conditions and complement evidence from randomized controlled trials.

Conclusions

This study found that a web-based health education program under the HBM model during the COVID-19 lockdown in autumn 2020 in northeast China, designed to teach patients who experienced a stroke about secondary prevention, may result in improved vascular risk factors and medication adherence. It provides insights into achieving secondary stroke prevention goals, recommended in real-world guidelines. It also serves as a reference for the use of telemedicine to conduct disease prevention under the “new normal” of COVID-19 and the shortage of medical staff.

Abstract

Background: 5G technology is gaining traction in Chinese hospitals for its potential to enhance patient care and internal management. However, various barriers hinder its implementation in clinical settings, and studies on their relevance and importance are scarce.

Objective: This study aimed to identify critical barriers hampering the effective implementation of 5G in hospitals in Western China, to identify interaction relationships and priorities of the above-identified barriers, and to assess the intensity of the relationships and cause-and-effect relations between the adoption barriers.

Methods: This paper uses the Delphi expert consultation method to determine key barriers to 5G adoption in Western China hospitals, the interpretive structural modeling to uncover interaction relationships and priorities, and the decision-making trial and evaluation laboratory method to reveal cause-and-effect relationships and their intensity levels.

Results: In total, 14 barriers were determined by literature review and the Delphi method. Among these, "lack of policies on ethics, rights, and responsibilities in core health care scenarios" emerged as the fundamental influencing factor in the entire system, as it was the only factor at the bottom level of the interpretive structural model. Overall, 8 barriers were classified as the "cause group," and 6 as the "effect group" by the decision-making trial and evaluation laboratory method. "High expense" and "organizational barriers within hospitals" were determined as the most significant driving barrier (the highest R–C value of 1.361) and the most critical barrier (the highest R+C value of 4.317), respectively.

Conclusions: Promoting the integration of 5G in hospitals in Western China faces multiple complex and interrelated barriers. The study provides valuable quantitative evidence and a comprehensive approach for regulatory authorities, hospitals, and telecom operators, helping them develop strategic pathways for promoting widespread 5G adoption in health care. It is suggested that the stakeholders cooperate to explore and solve the problems in the 5G medical care era, aiming to achieve the coverage of 5G medical care across the country. To our best knowledge, this study is the first academic exploration systematically analyzing factors resisting 5G integration in Chinese hospitals, and it may give subsequent researchers a solid foundation for further studying the application and development of 5G in health care.

Introduction

Background

With the advancement of information and communication technology, along with the gradual improvement of China's medical information system construction, China's medical industry is moving away from 1.0 medical informatization to 3.0 medical intelligence [1]. Leveraging the advantages such as ultralow latency, high capacity, high speed, seamless connectivity, high reliability, and low power consumption [2], 5G technology plays an essential role in realizing the interconnection and remote monitoring of medical equipment, patient monitoring, remote consultation, and other telemedicine scenarios. At the same time, 5G technology accelerates the data collection, circulation, analysis, and feedback of various applications in the broad medical and health field. With the advent of 5G technology, medical information can now flow and be shared seamlessly among patients, medical equipment, and hospital information systems. This has paved the way for hospitals to simplify the entire medical treatment and service process, right from prediagnosis to diagnosis and postdiagnosis stages [3].

In recent years, the Chinese government has invested considerably in developing innovative 5G smart hospitals to offer better health care to patients and improve their internal management. For example, in July 2021, a total of 10 departments including the Ministry of Industry and Information Technology, Office of the Central Cyberspace Affairs Commission, National Development and Reform Commission, Ministry of Education, Ministry of Finance, Ministry of Housing and Urban-Rural Development, Ministry of Culture and Tourism, National Health Commission, State-Owned Assets Supervision and Administration Commission of the State Council, and National Energy Administration, jointly released the Sailing Action Plan for 5G Applications (2021-2023). The plan aims to encourage the development of various 5G medical products such as robots, emergency vehicles, medical access gateways, and intelligent medical equipment across the country. The plan also emphasizes the need to strengthen the deployment of 5G medical and health network infrastructure, focusing on improving the coverage of 5G in top-tier national hospitals, disease prevention and control centers, elderly care institutions, and other critical locations. Additionally, the plan aims to build 5G networks and 5G medical edge clouds to enhance in-hospital medical care and telemedicine [4]. In September 2021, the Ministry of Industry and Information Technology, in collaboration with the National Health Commission, released the “Notice on Announcing Pilot Projects for 5G+Medical and Healthcare Applications.” This announcement identified 988 pilot projects aimed at advancing the application of 5G technology in various health care domains, including first aid, telediagnosis, teletreatment, tele-intensive care, traditional Chinese medicine diagnosis and treatment, hospital management, intelligent disease control, health management, and other directions. Among the pilot projects, as many as 611 5G smart medical projects are led by hospitals (general hospitals, emergency centers, and specialized hospitals) [5].

More and more hospitals in China are investing in 5G construction. For instance, Guangdong Provincial People's Hospital put into use the 5G hospital in July 2021, aimed to integrate 5G, big data, artificial intelligence, and other new technologies into various medical scenarios such as treatment, teaching, research, management, and service [6]. Shanghai aims to realize 100% 5G in-depth coverage and 5G typical services for all tertiary hospitals and at least 50% 5G in-depth coverage and 5G typical services for other hospitals by 2023 [7]. Sir Run Run Shaw Hospital Affiliated with Zhejiang University School of Medicine successfully performed a cholecystectomy for a patient from Xinjiang Corps Alar Hospital thousands of miles away by leveraging the robotic arm, which achieved a breakthrough in China's 5G ultraremote robot human liver and gallbladder surgery [8]. The Second Affiliated Hospital of Xi'an Jiaotong University has piloted several scenarios, such as 5G+emergency rescue, 5G+mobile computed tomography, 5G+unmanned aerial vehicle medical delivery, and 5G+integrated remote diagnosis.

However, though 5G technology undoubtedly introduces enormous benefits for hospitals if adequately applied, it has yet to be widely used in many health care scenarios. Hospitals are experiencing various challenges during the actual 5G application process. Different problems are met in the implementation process, including expertise, operation, resource, regulation, and market access factors, as described in the innovation resistance theory (IRT) [9]. At the same time, there are still no systematic studies that have explored the barriers to the adoption of 5G applications in hospitals in Western China. This is particularly important given that technological development in the Eastern region of China is more advanced compared to the Western region. The lag in 5G development in Western China may become another factor that increases the economic imbalance between these 2 regions [10]. Hence, more research is essential for Western China to provide a better understanding of the barriers hindering the adoption of 5G in health care.

Objectives

This study addresses the critical research question below: what are the barriers to implementing 5G in hospitals in Western China? Based on the question, the following research objectives have been formulated: (1) to identify critical barriers hampering the effective implementation of 5G in hospitals in Western China, (2) to identify interaction relationships and priorities of the above-identified barriers, and (3) to assess the intensity of the relationships and cause-and-effect relations between the adoption barriers.

Methods

Ethical Considerations

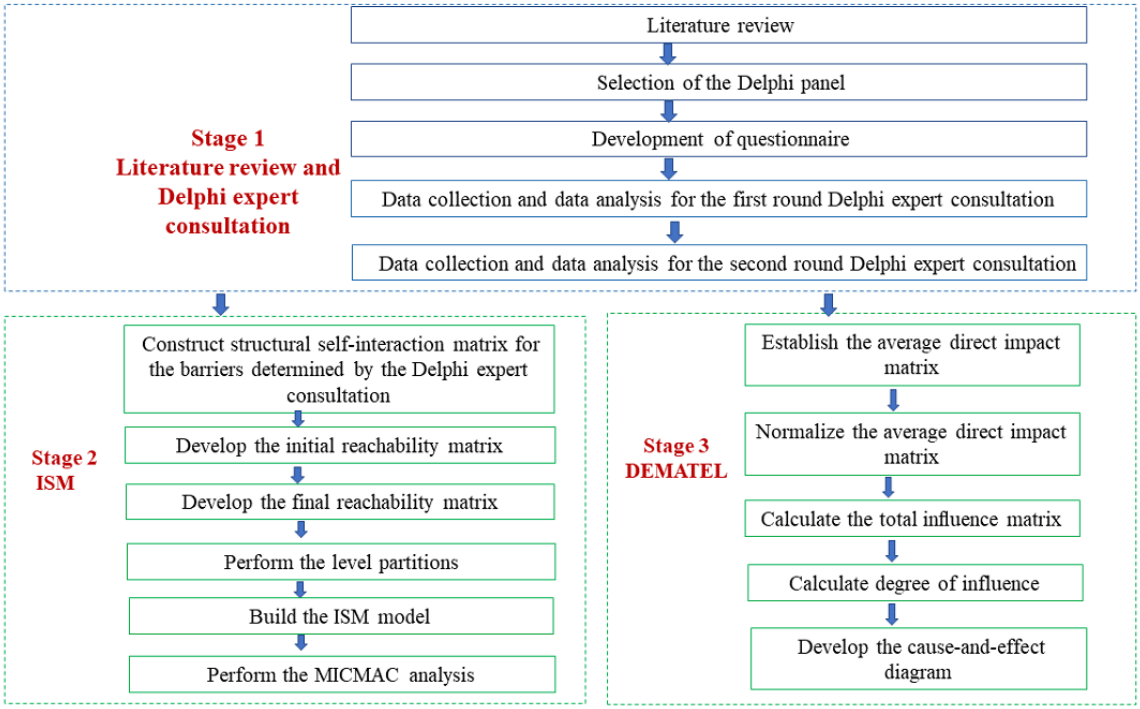
The data were collected through literature review and anonymous questionnaires, which posed no harm to individuals

and did not involve sensitive personal information or commercial interests. Based on the Regulation for Ethical Review of Life Sciences and Medical Research involving human beings issued by the Chinese National Health Commission, Ministry of Education, Ministry of Science and Technology, and State Administration of Traditional Chinese Medicine (Chapter III, Article 32) [11], ethical review was exempted for this study.

Study Design

To address objectives 1-3, a 3-stage hybrid research methodology was proposed by the authors. As shown in Figure 1, a flowchart of the research procedure is conducted. In the first stage, barriers are identified from the existing literature and discussed with experts for further modification and addition using the Delphi technique. The second stage incorporated the interpretive structural modeling (ISM) to obtain a hierarchical structure and interrelationship between the barriers. ISM has a significant advantage because it displays conclusions in the form of a hierarchical topology diagram that is highly intuitive. The hierarchical topology diagram clearly explains the causal relationship and ladder structure among system factors. However, more is needed to determine the intensity of the relationship between factors. It needs to provide the cause-and-effect relation among barriers, which limits the ISM approach [12]. The decision-making trial and evaluation laboratory (DEMATEL) method, on the other hand, can precisely overcome the limitations of the ISM approach. It can determine the strength of influence between variables within the identified structure, providing a deeper understanding of the causal relationship between influencing factors [13]. Therefore, this paper intends to combine Delphi expert consultation, ISM, and DEMATEL to study the hierarchical structure of driving factors and the causal relationship between them. The procedure is explained in more detail in the following section.

Figure 1. Flowchart of research methodology. DEMATEL: decision-making trial and evaluation laboratory; ISM: interpretive structural modeling; MICMAC: Matriced Impacts Corises-multiplication Appliance Classement.



Stage I: Determination of the Barriers Using Literature Review and Delphi Expert Consultation

Overview

This study conducted a literature review from November 20 to 30, 2022, to gather the resistance factors toward 5G development in health care. After that, a 2-round Delphi expert consultation was implemented to refine the factors identified from the above literature review on December 30, 2022, and February 9, 2023. The Delphi technique was developed by the Rand Corporation in 1953 and used as a multistage self-completed questionnaire with individual feedback [14]. It was initially developed as a method for forecasting but has since been widely applied in other areas, including health research [15,16].

Step 1: Literature Review

Web of Science, PubMed, Google Scholar, Chinese government's official websites, and gray literature, including industry reports, were searched by referencing keywords including “5G healthcare,” “5G smart healthcare,” “5G in hospitals,” “5G applications in healthcare,” and “digital health in China.”

Step 2: Selection of the Delphi Panel

To ensure the authoritative scoring results of the consulting expert group on the evaluation indicators, experienced professionals with intermediate or senior titles who are willing to cooperate actively and who are interested in this research were selected. Leaders responsible for informatization work in health authority, heads and frontline employees from the

hospital's information management department, 5G communication suppliers, and scholars in 5G and hospital informatization field were invited to this panel.

Step 3: Development of Questionnaire

To determine the importance of the barriers selected from the literature review, consolidated criteria have been designed in questionnaire format following a 5-point Likert-type scale (5=very important, 4=relatively important, 3=intermediate, 2=unimportant, and 1=very unimportant). To determine the degree of expert authority (Cr), the expert's familiarity with the indicator (Cs) and the judgment basis (Ca) were collected in the questionnaire. The quantitative values for Cs are divided into 5 levels (0.9=very familiar, 0.7=relatively familiar, 0.5=intermediate, 0.3=unfamiliar, and 0.1=very unfamiliar), and the quantitative values for Ca are present in Table 1. The questionnaire is also designed to allow the experts to offer their judgments, with space provided for them to add, remove, and justify their responses.

Table 1. Quantitative values for judgment basis.

Judgment basis (Ca)	Quantitative value of influence degree		
	High	Intermediate	Low
Theoretical analysis	0.3	0.2	0.1
Practical experience	0.5	0.4	0.3
Learn from domestic and foreign peers	0.1	0.1	0.1
Intuition	0.1	0.1	0.1

Step 4: Data Collection

The questionnaires were distributed and collected via the WeChat platform, the most widely and frequently used mobile social media in China, which is profoundly integrated into the daily life of Chinese people [17]. It is often used for distributing and collecting questionnaires.

Step 5: Data Analysis

An analytical stage followed each round of the Delphi questionnaires. The questionnaire recall rate expresses the degree of positivity of the experts. The degree of expert authority Cr can be calculated from the values of Cs and Ca as follows: Cr=(Cs+Ca)/2. The degree of coordination of expert opinions is judged by the coefficients of variation (CVs) and Kendall coefficient of concordance (W). In this study, the barrier screening standard is CV≤0.250. Barriers whose CVs are higher than 0.250 will be modified or deleted. CV is calculated by the mean value and SD. For Kendall coefficient of concordance, the larger the value, the better the coordination of expert opinions. After the analysis, experts' feedback and perspectives will be presented to all participants.

Stage II: Development of Research Framework Using ISM

The ISM method originated from structural modeling and was introduced by Warfield [18] for better decision-making when too many factors or constructs exist. It is a qualitative and interpretive method that involves a mutual learning process that uses the experience of experts to identify the relationship between factors, variables, enablers, and barriers [19,20]. Based on the relationship, an overall multilevel structure is extracted from the complex items. It is very suitable for interdisciplinary research of natural science and social science. The ISM method has been widely used in management and new technology research in different industries.

Referring to the above studies, the basic steps of the ISM method in this study are as follows.

Step 1 involved constructing a “structural self-interaction matrix (SSIM)” for the barriers determined by the Delphi expert consultation. In this step, the symbols “L, M, N, and O” are used to develop a link between the proposed barriers, where L indicates that barrier i has an impact on barrier j, M indicates that barrier j has an impact on barrier i, N indicates that barriers i and j interact with each other, and O indicates that barriers i and j have no interaction with each other.

Step 2 involved converting the SSIM into an “initial reachability matrix (IRM).” In this step, the symbols “L, M, N, and O” are converted into binary elements 0 and 1, and the conversion rules are shown in Table 2.

Step 3 involved checking the transitivity of the IRM to obtain the “final reachability matrix (FRM).” Some new interrelationships between barriers can be established during this step. Transitivity was tested as if barrier A influences barrier B, barrier B influences barrier C, and then, barrier A indirectly influences barrier C.

Step 4 involved performing the level partition through the FRM to get the hierarchy of barriers to plot the ISM. Based on the FRM, a “reachability set,” an “antecedent set,” and an “intersection set” for each barrier were developed.

Step 5 involved building the ISM, checking the model for conceptual inconsistencies, and modifying it accordingly.

Step 6 involved performing the Matriced Impacts Corises-multiplication Appliance Classement (MICMAC) analysis. The driving power (DP) and dependence power (DEP) of the identified barriers based on the FRM were calculated, and the barriers were classified into 4 clusters, known as an autonomous cluster, dependent cluster, linkage cluster, and independent cluster. The details of these 4 clusters are the following:

- Autonomous clusters: the barriers within the autonomous cluster have low DEP and DP. These barriers have no direct

relation with other barriers and can be considered almost isolated from the system.
- Dependent clusters: the barriers in this group do not have robust DP, but their DEP is strong.
- Linkage clusters: the barriers in this cluster are categorized by high DP and DEP. These factors are unstable, so making any changes to them will significantly affect other barriers and may influence them.
- Independent clusters: the barriers within this cluster have high DP and low DEP. These barriers affect other barriers but are less affected.

Table 2. Conversion rule for IRM[a].

(i,j) in SSIM[b]	(i,j) in IRM	(j,i) in IRM
L[c]	1	0
M[d]	0	1
N[e]	1	1
O[f]	0	0

[a]IRM: initial reachability matrix.

[b]SSIM: structural self-interaction matrix.

[c]L indicates that barrier i has an impact on barrier j.

[d]M indicates that barrier j has an impact on barrier i.

[e]N indicates that barriers i and j interact with each other.

[f]O indicates that barriers i and j have no interaction with each other.

Stage III: Identification of Cause-and-Effect Group Using DEMATEL

The DEMATEL approach is a system analysis method based on graph theory and matrix tools. It is used to analyze the cause-effect relationship between factors in complex systems and identify the interaction's intensity [19,21]. The basic steps to carry out DEMATEL analysis are as follows:

Step 1 establishes the average "direct relation matrix." In this step, experts are invited to evaluate each barrier's influence on another using an integer scale. The designed scale has 5 levels, including integers from 0 to 4, where 0 means no impact, 1 means slight impact, 2 means moderate impact, 3 means high impact, and 4 means extremely high impact. Accordingly, the direct influence matrix of each expert is obtained. Then, the average direct relation matrix is obtained by summarizing and averaging all feedback expert data. Given that *k* is the index of experts from a total of *p* experts, *q* is the index of the barriers, and *i* and *j* are the indices for 2 barriers, the decision matrix of each expert is given by  , and then, the direct impact matrix  is given by equation (1).

Step 2 normalizes the average direct relation matrix. The row and maximum value methods are used. The elements of each row in the average direct influence matrix are summed, and then, the maximum value is obtained by comparison. Finally, each element in the average direct relation matrix is divided by the maximum value. The calculation process can be expressed as equation (2):

D=S/x **(2)**

Step 3 calculates the "total influence matrix T" by adding all the direct and indirect effects using equation (3).

Step 4 develops the "cause-and-effect diagram" by adding elements of vector R (row) and vector C (column) using equations (4) and (5), where, R_i is the sum of the row and C_j is the sum of the column of the "total influence matrix." (R_i+C_j) is called the degree of centrality, and (R_i–C_j) is called the degree of cause.

The horizontal and vertical coordinates can be established according to the values of the degrees of centrality and cause. Among them, the degree of centrality is taken as the abscissa, and the degree of cause is taken as the ordinate. Meanwhile, the cause group and effect group are divided according to the positive and negative values of the (R_i–C_j). If the value of (R_i–C_j) is greater than 0, it indicates that this factor has a more significant influence on other factors in the system, and it is classified as a causal factor. If the value of (R_i–C_j) is less than 0, it indicates that other barriers influence this factor greater and attribute it to the outcome factor.

Results

Literature Review

The literature review identified 15 factors influencing the adoption of 5G in health care. Based on the IRT, we divided the barriers to adopting innovation into 5 primary dimensions: expertise, operation, resource, regulation, and market access.

Compared with the unified theory of acceptance and use of technology, technology acceptance model or technology acceptance model 2, and theory of reasoned action, IRT mentioned above has been verified as an effective and significant alternative for researchers who aim to uncover resistance factors in the health care context [22]. The details are listed in Table 3.

Table 3. Barriers influencing adoption of 5G in health care: review of literature.

Barriers	Descriptions
A. Expertise barrier	
A1 Lack of 5G technical talents	5G experts and 5G equipment operators within hospitals are understaffed [23-27].
A2 Insufficient informatization level	The level of informatization construction of different hospitals is uneven. Significant gaps in equipment networking capabilities, medical data collection, and information integration make it challenging to implement and replicate 5G solutions [28,29].
A3 Insufficient security verification	Most of the data in the medical field adopt cross-level and multichannel data collection and analysis methods, including hospital management data and private data such as patient physiology, psychology, and behavior data. The security of the data transmitted through 5G network still needs to be verified [28-35].
B. Operation barrier	
B1 Organizational barriers within hospitals	Not a lot of people understand what 5G is and how it works, and the willingness of traditional hospitals to upgrade and transform 5G networks is relatively low, considering the fact that mature 5G application is mainly concentrated in peripheral medical scenarios such as outpatient guidance and remote consultation [25,28,32,36,37].
B2 Communication obstacles among hospitals	Communication obstacles exist among hospitals, especially among the higher- and lower-level hospitals [24,28,29,38,39].
C. Resource barrier	
C1 High expense	Related equipment and communication costs are high, making it difficult for hospitals to afford [25,30,32,40].
C2 Huge time cost	Installing appropriate equipment and training relevant personnel demand significant time investment [28,40].
C3 Lack of well-trained medical and technical personnel	Existing medical care and technical personnel are insufficient for 5G integration in medical scenarios [33].
C4 Lack of mature compatible equipment and systems	It is difficult for 5G network to integrate with existing equipment and systems [31].
D. Regulation barrier	
D1 Lack of policies related to 5G smart medical integration	Currently, there is no established policy for the integration of 5G smart medical applications [24,28,34].
D2 Lack of ethics, rights, and responsibilities policies	Lack of policies on ethical controversies, rights, and responsibilities related to the application of 5G [28,31,33,34].
D3 Lack of standards for corresponding scenarios	There are many 5G smart medical application scenarios; different scenarios have different requirements for network and technical architecture. At present, there is a lack of 5G application standards corresponding to many medical scenarios [24,29,41-43].
E. Market access barrier	
E1 Lack of unified 5G product standards and listing standards	Emerging 5G smart medical products (such as wearable intelligent terminal equipment and medical instruments) still need unified and perfect listing standards [28,41].
E2 Lack of complete 5G smart medical product system	5G private network equipment and terminal equipment that meet the customized services of smart medical care still need to be further improved [28].
E3 Lack of mature business model	There need to be more mechanisms for cross-field cooperation and mature business models [28].

Delphi Expert Consultation

The Delphi panel in this study comprises 15 members, including practitioners from the health authority, academia, information management departments of the primary, secondary, and tertiary hospitals, and 5G network operators (see Table 4 for panel composition). A 2-round Delphi expert consultation was conducted to explore the views of different experts on the resistance factors toward 5G development in hospitals. The questionnaire was developed based on the literature review.

In the first and second round, we distributed 15 questionnaires each time. In the first round, all the distributed questionnaires were retrieved, while in the second round, 12 questionnaires were collected. The positive coefficient of experts=number of questionnaires returned/number of questionnaires distributed, which can reflect the degree of concern of experts to this study. Thus, in the first round, the positive coefficient of experts was 100%, while in the second round, this coefficient was reduced to 80%.

In the first and second rounds, we obtained data related to the degree of expert authority as follows:

- Degree of familiarity (Cs): 0.670 in the first round and 0.680 in the second round. It shows that the authority of experts in the 2 rounds of consultation is relatively high, and the opinions given are representative to a certain extent.
- Judgment basis (Ca): 0.930 in the first round and 0.920 in the second round.
- Authority coefficient (Cr): 0.800 for both the first and second rounds.

After the first round of expert consultation, the indicator adjustments are as follows, the selection results can be seen in Table 5:

1. Deleted indicators: original C3 (lack of well-trained medical and technical personnel), original C4 (lack of mature compatible equipment and systems), and original E3 (lack of mature business model).
2. Modified indicators: A1 (lack of personnel familiar with 5G within the hospitals) and D2 (lack of policies on ethics, rights, and responsibilities in core health care scenarios).
3. Newly added indicators: B3 (lack of cross-unit resource integration channels) and new C3 (lack of means for hospitals to manage their own 5G networks).

The consultation process of the second round is consistent with the first round. According to the expert's scoring, the CV was calculated, and the W test was carried out. As can be seen in Table 6, none of the CVs for the second round of barriers were higher than 0.250.

In the first and second rounds, we obtained the following data on Kendall coefficient of concordance W test: Kendall coefficient of concordance was 0.195 in the first round and 0.258 in the second round, χ^2_{14}=40.854 in the first round and χ^2_{13}=40.320 in the second round, and *P* value was <.001 for both first and second rounds, which is statistically significant, indicating that the coordination of expert opinions is good. The experts' opinions tended to be unanimous in the second round of consultation, with no modification and new indicators. The final determined barriers can be seen in Figure 2.

Results of ISM

Establish SSIM

In total, 10 experts from the abovementioned 15 were invited to develop the relationships between different barriers using L, M, N, and O. Due to the nonexistence of a special criterion in the literature of ISM concerning what establishes the majority and as in the methodology of ISM [44], this study adopted a 50% criterion to determine the final relationships between different barriers, such as in a relation, if 5 from 10 experts ticked L, the corresponding column is defined as L. However, to be unbiased, for this kind of relationship, the number of specialists answering by M or N or O should be lesser than or equivalent to 3. Fulfilling both requirements, 47 of 91 cases of relations were included to obtain final results, and the remaining cases were all taken as biased and to be taken for more discussion with experts. To analyze the relations of the remaining barriers, this study proceeded for more discussion with 2 senior experts. To eliminate biases, the selected experts were taken out of the given pool of 10 experts. The 2 senior experts were requested to analyze and discuss the remaining barriers until a consensus was reached. Doing so determined a final relationship between different barriers called SSIM, as shown in Table S1 in Multimedia Appendix 1.

Formation of IRM

Transformation of the SSIM into IRM uses the binary rule shown in Table 2. For example, the entry of A1 and D2 in the SSIM is “O,” which is replaced by “0” for A1 and D2 and “0” for D2 and A1 in the IRM (Table S2 in Multimedia Appendix 1).

Formation of FRM

FRM is formed after checking IRM for transitivity. It was done to represent all indirect connections to maintain the consistency of relationships among the barriers. For example, there is a direct relation between A1 and C2 and C2 and D1, but there is no relation between A1 and D1, as shown in the SSIM. Hence, according to the transitivity rule, there is an indirect relation between A1 and D1 corrected during the formation of FRM. It can be observed in Table S3 in Multimedia Appendix 1, where the relation of A1 and D1 is represented by 1*. All of the asterisk signs represent the indirect relation rectified during the formation of the FRM. The FRM calculates each barrier's DP and DEP. The DP is the summation of the value of all the row elements, while the DEP is the summation of all the column elements corresponding to the respective barrier.

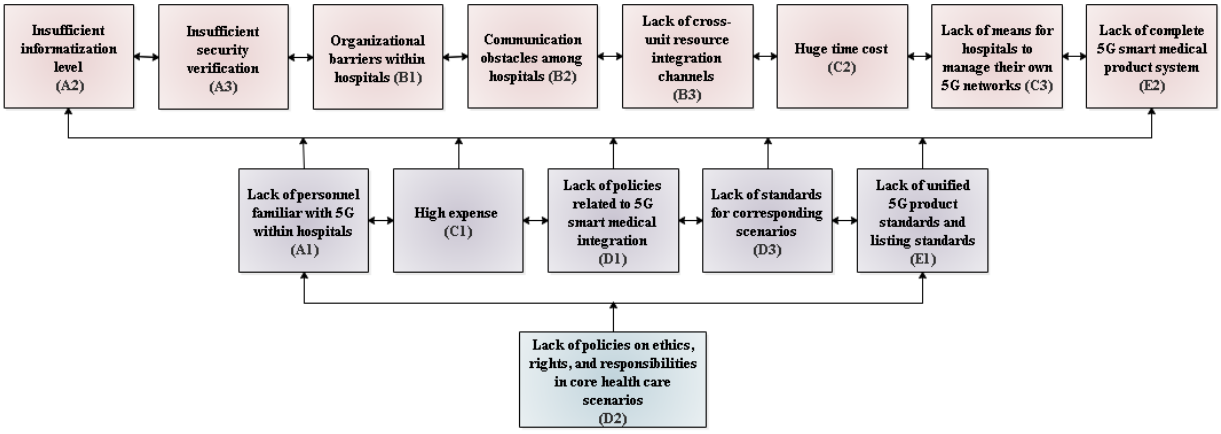
Level Partition

To have a clearer understanding of the relationship between the barriers, a hierarchical structure of the factors is required. Based on FRM, the reachability set, antecedent set, and intersection set for each barrier were developed. Suppose the reachability and intersection set for a specific barrier are identical. In that case, that barrier is deemed at level 1 and assigned the highest position in the ISM hierarchy. After the first iteration, the barriers constituting level 1 are removed, and the previously mentioned procedure is repeated with the remaining barriers until the levels of all barriers have been determined. The results of the different sets and the level iterations are shown in Table S4 in Multimedia Appendix 1.

Formation of ISM

ISM is formulated based on the partition level of barriers. In the first iteration, A2 (insufficient informatization level), A3 (insufficient security verification), B1 (organizational barriers within the hospitals), B2 (communication obstacles among hospitals), B3 (lack of cross-unit resource integration channels), C2 (huge time cost), C3 (lack of means for hospitals to manage their own 5G networks), and E2 (lack of complete 5G smart medical product system) were placed at the top of the ISM. The second iteration resulted in second-level barriers involving A1 (lack of personnel familiar with 5G within hospitals), C1 (high expense), D1 (lack of policies related to 5G smart medical integration), D3 (lack of standards for corresponding scenarios), and E1 (lack of unified 5G product standards and listing standards) placed below the first level. Similarly, in the third iteration, D2 (lack of policies on ethics, rights, and responsibilities in core health care scenarios) was placed below the second level. The developed framework or ISM of barrier adoption is shown in Figure 3.

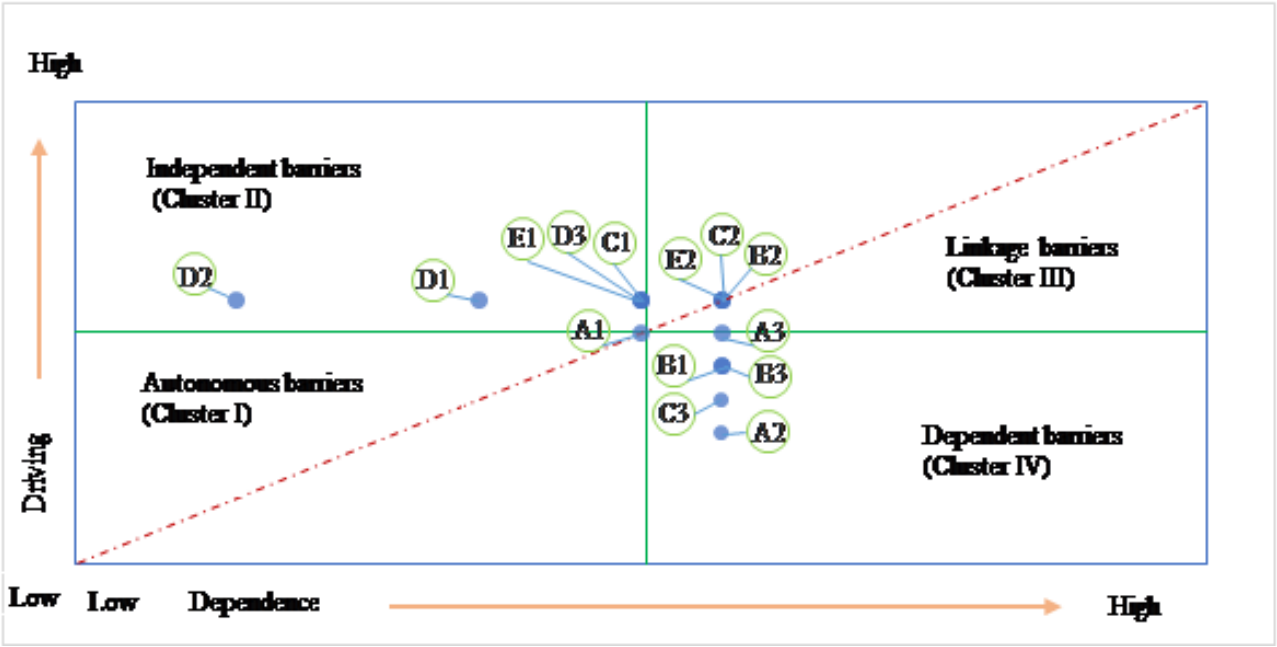
Figure 3. Interpretive structural model.



MICMAC Analysis

The MICMAC analysis is performed to identify barriers' DP and DEP and classify them accordingly. As shown in Figures 3 and 4, A2 (insufficient informatization level), A3 (insufficient security verification), B1 (organizational barriers within hospitals), B3 (lack of cross-unit resource integration channels), and C3 (lack of means for hospitals to manage their own 5G networks) were placed at the top of the ISM and fell under the "dependent" cluster. B2 (communication obstacles among hospitals), C2 (huge time cost), and E2 (lack of complete 5G smart medical product system) were categorized under the "linkage" cluster. The barriers under the linkage cluster were volatile due to high DP and DEP. C1 (high expense), D1 (lack of policies related to 5G smart medical integration), D2 (lack of policies on ethics, rights, and responsibilities in core health care scenarios), D3 (lack of standards for corresponding scenarios), and E1 (lack of unified 5G product standards and listing standards) were placed in the independent cluster. Considering these barriers as drivers of other barriers in the system, hospitals should prioritize them in their decision-making processes. In addition, D2 (lack of policies on ethics, rights, and responsibilities in core health care scenarios) has a relatively high driving force and low dependence force, which reveals that it strongly impacts the whole system as displayed in the ISM.

Figure 4. Driving and dependence diagram.

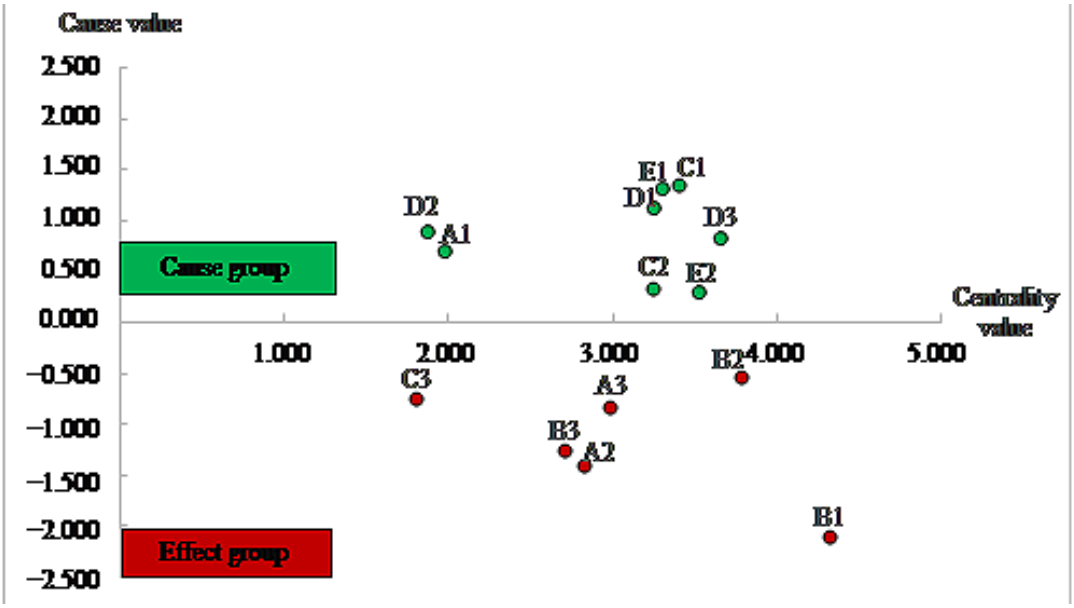


Results of DEMATEL

The abovementioned 10 experts in the ISM scoring process were also invited to participate in the data collection for the DEMATEL analysis. Experts were invited to evaluate each barrier's influence on another using a scale of 0-4. After collecting the direct relation matrix of each expert, the average direct relation matrix (Table S5 in Multimedia Appendix 1) was obtained by summarizing and averaging all feedback expert data. Then, the direct relation matrix was converted into a normalized direct relation matrix (Table S6 in Multimedia Appendix 1) using equation (2). Furthermore, the normalized matrix was converted into a total influence matrix (Table S7 in Multimedia Appendix 1) using equation (3). Finally, the degree of influence was calculated using equations (4) and (5). The cause-effect matrix is shown in Table S8 in Multimedia Appendix 1.

The barriers with an R–C value less than 0 were identified as the effect group, while barriers with an R–C value greater than 0 fell under the cause group. As shown in Figure 5, a total of 8 barriers could be classified in the "cause group," and 6 as the "effect group," in which C1 (high expense), E1 (lack of unified 5G product standards and listing standards), D1 (lack of policies related to 5G smart medical integration), and D2 (lack of policies on ethics, rights, and responsibilities in core health care scenarios) took high priority in the causal group, B1 (organizational barriers within hospitals) and A2 (insufficient informatization level) were the most influenced barriers.

Figure 5. Diagram of cause-effect of barriers.



Sensitivity Analysis

The sensitivity analysis was performed to verify the consistency of the calculated value and validate the stability of professional judgment. As shown in Table 7, a different weighting was assigned to one expert's feedback while keeping equal weightings for the other. Four different total relationship matrices and comparable matrixes were created by multiplying each weight assigned to the experts, the average relationship matrices were then computed, and the cause-effect relationships among the different barriers were established. As shown in Table 8, the same rank order for cause-effect barriers for each expert was obtained, accepting minor rank order variation. Based on Figure 6, the plots of all barriers during 4 iterations of sensitivity analysis are the same as the base rank. Therefore, it is clear that there was no major change in barrier rankings. The sensitivity analysis confirms the robustness of obtained results.

Table 7. Results of sensitivity analysis.

	Scenario 1		Scenario 2		Scenario 3		Scenario 4

Discussion

Principal Results

As shown in Figures 3 and 5, all the barriers in the bottom and middle levels fell into the cause group, indicating those barriers are the primary reasons why 5G technology cannot be adopted in hospitals. In particular, D2 (lack of policies on ethics, rights, and responsibilities in core health care scenarios) was the only factor at the bottom level, implying it is the underlying influencing factor of the whole system. It also has a relatively high driving force and low dependence force based on the MICMAC analysis, which is consistent with the analysis results of DEMATEL as it took high priority in the causal group with an R–C value of 0.900 and an R+C value of 1.875. The finding aligns with that of [28], which highlights that medical and health care fields are closely linked to people's safety. Additionally, ethical considerations and definitions of responsibilities and risks are the most significant obstacles to the evolution and development of 5G in the core areas of health care. It is suggested that the government should strengthen policy supervision to ensure the safe and ethical use of 5G in the medical field. Specific measures need to be implemented to supervise and regulate the application of 5G in the medical field. In addition, further research on relevant policies and norms is required. At the same time, clarification should be made in policy documents, laws, and regulations.

Another significant obstacle in promoting 5G medical applications is the massive capital investment required, as stated in C1, with the highest R–C value of 1.361, indicating its most significant driving force over other barriers. This finding reflects the facts stated by CN-HEALTHCARE [45]. The overall cost of 5G medical treatment includes the construction of 5G communication networks by operators, procurement and maintenance costs for 5G medical information systems and related medical equipment, purchase of medical care equipment, and services for users. The application of 5G in hospitals also

requires installing indoor base stations, software support, and computer room upgrades, all of which incur significant expenses. The high cost of 5G applications limits the financing capabilities of hospitals, especially in the Western China region, where hospitals are generally smaller and have limited funding. As a result, only a few large hospitals with telecom operator support have been able to implement 5G medical care. Meanwhile, smaller hospitals are expected to undertake 5G telemedicine with larger tertiary hospitals. Thus, at this stage, it is recommended that smaller hospitals increase their collaboration with larger hospitals to accelerate the adoption of 5G. At the same time, the government is essential to develop affordable solutions and provide financial support for 5G adoption in health care.

With the highest R+C value of 4.317, B1 (organizational barriers within hospitals) is the most closely related barrier to other factors, indicating that it is the most important barrier to adopting 5G in hospitals in Western China. It also has the lowest R–C value of –2.107, which means it is in the effect group and the most influenced barriers by other factors. These results echo the findings of CN-HEALTHCARE [46], which identified a lack of mature 5G applications in medical scenarios, varying levels of acceptance of new technology, concerns about 5G security, and limitations in human, financial, and material resources as factors influencing attitudes toward 5G adoption among different hospitals. Organizational barriers may be addressed through effective management and leadership, clear communication, and collaboration among different departments.

E1 (lack of unified 5G product standards and listing standards) has the second-highest R–C value of 1.316 and a relatively high R+C value of 3.300. The high R–C value specifies its driving force over the other barriers, while the high R+C value indicates its strong impact on the adoption process. This outcome is akin to the findings of Bruer and Doug [47], who mentioned that 5G standards play a crucial role in hardware infrastructure to software running on top of components, and unified 5G standards help to ensure that a range of devices and equipment can operate in a shared system. Therefore, developing unified 5G product standards and listing standards for corresponding scenarios are essential. It is recommended that the Chinese government, 5G network operators, and hospital administrators accelerate cooperation to establish unified 5G product standards and list standards to jointly promote the large-scale development of 5G in the health care sector.

B2 (communication obstacles among hospitals) is a part of the linkage cluster with the second-highest R+C value of 3.782, indicating it is one of the crucial factors in the whole system. This finding is consistent with that of Wang et al [39], who found that effective communication is critical for the success of 5G adoption in health care. Communication obstacles can lead to misunderstandings and a lack of trust. It is urgent to break through the communication obstacles among hospitals, especially between the higher- and lower-level hospitals, which need to accelerate top-level design, formulate policy documents, and improve relevant legislation and management mechanisms to promote the opening and sharing of 5G medical data and ensure the deep integration of the 5G medical industry.

Concluding Remarks

The paper comprehensively analyzes barriers to 5G adoption in hospitals in Western China. Experts from different stakeholders validated 14 resistance factors. Next, an integrated ISM-DEMATEL approach was applied to model the barriers as a network of factors and alternatives categorized into clusters. All barriers were related to human expertise, resource allocation, operational procedures, laws and regulations, and market access capability. Overall, the study shows that promoting the integration of 5G in hospitals in Western China faces multiple complex and interrelated barriers. It constructs a framework for the main barriers to 5G adoption in the hospital context and provides regulatory authorities, hospital managers, and telecom operators with theoretical and managerial insights into the strategic pathways.

Theoretical and Managerial Implications

- The barrier at the bottom level of the ISM should be emphasized for short-term strategy. The middle-level barriers can be considered for medium- and long-term strategies. The barriers at the top of the ISM can be a long-term strategic focus.
- The effect group can easily be influenced by the cause group, and therefore, managers should give the most attention to causal barriers when implementing 5G practices in hospitals.
- The ranking of cause-effect group barriers can assist regulatory authorities, hospital managers, and telecom operators in developing strategic policy during 5G implementation.
- To overcome these barriers, hospital managers should formulate a 5G adoption strategy that considers the specific needs of the institution and the local market. Specific measures include increasing investment in information infrastructure and human resources, establishing supplier communication channels, and promoting cross-unit resource integration.
- To expand the use of 5G in health care scenarios, it is recommended that the government accelerates the construction of an innovation system consisting of regulators, hospitals, telecom operators, academic researchers, and patient representatives.

Outlook of 5G Health Care

As the infrastructure of intelligent medical care, 5G allows the transmission of vast amounts of data and information, making the information superhighway a reality. Furthermore, with the full deployment of 5G medical care, especially the integration with big data, artificial intelligence, internet, internet of things, and blockchain technology, 5G is expected to bring significant changes to the current medical and health system and promote the evolution of the entire medical ecology, including hospital operation and management. In the long run, 5G health care promotes the sinking of high-quality medical resources and the development of China's “primary health care” and “family doctor” systems. It can improve the population's overall health, reduce medical expenses for ordinary people, and relieve medical insurance burdens. Therefore, no matter how barriers are faced, the benefits of 5G medical care are expected to

outweigh the costs, making it a worthy investment. In the development of 5G medical care, various technical, economic, institutional, interest, and ethical problems will inevitably be encountered. The regulatory authorities, hospitals, telecom operators, and the public must cooperate to explore and solve the problems in the 5G medical care era, aiming to achieve the coverage of 5G medical care across the country.

Limitations

Although this study suggests some useful implications, there are some limitations that could be considered for future research. First, due to the challenges in reaching out to health care professionals and telecom operators from all regions of China, most of the experts invited for this research were from representative cities in Northwest and Southwest China, including Xi'an, Chongqing, and Chengdu. This may not fully represent the entire country, as Eastern China is generally more developed than Western China. Therefore, there is a lack of balance among the groups of participants in this research. In future research, we plan to invite experts from Eastern China as a complement study. Second, the relations established among barriers might be biased because they are selected and analyzed based on expert opinions that are context-dependent and depend on their organization's culture and experience. Third, the outcome of this study is valid for the Chinese health care field and cannot be generalized for other sectors without modifications. It can be extended from the Chinese context to a broader coverage by selecting experts from different countries for benchmarking studies. Finally, only 4 groups of experts, namely, government information department staff, managers from the hospital information technology departments, telecom operators, and scholars, are involved in the research process. Other vital stakeholders, such as patients, can also provide crucial information and insights related to the development of 5G health care.

Acknowledgments

The authors acknowledged the support of the Key Research and Development Projects of Shaanxi Province, China (grant 2021SF-188), and the Youth Fund of the Second Affiliated Hospital of Xi'an Jiaotong University, China (grant YJ(QN)202018). The authors also acknowledged the support of Mr Duwei Dai, Ms Caixia Dong, and Ms Chunyan Zhang during the investigation and data analysis process.

Authors' Contributions

LZ was responsible for the initial concept development, formal analysis, and writing the first draft of the study. MJ contributed to the development of the research methods and edited the writing. RD and FZ were involved in data collection and curation. ZL and SX provided supervision and reviewed the writing. All authors contributed to the final version of the paper.

Abstract

Background: Physical therapy has demonstrated efficacy in managing nonspecific low back pain (NLBP) among patients. Nevertheless, the prevalence of NLBP poses a challenge, as the existing medical infrastructure may be insufficient to care for the large patient population, particularly in geographically remote regions. Telerehabilitation emerges as a promising method to address this concern by offering a method to deliver superior medical care to a greater number of patients with NLBP.

Objective: The purpose of this study is to demonstrate the physical and psychological effectiveness of a user-centered telerehabilitation program, consisting of a smartphone app and integrated sensors, for patients with NLBP.

Methods: This was a single-center, prospective, randomized controlled trial for individuals with NLBP for a duration exceeding 3 months. All participants were assigned randomly to either the telerehabilitation-based exercise group (TBEG) or the outpatient-based exercise group (OBEG). All participants completed a 30-minute regimen of strength and stretching exercises 3 times per week, for a total of 8 weeks, and were required to complete assessment questionnaires at 0, 2, 4, and 8 weeks. The TBEG completed home-based exercises and questionnaires using a telerehabilitation program, while the OBEG completed them in outpatient rehabilitation. The Oswestry Disability Index (ODI) served as the primary outcome measure, assessing physical disability. Secondary outcomes included the Numeric Pain Rating Scale, Fear-Avoidance Beliefs Questionnaire, and 36-item Short-Form Health Survey.

Results: In total, 54 of 129 eligible patients were enrolled and randomly assigned to the study. The completion of all the interventions and assessments in the TBEG and OBEG was 89% (24/27) and 81% (22/27). The findings indicate that no statistical significance was found in the difference of ODI scores between the TBEG and the OBEG at 2 weeks (mean difference −0.91; odds ratio [OR] 0.78, 95% CI −5.96 to 4.14; *P*=.72), 4 weeks (mean difference −3.80; OR 1.33, 95% CI −9.86 to −2.25; *P*=.21), and 8 weeks (mean difference −3.24; OR 0.92, 95% CI −8.65 to 2.17; *P*=.24). The improvement of the ODI in the TBEG (mean −16.42, SD 7.30) and OBEG (mean −13.18, SD 8.48) was higher than 10 after an 8-week intervention. No statistically significant differences were observed between the 2 groups at the 8-week mark regarding the Fear-Avoidance Beliefs Questionnaire (mean difference 8.88; OR 1.04, 95% CI −2.29 to 20.06; *P*=.12) and Numeric Pain Rating Scale (mean difference −0.39; OR 0.44, 95% CI −2.10 to 1.31; *P*=.64). In the subgroup analysis, there was no statistically significant difference in outcomes between the 2 groups.

Conclusions: Telerehabilitation interventions demonstrate comparable therapeutic efficacy for individuals with NLBP when compared to conventional outpatient-based physical therapy, yielding comparable outcomes in pain reduction and improvement in functional limitations.

Introduction

Background

Nonspecific low back pain (NLBP) is a broad category of low back pain (LBP) lacking identifiable etiology [1]. The Global Burden of Disease study report indicates that by 2020, the global prevalence of LBP will exceed 619 million, representing a 60% increase since 1990, with projections reaching 843 million by 2050 [2]. Years lived with disability is an index measuring the average duration of life lived with disability due to a disease from onset to death [3]. The Global Burden of Disease study reveals that LBP ranks first among 291 diseases in terms of age-standardized years lived with disability [4]. By 2020, 69 million individuals will experience limited life expectancy due to disability caused by LBP [2].

It is estimated that the annual economic burden for physical therapy of patients with LBP exceeded US $2.41 billion [5]. Nonspecific chronic LBP includes individuals experiencing pain exceeding 3 months, constituting 85% of the overall population with NLBP [6]. Therefore, it is urgent and necessary to explore innovative treatment modalities for individuals with NLBP.

Numerous clinical guidelines recommend incorporating exercise routines into the treatment of individuals with NLBP. This recommendation is based on the substantial pain relief and improved physical function observed in patients with NLBP through exercise interventions. These interventions also tend to have fewer adverse effects compared to pharmaceutical and surgical approaches [7-10].

Under the traditional clinic-based exercise model, patients are required to participate consistently in structured exercise programs. These programs are supervised by qualified physical therapists (PTs) over an extended period. However, the traditional clinic-based exercise model faces challenges because a substantial proportion of patients with NLBP face barriers to completing a structured exercise program due to time constraints, transportation limitations, and geographical challenges; in addition, a large proportion of individuals with NLBP, who live in remote areas, have no access to qualified exercise guidance because the medical resource is undistributed, especially in resource-limited countries [11-13].

As a result, the traditional clinic-based exercise model encounters difficulties in addressing the diverse needs of this patient population [14,15]. Given these circumstances, the telerehabilitation-based exercise model, incorporation of home-based exercises into a telerehabilitation program, emerges as a promising and effective strategy to address the previously mentioned challenges associated with managing NLBP. The telerehabilitation-based exercise model provides patients with a digitalized exercise plan, enabling patients with NLBP to complete their home exercise regimen promptly. In this model, patients' exercise performance is recorded, and any issues encountered are promptly addressed by professional health care providers. Compared to traditional clinic-based exercise models, the telerehabilitation-based model saves time, money, and medical resources.

In recent years, numerous research teams have studied telerehabilitation strategies for individuals with NLBP [16-21]. In the United States, Shebib et al [18] pioneered a comprehensive digital care program encompassing education, sensor-guided physiotherapy, aerobic exercise, and cognitive behavioral therapy tailored for patients with NLBP. Their investigation revealed superior therapeutic outcomes within the digital care program group compared to the control group [19]. In Germany, Toelle et al [19] developed the Kaia app (Kaia Health Corp) specifically designed for patients with NLBP. Results indicated that individuals receiving exercise guidance through the Kaia app exhibited significant pain relief and improvements in physical function compared to the control group [19].

Similarly, in the United Kingdom, Fatoye et al [20] integrated telerehabilitation with the McKenzie exercise approach. Remarkably, the telerehabilitation group achieved therapeutic outcomes equivalent to outpatient rehabilitation. It also demonstrated a lower average medical cost per patient compared to the outpatient group [20]. In resource-limited nations, such as China, the widespread adoption of telerehabilitation is important because of the large patient population and the lack of physical therapy services.

Furthermore, it is worth noting that psychosocial risk factors have a more significant impact on predicting pain-related outcomes in cases of NLBP compared to biomedical factors [22,23]. One widely accepted conceptual framework for understanding how psychosocial factors influence pain-related outcomes is the Fear-Avoidance Model [24]. According to the Fear-Avoidance Model, anxiety, depression, fear, and catastrophizing are risk factors that contribute to pain-related disability [25,26]. Marshall et al [27] found that a significant number of patients with NLBP did not experience improvements in pain intensity or limb disability after receiving professional exercise guidance and participating in weekly exercises. These patients were more susceptible to anxiety and fear [28]. In the traditional clinic-based exercise model, health care professionals, such as PTs, assist patients in correctly understanding pain and addressing their concerns to prevent the occurrence of anxiety and fear [28]. However, it remains unclear whether a telerehabilitation-based exercise model can reduce pain-related fear and anxiety in patients with NLBP.

Objective

The research team used the Healbone Intelligent Rehabilitation System (HIRS), comprised of a smartphone app and integrated sensors. The primary objective is to evaluate the efficacy of this intervention. The program guides and monitors patients with NLBP, as they engage in a structured home-based exercise

regimen. This study measures the program's impact on both the physical and psychological dimensions of NLBP management.

Methods

Ethical Considerations

This study has been approved by the ethics committees of the Peking Union Medical College Hospital (I-23PJ151) and registered in the Chinese Clinical Trial Registry (ChiCTR2300068984).

Trial Design

This study was a single-center, 2-arm, parallel-group, randomized controlled trial (RCT; participant-blinded) with 1:1 RCT, conducted in Peking Union Medical College Hospital, Beijing, China. All patients were assessed on pain, function, quality of life, and fear-belief avoidance. Assessments occurred at 0, 2, 4, and 8 weeks.

Inclusion and Exclusion Criteria

In this study, all participants were recruited from Peking Union Medical College Hospital. Two physicians selected patients with NLBP who met the inclusion and exclusion criteria and referred them to PTs. These patients were thoroughly informed about the purpose, procedures, and potential risks of the trial. Additionally, patients did not participate in any other medical interventions for LBP other than the exercise intervention of this trial until the study's completion. Upon obtaining informed consent, patients were included in the study.

Written informed consents were obtained from all patients. The inclusion and exclusion criteria are shown in Textbox 1.

Textbox 1. Inclusion and exclusion criteria for the study.

Inclusion criteria

- Aged between 18 and 60 years
- Numeric Pain Rating Scale equal to or greater than 3 points
- Oswestry Disability Index equal to or greater than 15 points
- Ongoing pain for at least 3 months
- Able to use a smartphone and complete the exercise protocol independently
- Those who could sign the informed consent independently

Exclusion criteria

- Patients with spinal deformity, spinal structure slip, spinal fracture history, and spinal tumor
- Diagnosed with rheumatoid arthritis and ankylosing spondylitis
- Patients with herniated disk
- Pregnancy
- Patients who receive other treatments before the experiments, including nonsteroid anti-inflammatory drugs or plasters, physical agents therapy, and acupuncture

Sample Size Calculation

The sample size was calculated using PASS 11 (NCSS Corp). Based on the principle of noninferiority RCTs [29] and previous clinical studies [20,30], the mean difference in the Oswestry Disability Index (ODI) between the telerehabilitation-based exercise group (TBEG) and the outpatient-based exercise group (OBEG) was 5, the SD was estimated to be 6 for both groups, and the noninferiority margin for the ODI was 10. A sample size of 38 was required based on a bilateral α=.05 and β=.2, and a sample size of 54 was required to account for a 30% dropout rate.

Blinding and Randomization

In total, 54 participants were assigned in a randomized manner, with equal distribution, to either the TBEG or the OBEG through a platform for randomization. Subsequently, based on the results derived from the platform (eg, C, T, C, T, T, and C), slips of paper labeled with the letters "T" and "C" were placed into sealed, opaque, and identically sized envelopes. After completing the baseline measurements for all participants, the envelopes were sequentially opened to reveal the group assignments. The allocation sequence was prepared by 2 researchers with no involvement in the study using a blocked randomization model.

Intervention

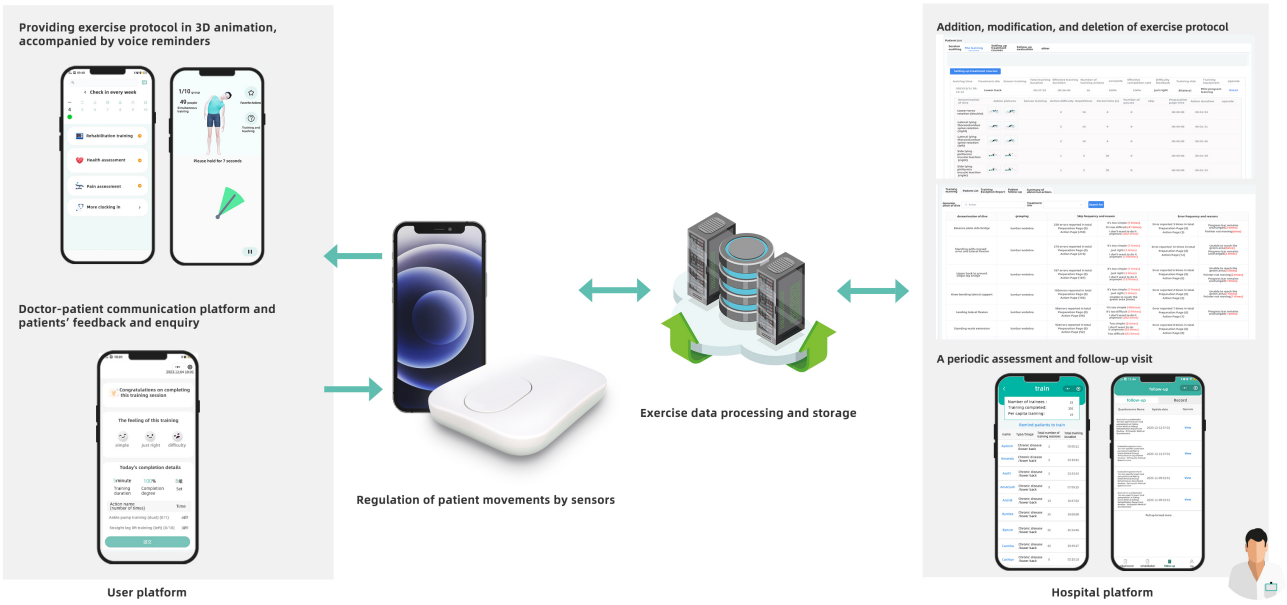
Overview

The exercise plan for patients with NLBP in both TBEG and OBEG was identical. Both consist of muscle strengthening and stretching exercises to increase lumbar stability, coordination, and posture keeping. The detailed exercise plan is shown in Multimedia Appendix 1. Before the initiation of this trial, 2 PTs were trained in three 40-minute sessions.

Telerehabilitation-Based Exercise Group

The HIRS was designed based on a user-centered theory to provide patients with a platform for self-management interventions. Additionally, the HIRS system is made available at no cost to all participants in this study. Figure 1 illustrates the 3 distinct components of HIRS: the physician portal, the user portal, and the transmission portal.

Figure 1. The 3 different parts of the Healbone Intelligent Rehabilitation System. The doctor's portal could be used to create and modify exercises, monitor training progress, and view patient data. The patients could use the user's portal to complete the prescribed exercises, view educational materials, and provide feedback to the physical therapists. Finally, the transmitter portal encrypts and transmits the data collected, ensuring the overall system's integrity.



Prior to the commencement of the experiment, professional medical personnel created specific videos for each training exercise in the rehabilitation program and uploaded them to the HIRS along with detailed instructions. At the onset of the experiment, an app was installed on the smartphones of the patients in the TBEG, through which they registered personal accounts. Subsequently, during the initial session, PTs sent digital exercise training protocols to the patients' personal accounts and educated them on the correct use of the app and sensors for home-based exercises.

Each time the patients engaged in the exercises, they were required to access the app via their personal accounts and calibrate the sensors to accurately perform each exercise within the regimen. Upon initiation of the exercise, the patients were to follow the instructions provided in the video to complete each action in the regimen. If a patient failed to exercise, the system would automatically send a reminder and notify the PTs, who would then contact the patient to ascertain the reason for nonparticipation. Concurrently, if an individual in the TBEG sought advice from the PTs regarding concerns or inquiries related to back pain, the PTs would provide the patient detailed responses to prevent the individual from experiencing fear or anxiety.

Over an 8-week period, all patients in the TBEG were mandated to complete exercise sessions every other day, 3 times a week, with each session lasting 30 minutes. The HIRS transmission portal collected the results of the patients' assessments and automatically recorded their exercise performance, including the duration of each session and the frequency of weekly exercises.

Finally, patients were required to complete digital assessment questionnaires via the app at weeks 0, 2, 4, and 8. The validity of HIRS had been verified by 25 patients before the trial.

Outpatient-Based Exercise Group

In the OBEG, patients underwent a consistent 30-minute exercise regimen every 2 days under the PTs' supervision, with sessions scheduled thrice weekly. Concurrently, during each hospital visit for exercise guidance, the PTs provide face-to-face consultations to address any questions or concerns the patients may have. Furthermore, assessment questionnaires are administered in the outpatient clinic at baseline (week 0), week 2, week 4, and week 8.

Outcome Measures

The ODI, as the primary outcome measure, has been verified for reliability and validity [31]. It is commonly used to evaluate physical function. The minimal clinically important difference (MCID) refers to the smallest change in score that patients perceive as beneficial, irrespective of side effects and costs. Bombardier et al [32] determined that the MCID for the ODI score in patients with NLBP is 5. This indicates that an improvement in the ODI score by at least 5 points after the intervention is considered clinically meaningful for the patient.

In addition, a set of secondary outcome measures was also used. These measures include the Numeric Pain Rating Scale (NPRS) for pain evaluation, the 36-item Short-Form Health Survey (SF-36) for quality of life assessment, and the Fear-Avoidance Beliefs Questionnaire (FABQ) to gauge fear-avoidance beliefs related to work and physical activity [33,34]. Previous studies have determined that the MCID for the FABQ in patients with NLBP is 11 [35], and for the NPRS, it is 2 [36]. However, Grönkvist et al [37] established that the MCID for the 8 dimensions of the SF-36 varies among patients with NLBP [37].

The reliability and validity of the Chinese version of the SF-36 and the FABQ have been confirmed [33,34]. The collection of the primary and secondary outcome measures occurred at weeks 0, 2, 4, and 8. Patients in the TBEG completed all assessments

through the HIRS, while patients in the OBEG completed these assessments in the outpatient clinic, guided by PTs.

Statistical Analysis

The outcomes were analyzed following the intention-to-treat approach, and all participants were analyzed according to the original group assignment. Missing data were handled using multiple imputations by chained equations [38]. Besides, subgroup analysis was conducted following per-protocol analyses in this study.

All the data in this study were analyzed using SPSS (version 23.0; IBM Corp). Demographic data are presented as means (SDs) and numbers (percentages). Descriptive statistics, independent sample 2-tailed *t* tests, and chi-square tests were used to analyze participant characteristics. The normality of distribution for all data was tested by an independent sample *t* test. The results of this study are presented as mean, SD, odds ratio (OR), and 95% CI. The statistical analysis was conducted by a researcher who was blinded and not involved in this study.

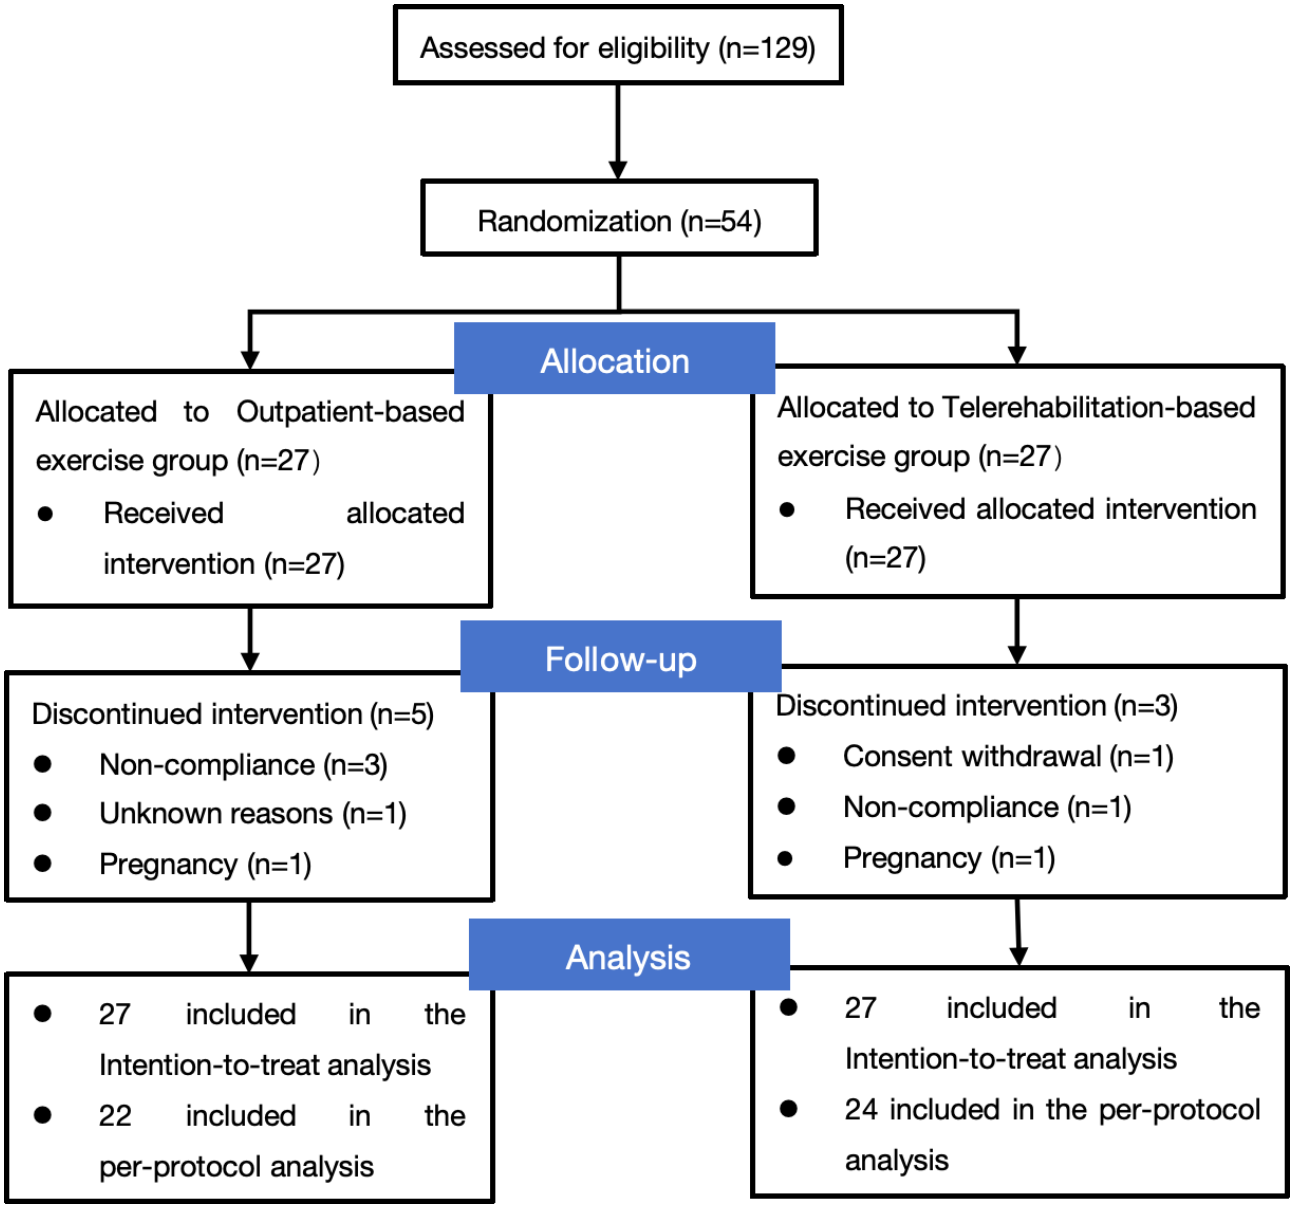
Results

Study Population and Follow-Up

Between March 9, 2023, and November 1, 2023, 129 patients were considered for eligibility. During the initial screening process, 35 patients did not meet the inclusion criteria or met the exclusion criteria. Among the remaining 94 eligible patients, 32 did not consent, and 8 patients withdrew prior to group randomization. Therefore, a total of 54 patients left for the final study. The population was randomly allocated into 2 groups: the TBEG (n=27) and OBEG (n=27), as illustrated in Figure 2.

All patients completed the baseline assessment at week 0 and were asked to complete assessments at weeks 2, 4, and 8. All participants underwent baseline assessments. During the study, 3 patients in the TBEG and 5 patients in the OBEG withdrew due to pregnancy or other reasons. Ultimately, 24 patients in the TBEG and 22 patients in the OBEG completed all treatments and the 8-week follow-up. The completion rates for treatment and assessments in the OBEG were as follows: 96% (26/27) at 2 weeks, 93% (25/27) at 4 weeks, and 81% (22/27) at 8 weeks. In comparison, the completion rates in the TBEG were 100% (27/27) at 2 weeks, 96% (26/27) at 4 weeks, and 89% (24/27) at 8 weeks, as illustrated in Figure 2. Between the 2 groups, patients showed similar clinical and demographic characteristics (Textbox 1).

Figure 2. Participant flowchart.



Primary Outcomes

The baseline ODI scores showed comparable values between the TBEG and the OBEG (Table 1). The mean ODI improvement for the OBEG was −4.70 (SD 9.20) at week 2, −8.40 (SD 10.13) at week 4, and −13.15 (SD 8.48) at week 8. The mean ODI improvement for the TBEG was −5.61 (SD 7.30) at week 2, −11.43 (SD 8.83) at week 4, and −13.70 (SD 7.30) at week 8. After 8 weeks of intervention, both the OBEG and TBEG demonstrated an improvement in ODI scores exceeding 10 points, indicating clinical significance (Table 2).

At the second week, the difference in ODI score changes between the TBEG and OBEG was 0.41 (OR 0.78, 95% CI −0.58 to 1.39); at the fourth week, the difference was −3.80 (OR 1.33, 95% CI −9.86 to 2.25); and at the eighth week, the difference was −3.24 (OR 0.92, 95% CI −8.65 to 2.17; Table 2). Statistical analysis revealed no significant differences between the TBEG and OBEG at weeks 0, 2, 4, and 8 (Figure 3). Following the 8-week intervention, the improvement in ODI scores in the TBEG was noninferior to that in the OBEG.

Table . Demographics and baseline characteristics of all participants.

Characteristics		OBEG[a] (n=27)	TBEG[b] (n=27)	*P* value
Age (years), mean (SD)		38.23 (11.55)	39.11 (10.45)	.77

[a]OBEG: outpatient-based exercise group.

[b]TBEG: telerehabilitation-based exercise group.

[c]OR: odds ratio.

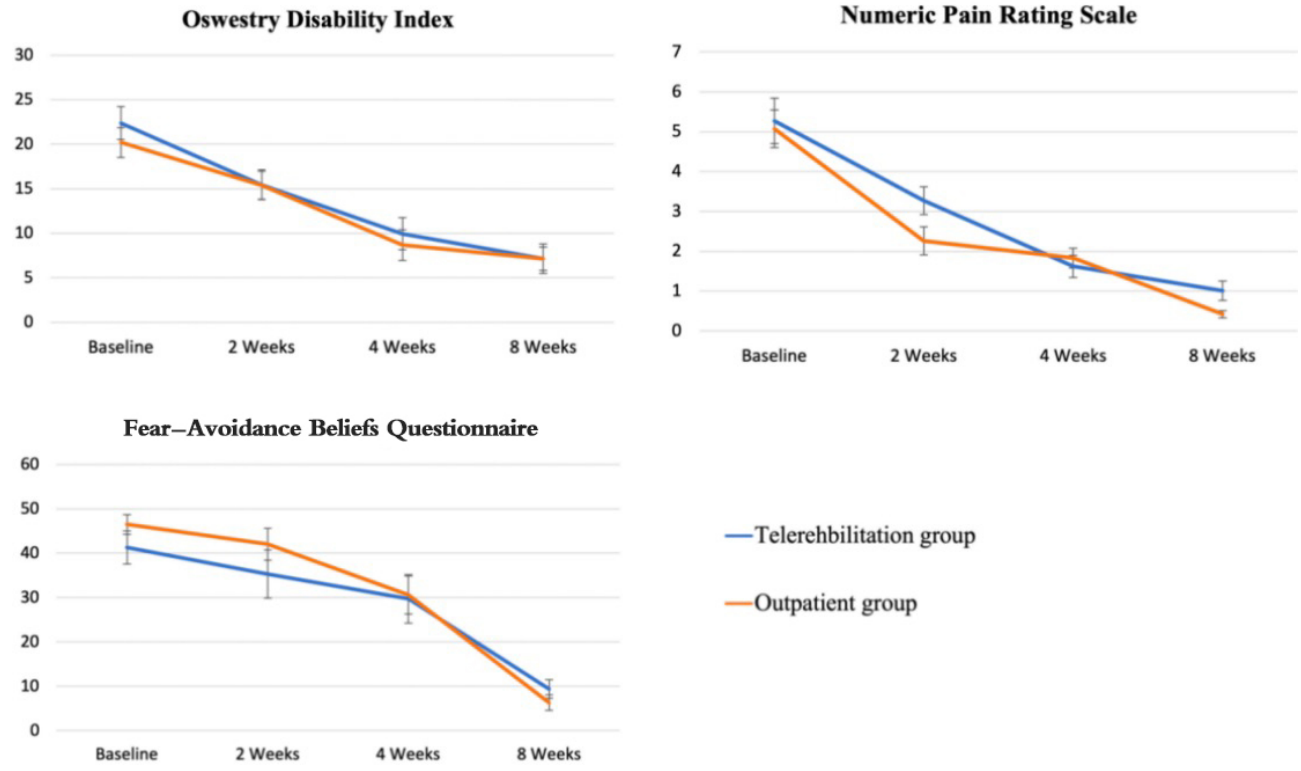
[d]ODI: Oswestry Disability Index.

[e]NPRS: Numeric Pain Rating Scale.

[f]FABQ: Fear-Avoidance Beliefs Questionnaire.

[g]SF-36: 36-item Short-Form Health Survey.

Figure 3. The primary and secondary outcomes Oswestry Disability Index, Numeric Pain Rating Scale, and Fear-Avoidance Beliefs Questionnaire at baseline and 2, 4, and 8 weeks; error bars represent 95% CIs.



Secondary Outcomes

The baseline NPRS scores showed comparable values between the TBEG and the OBEG. Statistical analysis found no significant differences between values for the TBEG and the OBEG at weeks 0, 2, 4, and 8 (Table 1). At week 8, the mean NPRS improvement from baseline was −4.65 (SD 2.01) in OBEG and −4.65 (SD 2.01) in TBEG (Figure 3).

The baseline FABQ scores showed comparable values between the TBEG and the OBEG. Statistical analysis found no significant differences between the values for the TBEG and the OBEG at weeks 0, 2, 4, and 8 (Table 1). At week 8, the mean improvement in FABQ scores from baseline was −40.15 (SD 13.38) in OBEG and −32.48 (SD 15.07) in TBEG (Figure 3).

No statistically significant differences were found in the mean change of the SF-36 scores at weeks 0, 2, 4, and 8 (Tables 1 and 2).

After an 8-week intervention, the NPRS, FABQ, and SF-36 scores in both the TBEG and the OBEG showed significant improvement compared to baseline values. Furthermore, the extent of improvement in NPRS, FABQ, and SF-36 scores in the TBEG was found to be noninferior to that observed in the OBEG.

Subgroup Analysis

After an 8-week intervention, both the OBEG and the TBEG demonstrated clinically significant improvements in the ODI, with a reduction exceeding 10 points, and no statistical differences were found in the changes of the ODI between 2 groups, demonstrating noninferiority (Table 3).

Table . Subgroup analysis of primary and secondary outcomes for the OBEG[a] and the TBEG[b].

[f]FABQ: Fear-Avoidance Beliefs Questionnaire.

[g]SF-36: 36-item Short-Form Health Survey.

Discussion

Principal Findings

This study was designed to determine the efficacy of the treatment between the TBEG and the OBEG. After an 8-week intervention, the completion rate was 89% (24/27) in the TBEG and 81% (22/27) in the OBEG. The completion rate of exercise was higher in the TBEG compared to the OBEG. In the primary outcomes, there was no statistically significant difference between the TBEG and the OBEG in improving pain-related physical dysfunction, demonstrating noninferiority of telerehabilitation. However, both groups demonstrated an improvement in the ODI score exceeding 10 points, indicating that both telerehabilitation exercises and outpatient exercises have clinical significance in improving the ODI for patients with NLBP. Regarding secondary outcomes, there were no statistically significant differences in the SF-36, NPRS, and FABQ between the groups; the improvements in the SF-36, NPRS, and FABQ surpassed the MCID. This suggests that both TBEG and OBEG interventions have clinical significance in pain relief, reduction in fear-avoidance beliefs, and enhancement of quality of life following an 8-week intervention with similar efficacy.

The Efficacy and Benefits of Telerehabilitation for Patients With NLBP

Compared with previous studies [39-41], this study also demonstrates the efficacy of telerehabilitation for patients with NLBP in the improvement of pain intensity, physical disability, and quality of life.

Additionally, we also found that exercise helped patients in both groups to reduce the impact of pain-related fear on work and daily activity after an 8-week intervention. Figure 2, which visually presents the data, indicates significant improvements in both the NPRS and ODI by week 4. Moreover, the FABQ demonstrates a noticeable reduction by week 8, suggesting a delayed improvement in patients' psychological fear.

Exercise is an important and widely accepted treatment for patients with NLBP [42,43]. To achieve the expected results, it is crucial for patients to consistently follow a prescribed exercise plan for an extended time. However, a study by Palazzo et al [12] found that patients with NLBP face challenges in adhering to home-based exercises. These challenges include factors such as remote locations, difficulties in the exercise program, the patient's attitude toward exercise, and the lack of supervision and follow-up outside of the hospital. Altogether, these factors reduce the effectiveness of the treatment [11,12].

Hence, we have introduced a telerehabilitation system using a smartphone app combined with sensors. This system is designed to offer better monitoring and follow-up beyond usual care. The exercise plan includes stretching and strength exercises, which have been shown to reduce pain and improve physical function [44-46]. The smartphone app uses visual and audio content to enhance patient experience.

Furthermore, the telerehabilitation system allows patients to receive prompt guidance from PTs. PTs can monitor the real-time physical functional status and exercise progression of patients. The exercise routines span over 8 weeks, with sessions occurring every 2 days, 3 times per week. In contrast to patients in the OBEG who need to schedule appointments with PTs in the clinic, those in the TBEG can complete their exercises at home.

In contrast to the OBEG, patients with NLBP in the TBEG exhibited greater flexibility in their exercise scheduling. Within the scope of this study, they consistently adhered to their exercise regimens in a timely manner, which contributed to improved compliance with exercise plans and benefited patients with NLBP. Moreover, the exercise model based on remote rehabilitation can help individuals save more time and expenses related to hospital visits, offering greater convenience compared to outpatient-based exercise models. Simultaneously, the remote rehabilitation–based exercise model provides patients with NLBP with the opportunity to receive qualified exercise guidance. Finally, this remote rehabilitation–based exercise model alleviates the burden on health care institutions and reduces treatment costs.

The telerehabilitation system enables patients with NLBP to adhere to their treatment plans and allows them to manage their health at home with remote supervision. In long-term follow-ups, Hou et al [47] found that patients using telerehabilitation showed more improvement in functional limitations compared to those relying on the traditional in-clinic method. This is especially promising in areas lacking medical accessibility.

Limitations

This study was conducted at 1 medical center to compare telerehabilitation with traditional on-site rehabilitation for patients with NLBP. A total of 54 patients participated in the trial, with 27 in the TBEG and 27 in the OBEG. The exercise routines span over 8 weeks, and assessments were scheduled at weeks 0, 2, 4, and 8.

This was a single-center RCT with a relatively small sample size. To address this limitation, the research team plans to conduct subsequent multicenter RCTs in regions with limited medical resources where patients with NLBP have difficulty accessing professional exercise guidance. Additionally, due to the relatively short follow-up period, future studies will involve

more participants to investigate the effects of remote rehabilitation–based exercise interventions on patients with NLBP over 6 months, 1 year, or even longer durations [47], focusing on adherence, pain relief, and improvement in pain-related physical dysfunction.

This study demonstrates that remote rehabilitation–based exercise training has therapeutic effects on pain relief and improvement in pain-related physical dysfunction in patients with NLBP. However, there is currently limited research analyzing the factors influencing the efficacy of remote rehabilitation in patients with NLBP, and it remains unclear which types of patients with NLBP are more suitable for remote rehabilitation treatment.

Furthermore, the research team plans to validate the effectiveness of the telerehabilitation program through a multicenter clinical trial. These future efforts are designed to study the benefits of telerehabilitation in managing NLBP, providing valuable insights to the medical community.

Conclusions

This study confirms that telerehabilitation and traditional outpatient rehabilitation methods produce comparable outcomes for patients with NLBP. Additionally, telerehabilitation reduces time, cost, and medical resources. It exhibits potential as an alternative for patients lacking access to high-quality rehabilitation services.

Acknowledgments

This study was funded by National High-Level Hospital Clinical Research Funding (2022-PUMCH-B-053).

Authors' Contributions

The inception of the study was facilitated through the collaborative efforts of YB, LC, and WY. YL, YZ, and WS undertook the experimental procedures and were responsible for the composition of the manuscript. Substantial contributions to the analysis and preparation of the manuscript were made by DL, Houqiang Zhang, and Huiling Zhang. QF executed the data analyses, and WS played a crucial role in the analytical process through constructive discussions.

Conflicts of Interest

None declared.

Abstract

Background: Up to 50% of people in low- and middle-income countries do not receive the rehabilitation they require. Telerehabilitation has the potential to improve access to neurorehabilitation services especially in low- and middle-income countries. Although there are reports of the barriers and facilitators to telerehabilitation in such settings, almost all are anecdotal. Furthermore, family or carers have a significant influence on the adoption and success of telerehabilitation, but their views have not been reported.

Objective: This study aimed to investigate the views of service users, their family or carers, and health care professionals (HCPs) on telerehabilitation for people with neurological conditions in Ghana.

Methods: Two focus groups were held at Komfo Anokye Hospital in Kumasi, Ghana: one in person for service users (n=11) and their family or carers (n=9), conducted in the Ghanaian language of Twi, and one hybrid for HCPs (n=18) conducted in English. The mean (SD) age of the service users was 59.8 (8.6) years; 5 users had a stroke and 6 had Parkinson disease. The HCP group consisted of 7 speech and language therapists, 3 physiotherapists, 3 occupational therapists, 3 medical staff, 1 nurse, and 1 industry representative. Focus groups were semi-structured and explored previous experiences of telerehabilitation, perceived benefits and challenges, and solutions to overcome these challenges. Focus groups were audio transcribed, and the service user transcript was translated into English. The resulting transcripts were analyzed using thematic analysis.

Results: Overall, participants were positive about the role of telerehabilitation but recommended hybrid delivery, with in-person rehabilitation in the early stages and telerehabilitation in the later stages. In relation to telerehabilitation in Ghana, there were 3 main themes: benefits, challenges or barriers, and implementation. Benefits included the convenience and lower cost for service users, the higher dose of therapy possible, and increased access for people in remote areas. However, challenges included lack of a stable internet connection, cost of phones and data packages, and low levels of literacy. Implementation issues included cultural relevance, information governance, and the platform used to deliver telerehabilitation, with most participants being familiar with WhatsApp.

Conclusions: Telerehabilitation has the potential to be a useful method of delivering rehabilitation to people with neurological conditions in Ghana, especially in a hybrid rehabilitation model with telerehabilitation augmenting in-person sessions. However, many people were unaware of telerehabilitation, and challenges such as a reliable internet connection, cultural relevance, and costs need to be addressed. Clinical trials of low-cost telerehabilitation interventions contextualized to the specific user group are required.

Introduction

The World Health Organization defines rehabilitation as "a set of interventions designed to optimize functioning and reduce disability in individuals with health conditions in interaction with their environment" [1]. They also highlight the significant unmet need for rehabilitation services that is most evident in some low- and middle-income countries (LMICs), where up to 50% of people do not receive the rehabilitation they require [1].

Rehabilitation in Ghana, an LMIC, is provided by the public and private sector and costs between US $5 and $20 per session. Rehabilitation sessions are paid for by the individual or through various national insurance schemes. Even where individuals have insurance, the coverage may be limited and "top-up payments" are required. The duration of neurological rehabilitation can vary between 3 and 12 months depending on the condition, and often, there is a waiting list of 1-2 months.

Numerous barriers to rehabilitation have been cited in LMICs, such as Ghana, including low numbers of therapists, especially in rural locations, services being concentrated in main towns or cities with the majority of the population living rurally, transport issues, costs for appointments, and lack of specialist staff and equipment [2-5].

As well as experiencing barriers to rehabilitation, LMICs are experiencing an increase in life expectancy and greater numbers of people with noncommunicable diseases including neurological conditions [2,6,7]. Although in its early stages, telemedicine is increasingly being explored in LMICs to deliver care to challenging or remote areas. Telerehabilitation, a branch of telemedicine, may provide part of the solution to the increased patient demand coupled with restricted service especially in neurological rehabilitation. Telerehabilitation is defined as the provision of rehabilitation, including physiotherapy, speech and language therapy, and occupational therapy, over distance and, oftentimes, using communication technology [8]. Potential telerehabilitation technologies include telephone and video calls, apps, virtual reality, and robotics [4]. A recent review suggests that the telephone or video is the main media through which telerehabilitation is delivered worldwide [9].

The evidence base for the acceptability, feasibility, and clinical and cost-effectiveness of telerehabilitation for people with neurological conditions is increasing. Several recent systematic and scoping reviews suggest that telerehabilitation improves access to services and is generally well received by patients and therapists, with high adherence to telerehabilitation programs and low adverse events, supporting its safety in practice [10,11]. Evidence of the clinical effectiveness of telerehabilitation for people with neurological conditions is mixed, but overall it is reported to be at least equivalent to standard care [12,13]. There is, however, limited evidence on the cost-effectiveness of telerehabilitation [6,9]. Much of the research in telerehabilitation has been undertaken in high-income countries, with notably fewer studies in LMICs [6,14,15], where the rehabilitation context, as well as the barriers and facilitators to the feasibility, adoption, scalability, and sustainability of telerehabilitation, may be quite different. In terms of neurological conditions, most telerehabilitation research in LMICs has been conducted in stroke [3,14,16].

To influence rehabilitation and improve patient outcomes, technology needs to be adopted into services. There are various models and theories of technology adoption including the Technology Acceptance Model and Self-Determination Theory. Central to these models are the beliefs and attitudes of the users of the technology. In the context of telerehabilitation, only a few previous studies exist on the views and beliefs of therapists and patients in LMICs and beyond [7]; however, these studies tend to be process evaluations of specific telerehabilitation interventions that are being researched and thus are open to selection bias as participants are exposed to the technology under study conditions. Furthermore, although telerehabilitation generally happens at home, there is a recognition that almost no research has sought the views of the patient, carer, or family member—although they have a strong and significant influence on the adoption and success, or otherwise, of telerehabilitation interventions [17].

Telerehabilitation is in its infancy in LMICs, including Ghana; however, to ensure successful adoption, implementation to routine practice, and scalability, it is important to understand the views of health care professionals (HCPs), service users (patients), and their carers. Therefore, the aims of this study were to investigate the views of HCPs involved in neurological rehabilitation, service users with a long-term neurological condition, and the carer or family member of someone with a long-term neurological condition in terms of previous experience of telerehabilitation, the perceived potential benefits, the potential challenges, and possible solutions to overcome these challenges in Ghana.

Methods

Study Design

Focus groups were used as the method of data collection for this qualitative study, and this paper is presented in line with the Consolidated Criteria for Reporting Qualitative Research guidelines. Separate focus groups were conducted: one for service users and carers or family members and another for HCPs and IT industry representatives. Both focus groups were conducted in person in Komfo Anokye Hospital in Kumasi, Ghana, with HCPs given the option of joining remotely via teleconference. The service user focus group was conducted in person to ensure that those who did not have technology or technology skills could contribute, to encourage engagement, and to support those with communication problems. For service users and carers traveling, expenses were covered and both groups were provided with lunch at the end of the focus group. The service user and carer focus group was conducted in Twi,

the local language, and the HCP focus group was conducted in English.

Inclusion Criteria

Inclusion criteria for the stakeholder group were HCPs (physiotherapists, occupational therapists or speech and language therapists, or medical staff) with experience of working in neurological rehabilitation in Ghana or staff with expertise in commissioning or delivering health services (commissioner or industry expert) and able to speak and understand English and attend the focus group either in person or via teleconference (Zoom).

Inclusion criteria for the service users were people with a neurological condition such as stroke, Parkinson disease (PD), or spinal cord injury and able to travel to the venue. Carers or family members had to have experience of caring for someone with a neurological condition and able to travel to the venue.

Recruitment

A convenience sample of service users, who fulfilled the inclusion and exclusion criteria, was identified from two sources: (1) members of a support group for people with PD were telephoned by the research coordinator (SOA) and (2) stroke survivors attending a neurology clinic at Komfo Anokye Hospital 2 weeks before the focus groups were approached by the research coordinator. The study was explained to potential participants, and if they were happy to take part, they were given the details of the focus group date, time, and venue. They were given the option of bringing a carer or family member to the focus group although that was not a requirement. A convenience sample of HCPs was recruited from the professional networks of the research team. They were contacted through email or WhatsApp groups and asked to take part. If they were interested, study information was emailed to them with details of the date, time, and venue of the focus group, or if attending via Zoom, a link was shared. Consent was taken from all participants at the start of the focus group.

Focus Groups

A focus group schedule was prepared for each of the 2 focus groups including main questions and prompts. For both groups, the questions were related to their experiences of telerehabilitation, perceived potential benefits of delivering or receiving rehabilitation via telerehabilitation, perceived potential challenges or difficulties, and suggestions for overcoming these difficulties.

The service user and carer focus group was facilitated by the male research coordinator in the room (SOA). This facilitator had been involved in recruitment of participants, had experience of conducting focus groups, and spoke the local dialect (Twi). The HCP focus group was facilitated by a senior female researcher from the United Kingdom (LP) via Zoom. This facilitator was a physiotherapist, with experience in telerehabilitation research and facilitating focus groups. She did not know any of the participants except those within the research team. The research team was introduced, and participants were provided with background information on the purpose of the study. The service user focus group lasted approximately 1 hour and the HCP group 1.5 hours. Both were audio-recorded and transcribed verbatim in the language in which they were conducted. The transcript of the service user and carer focus group was translated into English by professional transcribers from the University of Energy Sunyani, Ghana, and checked by the research team for accuracy. In addition, research team members made field notes during and after the focus groups.

Analysis

Thematic analysis was the method of data analysis using the 6 phases outlined by Braun and Clark [18], including data familiarization, generation of initial codes, generation of themes, review of themes, definition of themes, and writing the report. Initial coding of the transcripts was completed by one researcher (KT) who had no previous relationship with study participants and checked by a second researcher (LP) who had conducted the HCP focus groups. Themes were derived from the data, and initial themes were presented to the research team (in verbal, written, and diagrammatic form), which were further refined after feedback and discussion. Thematic analysis was undertaken using Microsoft Word (Microsoft Corporation) with documentation shared at each stage ensuring transparent recording of the data analysis process with the research team. Thematic analysis of each focus group took place separately before a final round of analysis integrated these together. Further feedback was provided by the research team before the final themes were confirmed.

Ethical Considerations

Ethical approval was received from the Ethics Committee of Kwame Nkrumah University of Science and Technology, Kumasi, in December 2022 (reference CHRPE/AP/822/22), and all participant data were deidentified. Informed consent was provided by all participants. Travel expenses were covered and lunch was provided for participants who attended in person focus groups.

Results

Characteristics of Participants

A total of 13 service users agreed to take part in the focus group; however, 2 were unable to attend on the day of the focus group, so overall 11 service users (9 male users) took part (Table 1). Service users had a mean (SD) age of 59.8 (8.6) years; 6 lived in an urban location, and 5 in a semiurban location. Six service users had PD, and 5 had had a stroke. The mean (SD) age of those with stroke was 53 (8.3) years, and the mean (SD) time since stroke was 4 (1.6) years. In contrast, the mean (SD) age of those with PD was 65.5 (2.5) years, and they had had the condition for a mean (SD) of 3.8 (2.1) years. In addition, 9 carers took part (4 male carers), and their mean (SD) age was 38.4 (8.6) years. They had a variety of occupations and had been caring for people with PD (n=6) and stroke (n=3) for a mean (SD) of 3.4 (2.2) years (Table 1).

Service users had different prior exposure to telerehabilitation, both synchronous and asynchronous. One had participated in a previous trial of an app that delivered an individualized rehabilitation program remotely supervised by a therapist [14],

some had received rehabilitation plans via WhatsApp to undertake without supervision, and others had no previous experience of telerehabilitation.

Table 1. Demographic details of service users (n=11) and carers (n=9).

Demographic	Value
Service users (n=11)	
Sex, n	
Male	9
Female	2
Age (years), mean (SD)	59.8 (8.6)
Diagnosis of service user, n (%)	
Stroke	6 (55)
Parkinson disease	5 (45)
Time since diagnosis (years), mean (SD)	6.0 (3.9)
Residence, n (%)	
Urban	6 (55)
Semiurban	5 (45)
Rural	0 (0)
Carer or significant other (n=9)	
Sex, n	
Male	4
Female	5

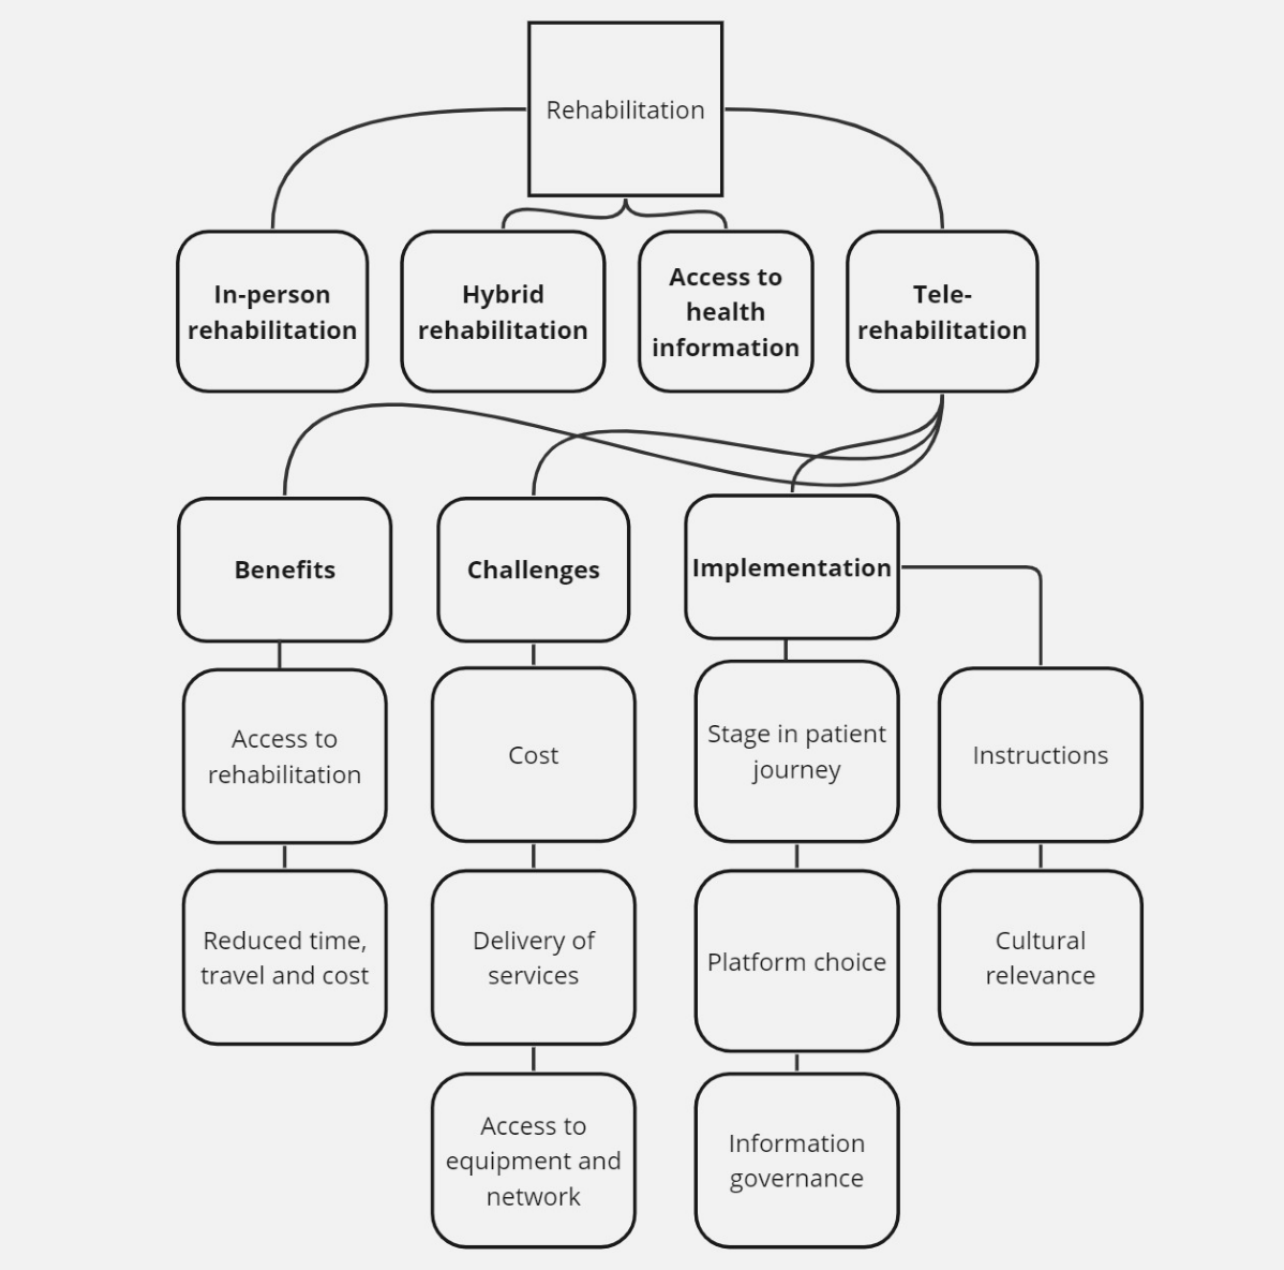
Seamstress	1 (11)
Student	1 (11)
Residence, n (%)	
Urban	5 (56)
Semiurban	4 (44)
Rural	0 (0)

Eighteen stakeholders took part in the focus groups (10 female and 8 male). In total, 7 speech and language therapists, 3 physiotherapists, 3 occupational therapists, 2 neurologists, and 1 specialist physician, 1 nurse, and 1 person from industry participated. Eleven of the participants were aged 30-39 years, 3 were aged 20-29 years, and 3 were aged over 40 years. They had been in their current post for a mean of 4.8 (SD 3.3) years, and all worked in urban locations, most in the 2 main cities of Accra and Kumasi.

Analysis of the focus groups resulted in the following themes and subthemes (Figure 1).

Figure 1. Focus group themes.



Rehabilitation Services

Service users identified different ways of accessing rehabilitation services, in-person services, telerehabilitation, and hybrid (a combination of in-person and remote services). Service users also expressed a need for increased awareness of the differing ways to access rehabilitation services and a need for reliable health information.

In-Person Rehabilitation

Service users valued in-person rehabilitation for the purpose of monitoring their rehabilitation progress and receiving feedback on this.

> *If there is an improvement, the doctor or the health facility that will tell you to either reduce or increase some aspect of your rehabilitation so that the body will recover.* [Service user]

It was however acknowledged that in-person rehabilitation had limitations particularly when there was a large demand for

services, which could result in long queues at the health care facility, or the feedback received was not as hoped.

> *I stopped the rehab because of waking up early to join a queue.* [Service user]
>
> *One physio teasingly told me that my rehab has taken too long which downed my emotion and that made me stop coming for physio.* [Service user]

Hybrid Rehabilitation

Some service users and carers expressed a preference for a hybrid model of rehabilitation (in-person and telerehabilitation), which they had previously found useful.

> *I feel like if we combine the two it will help, both should go hand in hand.* [Service user and carer]
>
> *Both, because sometimes you may miss or do certain procedures wrongly without knowing but going to the hospital you will be able to know the exact procedure, then you can go ahead and practice at home.* [Service user]

Access to Health Information

A need for access to reliable health information was highlighted by both patients and carers with the potential for technology to be used as means of distributing information. Concern was expressed at misinformation, which hindered treatment such as medication use.

> *There should be associations to broadcast to people and to serve as guidance for others to follow.* [Service user and carer]
>
> *I have seen that everything is going on well here, but the information given is very low and because of that most people depend on herbal medicines.* [Service user and carer]

Telerehabilitation

Service users and carers who had experienced telerehabilitation found this to be a helpful way to access services and were happy to recommend this method of service delivery to others.

> *Yes, (I would recommend it) because I have tried and tested and it really helped me.* [Service user and carer]
>
> *We the caregivers also go through the same stress as the patients, so our experiences shows that the tele-rehab is very good.* [Carer]

For others, this was a novel way to access rehabilitation services, which, they thought, would be of benefit, indicating that they would be happy to try this in the future.

> *Gives me hope that even if a person gets any neurological disorder, the telerehab is there to help them get back their strength.* [Service user and carer]

However, there was a lack of awareness of telerehabilitation with service users, suggesting that further awareness raising was needed as well as ensuring that access was available throughout Ghana.

> *Many Ghanaians are not aware of the telerehab and so it should be publicised through TV and other media groups.* [Service user and carer]
>
> *Telerehabilitation should be extended to clinics to enhance easy access. It should not be in the big hospitals alone.* [Service user and carer]

A range of telerehabilitation services were described by service users who had experienced stroke (including those with aphasia), those with PD, and those with tinnitus or balance issues. These services included checking rehabilitation progress or receiving speech and language therapy sessions. In addition, service users sought further follow-up and reminders through telerehabilitation.

HCPs also had a range of experiences using telerehabilitation ranging from no involvement to using telerehabilitation for a range of rehabilitation purposes including teaching exercises, promoting engagement in activities, conducting hearing assessments, sending intervention messages and information, balance re-education, and reviewing videos to direct parent-led rehabilitation.

Benefits of Telerehabilitation

Reduction in Travel, Time, and Associated Costs

A range of benefits were identified by service users, carers, and HCPs, including a reduction in travel, which made rehabilitation more convenient, easier to access, less stressful, accommodated other caring responsibilities, and was more affordable. Less time was also spent waiting for rehabilitation once patients and carers arrived at the rehabilitation unit.

> *It helped because having her come all the way to the clinic and the child who didn't sit and fussy two hours was also time that was solved with tele-therapy.* [HCP]
>
> *It reduces financial costs to the hospital and the stress involved in sitting in a trotro (car).* [Service user and carer]

Increased Access to Rehabilitation

HCPs identified that they were able to access service users who lived some distance away (including visual access to the home environment) increasing access and relevance of the rehabilitation services delivered. This provided the opportunity for further rehabilitation, increasing the intensity, consistency, and adherence to rehabilitation offered.

> *with the in-person you're scheduled to come let's say two or three days a week but with telerehabilitation, even if you want to do it every day as far as the resources are there, you can do it every day. It also allows you to do it more frequently and over a more sustained period of time. That's one of the benefits.* [HCP]
>
> *It can help with intensity because the more we meet them online we can achieve our goals. It is easy to find your therapy with more therapy sessions without having to move from one location to another. You sit in the comfort of your home and have more therapy*

> *sessions within the scheduled period but with a cost-effective system.* [HCP]

HCPs also saw the benefits of using devices such as mobile phones as a repository for information. This provided service users with a reminder of their rehabilitation exercises.

> *Most patients forget the therapy exercise we do for them so probably videoing it and saving for patients can help them do it at their leisure time.* [HCP]

HCPs reported that developing new ways of delivering rehabilitation services encouraged them to be creative in their approach including delivering content in a range of local dialects with the potential of developing new rehabilitation services or using technology to measure changes in service user knowledge for example.

> *I would like to add it makes you creative as a professional because you look for other means of making it fun with telerehabilitation in order to suit your client. It brings out creativity in you.* [HCP]
>
> *I think it will give the opportunity to assess the clients' environment for recommendations for possible adaptations to enhance function because when the person comes in-person, they may describe the home environment and we don't know exactly how it looks but through telerehab with video conference or picture you can see how the environment really looks like for recommendations for the adaptations.* [HCP]

Rehabilitation Progress Using Telerehabilitation

Service users highlighted the progress that they had made with their rehabilitation delivered using telerehabilitation, which included improvements in speech, arm movements, activity levels, and independence in activities.

> *It is through the tele-rehab that I am able to lift my hand today. It really helped me.* [Service user]
>
> *I'm forever grateful for the physios because up till date, they still call me and they helped in so many ways.* [Service user]

Challenges of Telerehabilitation

Challenges of delivering telerehabilitation were identified by service users, carers, and HCPs including access to equipment and availability of a reliable internet connection, the cost of data packages, and challenges to rehabilitation delivery.

Equipment and Network Access

Availability of equipment and the requirement of a reliable network needed for telerehabilitation were highlighted as a barrier. Most service users in the focus group had access to mobile phones (including smartphones that access the internet), but not all did. Challenges with unreliable internet connections meant therapists often prepared alternatives such as printed exercise sheets, sending SMS text messages to promote engagement, watching videos offline, use of images (rather than videos), or switching platforms seeking a better connection. At times, however, the connection was so poor that therapy sessions were abandoned and rescheduled or therapists advised returning to in-person rehabilitation. For some service users, this meant finding other solutions including referral to local therapists to access rehabilitation.

> *Only 35% of our patients said that they own a smartphone and even of that 35% it's not necessarily their own but there is a smartphone in the house. It's not as if the smartphone belongs to them.* [HCP]
>
> *The network decided to fail all of us. When we call again, we can't hear anything. We used other platforms FaceTime, other things, but the network just wouldn't channel us until we had to put the whole therapy to an ending try to refer to someone closer to him.* [HCP]
>
> *In terms of connectivity, we can record the videos, store them, and send them so that when the connectivity improves the person can use the stored videos to be able look back on their exercise.* [HCP]

Financial Cost

Those who did have access to smartphones acknowledged that there was a financial burden of purchasing packages or "bundles" for calls and network access. Some rehabilitation services that required use of additional equipment provided this, but not all did.

> *Most of us are retired so money is hard to come by so it will really help us (if the equipment and data package are provided).* [Service user]

Rehabilitation Delivery

Use of telerehabilitation meant that therapists had to find new ways of delivering therapy services for an individual rather than their usual in-person service that included group therapy, acknowledging that not all service users had the digital literacy skills or ability needed to use technology.

> *because if I am at the physiotherapy department I can supervise maybe 4 or 5 patients simultaneously; this one is doing this, this one is doing that, I can just observe them but in telerehab they have to do one on one supervision so that may also eventually reduce the number of participants or patient they can attend to at a time if it is ongoing supervision they have to do.* [HCP]
>
> *Sometimes they are not very tech savvy so we need to see them in-person. And we have had some patients try it but most are not tech savvy so we haven't been able to expand this to all our clients.* [HCP]
>
> *Another barrier I was thinking about was that if the client has multiple deficits so maybe visual needs and other possible deficits, I think that may impact teletherapy.* [HCP]

Other challenges with delivery of rehabilitation, such as location or timing of therapy sessions, the move toward carer involvement, and the type of therapy session being delivered, were highlighted.

> *Mum and I decided to have teletherapy instead [for the child] because they were coming from far. But each time I book them, I give them a time. But each*

> *time I am ready to have the teletherapy the child might be asleep or would be at a place where it is uncomfortable place to have teletherapy.* [HCP]
>
> *So let me add one more barrier, with the issue of adaptive devices especially if there are no caregivers who really understand or who can be trained on how to retrain the patient on how to use the assistive device it becomes difficult Then unless the patient comes in-person for you to maybe fabricate or measure their assistive device and then train the patient in how to use it.* [HCP]

Implementation of Telerehabilitation

Stage in the Patient Journey

Service users had a range of opinions on what stage in their rehabilitation journey they preferred to receive telerehabilitation, from the initial stages of diagnosis to using telerehabilitation following a period of in-person rehabilitation.

> *Initial stages of my condition.* [Service user]
>
> *At the initial stages, you should visit the hospital for physio then later, join the telerehab.* [Service user and carer]

Platform of Choice

WhatsApp was the preferred platform although Microsoft Teams, Zoom, and FaceTime were also used. Ease of use was important with WhatsApp reported to be familiar with options for low data consumption.

> *Some find zoom cumbersome it's difficult for them to manage their way through zoom and then having meetings with them, but WhatsApp is just like having a call. I just call you; you see me on the video and then whatever we need to, it's easier using that platform compared to the other platforms. I used WhatsApp because I think it is easier over here and with data consumption, you know it has the option for you to select low data mode where the streaming is easier for the patient.* [HCP]

Information Governance

Integrating use of personal technology (such as mobile phones) into therapy did cause concern for information security particularly when sharing media such as videos.

> *I have been thinking about ever since I started working with the clients that I work with. Recently I lost the password to my laptop, and I was thinking there might be a case where a third party has to come in. My phone gets called or any other thing, it's just confidentiality how is it handled? because a third party will have to come in and help me unlock or do something to my phone Videos, I have a lot of videos of the same person doing mostly I delete them, but I have been thinking about situations where I might forget, or something would happen that another person had access to the videos. So sometimes you know a client may feel uncomfortable sharing videos across, because they don't know where that would end so that's one of the barriers I think.* [HCP]

Instructions for Use

Participants felt that further instructions or information was needed to take full advantage of rehabilitation delivered via technology with access to videos requested.

> *I only had to follow the instructions on the phone.* [Service user and carer]
>
> *I feel like the physiotherapists should be involved in the video demonstrations. There should be visual demonstration videos so the patient can see the physio demonstrating the exercise and imitate it correctly.* [Service user and carer]

Cultural Relevance

It was highlighted that many of the current telerehabilitation exercise videos featured White individuals with instructions in English. To increase the cultural relevance of the materials, videos should be in a local dialect featuring Black individuals completing exercises.

> *It should be conducted in our local dialect Twi to be specific.* [Service user and carer]
>
> *Language shouldn't be an issue if we stick to the local dialect. But using English it could be a challenge...another one has to do with the videos where a white person is involved, it makes it difficult for the most clients to understand but it can solve by introducing blacks in such videos.* [HCP]

Discussion

Principal Results

Participants from both focus groups were overall positive in terms of telerehabilitation for people with neurological conditions in Ghana but identified a number of challenges. The conceptual framework for sustainable eHealth in resource-limited countries proposed by Fanta and Pretorius [19], comprising technological, social, economic, and organizational factors, will be used to discuss the findings of the focus groups.

In terms of *technological* factors, one of the main challenges was the lack of a stable internet connection to conduct a telerehabilitation session. This has been identified as one of the main barriers to successful implementation of telerehabilitation in many others studies in LMICs [4,14,15,20], especially in relation to the transfer of images or videos. There was also an appreciation that not all service users had access to a smartphone, as previously reported [5,16]. Interestingly, only 1 therapist raised concerns about the security of service user data particularly when videos of service users completing tasks are sent. In terms of the technology used, this is one of the first studies to report that WhatsApp was the preferred platform for delivering telerehabilitation as it is commonly used in Ghana by both HCPs and service users, so people are familiar with its use and it also has an option for a low data mode. Previous studies of telerehabilitation in LMICs have provided patients

with videos to play in a video player [21] or have used Skype [15].

Social factors were most commonly raised within the focus groups. Participants overall had positive views on telerehabilitation but also discussed the advantages or preferences of in-person rehabilitation especially with regard to the HCP monitoring their progress. Previous research particularly in relation to patients receiving speech and language therapy also reported good satisfaction with telerehabilitation interventions, but many preferred in-person therapy where there was better eye contact between the patient and the therapist and it was easier to understand facial expression [15,22].

Participants in this study however recognized that there were many barriers to service users accessing in-person rehabilitation. Service users also highlighted the lack of awareness of telerehabilitation services in Ghana.

Like previous studies of telerehabilitation generally [11,13,20] and specifically in relation to LMICs [3,23], participants reported a number of benefits to telerehabilitation especially the convenience, requiring less travel time and reduced travel cost. Some HCPs raised that telerehabilitation improved access to rehabilitation services for patients, especially those who stayed a distance from the clinic. In Ghana, up to 43% of people after stroke access herbal medicines [24], as was raised by 1 person in the focus groups, for which there is little or no efficacy data. Improving access to rehabilitation may reduce the reliance on herbal medicine for some patients.

However, there were also some negative aspects. Not all service users had a smartphone, and furthermore, low levels of literacy and digital skills were barriers to implementing telerehabilitation in line with previous papers [3,4,25]. Although there were examples of some apps being used by therapists, they were not felt to be culturally relevant for the Ghanaian context as they were in English rather than the local dialect and tended to have White people (generally Americans or Europeans) demonstrating the activity, which had the potential to reduce engagement of service users. Odetunde et al [21] developed a telerehabilitation video solution for patients with stroke in Nigeria, delivered both in the local language Yoruba and in English, and this was positively received by participants. To promote uptake and adherence, future development of telerehabilitation interventions should consider the local language and other contextual issues [4,10].

In terms of *economic factors*, as discussed above, not all service users had access to a smartphone, and the financial implications of requiring such a phone and data package were a barrier for many people. Sarfo et al [16] reported that only 35% of their respondents owned a smartphone although 80% had a family member who did. A 2020 household survey of information and communication technology use in Ghana reported that 47.9% of the population had a basic phone and 46.1% had a smartphone; however, in rural areas, 61.3% of people had a basic phone and only 28.1% had a smartphone [26]. However, the figures suggest that family or carers may need to be actively involved for telerehabilitation to be implemented, especially in rural areas of Ghana and in other LMICs. On the positive side, telerehabilitation reduced costs and time required to travel to in-person appointments. In terms of clinical effectiveness, telerehabilitation is variable with some evidence in support of telerehabilitation and other evidence suggesting that it is not superior to conventional care [13,27]. Although there are associated costs, even if it is not superior, the convenience, reach of services, and time-saving aspects would support its further development; however, cost-effectiveness analyses of telerehabilitation for neurological conditions generally and specifically related to resource-limited settings are required [6,9].

Organizational factors were generally related to the delivery of the telerehabilitation interventions. Telerehabilitation was felt to be a positive development that could address long waiting times and high demand on services. A number of service users with stroke and PD had used telerehabilitation with examples of telerehabilitation delivery across different allied HCP groups: physiotherapy, occupational therapy, and speech and language therapy. Service users however felt that they would have liked more instructions on how to use telerehabilitation.

HCPs reported using telerehabilitation for undertaking patient assessments, sending information to service users, and receiving videos of patient progress. Neurological rehabilitation often involves intensive therapy with highly repetitive, task-specific exercise to optimize neuroplastic changes in the central nervous system [12]. A novel finding of this study was that therapists reported that telerehabilitation, in this resource-limited setting, allowed more intensive and consistent therapy than would be possible in person and which importantly facilitated increased adherence and improved outcomes. An additional novel finding was that therapists felt that new ways of delivering therapy encouraged them to be more creative in their approach.

The negative aspects considered under organizational factors were the location and timing of telerehabilitation sessions that were arranged in advance; however, when the appointment time came, the service user was not available, or it was not appropriate to complete the session. This often meant that therapists had to have alternative plans in place should that occur. There was also an appreciation that some activities, such as providing assistive devices, required to be done in person.

Strengths and Limitations

This research had a number of strengths. The views of service users and carers, HCPs, and other stakeholders on telerehabilitation in Ghana were sought directly. Aljabri et al [5] recommended that future research should explore the views of HCPs from different disciplines, which we did, including a range of HCPs such as occupational therapy and speech and language therapy, professions seldom included in the telerehabilitation literature in LMICs—perhaps due to their relatively small numbers compared with, for example, physiotherapy. This is also the first study to include participants with PD from LMICs, although there are previous reviews of telerehabilitation in PD but not in an LMIC context [27]. To be as inclusive as possible, the service user and carer focus group was conducted in the local language. The use of teleconferencing for the stakeholder focus group allowed a wide geographical spread of participants from across Ghana. However, this research also had a number of limitations. Although traveling expenses

and refreshments were provided, service users and their carers had to be able to travel to the hospital to take part in the focus group, possibly biasing the sample to a local, urban dwelling and less disabled group. Also, many had had experience of using telerehabilitation, so perhaps they did not represent the views of most people with neurological conditions in Ghana; however, it was important that they were able to share their experiences. Also, none of the study participants resided in a rural setting, thus limiting the transferability of the views captured in this study.

Conclusions

This is the first study to elicit the views of service users, carers, and HCPs of telerehabilitation for people with neurological conditions in a resource-limited setting of Ghana. The focus group findings overall demonstrated that service users, carers, and HCPs had positive views and experiences of telerehabilitation, especially the convenience and lower cost for service users and the consistency and higher intensity of therapy possible, with some negative aspects including lack of a stable internet connection, cost of phones and data packages, and low levels of literacy. Overall, the findings suggest the need for future research of the clinical and cost-effectiveness of lost cost telerehabilitation interventions for people with neurological conditions, taking into account the local context in Ghana and other LMICs. Telerehabilitation in Ghana is currently not covered within the National Insurance system; however, these findings support the development of telerehabilitation in Ghana with suggestions for future implementation and scale.

Acknowledgments

We would like to thank all the participants for their active contribution and professional transcribers from the University of Energy Sunyani Ghana transcribing the focus group recordings. This work was supported by the Academy of Medical Sciences Global Challenges Research Network Grant (Ref GCRFNGR5\1278).

Abstract

Background: The development of digital applications based on behavioral therapies to support patients with knee osteoarthritis (KOA) has attracted increasing attention in the field of rehabilitation. This paper presents a systematic review of research on digital applications based on behavioral therapies for people with KOA.

Objective: This review aims to describe the characteristics of relevant digital applications, with a special focus on the current state of behavioral therapies, digital interaction technologies, and user participation in design. The secondary aim is to summarize intervention outcomes and user evaluations of digital applications.

Methods: A systematic literature search was conducted using the keywords “Knee Osteoarthritis,” “Behavior Therapy,” and “Digitization” in the following databases (from January 2013 to July 2023): Web of Science, Embase, Science Direct, Ovid, and PubMed. The Mixed Methods Assessment Tool (MMAT) was used to assess the quality of evidence. Two researchers independently screened and extracted the data.

Results: A total of 36 studies met the inclusion criteria and were further analyzed. Behavioral change techniques (BCTs) and cognitive behavioral therapy (CBT) were frequently combined when developing digital applications. The most prevalent areas were goals and planning (n=31) and repetition and substitution (n=27), which were frequently used to develop physical activity (PA) goals and adherence. The most prevalent combination strategy was app/website plus SMS text message/telephone/email (n=12), which has tremendous potential. This area of application design offers notable advantages, primarily manifesting in pain mitigation (n=24), reduction of physical dysfunction (n=21), and augmentation of PA levels (n=12). Additionally, when formulating design strategies, it is imperative to consider the perspectives of stakeholders, especially in response to the identified shortcomings in application design elucidated within the study.

Conclusions: The results demonstrate that “goals and planning” and “repetition and substitution” are frequently used to develop PA goals and PA behavior adherence. The most prevalent combination strategy was app/website plus SMS text message/telephone/email, which has tremendous potential. Moreover, incorporating several stakeholders in the design and development stages might enhance user experience, considering the distinct variations in their requirements. To improve the efficacy and availability of digital applications, we have several proposals. First, comprehensive care for patients should be ensured by integrating multiple behavioral therapies that encompass various aspects of the rehabilitation process, such as rehabilitation exercises and status monitoring. Second, therapists could benefit from more precise recommendations by incorporating additional intelligent algorithms to analyze patient data. Third, the implementation scope should be expanded from the home environment to a broader social community rehabilitation setting.

Introduction

Knee osteoarthritis (KOA) is a prevalent musculoskeletal disorder that ranks among the primary contributors to disability [1,2]. Possible long-term ramifications encompass diminished levels of physical activity (PA), the development of body dysmorphic disorder, compromised sleep patterns, depressive symptoms, and the onset of disability [3,4]. In recent times, there has been a notable shift in the approach to treating KOA, with a greater emphasis on nonpharmacologic interventions. This change is supported by evidence indicating that nonpharmacologic treatments are more effective in delivering sustained symptom alleviation and in delaying or even preventing functional deterioration [5,6]. The primary nonpharmacological interventions for KOA include educational programs, PA interventions, and weight management strategies [3]. Patient initiation and adherence to these treatments are essential factors for achieving effective symptom control [7]. Traditional nonpharmacological interventions, however, require professional guidance to achieve the desired results, which is associated with high costs and unequal health care resources [8].

Digital health interventions have the potential to offer widespread, cost-effective, readily available, and easily expandable patient education and self-management interventions for individuals with KOA [9-11]. Several research investigations have been carried out to substantiate their efficacy in rehabilitating musculoskeletal problems. For instance, digital health interventions have been found to be successful in decreasing pain, improving functionality, and promoting the self-management of musculoskeletal pain syndromes [12,13]. Significant increases in adherence have also been observed throughout the mid-term follow-up [14]. These systematic evaluations have focused on summarizing various techniques for digital health or intervention effectiveness in relation to health outcomes [15,16]. However, digital interventions do not always provide desirable outcomes. Providing guidance on the ideal dosage required to achieve significant benefits or disclosing the elements of effective digital health treatments is challenging owing to the variations in interventions and the insufficient information in interventions [15]. In recent years, it has been discovered that theory-driven interventions can help organize the content of digital interventions, resulting in improved health outcomes [17-19].

A growing number of studies have used the behavioral psychology theoretical framework in digital format [20]. Compared to generic digital interventions, behavioral therapy-based digital interventions are significantly more effective at relieving pain, improving physical dysfunction, and increasing self-efficacy in patients with KOA [21,22]. Physiotherapists use scalable interventions along with some digital tools to enhance treatment adherence [16,23]. The concept of behavioral therapy (BT) incorporates various therapeutic approaches, including behavioral change techniques (BCTs), dialectical behavioral therapy (DBT), and cognitive behavioral therapy (CBT). It has been used to aid complex intervention designs that include facilitating the adoption of behavior change, promoting behavioral compliance, sustaining behavioral change, and preventing behavioral relapse [24]. Previous studies have employed BCTs in combination with digital interventions among individuals with musculoskeletal pain [25]. These studies have reported the efficacy of such interventions in facilitating the transition of patients from a sedentary lifestyle to an active one [21,22,26]. Multiple studies have demonstrated that the integration of CBT with standard care yielded noteworthy outcomes in the management of KOA. Specifically, the implementation of CBT interventions resulted in a considerable reduction in pain levels and an improvement in insomnia symptoms when compared to the utilization of standard care alone, as indicated by previous investigations [27,28].

Currently, there are evaluations investigating the rehabilitative impacts of digitalization in KOA and highlighting the significance of behavioral theory in some applications [19]. Nevertheless, there is a shortage of thorough exposition of the behavioral theory in digital applications, as well as an absence of an assessment of the suitability of these applications from the patient's point of view. Thus, this review offers a methodical and thorough examination of digital applications rooted in behavioral therapy. It shifts the focus of digital applications from mere practical usability to providing support for behavioral change theories. Additionally, it meticulously analyzes the functional reasoning behind various products, thereby serving as a comprehensive guide for designing future digital interventions. Hence, the objectives of this review are to (1) provide a concise overview of the existing landscape of digital behavioral therapy applications for individuals diagnosed with KOA and examine the potential of digital applications in augmenting the rehabilitation process for KOA patients, and (2) present a comprehensive analysis of the underlying psychological theories, fundamental mechanisms, design methodologies, typical attributes, efficacy of treatment outcomes, and patient preferences pertaining to this particular mode of recovery intervention.

Methods

Registration

This review has been registered in the International Prospective Register of Systematic Reviews (PROSPERO; registration number: CRD42023430716). Furthermore, the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines have been applied (Multimedia Appendix 1) [29].

Search Strategy

Literature searches were conducted in 5 databases: Web of Science, Embase, Science Direct, Ovid, and PubMed. The selection of these databases was based on their provision of comprehensive access to full-text journals and conference

proceedings pertaining to prominent conferences and meetings focused on digital technology and medicine.

To locate relevant articles, we conducted a search by filtering papers based on 3 primary categories of MeSH (Medical Subject Headings) terms: "Knee Osteoarthritis," "Behavioral Therapies," and "Digitization." According to MeSH terminology, "Behavioral Therapy" is divided into "Behavioral Therapy," "Cognitive Behavioral Therapy," and "Dialectical Behavioral Therapy." In this review, in order to understand the categorization of all behavioral therapies, we collected information on the subcategories of these 3 categories related to behavior. In relation to the subject of "digital" content, we gathered relevant material from the report by Safari et al [19] on digital literature, encompassing topics, such as "Telehealth," "Email," "Smartphone," "Computer Systems," "Digital Technologies," and "Mobile Applications," and other forms of digitization. Table 1 illustrates sample search strategies used for the PubMed digital library. The article titles, keywords, and abstracts were searched. Similar search strategies were applied to the remaining 3 databases. Relevant articles published between January 2013 and July 2023 were gathered. We included journal papers and peer-reviewed conference proceedings. Only articles written in English were considered.

Table 1. Literature search strategy.

Eligibility Criteria

The authors DZ and JZ were assisted in the literature search by an experienced librarian well versed in medical database searching. This literature review was guided by the question of how behavioral therapies can be integrated with digital applications in the rehabilitation of patients with KOA. On this basis, we anticipated that this review would (1) generalize and summarize the digital applications used in behavioral therapy, and (2) describe the overall research status and research trends of these digital applications.

Inclusion Criteria

The inclusion criteria were as follows: (1) adult participants (age ≥18 years) with KOA diagnosed by self-reported symptoms or imaging; (2) patients had access to digital applications; (3) any form of intervention or treatment based on the inclusion of at least one behavioral treatment was delivered through any digital application (eg, website or app) within any time frame; and (4) the described interventions were compared to waiting list control (no intervention) or alternative (standard) delivery modalities (eg, face-to-face approaches, classroom-based approaches, and printed materials or handouts), nondigital self-management interventions, and noninteractive digital interventions (eg, web pages with flat copies).

Exclusion Criteria

The exclusion criteria were as follows: (1) patients with KOA were not included; (2) nondigital interventions were assessed; (3) behavioral therapies were not included; (4) research protocols, reviews, conceptual articles, case studies or discussion papers, and conference abstracts; (5) market research; (6) digitization was not designed for the recovery process; (7) text was not written in English; and (8) duplicate reports of the same study from different sources.

Data Extraction

Data relevant to the purpose of the study were extracted independently by the authors MW, WZ, and BC, and any misunderstandings and disagreements were resolved through negotiation. Extracted data included study context details, study population, and digital application details. In more detail, the template included the following categories: (1) basic information (author, year, origin, study population, sample size, presence of a physiotherapy intervention, and duration of the intervention); (2) digital application details (digitalization of behavioral therapy, interactive device function, study outcomes, and application deficiencies); and (3) type of study (randomized controlled trial, cohort experiment, experimental protocol, and qualitative study).

Quality Assessment

The Mixed Methods Assessment Tool (MMAT) was used to evaluate the methodological quality of the included studies [30]. This tool was initially created in 2006 through a comprehensive analysis of systematic evaluations that integrated qualitative and quantitative evidence. In 2018, a revised version of the MMAT was developed by assessing its usefulness, reviewing key assessment tools in the literature, and conducting a modified e-Delphi study involving methodology experts to determine the essential criteria (Multimedia Appendix 2). The MMAT

evaluates the caliber of research employing qualitative, quantitative, and mixed approaches. The primary emphasis is on methodological standards, which encompass 5 fundamental quality criteria for 5 distinct study designs: (1) qualitative, (2) randomized controlled, (3) nonrandomized, (4) quantitative descriptive, and (5) mixed methods.

Results

Overview

Figure 1 provides a summary of the outcomes at various phases of article selection. The search results of the databases are provided in Multimedia Appendix 3. Based on the search strategy, 2975 articles were found initially, and 2507 articles remained after title and abstract screening and removal of duplicates. Next, full-text articles were chosen based on the inclusion and exclusion criteria. We included a total of 131 articles explicitly related to digital behavioral therapy for KOA. Moreover, 4 articles were identified following a manual search of the references for articles that were cited. Final consideration was given to 36 articles for systematic evaluation (Table 2).

[a]KOA: knee osteoarthritis.

[b]HOA: hip osteoarthritis.

[c]OA: osteoarthritis.

[d]Data not available.

[e]TKR: total knee replacement.

[f]N/A: not applicable.

[g]MD: musculoskeletal disorder.

Methodological Quality

Among the included studies, 12 met 100% of the quality assessment criteria, 15 fulfilled 60%-80% of the quality assessment criteria, and 2 met 40% of the quality assessment criteria (Multimedia Appendix 4 [11,21,22,31-63]). The remaining 7 studies could not be evaluated for their quality owing to the absence of results. Nevertheless, the application description portion involved in the studies was highly valuable for analysis.

Digitalization of Behavioral Therapy

Behavior Change Therapy

The majority of digital applications for KOA rehabilitation are based on BCTs. BCTs (achieving objectives, setting goals, restructuring beliefs, and inducing acceptance) are applicable to addressing the central issues of initiating and maintaining PA [64]. The primary categories of BCTs used in the reviewed studies were based on the V1 Taxonomy of Behavior Change by Michie et al [65], which was devised by behavior change researchers [66]. The taxonomy comprises 93 distinct BCTs

organized into 16 hierarchical structures and has been extensively used in the literature on behavior change (Table 3): (1) goals and planning; (2) feedback and monitoring; (3) social support; (4) shaping knowledge; (5) natural consequences; (6) behavioral comparisons; (7) associations; (8) repetition and substitution; (9) outcome comparisons; (10) rewards and threats; (11) regulation; (12) presuppositions; (13) identity; (14) intended consequences; (15) self-confidence; and (16) implicit learning.

Table 3. Behavioral change techniques in digital applications.

Cluster label and component behavioral change techniques	References
1: Goals and planning	
1.1: Goal setting (behavior)	[11,31-37,39-47,49-52,54,58,59,61,62]

1.5: Review of behavior goal(s)	[11,31,33,34,39,43,52]
1.7: Review of outcome goal(s)	[11,34,58,62]
2: Feedback and monitoring	
2.2: Feedback on behavior	[33,42,56,57]
2.3: Self-monitoring of behavior	[31,32,36,39,42,44,47,55,57-59,62]
2.4: Self-monitoring of the outcome of behavior	[33,47,58,61]
2.6: Biofeedback	[11,33-35,37,39,42,47,56-58,61,62]
2.7: Feedback on behavioral outcomes	[32,36]
3: Social support	
3.2: Social support (practical)	[33,59]
3.3: Social support (emotional)	[43,60]
4: Shaping knowledge	
4.1: Instructions on how to perform a behavior	[21,32,42-44,46-50,52-54,56,59,61]
4.2: Antecedents	[32,36,38]
5: Natural consequences	
5.1: Health consequences	[32,36,39,41,42,50,51]
5.4: Self-assessment of affective consequences	[33,43]
5.5: Anticipated regret	[35,39,43,63]
6: Comparison of behavior	
6.1: Modeling of behavior	[42,56]
6.2: Social comparison	[33,53,60]
6.3: Information about others' approval	[32,36,42-44,49,53,58,59,61-63]
7: Associations	
7.1: Prompts/cues	[11,21,22,31,34,37,40,43,45,48,50,54,55,59,60]
8: Repetition and substitution	
8.1: Behavioral rehearsal/practice	[11,21,34,35,37,39-43,46,48,49,51,56,58,59,61-63]
8.6: Generalization of a target behavior	[33,38,42]
8.7: Graded tasks	[31,33,45,49,63]
10: Reward and threat	
10.3: Nonspecific reward	[32,36]
11: Regulation	
11.2: Regulate negative emotions	[33,38,42,43,50,52,59]
12: Antecedents	
12.4: Distraction	[32]
13: Identity	
13.1: Identification of self as a role model	[52]
15: Self-belief	
15.1: Verbal persuasion to boost self-efficacy	[32,36,39]

Cluster label and component behavioral change techniques	References
16: Covert learning	
16.2: Covert conditioning	N/A[a]
16.3: Vicarious reinforcement	[43]

[a]N/A: not applicable.

In 31 studies, objectives and planning were mentioned, including goal setting (behavior), problem solving or coping planning, and reviewing behavioral or outcome goals. Among these factors, goal setting and action planning were shown to be the most prominent components within the area. A total of 26 applications included goal setting, which has a very broad definition in the taxonomy (setting goals defined according to the behavior or outcome to be accomplished) [11,31-37,39-47,49-52,54,58,59,61,62]. Applications created evidence-based, individualized, progressive home exercise plans; promoted increased general PA; and established short-term objectives. Moreover, 16 applications [11,21,31-37,43,46,48,52,53,60,66] contained action planning in which patients were asked or chose to perform activities until their pain tolerance was attained, based on which the patients prescribed their own individual therapeutic actions. Additionally, 5 applications [35,39,44,54,63] addressed problem solving and coping strategies encountered during rehabilitation by other individuals or physiotherapists. Furthermore, 9 applications contained a review of behavioral or outcome objectives [11,31,33,34,39,43,52,58,62], encouraging participants to monitor their progress and assisting them in identifying personal barriers and strategies for overcoming them.

A total of 19 investigations included various forms of feedback and monitoring, such as feedback on behavior, self-monitoring of behavior, biofeedback, self-monitoring of behavioral outcomes, and feedback on behavioral outcomes. Feedback was provided on behavior wherein activities or exercises were recorded on performance metrics through a digital application and discussed by the physiotherapist during follow-up [33,42,56,57]. Among the included studies, 12 involved self-monitoring for managing exercise reminders and records, viewing progress charts, and setting or modifying exercise objectives [31,32,36,39,42,44,47,55,57-59,62]. Moreover, 13 studies offered participants a wearable device with additional features, such as the ability to monitor activity intensity and visualize activity performance over time [11,33-35,37,39,42,47,56-58,61,62]. These features enabled individuals to monitor progress and receive real-time feedback on objective achievement.

A total of 18 studies applied shaping knowledge. They primarily incorporated videos or lectures on osteoarthritis (OA), the effects of PA, self-management, and coping strategies [21,32,42-44,46-50,52-54,56,59,61]. Three of these studies presented information about antecedents via multiple online physical therapy consultations using video phone services [32,36,38].

A limited subset of digital applications employed social support. The programs offered online platforms where individuals could engage in discussions pertaining to joint pain. Four studies documented the beneficial effects of engaging with social organizational structures on the rehabilitation of individuals with KOA [33,43,59,60].

The concept of natural consequences was addressed in 11 investigations [32,33,35,36,39,41-43,50,51,63], and it included information regarding health consequences, monitoring of emotional consequences, and anticipated misgivings. At each online meeting, the interventionist provided the patient with information about the benefits and costs of engaging in or refraining from a particular course of action. In addition, reminders regarding obstacles and facilitators were provided beforehand.

Comparison of behavior was addressed in 16 studies [32,33,36,42-44,49,53,56,58-63]. It was primarily implemented with behavior evidence, social comparisons, and information about the approbation of others. Three studies on group therapy prompted patients to establish a “buddy” system to change their behavior [33,56,59]. In some cases, a physiotherapist was included to provide the patient with assistance or instrumental social support. Twelve studies referred to information about other people’s perceptions of a person’s behavior and whether others would approve or disapprove of any proposed behavioral change to encourage people to decide to set overall goals [32,36,42-44,49,53,58,59,61-63]. For instance, making behavioral decisions was practiced more the following week, along with identifying obstacles to executing the behavior and devising strategies to overcome them.

A total of 16 studies referred to associations, particularly prompts, as reminders for the patient to perform a particular behavior [11,21,22,31,34,37,40,43,45,48,50,54,55,59,60]. The defined frequency, intensity, or duration of the specified behavior, along with a description of at least one context, location, time, and manner, was included. Of those, 12 involved primary distribution by the physiotherapist via short messages or email timed reminders. In addition, 8 studies involved prompts by the application’s included features [21,22,31,40,48,54,55,59].

Repetition and substitution, which involve behavioral practice or rehearsal, generalization of target behaviors, and grading tasks, were the most common components of the applications. In 27 studies, patients were required to rehearse and repeat KOA exercises [11,21,34,35,37,39-43,46,48,49,51,56,58,59,61-63]. Additionally, 1 study described neuromuscular exercises designed to enhance the physical function of the lower extremities, and the targeted behaviors were broken down into daily video bundles sent to patients [59]. Five studies divided the exercises into varying intensities and progressively increased the difficulty until the desired behaviors were achieved [31,33,45,49,63]. Individual progress and the patient’s

perception of the capacity to exercise without aggravating discomfort were taken into account.

Rewards and threats were mentioned in 2 studies [32,36]. Mobile health apps were supplemented with motivation-enhancing techniques, such as praise, encouragement, and material rewards, for the achievement of specific goals.

The primary goal of regulation was to reduce negative emotions in patients. Seven studies trained users to recognize negative thoughts and reactions to them by relaxing mood through thoughts, emotions, and behaviors that affect pain [33,38,42,43,50,52,59]. One study adhered to the practice by revisiting pleasant imagery and distractions from the previous week [32]. In addition, 1 study discussed the potential for novel or alternative pain medications in applied implicit learning [43].

CBT

Complementary and alternative medicine therapy refers to a deliberate, intentional, and organized form of psychotherapy intervention aimed at improving psychological issues by impacting the beliefs and behaviors of patients [67,68]. CBT combines techniques to develop more adaptive cognitions and behaviors, such as psychoeducation, cognitive restructuring, relaxation therapy, and guided imagery (eg, to reduce muscle tension and autonomic arousal), as well as positive thinking training, problem-solving, and stress management [69,70].

Specifically, CBT focuses on reducing pain and distress by altering bodily sensations, catastrophic and contemplative thinking, and maladaptive behaviors, as well as enhancing self-efficacy [71,72]. Four studies addressed common CBT topics, such as catastrophizing, positive coping methods, and anxiety avoidance, through educational interactive modules and internet courses pertaining to behavior change [42,50,52,61]. The remaining 4 studies addressed common barriers to exercise (eg, pain, low confidence, weather, and relapse) and ways to overcome them (eg, increasing confidence through exercise, seeking social support, teaching proper exercise routines and postures, and promoting positive reasoning) in conjunction with programmatic elements of social cognitive theory and goal-setting strategies for exercise behaviors [32,36,43,44].

Interactive Device Function

Digital Presentation Modalities

The emergence of the internet in the health field has drastically altered the medical information available to patients and the manner in which physicians and patients communicate [73]. A significant number of digital applications involving KOA utilize information and communication technology (ICT) to facilitate behavioral therapy. The included studies covered 5 types of digitization (Table 4): (1) app, (2) website, (3) teleconferencing software/remote phone contact, (4) wearable electronic device, and (5) SMS text message/telephone/email.

Table 4. Forms of digital applications.

Digital application type	References
App/website + SMS text message/telephone/email	[11,21,31,34,36,44,48,50,52-54,59]
App/website	[32,33,37,41,46,49,51,63]
Teleconferencing software/remote messaging	[22,40,43,45,55,60]
Wearable electronic device + SMS text message/telephone/email + app/website	[35,38,39,42,47,56,57,61]
Teleconferencing software + wearable electronic device + app/website	[58,62]

Twelve studies adopted the combination of app/website plus SMS text message/telephone/email. Physiotherapists in 2 studies provided verbal and written education or information about OA, benefits of PA or exercise, and strategies to increase adherence [11,44]. In addition, a progressive individualized home exercise program based on scientific evidence was devised, which included several lower extremity exercises and was accessible through an app or website. In 2 studies, weekly emails containing OA-specific content and resources were sent directly to patients. The emails included (1) nutritional advice; (2) an instructional video on exercise; and (3) a video on positive thinking and advice on self-care, motivation, and stress management [36,59]. Nine studies supported general health and wellness behavior change through free website support [11,21,31,34,36,48,53,54,59]. To increase patient compliance, physiotherapists conducted regular telephone counseling sessions to determine if the use of optional sessions should be based on participant preference, confidence, and success in achieving the desired behavior change. In 3 other investigations, the aforementioned functions were implemented in their entirety within a single application [44,50,52].

Eight studies used apps or websites for self-management and coping with arthritis pain through exercise [32,33,37,41,46,49,51,63]. The websites included information on PA or exercise, goal setting, action plans, pacing, medication management, diet, home exercise, understanding pain, pain management, and relaxation modules. One study explained how individuals can input data and view graphical feedback regarding the amount of exercise they have performed, their activity levels, and their mood [33].

Five investigations [22,40,43,45,60] applied teleconferencing software or telemessaging, and 3 programs provided patients with complimentary access to online webinars featuring “expert advice” [43,45,60]. Participants could ask the facilitator queries about nutrition, exercise, or positive thinking. Registered dietitians, registered psychologists, and kinesiologists led the sessions in pairs according to a rotating schedule. Two other studies addressed recommendations for the development of health behavior interventions utilizing only SMS text messaging on mobile phones [22,40].

Eight studies used the combination of wearable electronic devices plus SMS text message/telephone/email plus

app/website to guide participants in setting specific, measurable, achievable, pertinent, and time-bound PA goals [35,38,39,42,47,56,57,61]. Self-monitoring is typically assessed using commercially available wrist-worn wearable activity trackers (such as Fitbit) or other similar devices. These devices collect measures and communicate them through Bluetooth to a smartphone, tablet, or computer application. Subsequently, the application transmits the data to the Fitbit server. Individuals who possess apprehensions over engaging in PA have the option to communicate their concerns via electronic mail to their physiotherapists.

Two studies [58,62] employed teleconferencing plus electronic devices plus apps. The program comprised 3 elements: (1) a 1-time knee boot camp where participants worked at home on their exercise therapy and PA goals; (2) weekly personalized in-home exercise therapy, PA, and tracking where participants received a Fitbit Inspire activity tracker; and (3) weekly physiotherapist-guided exercise therapy and activity action plans via videoconference on Zoom, optional group exercise classes, and exercise therapy and PA goal setting. In the TeleHab app, exercise therapy objective completion levels, target rating of perceived effort, and any associated pain were recorded, and Fitbit data were synchronized with the Fitbit online dashboard.

Design Methodology

Although researchers and developers typically validate their digital applications with end users, it is uncommon for relevant studies to include end-user participation in the design phase. Of the 36 studies in our review, 8 (22%) reported end-user participation in the design phase [31,33,37,40,41,48,50,56], and 6 (75%) of these 8 studies also reported the participation of stakeholders other than end users [33,37,40,41,50,56]. These stakeholders also included caregivers, coaches, physiotherapists, and other individuals who provide care or services to the target population.

Heuristic assessments were used in a study to explore usability of the intervention for patients with KOA. Based on the outcomes of the interviews and heuristic evaluations, the program's time structure was modified to be more flexible. In the most recent iteration, users had the option of repeating modules and adjusting module difficulty. The strategy also addressed improper website design and placement of multiple icons [31]. In addition, a study involved 3 patients with KOA who provided feedback on the prototype to inform the final design. Regarding how participants perceived interventions used outside the study setting, the majority suggested that health professionals, particularly general practitioners or physiotherapists, could deliver interventions to enhance or improve care [48].

Additional stakeholders were included in the qualitative study analysis. One study referred to experimental websites where patients with KOA and physiotherapists provided feedback on prototypes to inform the final design [40,41,50]. In a separate study, the app was also developed in collaboration with physiotherapists, physicians, and patient representatives. Named members of the project team submitted a list of 30 SMART (Specific, Measurable, Achievable, Relevant, and Time-bound) objectives related to OA treatment [41].

Study Outcomes

A total of 23 experimental studies, 7 experimental protocols, and 6 qualitative studies were included in this literature review. The primary outcomes of using digital behavioral therapy for rehabilitation of patients with KOA were (1) pain, (2) symptoms, (3) physical functioning, and (4) PA. Moreover, the secondary outcomes included (1) self-efficacy, (2) usability and user needs, (3) health-related quality of life, (4) satisfaction, (5) negative emotions, (6) quality of sleep, (7) adherence, (8) surgical intent, and (9) understanding of the condition (Table 5).

Table 5. Rehabilitation outcomes for patients with knee osteoarthritis.

Outcome of the intervention	References
Pain	[11,21,22,31,32,34,36,38,41,42,45,46,49-56,59-61,63]
Symptoms	[31,35,36,41,44,47,49-52,60]
Physical function	[11,21,22,31,32,34,36,38,39,41,44-46,49,50,52-55,59,63]
Physical activity	[21,22,31,34,35,39,41,44,46,47,49-51,53-56,58,60,61]
Self-efficacy	[11,21,22,32,36,46,52,55,58-60]
Usability and user requirements	[33,37,40,42,48,49,54,56,58,62]
Satisfaction	[21,42,45,46,55,59,61,63]
Health-related quality of life	[11,21,22,34,36,46,48-51,53-55,59,63]
Negative emotions	[22,32,42,44,52,53,61]
Quality of sleep	[42,61]
Adherence	[22,36,42,43,49,55,58]
Surgical intention	[38,55,59]
Understanding of the condition	[38,51]

A total of 24 studies that aimed to reduce pain in patients with KOA were ultimately identified in this review [11,21,22,31,32,34,36,38,41,42,45,46,49-56,59-61,63]. Moreover, 12 studies reported statistically significant decreases

in pain [11,21,31,32,36,38,41,42,49,59-61]. Of the 12 studies that did not demonstrate improvement, 6 involved randomized controlled trial protocols and 2 involved qualitative studies. In the studies that showed improvement, intervention durations ranged from 9 weeks to 9 months, and in those that did not show positive results, intervention durations ranged from 8 weeks to 6 months.

Overall, 21 studies assessed physical dysfunction [11,21,22,31,32,34,36,38,39,41,44-46,49,50,52-55,59,63], and of these, 6 reported statistically significant improvements [21,34,41,44,45,59]. Among the 15 studies that did not demonstrate improvement, 7 were randomized controlled trial protocols and 2 involved qualitative research. In studies that demonstrated improvement, intervention durations ranged from 3 weeks to 9 months, while in studies that demonstrated no improvement, intervention durations ranged from 4 weeks to 4 months.

A total of 12 studies measured PA outcomes [21,22,31,34,35,39,41,44,46,47,49-51,53-56,58], and 5 of them reported statistically significant improvements [34,41,47,49,60]. Among the 15 studies that did not demonstrate improvement, 6 were randomized controlled trial protocols and 2 involved qualitative research. In studies that demonstrated improvement, intervention durations ranged from 3 weeks to 9 months, while in studies that demonstrated no improvement, intervention durations ranged from 4 weeks to 12 months.

Physical symptoms were assessed in 11 studies [31,35,36,41,44,47,49-52,60], and of these, 4 studies reported statistically significant improvements [31,35,44,49]. In studies that demonstrated improvement, the intervention duration was 2 months, while in studies that demonstrated no improvement, intervention durations ranged from 2 to 9 months.

Self-efficacy was examined in 11 studies [11,21,22,32,36,46,52,55,58-60], and of these, 3 studies reported statistically significant improvements [11,36,58]. A total of 15 studies reported health-related quality of life [11,21,22,34,36,46,48-51,53-55,59,63], and of these, 3 studies reported statistically significant improvements [11,49,59]. Satisfaction was assessed in 8 studies [21,42,45,46,55,59,61,63], and of these, 1 study reported significant improvements [61]. Seven studies reported improvements in self-reported negative affect after the intervention [22,32,42,44,52,53,61]. Adherence was evaluated in 7 studies [22,36,42,43,49,55,58], and of these, 2 studies reported statistically significant improvements [22,58]. Sleep quality was assessed in 2 studies [42,61], and of these, 1 study [61] reported significant improvements. Three studies examined surgical intent [38,55,59]; however, none of the studies reported significant changes in patients' surgical intent. Patients' understanding of their condition was examined in 2 studies [38,51]; however, no improvement was identified.

Application Deficiencies

The design recommendations of users and stakeholders for the app were reported at different stages of the final app study design. Two studies identified the negative emotions associated with the app [31,56]. For instance, Östlind et al [56] found that a wearable activity tracker facilitated PA in various ways and increased the awareness of the optimal number of steps to treat OA symptoms. However, not all participants found the wearable activity tracker to be motivating, and in some cases, if they missed a weekly PA, the app's prompts about PA caused them to feel anxious and frustrated [31].

Two studies examined the efficacy of applying various characteristics. For instance, the study by Lindberg et al [50] demonstrated the combined efficacy of education, exercise therapy, and internet-based CBT, but was unable to distinguish between these interventions individually. Moreover, Dunphy et al [49] suggested that some participants viewed the physiotherapist's participation as positive, customizing the digital program and monitoring their progress. Others described it as restrictive, particularly if the physiotherapist did not understand how the digital program operated.

In terms of how to promote PA, the studies suggested various potential solutions. For instance, setting and achieving a daily step objective would motivate individuals to walk more than usual [56]. In addition, there was a strong desire for support from health care professionals who could monitor and guide progress; reinforce health messages; and offer reassurance, motivation, and encouragement. In the interviews, peer support through online communities (eg, forums and blogs) was also mentioned as a positive feature where people could share their experiences and learn from and support others experiencing joint pain, although users felt that it needed to be supervised to prevent inaccurate and inappropriate posts [37].

Discussion

Overview

This review presents an analysis of 36 papers that examined the use of digital behavioral therapies for patients with KOA. The analysis provides insights into 3 key areas: (1) the effectiveness of digital and behavioral therapies, (2) the role of digital technologies in these treatments, and (3) the importance of involving users and stakeholders throughout the design phase.

Digitalization and Behavioral Therapy

Several digital applications designed to provide behavioral therapy–based approaches for KOA were reviewed. Various theories of behavior modification and cognition were incorporated into these applications to increase their applicability and efficacy. In this review, we discuss behavioral therapy elements that are frequently combined to form applications.

Physiotherapists or applications, goal setting based on the user's current physical status, and BCTs derived from a control theory framework can enhance long-term sustained exercise in patients with KOA [74]. Positive reinforcement of progressive PA is the most essential element of goals and planning [75]. Gradual increases in PA alter the perception that PA is associated with pain and increase confidence in improving PA performance, resulting in favorable physical (eg, physical ability, muscle strength, and joint flexibility) and psychological (eg, self-esteem, pain perception, and anxiety) changes. Repetition and substitution are intended to boost application engagement and health-related behaviors. A "severe" to "extremely severe" program and specific dosages are designed to stimulate strength

gains, resulting in enhanced function. Physiotherapists assisted participants in devising a PA program intended to increase PA, with exercises targeting the hips, knees, and ankles, including sit-to-stand exercises and seated knee extensions. Our findings indicate that the aforementioned 2 BCTs were covered in virtually all of the applications we reviewed.

It has been demonstrated that reminders increase adherence to unsupervised home strengthening exercises [76]. This feature provides personalized behavior change messages to help patients with KOA surmount barriers to exercise participation. The physiotherapist or the application sends reminder messages based on completion to assist and remind the user to reach their exercise objectives. In the mobile app or wearable device, graphical displays were used to monitor workout adherence and provide feedback. These approaches provided the ability to register the completion of weekly workout sessions and send regular messages to encourage weekly workout participation. Despite the prevalence of wearable devices, their effectiveness in enhancing PA has been questioned. These devices frequently incorporate motivational techniques, such as self-monitoring and real-time feedback, but rarely address skills such as action planning and problem solving, which are essential for altering PA behaviors. Some studies also examined common CBT topics, such as catastrophizing, positive coping strategies, and fear avoidance [42]. Specifically, supervised exercise therapy through patient education enables users to access information regarding OA treatment modalities as well as topics such as the advantages of a healthy lifestyle, PA, vitality, and nutrition.

Our analysis revealed that OA digital management applications may be an alternative to traditional therapy and may further assist with the implementation of OA standards in the wider community [77,78]. However, the engagement of a physiotherapist is a vital aspect. Most participants had favorable experiences with their assigned physiotherapist and were motivated by the daily contact and the support and encouragement provided [79].

Insights From Technology

The use of digital technologies in communication by the patient care team can contribute to the enhancement of information flow, facilitation of patient information retention, improvement of information accessibility and portability, customization of information based on individual needs, and provision of tools for patients to actively participate in their health care [75,80]. In our analysis, the process of digitization manifested through a convergence of several technological mediums, including apps and websites, text messaging, phone calls, emails, and wearable gadgets.

New patient self-management programs have emerged in recent years, demonstrating the importance and efficacy of eHealth interventions such as websites and mobile apps. Current topics include PA, exercise, goal setting, action plans, pacing, medication management, nutrition, at-home exercise, pain comprehension, pain management, and relaxation. They may be combined with multimedia technologies to facilitate the sharing of content and with human-computer interface technologies to enhance accessibility.

Most health and medical apps fail to retain users beyond 90 days. This is due to their missing potential for facilitating disease management and provider-patient communication. The development of teleconferencing software or telematic messaging technology is supported by reminders and distinct objectives [81]. The development of text messaging program functionality and message libraries (including message types, message frequency, and program interaction levels) has the potential to increase adherence to unsupervised home exercise.

Wearable electronic devices aid in tracking the user's daily activities and offer continuous visualization support. However, such devices typically carry a greater risk of privacy invasion and social stigmatization. Our findings indicate that none of the studies specifically addressed privacy concerns. Therefore, designers of pertinent systems should be encouraged to consider these factors more thoroughly. In addition, current wearable electronic devices collect limited data, and their primary function is still to provide feedback on physiological signals (steps, consumption, asymmetry, etc), lacking the accumulation of electrical signals unique to KOA. In the future, machine learning can be introduced into ubiquitous devices to predict patient activity in order to improve patient care.

In the reviewed studies, the combination of app/website plus SMS text message/telephone/email was the most common. It has been shown that text messaging programs combined with unsupervised web-based exercise can reduce pain and dysfunction in patients with KOA [22,40]. Although the addition of wearable electronic devices would improve the intervention process by providing more accurate monitoring data, the experience would not be enhanced. However, the cost of ubiquitous electronic devices and the complexity of their operation continue to prevent their widespread adoption.

Insights From the User or Stakeholder Experience

Less than half of the reviewed studies reported structured user or stakeholder participation in the design phase of their systems, according to our analysis. Nonetheless, there is a distinct trend indicating that an increasing number of studies are emphasizing the significance of involving users in the design and development phases (and not just the validation or deployment phases). Specifically, we summarize a set of emerging user or stakeholder involvement design trends in emerging research on the application of digital behavioral therapy for KOA. Based on the interviews conducted for the qualitative study, issues were identified with the digital app user experience of KOA patients [52,56,62].

First, direct patient feedback was not taken into account when developing the content of the apps, and the content was based solely on the knowledge and experience of hospital staff. In future studies, patients should play a more important role in the development of the content of patient-specific apps, evaluating and further optimizing the preferable mode of information for outcomes [26]. Moreover, there is a need for a structured collaborative design involving patients, physicians, and researchers in order to establish multiple collaborative processes based on shared concepts, mutual learning, and respect for diversity and divergent opinions [82].

Second, digital support is regarded as an integral component of OA care. An ideal approach would be one that combines traditional OA care with digital OA care to offer solutions for personalized, comprehensive, straightforward, dependable, and continuous hybrid care [56,81]. The experience of digital applications is divided into 4 subcategories [79]: (1) simplicity of implementation, (2) flexibility in choosing time and location, (3) significance of interaction with health care professionals, and (4) additional motivating factors. Consequently, our research contends that digital applications must incorporate and differentiate between various user experience stages.

The functional requirements of apps that patients, physicians, and researchers deemed most essential, convenient, desirable, and actionable differed significantly. Participants in the studies agreed, despite their differences, that minimum viable products should be electronic, should monitor patients' symptoms and activities, and should include features tailored to factors identified by patients and physicians as well as self-management strategies based on international guidelines. Over the course of the study, participants came to a consensus regarding the order of their functional requirements. Visual symptom mapping, goal setting, exercise programs, daily monitoring, and self-management strategies had the highest priorities.

Future Work

After conducting a thorough study, a set of recommendations were summarized to improve the quality of applications. These recommendations are focused on making the process more efficient and improving future design and development endeavors. Suggestions for future studies are presented below.

Digital Applications that Provide Comprehensive Monitoring of the Entire Treatment Process

To enhance the rehabilitation of patients, it is necessary to thoroughly investigate the efficacy and impact of different behavioral therapies. This will enable the development of more precise application strategies. Multiple behavioral therapies should be integrated to cover all aspects of the rehabilitation process, including rehabilitation exercises, status monitoring, and self-screening, in order to ensure that patients receive comprehensive care. Simultaneously, by promptly understanding the wants of patients, we can bolster their trust in the process of recuperation. This customized service model can enhance patient happiness and confidence, while also facilitating the seamless advancement of the rehabilitation process. Further investigation can enhance our comprehension by examining particular facets of digital health care platforms, such as network effects and the strategic management of platform ecosystem innovation [83].

Data Analysis Requirements of Patients Based on Intelligent Algorithms

Artificial intelligence algorithms are crucial for extracting important insights from vast quantities of data and offering therapists precise recommendations. As an illustration, the algorithm may examine a patient's exercise data while they are undergoing rehabilitation and detect tiny modifications. This helps the therapist in fine-tuning the intensity and substance of the training. Furthermore, through the comparison of data from many patients, the algorithm can investigate the efficacy of different treatments for specific patient groups, thereby establishing a strategic foundation for later treatment decisions. Significantly, these data serve the dual purposes of enhancing the precision and pertinence of treatment and evaluating the impact of different behavioral interventions. In conventional rehabilitation programs, this procedure is frequently based on subjective criteria. By employing a data-driven methodology, we can impartially evaluate the true efficacy of each technique, establishing a strong basis for further research and applications.

Community-Based Rehabilitation Scenarios With Digital Technology Integration

In order to enhance the adoption of digital behavioral therapy in rehabilitation, our objective is to extend its implementation from the domestic setting to the broader social community rehabilitation setting. The community rehabilitation setting offers a platform for patients to engage and assist one another, and fosters patients' motivation and assurance in their recovery process. For instance, an internet-based community can be established to facilitate patients in exchanging their recovery experiences, offering reciprocal motivation and assistance, and deliberating the obstacles and remedies related to the recovery journey. Additionally, offline activities, including rehabilitation lectures, group seminars, and interactive games, can be arranged to augment patients' social interaction and foster a sense of team camaraderie. Strong partnerships can be fostered with medical organizations and rehabilitation professionals in the community to offer comprehensive assistance for patient recovery. This not only enhances patient rehabilitation outcomes and quality of life, but also fosters the integration and optimization of community rehabilitation resources and promotes overall progress in the field of patient recovery.

Limitations

This research has some limitations. Initially, our evaluation thoroughly examined the present state of digital behavioral therapy applications using qualitative analysis. However, it is indisputable that quantitative analysis yields more robust clinical value. Hence, a complete quantitative meta-analysis will be conducted to assess the efficacy of digital behavioral therapy applications. Future research will integrate both qualitative and quantitative analyses to provide a more thorough evaluation. In addition, our search was limited to English-language research publications, and it is possible that there are significant findings in other languages. The search for research papers was restricted to 5 databases (Web of Science, ScienceDirect, PubMed, Ovid, and Embase). As algorithms are added to digital intervention tools, additional computer science databases, such as IEEE and ACM, could be added to increase the comprehensiveness of the assessment. Furthermore, this review was limited by the search criteria employed and the time period during which the papers were published. However, a focus on the last 10 years went a long way in ensuring that this systematic review includes the most recent research.

Conclusion

This review provides an overview of digital behavioral therapy applications for patients with KOA. In this systematic review,

36 studies were examined. The results demonstrate 14 BCTs and show that behavioral cognitive therapies are frequently combined when developing digital applications. The most prevalent areas were “goals and planning” and “repetition and substitution,” which were frequently used to develop PA goals and PA behavior adherence. The most prevalent combination strategy was app/website plus SMS text message/telephone/email, which has tremendous potential. Consequently, this research provided results for digital applications in terms of pain relief, physical function improvement, self-confidence, and improvement in health-related quality of life among patients with KOA. Nevertheless, there was a shortage of evidence indicating enhanced surgical intention, compliance, and disease knowledge. Subsequent quantitative analysis of this phenomenon is required in the future. Moreover, the incorporation of several stakeholders in the design and development stages might enhance the user experience, considering the distinct variations in their requirements. Based on the findings, digital applications should incorporate various stages of user experience and should include a combination of traditional and digital solutions for OA care.

Abstract

Background: Cardiac rehabilitation is fundamental among patients recovering from a coronary event, and mHealth technology may constitute a useful tool that provides guidelines based on scientific evidence in an entertaining, attractive, and user-friendly format.

Objective: This study aimed to compare the efficacy of an mHealth intervention involving the eMOTIVA app and that of usual care regarding compliance with cardiac rehabilitation guidelines in terms of lifestyle, cardiovascular risk factors, and satisfaction among patients with acute coronary syndrome.

Methods: A randomized controlled clinical trial with a parallel group design was conducted. It included 300 patients (mHealth group, 150; control group, 150) who underwent percutaneous coronary intervention for acute coronary syndrome. Both groups underwent evaluations initially (during hospitalization) and after 3 and 6 months (face-to-face consultations). The eMOTIVA app incorporates a virtual classroom providing audio and video information about a healthy lifestyle, a section for self-recording cardiovascular risk factors, and a section for feedback messages and gamification. The primary outcome variables were (1) adherence to the Mediterranean diet and the frequency of consumption of food; (2) physical activity level, sedentary time, and exercise capacity; (3) smoking cessation and nicotine dependence; (4) level of knowledge about cardiovascular risk factors; and (5) app satisfaction and usability.

Results: The study analyzed 287 patients (mHealth group, 145; control group, 142). Most participants were male (207/300, 69.0%), and the mean age was 62.53 (SD 8.65) years. Significant improvements were observed in the mHealth group compared with the control group at 6 months in terms of (1) adherence to the Mediterranean diet (mean 11.92, SD 1.70 vs 8.92, SD 2.66 points; P<.001) and frequency of eating foods (red meat [≤1/week]: 141/143, 97.9% vs 96/141, 68.1%; industrial pastries [<2/week]: 129/143, 89.6% vs 80/141, 56.8%; oily fish [≥2/week]: 124/143, 86.1% vs 64/141, 41.4%; vegetables [≥2/day]: 130/143, 90.3% vs 78/141, 55.3%; fruit [≥2/day]: 128/143, 88.9% vs 85/141, 60.2%; all P<.001); (2) physical activity (mean 2112.66, SD 1196.67 vs 1372.60, SD 944.62 metabolic equivalents/week; P<.001) and sedentary time (mean 8.38, SD 1.88 vs 9.59, SD 2.09 hours; P<.001); (3) exercise capacity (distance: mean 473.49, SD 102.28 vs 447.25, SD 93.68 meters; P=.04); and (4) level of knowledge (mean 117.85, SD 3.83 vs 111.00, SD 7.11 points; P<.001). App satisfaction was high (mean 42.53, SD 6.38 points), and its usability was excellent (mean 95.60, SD 4.03 points).

Conclusions: With the eMOTIVA app, favorable results were obtained in the intervention group in terms of adherence to the Mediterranean diet, frequency of eating certain foods, physical activity, sedentary time, exercise capacity, knowledge level, systolic blood pressure, heart rate, and blood sugar level. Furthermore, participants reported high app satisfaction and rated its usability as excellent. Thus, this innovative tool is very promising.

coronary event; coronary heart disease; eHealth; lifestyle; mHealth; mobile health

Introduction

Cardiovascular disease remains the main cause of death worldwide and is responsible for 17.9 million fatalities every year [1]. In Europe, about 4 million deaths occur each year due to cardiovascular diseases. Although significant progress has been made in the diagnosis and treatment of acute coronary syndrome (ACS), nearly half of these deaths are due to ischemic heart disease [2,3]. In Spain, coronary heart disease (mainly acute myocardial infarction [AMI]) remains the leading cause of death, causing 29,068 deaths per year. Thus, reducing the prevalence of ACS is a crucial objective of public health [4,5].

A large amount of evidence has shown that leading a healthy lifestyle and modifying cardiovascular risk factors (CVRFs), such as stopping smoking, consuming a healthy diet, losing weight, achieving a suitable level of physical activity (PA), and adhering to medication, are vital in the prevention of major adverse cardiac and cerebrovascular events and death in people with coronary artery disease (CAD) [6]. However, a third of patients with CAD do not follow advice about eating healthy, doing PA, and stopping smoking [7].

Owing to medical advances, the mean hospital stay of patients after percutaneous coronary intervention (PCI) has decreased greatly in recent years, meaning that less time is available for providing health care education. Health education plays a fundamental role in the process of cardiac rehabilitation (CR) following ACS, as it empowers patients to take control of their health, improve treatment adherence, prevent future cardiovascular events, and enhance their overall quality of life [8,9]. Providing patients with ongoing support after their hospital discharge may be important after ACS. This should include changes in lifestyle, adherence to medication, and psychosocial well-being [10]. Secondary prevention, which focuses on reducing the risk of recurrent cardiovascular events in individuals who have already experienced ACS, plays a crucial role in the comprehensive management and ongoing care of these patients. CR after AMI is of utmost importance for several reasons. It reduces the risk of experiencing another cardiovascular event. Moreover, CR improves cardiovascular health through a structured program of physical exercise, health education, dietary advice, and emotional support designed to improve the quality of life of people who have experienced ACS. These programs help to control blood pressure, reduce stress, and promote healthy lifestyle habits, which contribute to better cardiovascular health. These programs also contribute to functional recovery. After AMI, many people may experience limitations in their physical and functional abilities. CR can help regain muscle strength, endurance, and cardiac function, allowing patients to return to daily activities and work. Psychosocial support is also critical. CR offers emotional and psychological support, which can be instrumental in helping patients cope with anxiety, depression, and stress closely related to coronary heart disease [11]. However, despite its benefits, less than 50% of patients with coronary heart disease who are eligible for a CR program participate in CR after an acute coronary event. This may be due to limited accessibility and availability owing to a lack of facilities and long waiting lists. Patients may also experience logistical and transport barriers that make regular participation in face-to-face CR sessions difficult [12]. The widespread use of information and communication technology via smartphones may make it easier for health care professionals to handle these patients. Mobile health (mHealth) technology can provide evidence-based health care advice in an entertaining, attractive, and user-friendly format, thereby reducing the cost of health care [13]. In some cases, it may be a viable alternative or complementary approach to conventional CR. This modality involves participation in distance rehabilitation programs that encompass essential elements such as remote counseling, social interaction, supervision, and distance education [14].

A recent meta-analysis [15] concluded that mHealth technology has a positive effect on patients who have experienced a coronary event. It analyzed the effectiveness of different kinds of mHealth programs in changing lifestyle, promoting treatment compliance, and controlling modifiable CVRFs. The analysis found improvements in exercise capacity, PA, physical and mental quality of life, and medication adherence. In addition, readmissions for all causes and cardiovascular causes were lower, although no significant improvements were found regarding blood lipids, arterial blood pressure, BMI, and waist circumference (WC). Another meta-analysis analyzed the effects of mHealth interventions on the risk factors of coronary heart disease, showing that they can lead to significant improvements in BMI, WC, blood lipids, diastolic blood pressure (DBP), and levels of depression. However, no improvements were found in systolic blood pressure (SBP) and anxiety [16].

This clinical trial aimed to assess the efficacy of an mHealth intervention based on a mobile phone health (eMOTIVA) app compared with usual care for improving compliance with CR guidelines and evaluate the secondary prevention outcomes in patients who have experienced ACS. The following variables were assessed: improvements in lifestyle (adherence to the Mediterranean diet, frequency of foods consumed, PA, exercise capacity, sedentary time, smoking cessation, and level of

knowledge); control of CVRFs, such as BMI, WC, blood pressure, heart rate (HR), total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), triglycerides, blood sugar, and HbA_{1c}; and usability and satisfaction with the app.

Methods

Study Design

We conducted a randomized controlled clinical trial with a parallel group design that included 300 patients with CAD who underwent PCI with stent implantation after ACS. The trial was conducted in the Cardiology Service of a public reference hospital in the south of Spain, in which 1500 PCIs are conducted every year.

The trial has been developed and reported in agreement with the CONSORT (Consolidated Standards for Reporting Clinical Trials) checklist (Multimedia Appendix 1) [17]. The trial was registered at ClinicalTrials.gov (NCT05247606). The study protocol has been previously published [18].

Participants

During hospitalization, patients were considered eligible to participate if they had experienced myocardial infarction or angina and undergone revascularization with stent implantation, were younger than 75 years, had a smartphone or tablet with internet access for the duration of the study, and were able to manage the software. Patients were excluded if they had an expected survival of less than 1 year, had a physical disability, had severe heart failure, had a severe psychiatric illness, had dementia, did not speak Spanish, had a congenital heart disease with a rheumatic etiology, or required triple heart bypass surgery.

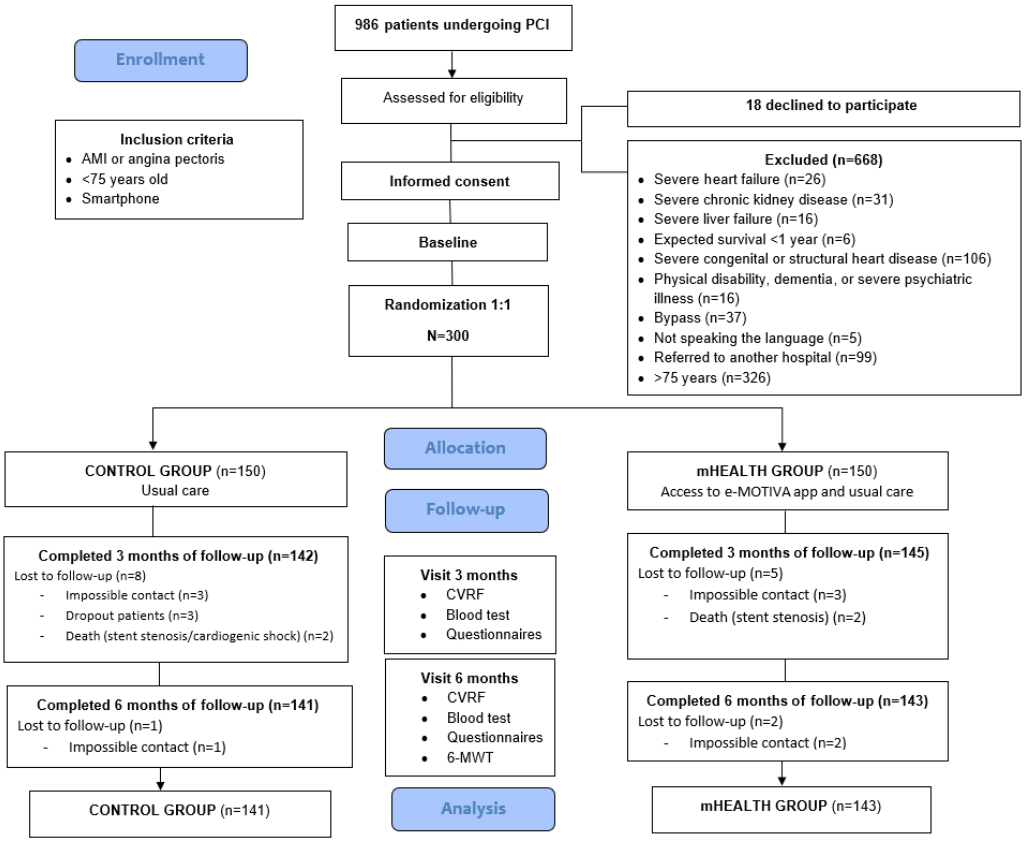
A total of 150 patients were included in each arm. This sample size was considered sufficient to detect a mean effect size (Cohen *d*) of 0.5 [19] with regard to adherence to the Mediterranean diet (mean 8.6, SD 2.0 points) [20], adherence to PA (mean 210.2, SD 221.8 metabolic equivalent (MET)-min/week) [21,22], and a 12% decrease in the prevalence of smokers (prevalence of 21% from the prior pilot study), with a 95% confidence level and a statistical power of 80%.

Recruitment, Randomization, and Blinding

Recruitment took place between February 2022 and February 2023, and the follow-up continued until September 2023. The flow diagram of participants is shown in Figure 1.

Participants meeting the inclusion criteria described above were randomly allocated using a computerized random number generator (1:1) to either the mHealth or control group (usual care). The researchers analyzing the results were blinded to the allocation of the participants.

Figure 1. Flow diagram. 6-MWT: 6-minute walk test; AMI: acute myocardial infarction; CVRF: cardiovascular risk factor; PCI: percutaneous coronary intervention.



Intervention

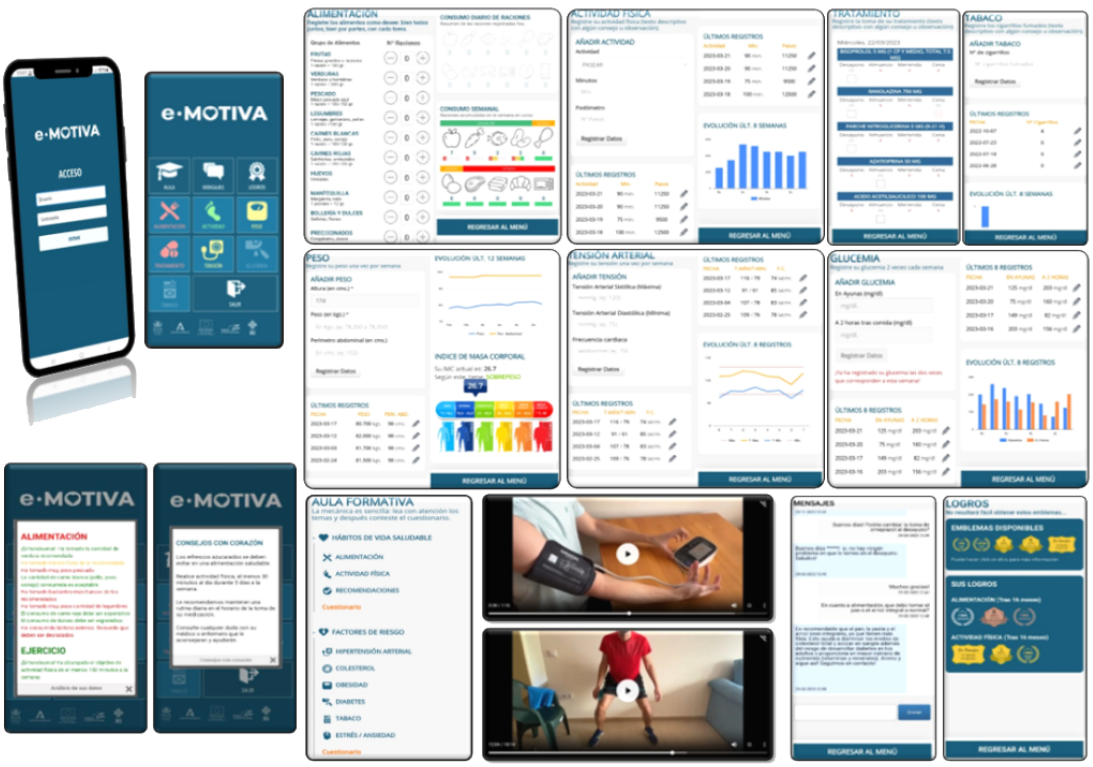
The intervention began while the patient was in the hospital after the coronary event. All participants in the mHealth group had the eMOTIVA app installed on their mobile phones or tablets. The app incorporates a virtual classroom that comprises a space for participation that guides the user using information based on scientific evidence to reach the treatment goals recommended in the clinical practice guidelines and to maintain a healthy lifestyle. This section addresses four cornerstones of the secondary prevention of cardiovascular diseases: (1) healthy lifestyle habits (diet, PA, and recommendations); (2) risk factors (high blood pressure, cholesterol, obesity, diabetes, tobacco use, and stress/anxiety); (3) compliance with the treatment; and (4) goals to be reached regarding diet, PA, body weight, blood pressure, blood sugar, smoking, and treatment. Each section includes online interactive videos (about indoor and outdoor PA, the correct self-measurement of blood pressure and WC, the treatment of cardiac events, and a guided mindfulness relaxation audio). In addition, the classroom provides documents that can be downloaded and printed such as weekly menus and graphics with information (food pyramid, heart health, characteristics and benefits of physical exercise, and recommendations for a healthy lifestyle to stop smoking and control stress). Each section includes a questionnaire that needs to be completed to obtain feedback about the knowledge acquired in the educational sessions. The app includes the use of behavioral strategies to achieve changes in habits through the self-recording of data in the sections related to food consumption, weekly body weight, treatment compliance, PA, smoking, and capillary blood sugar in patients with diabetes.

To motivate the participants to improve and maintain healthy habits, the app includes some functions. First, reminders about healthy habits are generated at random on a pop-up screen once a week. Second, personalized messages are provided according to the user's achievements, and recommendations are adapted to aspects that need to be improved, using information recorded during the previous week. These messages may be green (goal reached), yellow (goal partially reached), or red (goal still to be reached). Furthermore, each icon on the home page of the app appears in the colors according to the goals reached and aspects that need to be improved (Figure 2).

The app uses gamification in the form of achievement icons. Users can obtain different medals if they meet the established recommendations for diet and PA during the months in which they use the app. These systems with fun rewards, such as digital badges obtained for specific objectives, are related to the participation and motivation of users in mHealth interventions, and they encourage an initial and sustained commitment among users to modify CVRFs [23,24]. In addition, gamification can make the intervention more enjoyable, and this is in line with the theory of self-reliance, which assumes that a key part of intrinsic motivation is enjoyment [25]. The app also has fun and colorful warnings and messages, advice, feedback, and self-comparisons through graphics detailing weekly progress (Figure 2).

The app has a messaging section through which the patient can contact health care professionals and resolve any queries (Figure 2). The patients from both groups were evaluated through face-to-face consultations and assessments of medical records at the start and then 3 and 6 months after hospital discharge.

Figure 2. Contents of the eMOTIVA app.



Outcome Variables

The primary outcome measures at the end of the intervention in both groups were changes in behavior regarding (1) healthy diet (adherence to the Mediterranean diet and frequency of eating each food group); (2) level of PA (METs/week and min/week), sedentary time (hours sitting/week), and exercise capacity (6-minute walk test [6-MWT]); (3) smoking cessation in smokers and nicotine dependence; (4) level of knowledge acquired about CVRFs; and (5) app satisfaction and usability.

The secondary outcome measures were (1) BMI and WC; (2) arterial blood pressure and HR; (3) TC, LDL-C, and triglycerides; and (4) HbA_{1c} and blood sugar in patients with diabetes.

Primary Outcomes

Adherence to the Mediterranean diet questionnaire was used (total score: 14 points; <9 points: low adherence, ≥9 points: good adherence) to evaluate diet [20]. The frequency with which each food group was consumed was measured using a food consumption frequency questionnaire (for each food, the participant was required to tick the box indicating the mean frequency of consumption during the last week) [26]. PA time (min/week), intensity (METs/week), and sedentary time (hours seated/week) were analyzed using the International Physical Activity Questionnaire (IPAQ) [27] (light PA: minimum recommended walking of 150 min/week or 495 METs/week, moderate PA: minimum 600 METs/week, and vigorous PA: at least 3000 METs/week). Exercise capacity was measured with the 6-MWT (meters) [28]. Healthy people can walk between 400 and 700 meters in 6 minutes, depending on their age, height, and sex. A greater distance covered is associated with a higher exercise capacity. To this end, a change of 50 meters was established as a clinically significant improvement. A distance below 350 meters is considered a predictor of higher mortality in patients with chronic diseases [29,30]. Smoking cessation was self-reported and nicotine dependence was assessed using the Fagerström test (<4 points: low dependence, 4-7 points: moderate dependence, and 8-10 points: high dependence) [31]. Level of knowledge of CVRFs and a healthy lifestyle were analyzed using a scale validated by the research team in these kinds of patients (maximum score: 120 points). The scale comprises 24 items, each with a score between 1 and 5 points, and respondents were considered to have a high level of knowledge when the correct response was chosen for over 75% of the items (90 points) [32].

Secondary Outcomes

During hospital admission and in the physical follow-up visits, the following measurements were taken: body weight and height to calculate BMI, WC, SBP and DBP, HR, lipid values (TC, HDL-C, LDL-C, and triglycerides), HbA_{1c}, and blood sugar.

Finally, satisfaction with the app was assessed using a specific questionnaire developed by the research team (maximum score: 50 points; a higher score indicates more satisfaction), and the usability of the app was measured using the System Usability Scale (SUS) questionnaire (total score: 100 points; excellent: >80.3 points, good: 68-80.3 points, poor: 51-67 points, and very poor: <51 points) [33].

Statistical Analysis

A descriptive statistical analysis was performed. Continuous variables have been summarized as mean (SD), median, SD, 95% CI, and interquartile interval, depending on the distribution of the values (normal or nonnormal), and categorical variables have been summarized as frequency and percentage. At the end of the 6-month follow-up period, the means of the quantitative primary outcomes of the 2 groups (mHealth and control) were compared using the Student *t*-test (variables with normal distribution) and the Mann-Whitney *U* test (variables with nonnormal distribution). The chi-square or Fisher test was used for the comparison of the proportions of qualitative variables between the 2 groups (mHealth and control). A 2-tailed *P*-value of <.05 was considered statistically significant in all tests. SPSS version 24.0 (IBM Corp) was used for the analyses. The researchers analyzing the results were blinded to the allocation of the participants to each group.

Ethical Considerations

The project was approved by the Costa del Sol Research Ethics Committee, Ministry of Health and Families, Junta de Andalucía and was authorized by the hospital (approval number: 002_jun20_PI-RECAMAR-190. The study complies with Law 14/2007 on Biomedical Research and with the General European Data Protection Regulations, and was conducted following the standards and criteria set out in the latest version of the Helsinki Declaration issued in Fortaleza (Brazil) in October 2013. Moreover, all participants gave their written informed consent to participate in the study.

Concerning the privacy and security of the app, each participant had a private username and password to access the app. Data were stored on a web server and not on a local computer. This web server works with anonymous data and is in Spain to comply with the regulations for the protection of high-level data. The web server performs daily backups of all files, and backups are performed by the software on demand. Thus, the data and program are protected.

Results

Overview

During the recruitment period (February 2022 to February 2023), 986 patients underwent PCI and were evaluated for inclusion in the study. Among the patients evaluated, 668 were excluded for not fulfilling the inclusion and exclusion criteria, and 18 refused to participate. In the end, 300 patients were randomized into either the mHealth or control group (150 in each group). There were 9 dropouts in the control group (8 after 3 months and 1 after 6 months). In the mHealth group, there were 7 dropouts (5 after 3 months and 2 after 6 months) (Figure 1).

The baseline characteristics of the participants are shown in Table 1. Most of the participants were male (207/300, 69.0%), and the mean age was 62.53 (SD 8.65) years. In general, both groups were homogeneous.

Table 1. Patient baseline characteristics.

Characteristic	Total (N=300)	mHealth[a] (n=150)	Control (n=150)	*P* value
Male sex, n (%)	207 (69.0)	103 (68.7)	104 (69.3)	.90

Outcome Variables

Primary Outcomes

The primary outcome variables are shown in Table 2. The score for adherence to the Mediterranean diet was significantly higher in the mHealth group than in the control group after both 3 months (mean 11.63, SD 1.70 points vs mean 9.32, SD 2.55 points; *P*<.001) and 6 months (mean 11.92, SD 1.70 points vs mean 8.92, SD 2.66 points; *P*<.001). The percentage of participants with good adherence to the Mediterranean diet (>9 points) was also significantly higher in the mHealth group than in the control group after 3 months (136/145, 93.8% vs 96/142, 67.6%; *P*<.001) and 6 months (135/143, 94.4% vs 85/141, 60.3%; *P*<.001).

Regarding the frequency of eating food, the consumption of red meat was lower in the mHealth group than in the control group at 3 months (≤1 time/week: 142/145, 97.9% vs 107/142, 75.3%; *P*<.001) and 6 months (≤1 time/week: 141/143, 97.9% vs 96/141, 68.1%; *P*<.001). Moreover, the consumption of industrial pastries was lower in the mHealth group than in the control group at 3 months (<2 times/week: 128/145, 88.2% vs 89/142, 62.7%; *P*<.001) and 6 months (<2 times/week: 129/143, 89.6% vs 80/141, 56.8%; *P*<.001). In addition, the consumption of the following foods was significantly higher in the mHealth group than in the control group: oily fish (≥2 times/week: 116/145, 80.0% vs 68/142, 47.9%; *P*<.001 at 3 months and 124/143, 86.1% vs 64/141, 41.4%; *P*<.001 at 6 months), vegetables (≥2 times/day: 124/145, 85.5% vs 77/142, 54.2%; *P*<.001 at 3 months and 130/143, 90.3% vs 78/141, 55.3%; *P*<.001 at 6 months), fruit (≥2 times/day: 125/145, 86.2% vs 90/142, 63.4%; *P*<.001 at 3 months and 128/143, 88.9% vs 85/141, 60.2%; *P*<.001 at 6 months), and whole-meal cereals (≥1 time/day: 89/145, 61.3% vs 43/142, 30.2%; *P*<.001 at 3 months and 96/143, 66.7% vs 42/141, 29.8%; *P*<.001 at 6 months).

Regarding the time spent doing PA each week (min/week), the mHealth group did significantly more PA than the control group at 3 months (mean 578.10, SD 326.14 min/week vs mean 443.46, SD 278.11 min/week; *P*<.001). Likewise, at 6 months, PA was higher in the mHealth group than in the control group (mean 614.51, SD 332.26 min/week vs mean 408.40, SD 274.49 min/week; *P*<.001). Regarding the intensity of PA (METs/week), the mHealth group performed more intense activity than the control group at 3 months (mean 1991.74, SD 1176.71 METs/week vs mean 1490.48, SD 925.89 METs/week; *P*<.001) and 6 months (mean 2112.66, SD 1196.67 METs/week vs mean 1372.60, SD 944.62 METs/week; *P*<.001). The PA was of moderate intensity in both groups.

The control group had a significantly more sedentary lifestyle than the mHealth group (number of hours seated: mean 9.34, SD 2.13 vs mean 8.57, SD 1.89; *P*=.002 at 3 months and mean 9.59, SD 2.09 vs mean 8.38, SD 1.88; *P*<.001 at 6 months).

Exercise capacity, assessed using the distance covered in meters during the 6-MWT, was significantly higher in the mHealth

group than in the control group (mean 473.49, SD 102.28 meters vs mean 447.25, SD 93.68 meters; *P*=.04).

Regarding smoking cessation, although more participants gave up smoking in the mHealth group than in the control group, the difference was not significant. However, the scores for nicotine dependence at 3 months decreased significantly in the mHealth group compared with the control group (mean 2.30, SD 2.27 points vs mean 4.14, SD 2.96 points; *P*=.03).

The level of knowledge of CVRFs and a healthy lifestyle was significantly higher in the mHealth group than in the control group at both 3 months (mean 116.14, SD 4.23 points vs mean 111.02, SD 6.94 points; *P*<.001) and 6 months (mean 117.85, SD 3.83 points vs mean 111.00, SD 7.11 points; *P*<.001).

Finally, the participants in the mHealth group expressed a high level of satisfaction with the app at 3 months (mean 42.32, SD 5.96 points) and 6 months (mean 42.53, SD 6.38 points), and rated it as excellent (>80.3 points) for usability at 3 months (mean 95.75, SD 4.04 points) and 6 months (mean 95.60, SD 4.03 points).

Table 2. Primary outcome variables at baseline, and 3 and 6 months.

Variable	Total	Mobile health group	Control group	*P* value
Participants, n				—[a]
Baseline	300	150	150	
3 months	287	145	142	
6 months	284	143	141

[e]6-MWT: 6-minute walk test.

[f]CVRF: cardiovascular risk factor.

Secondary Outcomes

The secondary outcome variables are shown in Multimedia Appendix 2. The anthropometric variables (BMI and WC) improved slightly in both groups, with no significant differences between the groups.

SBP was significantly lower in the mHealth group than in the control group at both 3 months (mean 128.96, SD 15.87 mmHg vs mean 133.27, SD 14.85 mmHg; *P*=.01) and 6 months (mean 130.00, SD 21.90 mmHg vs mean 135.78, SD 16.73 mmHg; *P*=.01). However, no significant differences were found in DBP between the groups. HR was significantly lower in the mHealth group than in the control group at 3 months (mean 66.75, SD 8.91 beats/min vs mean 71.93, SD 9.86 beats/min; *P*<.001) but not at 6 months.

The levels of lipid variables (TC, HDL-C, LDL-C, and triglycerides) showed large decreases in both groups, with no significant differences between the groups.

Blood sugar levels were significantly lower in the mHealth group than in the control group at 6 months (mean 101.10, SD 18.57 mg/dL vs mean 115.44, SD 39.46 mg/dL; *P*=.007). However, improvements were not reflected in the HbA_{1c} value.

Discussion

Principal Findings

This clinical trial evaluated the efficacy of an mHealth intervention based on the eMOTIVA app with regard to secondary prevention outcomes in patients who experienced ACS. The following variables were assessed: improvements in lifestyle (adherence to the Mediterranean diet, frequency of consumption of foods, PA, exercise capacity, sedentary time, smoking cessation, and level of knowledge) and control of CVRFs (BMI, WC, blood pressure, HR, TC, LDL-C, HDL-C, triglycerides, blood sugar, and HbA_{1c}). Our results showed that the eMOTIVA app achieved significantly more favorable results in the intervention group compared with the control group in terms of adherence to the Mediterranean diet, frequency of consumption of foods, time and intensity of PA, sedentary time and exercise capacity, level of knowledge about CVRFs, SBP, HR, and blood sugar. Moreover, the participants reported being very satisfied with the app, and they rated its usability as excellent.

Primary Outcome Variables

Healthy Diet

A healthy diet plays a very important role in both the prevention and treatment of CAD. Strong evidence exists about the efficacy of the Mediterranean diet for managing CVRFs for secondary prevention in patients [34,35]. In our trial, adherence to the Mediterranean diet increased significantly in the mHealth group compared with the control group at both 3 and 6 months. Moreover, in the mHealth group, an increase was observed in the consumption of healthy foods, such as fruits, vegetables, whole-meal cereals, and oily fish, and a decrease was observed in the consumption of red meats and industrial pastries. In a previous study that analyzed a cardiac telerehabilitation program with a mobile care monitoring strategy after ACS, significant improvements were noted in adherence to the Mediterranean diet in the intervention group [36]. By contrast, other authors have not reported significant differences between groups for healthy eating with the use of a support program based on text messages for patients with CAD, type 2 diabetes, or both [37]. Given our results, mHealth technology involving an app may be useful for improving eating behavior and maintaining a healthy diet in these patients compared with interventions based on text messages alone. The clinical benefits of these improvements in diet have been reported. For example, studies have stated that eating fish that is rich in omega-3 polyunsaturated fatty acids, such as oily fish, at least once a week is associated with a 16% decrease in the risk of cardiovascular disease [38]. Likewise, an increase in fiber consumption of 7 g/day is associated with a 9% decrease in the risk of cardiovascular disease [39].

Overall PA

PA is a modifiable factor that plays a crucial role in decreasing recurrent coronary events and mortality. The cardiovascular benefits of PA are well known, with recent meta-analyses reporting that it is significantly associated with a decrease in cardiovascular and all-cause mortality in patients with CAD [40-42]. Our results are promising because participants who used the eMOTIVA app performed more PA and were less sedentary. Although PA was self-reported in our trial, an objective test was conducted to measure exercise capacity using the 6-MWT, and participants in the mHealth group were found to have significantly better exercise capacity. Our results are in line with those obtained in other trials in which the effectiveness of mHealth in CAD patients was analyzed [43-46]. Recent meta-analyses have revealed that the use of interactive mobile apps with self-recording and feedback can achieve an increase in the amount of PA performed by participants and an improvement in their functional capacity [15,47].

Tobacco Use

Stopping smoking is one of the most effective secondary prevention measures after experiencing ACS [48]. The EUROASPIRE study [49], which assessed smoking cessation rates in patients with CAD in the whole of Europe and had a follow-up of 2-10 years, stated that individuals who stopped smoking showed a reduction in general mortality of nearly 50%. In our study, although no differences were observed between the groups regarding smoking cessation, nicotine dependence after 3 months, measured by the Fagerström test, was significantly lower in the mHealth group than in the control group. A recent meta-analysis [48] that analyzed smoking cessation and risk factors to continue smoking after ACS concluded that the smoking cessation rate after ACS was 45%. These results are similar to our findings, where we observed that 46.8% (22/51) of participants in the control group stopped smoking, while this figure was higher in the mHealth group (32/56, 65.3%), suggesting that our interactive tool helped participants to maintain the willpower to change, possibly owing to the support and motivation they perceived. Another recent meta-analysis [50] found that telehealth interventions had a significant effect on smoking cessation in patients with CAD.

By contrast, other meta-analyses did not find significant differences in smoking cessation between groups using telehealth interventions, but these interventions did not use interactive tools with recording, feedback, or gamification [47,51,52].

Knowledge of CVRFs

The level of knowledge of CVRFs and a healthy lifestyle in patients is not adequately addressed in trials analyzing the efficacy of mHealth. In our study, the level of knowledge was significantly higher in the mHealth group than in the control group. These results are in line with those obtained by other authors who reported that the use of a social media platform with learning modules significantly increased the knowledge and awareness of CAD [43]. Therefore, interactive and innovative mHealth tools can play a part in increasing the knowledge of a healthy lifestyle. In our study, the virtual classroom incorporated in the app may have been responsible for the observed increase in knowledge.

Secondary Outcome Variables

BMI and WC

A recent meta-analysis that analyzed the efficacy of mHealth for decreasing risk factors related to CAD found significant decreases in both BMI and WC in the intervention group [16]. However, other recent meta-analyses have reported no significant reductions in these anthropometric values with the use of an app [15,47,51,52], which is in agreement with our results. The participants in the mHealth group in our study consumed more vegetables, fruits, whole-meal cereals, and fish, and less red meat and industrial pastries. Moreover, they complied with the recommendation to perform at least 150 minutes of PA per week. Our application, however, was not specifically designed with weight loss in mind, although it did include dietary advice, and losing weight is known to involve more than merely eating healthy food. It is also necessary to limit calorie intake and increase energy expenditure through PA [53].

Blood Pressure and HR

In our study, SBP was significantly lower in the mHealth group than in the control group. Our results are in agreement with the results of other studies that analyzed the use of health care apps in patients with CAD [43,54,55]. This clinical benefit is of note because a meta-analysis [56] concluded that a 10-mmHg decrease in SBP reduces the risks of major cardiovascular events by approximately 20%, CAD by 17%, and all-cause mortality by 13%. However, no significant improvements were found in DBP, possibly due to the intensive drug treatment prescribed after a coronary event that had similar effects on patients in both the mHealth and control groups. On the other hand, the significant decrease in SBP found in our study could be explained by greater compliance with antihypertensive treatment among participants using the app or by greater adherence to the Mediterranean diet and an increase in PA. The recent prevention guidelines for cardiovascular diseases state that lifestyle interventions involving a healthy diet and physical exercise among patients with high blood pressure may be enough to control blood readings and even reduce the amount of medication required to control them [57]. Regarding HR, several trials found that mobile technology did not result in significant differences between groups [24,46,58]. By contrast, Dorje et al [43] reported a significant decrease in HR after 6 months through the use of a WeChat platform. In our study, decreases in HR to below 70 beats/min were found after both 3 and 6 months in the intervention group, but only the decrease at 3 months was significant. The higher HR decrease in the mHealth group compared with the control group may be because the mHealth group performed more PA, which has been shown to be related to a decrease in resting HR [59]. Increases in HR have a direct correlation with cardiovascular events. Several kinds of medications, including beta blockers, have been shown to help with the treatment aim of reducing HR in patients with CAD. Thus, an HR below 80 beats/min and close to 70 beats/min is a treatment goal in hypertensive patients with CAD [60].

Lipids, HbA1c, and Blood Sugar Values

Keeping blood lipid levels under control is a very important aim in the secondary prevention of cardiovascular diseases [54]. A meta-analysis conducted by Cholesterol Treatment Trialists' Collaboration [61] reported that the risk of major vascular events decreased by 21% for each 1 mmol/L reduction in LDL-C achieved with statin treatment. In our study, as in other clinical trials on the efficacy of mHealth in patients with coronary disease, blood lipid values decreased drastically, but no significant differences were found between the groups due to the powerful drug treatment received by all patients after a coronary event [37,46,62]. Likewise, a high blood sugar level is also an important risk factor that can lead to the onset and development of CAD. Diabetes mellitus is an important risk factor for AMI and a common comorbidity among patients hospitalized with AMI (present in approximately 30% of cases) [63]. Our study did not find a significant decrease in HbA_{1c}. However, blood sugar levels decreased significantly in the mHealth group after 6 months. These findings for HbA_{1c} may also be a result of the intensive drug treatment followed by the patients in both the mHealth and control groups.

Satisfaction and Usability

High levels of satisfaction and acceptance of the health care received have been observed to have positive implications for health outcomes and the patient's experience, thereby reducing health care costs and the use of emergency services [64]. In our study, satisfaction after 6 months of using the app reached a mean of 42.53 (SD 6.38) points out of 50 points, which was considered a high level of satisfaction, while the score for usability reached a mean of 95.60 (SD 4.03) points out of 100 points, which was considered to be excellent. The self-recording of PA, diet, and clinical variables along with positive personalized feedback likely contributed to the high level of satisfaction and usability reported by the participants who used the eMOTIVA app. Other studies that have used mHealth interventions with these patients have also reported high levels of usability of 80.4 points out of 100 [36] and 87.3 points out of 100 [65]. These findings highlight the potential of mHealth apps as useful tools for improving recovery and supporting secondary prevention after a coronary event. They are

particularly relevant for populations in which access to a medical center to take part in CR is difficult, either due to living in remote areas or economic reasons.

Limitations

This study has some limitations. First, one of the inclusion criteria was that patients had to have a smartphone. However, the ever-increasing use of these devices in the lives of people globally suggests that this limitation is of little importance. Due to the nature of the study, as in most trials with digital tools, it was impossible for either the patients or health care staff to be blinded. However, the staff analyzing the data were indeed blinded to the group allocation of each participant. Some variables were self-reported by patients (adherence to the Mediterranean diet and PA), which could have resulted in them overestimating their health-promoting behavior. However, the results were confirmed by other variables that were measured by health care professionals, such as exercise capacity assessed using the 6-MWT and blood pressure. Another possible limitation is that patients in the control group were 2 years older than patients in the mHealth group, and the proportion of patients receiving insulin, oral antidiabetics, and antihypertensives was slightly higher in the control group.

Strengths

A strength of the study that stands out is the relatively high number of participants included considering that this was a voluntary intervention study using mHealth, and there were very few dropouts. This might imply that the app was easy to use and that the patients were motivated to change their habits. The use of validated questionnaires specific to this population is another strength. In addition, the hospital where the intervention was conducted is a public reference hospital that treats patients from urban and rural areas. Thus, the sample is representative for the generalization of the results. Finally, the educational sessions and app were designed taking into consideration validated psychological theories. Likewise, our eMOTIVA app included setting objectives, self-monitoring of diet and PA, feedback, and gamification, which are resources that have been shown to improve the results obtained with these mHealth tools [36].

Conclusions

With the use of the eMOTIVA app, favorable results were obtained in the mHealth group compared with the control group in terms of adherence to the Mediterranean diet, frequency of eating certain foods, PA, sedentary time, exercise capacity, level of knowledge of CVRFs, SBP, HR, and blood sugar levels. This trial highlights the potential of mHealth as a complementary or alternative approach to CR programs conducted in medical centers, which are often overburdened. In addition, the participants reported high levels of satisfaction with the app, and it presented excellent usability. Thus, it could be a promising new tool for the CR of patients with CAD in general and for patients who have difficulty attending a health center or hospital in particular.

Abstract

Background: Exercise therapy is recommended by international guidelines as a core treatment for patients with knee osteoarthritis. However, there is a significant gap between recommendations and practice in health care. Digital exercise apps are promising to help solve this undersupply.

Objective: This study aims to evaluate the efficacy of a 12-week fully automated app-based exercise intervention with and without a supporting knee brace on health-related outcomes, performance measures, and adherence in patients with knee osteoarthritis.

Methods: This closed user group trial included participants with moderate to severe unicondylar painful knee osteoarthritis. Randomization was 1:1:2 into an intervention group (IG) with 2 subgroups (app-based training [IG A] and app-based training and a supportive knee brace [IG AB]) and a control group (CG). The intervention included a 12-week home exercise program with 3 sessions per week. Instructions for the exercises were given via the app and monitored using 2 accelerometers placed below and above the affected knee joint. Participants in the CG did not receive any study intervention but were allowed to make use of usual care. Osteoarthritis-specific pain (Knee Injury and Osteoarthritis Outcome Score) was defined as the primary outcome, and secondary outcomes included all other Knee Injury and Osteoarthritis Outcome Score subscales, general health-related quality of life (Veterans RAND 12-item Health Survey), psychological measures (eg, exercise self-efficacy), performance measures (strength and postural control), and the monitoring of adherence and safety. Outcomes were assessed at baseline and after 12 weeks. Intervention effects were calculated using baseline-adjusted analysis of covariance for the joint comparison of IG A and IG AB versus the CG using a per-protocol approach. Subgroup analyses were conducted for each IG separately.

Results: A total of 61 participants were included (IG: n=30, 49%; CG: n=31, 51%; male: n=31, 51%; female: n=30, 49%; mean age 62.9, SD 8.5 years; mean BMI 27.7, SD 4.5 kg/m^2). Analysis revealed statistically significant effects in favor of the IG for pain reduction (P<.001; effect size [ES]=0.76), improvements in physical function (P<.001; ES=0.64), improvements in symptoms (P=.01; ES=0.53), improvements in sport and recreation activities (P=.02; ES=0.47), improvements in knee-related quality of life (P<.001; ES=0.76), and improvements in the physical component of general health-related quality of life (P<.001; ES=0.74). Mean differences ranged from 6.0 to 13.2 points (scale range 0-100). ESs indicated small to medium effects. No effects were found for psychological and performance measures. Participants adhered to 92.5% (899/972) of all scheduled exercise sessions.

Conclusions: Individuals with knee osteoarthritis undergoing a 12-week sensor-assisted app-based exercise intervention with or without an additional knee brace experienced clinically meaningful treatment effects regarding pain relief and improvements in physical function as well as other osteoarthritis-specific concerns compared to controls.

Introduction

Background

Osteoarthritis is a degenerative joint disease and one of the major contributors to global disabilities [1]. The prevalence rate of osteoarthritis increases with age, with women being more frequently affected than men [1,2]. Almost 30% of the German population in the sixth decade of life have been diagnosed with osteoarthritis [3]. The knee joint is the most commonly affected joint of the lower extremities. With disease progression, knee osteoarthritis is more frequently associated with increasing pain, limitations in physical function [4], and decreased health-related quality of life (HRQoL). National and international guidelines recommend exercise therapy as a nonpharmacological core treatment for patients with knee osteoarthritis [5-8]. Exercise programs have shown to decrease pain and improve physical function [9]. They can include strengthening exercises but also aerobic training, neuromuscular training, balance training, mixed exercise programs, aquatic exercises, or mind-body activities such as tai chi or yoga [5,6,8,10]. Different training settings (individual, group based, and home based) have also shown to be effective, allowing patients to exercise according to their individual preferences [5]. However, it is suggested that most people with knee osteoarthritis need some form of ongoing monitoring or supervision to optimize the clinical benefits of exercise treatment [9,10]. Despite given consensus on the need to recommend exercise with some kind of supervision, there is a considerable discrepancy regarding its implementation in health care. In 2016, <40% of patients with hip, knee, or polyarticular osteoarthritis who were customers of a German statutory health insurance company received a prescription for therapeutic exercise [11], and similar numbers have been described in an international meta-analysis [12]. Therefore, it seems reasonable to explore alternative approaches for people with limited access to therapeutic services [13]. In this regard, digital apps for exercise instructions could be particularly suitable to support patients in doing exercises. A recently conducted questionnaire study with health care professionals revealed very high acceptance of mobile health (mHealth)–based intervention therapies in osteoarthritis treatment. This indicates that they would also recommend or prescribe m-Health exercise interventions [14]. The main advantages of apps are related to their use independent of time and location, making this kind of intervention available for many patients even in rural areas [15-17]. In addition, special app features such as information and advice for guidance, tracking and self-monitoring of health behavior, feedback mechanisms, and reminders via push notifications can be of particular value [18,19]. The integration of accelerometers can additionally support patients in conducting exercises in a correct and safe manner by imitating human supervision. In general, 2 main types of mHealth apps are differentiated: interactive and stand-alone apps. Interactive mHealth apps can be used for communication between patients and health care professionals such as physical therapists [20]. These kinds of apps are frequently used in the context of blended care [21]. In contrast, stand-alone apps do not involve interaction with a health care professional, and patients exercise autonomously [22,23].

Both kinds of apps can provide an added value for patients by supporting them in implementing and maintaining exercise in their life and profiting from associated health benefits. A recent meta-analysis reported short-term improvements in pain relief and quality of life (QoL) in patients with knee osteoarthritis or chronic knee pain following the use of technology-based exercise and physical activity programs [19]. However, only 2 of 12 included randomized controlled trials explicitly used an mHealth app [23,24], and only one of these examined a structured exercise program [23]. Therefore, it seems reasonable to conduct further research specifically to evaluate mHealth-based structured exercise programs for patients with knee osteoarthritis. Consideration should also be given to the type of interaction between patients and health care providers in the app.

In addition to exercise, unloading knee braces for patients with tibiofemoral unicondylar medial knee osteoarthritis can be used with the aim to reduce pain, joint stiffness, and medial compartment loading and enhance joint proprioception and functional stability [6,10,25,26]. These effects may also support the conduction of exercises, and in that case, unloader braces have the potential to serve as a treatment-supporting device. Despite limited evidence of the effectiveness of knee braces [6,8], the German guideline for the treatment of knee osteoarthritis recommends unloader knee braces as a “can do” option [7].

Objectives

Considering that exercise is one of the core treatment options for knee osteoarthritis, as well as the fact that mHealth provides new opportunities to guide home-based exercise, and the potential benefit of unloader braces to support exercise conduction, this study aimed to investigate the efficacy of a 12-week mHealth app–supported exercise intervention (re.flex) with (intervention group [IG] AB) and without (IG A) a corrective knee brace in comparison to a control group (CG) on health-related outcomes in patients with moderate to severe unicondylar knee osteoarthritis. The primary outcome was the joint comparison of the 2 app-based study arms (IG A and IG AB) regarding osteoarthritis-specific pain (Knee Injury and Osteoarthritis Outcome Score [KOOS], pain subscale) versus the CG immediately after the 12-week intervention phase.

Methods

Study Design

This study was conducted as a randomized controlled superiority trial. Study participants were randomly assigned in a 1:1:2 ratio to an IG with 2 subgroup arms (app-based exercise training [IG

A] and app-based exercise training in combination with a supportive knee brace [IG AB]) and a CG. The study is reported following the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist [27] and the Consensus on Exercise Reporting Template checklist for reporting exercise interventions [28].

Ethical Considerations

Ethics approval was obtained from the ethics committee of the University Hospital Tübingen (550/2020BO). The participants signed a written informed consent and were given a study ID number. Identifiable information was stored on password-protected servers. There was no compensation for participation in the study. Study materials were provided to participants for free. The study was registered in the German Clinical Trials Register (DRKS00023269).

Participants

Participants with knee osteoarthritis were recruited via advertisements in regional newspapers as well as emails sent to the employees of the University Hospital Tübingen and the University of Tübingen. Interested persons were screened for eligibility via phone call. Final inclusion or exclusion took place at the University Hospital Tübingen in the context of the medical examination at baseline. Inclusion and exclusion criteria are described in Textbox 1.

Textbox 1. Inclusion and exclusion criteria for study participants.

Inclusion criteria

- Age of ≥18 years
- Knee osteoarthritis (self-reported according to the wording of the study questionnaire Gesundheit in Deutschland aktuell [29] and verified by the study physician at t0)
- Unicondylar tibiofemoral concerns
- Moderate to severe knee osteoarthritis assessed using the Knee Injury and Osteoarthritis Outcome Score, pain subscale (≤60 points at the time of screening)
- Knee osteoarthritis as the primary location of symptoms
- Access to a tablet or mobile phone with iOS operating system
- Willingness to use the app to exercise
- Willingness to wear a brace while exercising
- Informed consent for study participation

Exclusion criteria

- Scheduled or implanted knee joint replacement
- Osteoarthritis primarily located in the hip joint or a joint other than the knee
- Diffuse knee pain or retro-patellar pain only
- Concerns affecting physical performance in everyday life (measured using the Physical Activity Readiness Questionnaire [30,31] and verified by the study physician at t0)
- Concerns located at the back or lower extremities currently treated by a physician or health professional and other previous surgeries, injuries, or concerns that may impair measures of strength and balance or the exercise intervention itself
- Insufficient German language skills for self-administered questionnaires and app instructions during training

Development of the Intervention

The re.flex intervention (Kineto Tech Rehab SRL) served as the underlying software and hardware for the intervention, including the basic app structure and the biofeedback via an avatar of the moving body part that is regulated by 2 accelerometers to guide and control training exercises. On the basis of this, a 12-week exercise program specifically designed for patients with knee osteoarthritis was developed by a team of experts of the Department of Sports Medicine at the University Hospital Tübingen. This program was then implemented into the app by the software manufacturer. Exercises were selected based on current knee osteoarthritis–specific recommendations from international guidelines [5,6,32] and years of experience by the study team in planning and conducting exercise interventions for patients with hip and knee osteoarthritis [33-38]. To test, analyze, and improve the re.flex knee osteoarthritis intervention during the development process, an iterative design approach [39] was used. In 2 test phases of 2 and 4 weeks, parts of the exercise program, as well as the app handling and usability, were tested by volunteers with knee concerns (data not published). Volunteers involved in the test phases were not included in the randomized controlled trial. In this study, the iOS app version 1.1.38 at the time of intervention completion of the IG was evaluated. During the intervention phase, minor technical bugs were fixed.

App-Guided Exercise Intervention

The exercise intervention was a 12-week app-guided home training program specifically designed for patients with knee osteoarthritis.

App Features

The re.flex app can be classified as a fully automated, digital health app including a training app and 2 accelerometers to monitor joint movement. It was used to guide and monitor the 12-week exercise intervention of this study. Sensors were attached proximally and distally to the affected knee joint or to the more affected joint (ie, signal joint) in case of bilateral knee osteoarthritis. They were directly attached to the skin using a hook-and-loop tape (IG A; Figure 1, left) or integrated into the brace (IG AB; Figure 1, right). Before each training session, sensors had to be calibrated by performing a movement task. The app acted as a virtual training partner, providing exercise descriptions and videos as well as setting the number of repetitions and sets of the exercises. Movement execution was monitored by the sensors and visualized via a blue avatar leg in the app interface. The blue avatar had to be aligned with another displayed gray avatar leg that moved according to the recommended movement velocity. A movement bar further visualized the current range of motion of the training leg. This bar served as an orientation on how far the leg should be moved in each direction relative to the starting position. If an exercise was not performed correctly, verbal instructions were given (eg, “extend your knee more”). After each set of exercises with the sensor-equipped leg, patients were called to conduct the set with the other leg as well. However, sets and repetitions of the other leg were performed autonomously and were not monitored in the log files of the app. Another feature of the app was to remind users of upcoming training sessions via push notifications. Figure 2 and the app manual (Multimedia Appendix 1) illustrate the structures and features of the re.flex app. The use of the app and sensors for IG A and IG AB was introduced after randomization at baseline by the pretrained study staff. Patients further received a user manual for software and hardware and log-in data for their personal anonymous and free app user account. The login data did not contain any personal data of the participants but used a fake email address with the patient’s pseudonym and an individual password. Only the authors of this study were able to reidentify them with their personal data.

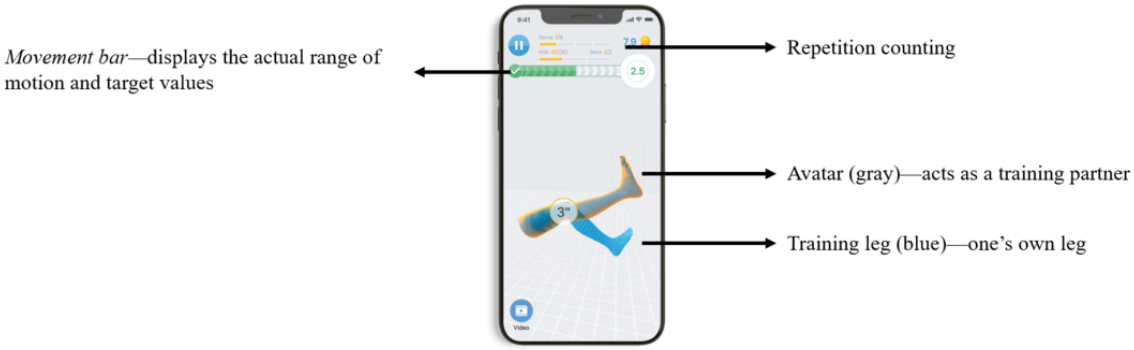
Figure 2. Screenshot with features of the re.flex app.

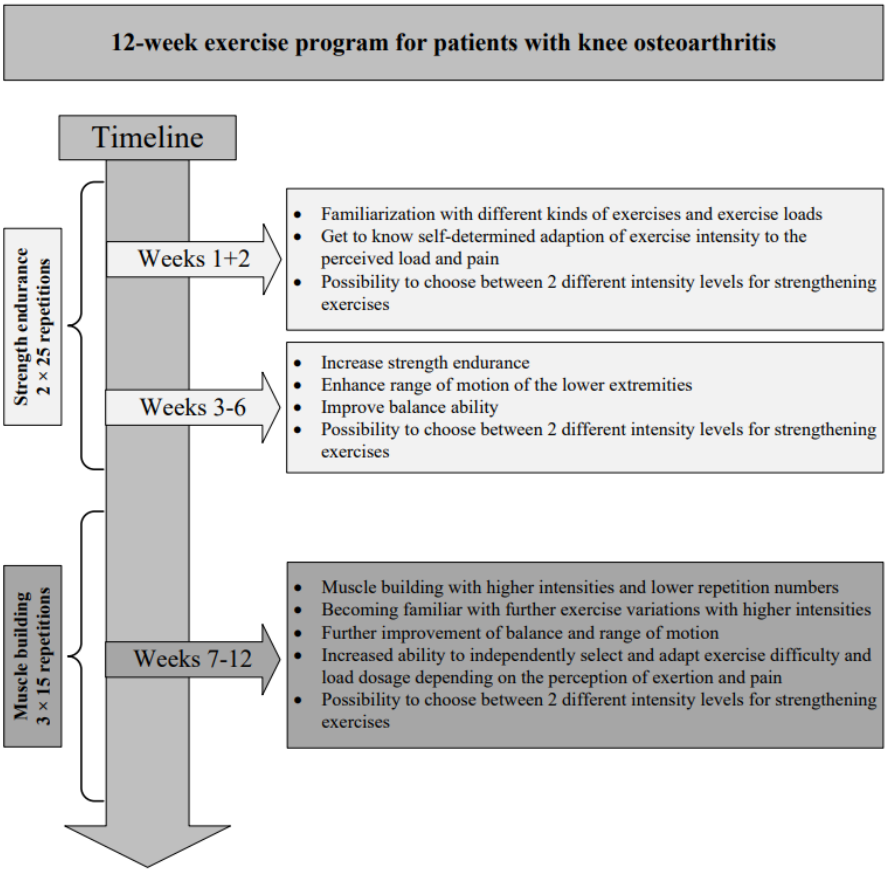


Exercise Program

The progressively designed 12-week program included 3 sessions per week with 5 different exercises and a duration of 25 to 30 minutes each. The exercise poses differed between supine, sitting, and standing. The primary focus of the intervention was to strengthen knee extensors, knee flexors, and hip abductors. Furthermore, exercises aimed for mobilization, muscle stretching, and balance training. The required training material included a chair, a ball or a pillow, and the provided training bands with different resistance levels.

The first 2 weeks focused on familiarization with different kinds of exercises and exercise loads. In this regard, patients were able to adapt exercise intensity self-determinately according to perceived strain and pain, which were assessed after each set of exercises as well as before and after each training session using in-app scales. After the period of familiarization, the exercise sessions of the following 4 weeks were designed to increase strength endurance, enhance the range of motion of the lower extremities, and improve balance ability. From week 7 on, the intervention mainly focused on muscle building. Concurrently, the complexity of the balance tasks was increased accordingly by reducing the sensory input (eg, eyes closed) or modifying the supporting surface (eg, tandem stance). The exercises provided in 2 intensity levels were predefined for each session. An overview of the different phases and objectives within the 12-week exercise program is given in Figure 3. Throughout the intervention phase, users could contact the provider for technical and medical issues using the app messenger service. In the context of the study, this function was supervised by the study personnel.

Figure 3. Objectives of the 12-week exercise program.



Individual Exercise Dosing

At baseline, participants were instructed by the study staff to perform the last 2 to 3 repetitions of each set within a strenuous to very strenuous exertion level. During balance tasks, participants were instructed to perform the task properly at all times while still maintaining the challenge. To ease the fitting of the optimal intensity level, patients could always choose between 2 different intensity levels via an in-app button feature and could further vary the resistance of elastic exercise bands, if applicable. In addition to the intensity specifications, exercises should be performed in a pain-free to low-level pain range. The following instructions were given to the patients if they experienced increased pain during exercising: (1) check exercise performance and correct if necessary, (2) reduce training intensity by selecting an easier exercise variation or reducing the number of repetitions or sets, or (3) skip the exercise. Exercise adaptations in case of increased pain were prioritized versus intensity specifications. The information and guidance for training were provided both orally and written on a fact sheet.

Knee Brace Intervention (Additional to Exercise)

The 2 exercise groups (IG A and IG AB) only differed with respect to the additional use of a corrective knee brace (GENUDYN OA SMART; Sporlastic GmbH) in IG AB. The brace works according to the 3-point principle and exerts pressure onto the unaffected condyle to correct the leg axis.

Thus, it is indicated for patients with unicondylar concerns only. The use of the brace while exercising was mandatory. However, patients were free to use the brace in everyday life as well. Participants were asked to document the wear time of the brace in a paper-and-pencil study diary. The brace was worn at the knee joint affected by osteoarthritis or at the signal joint in case of bilateral knee osteoarthritis. It was fitted by an orthopedic technician during the baseline examination.

CG Arm

Participants on the waiting list did not receive any study intervention or instruction for any change to their normal habits—"Just keep on like before." They were allowed to make use of usual care provided by the treating physician, if applicable. Usual care was defined as any kind of prescribed pharmacological or physical interventions a patient with knee osteoarthritis usually receives when consulting a medical doctor because of knee osteoarthritis. These may include physical therapies such as regular physiotherapy, manual therapy, electrotherapy as well as orthotic devices, and medical prescriptions for pharmacological agents such as nonsteroidal anti-inflammatory drugs (NSAIDs). These reflect the relevant treatment options according to the current national guidelines in Germany [7]. Moreover, participants in this group were informed about the opportunity to make use of the app after the follow-up assessment.

Outcomes

Data collection was conducted at baseline (t0) and at the 3-month follow-up (t3). Medical examinations and the outcome assessments of performance measures before and after the intervention (t3) took place on-site at the University Hospital Tübingen. Patient-reported outcome measures (PROMs) were assessed using web-based questionnaires (Questback GmbH). Questionnaires were activated on the days of assessment (t0 and t3), and study participants were asked to answer promptly. In case of delayed response, participants received a reminder via email.

Patient Characteristics

Age, gender, BMI, medical history (eg, relevant diagnoses and previous injuries or surgeries at the lower extremities or lower back), previous experiences with strengthening exercises or hip or knee exercise groups, and technical affinity were determined at baseline (t0).

Primary Outcome

The primary outcome measure was the joint comparison of the 2 app-based study arms (IG A and IG AB) versus the CG with regard to osteoarthritis-specific pain immediately after the 12-week intervention phase (t3). Pain was determined using the 10-item pain subscale of the KOOS [40,41]. The KOOS is a patient-reported outcome measurement instrument developed to assess the patient's opinion on their knee and associated problems and uses a 5-point Likert scale. It evaluates short-term and long-term consequences of knee injuries and primary osteoarthritis in 5 separately scored subscales. Each subscale is transformed to a scale of 0 to 100 points, with a higher score reflecting a better health status.

Secondary Outcomes

Overview of PROMs

Osteoarthritis-specific symptoms, physical function (activities of daily living), sport and recreation, and knee-related QoL were assessed using the other KOOS subscales. Patient-reported HRQoL was evaluated using the Veterans RAND 12-item Health Survey [42,43]. The Mental Component Score (MCS) and Physical Component Score (PCS) were calculated and used for further analysis. They both can adopt values in the range of 0 to 100 points. Higher scores indicate a better overall HRQoL. Patients' fear of movement was determined using the 11-item German version of the Tampa Scale of Kinesiophobia [44], with a scoring range of 6 to 24 whereby a higher score indicates a greater fear of movement. Physical and sports activity of a typical week, including frequency and time spent on transportation-related cycling and sports, fitness, or recreational activities, were quantified using the European Health Interview Survey–Physical Activity Questionnaire [45]. Exercise-specific self-efficacy was examined using the 9-item multidimensional Self-Efficacy for Exercise Scale [46], which ranges from 0 (not safe at all) to 10 (absolutely safe). The scale was used as a total score and then further divided into 3 subscales: task, coping, and scheduling. Higher scores indicate a higher exercise-specific self-efficacy. Control competence for physical exercising is a subcompetency of the physical activity–related health competence model. It relates to the perceived competence to individually structure and control physical activity in a health-effective way. It is mainly based on action-related knowledge but also requires the ability to sense and interpret body signals (eg, to adjust intensities based on muscle soreness) [47]. Control competence for physical exercising was quantified using 6 items according to Sudeck and Pfeifer [47] and 4 self-constructed items specifically focusing on exercises for the lower limbs [15]. Each item was scored on a 4-point Likert scale ranging from 1 (totally disagree) to 4 (totally agree). The mean value of all items was used for analysis, with higher scores reflecting a higher level of control competence.

Performance Measures

Performance measures included isometric maximum strength measurement of the knee extensors and knee flexors using DAVID strength machines (F200 Leg Extension and F300 Leg Curl; Schupp GmbH & Co. KG). Knee extensor strength was measured at 60° knee flexion, and knee flexion strength was measured at 30° knee flexion. Before testing, participants were instructed to conduct 5 to 8 dynamic concentric repetitions of the target movement at 50% to 60% of maximum force and 2 isometric repetitions at submaximal force in the given test position. Participants were instructed not to provoke an increase in pain level during testing. All measures were taken twice for each leg, and the highest value was used for analysis. Relative values (Newton meters per kilogram of body weight) were reported.

The 30-second chair stand test [48] is an instrument to measure leg strength endurance. Participants were seated with a straight back in the middle of a chair (seat height: 17 inches; participants with a knee angle of <90° received a pad to increase chair height) with hands and arms crossed in front of the upper body.

The feet were completely positioned on the floor. Participants were asked to stand up to full knee extension and then sit back again as many times as possible within 30 seconds. The total number of times the patient did come to a full standing position within the 30 seconds were counted. One complete movement execution was allowed before measurement.

Postural control tests were performed using a plantar pressure mat (zebris GmbH) to evaluate the course of the center of pressure in four different conditions: (1) bipedaled parallel stance with eyes open and (2) eyes closed, (3) bipedaled tandem stance with eyes open and the leg with knee osteoarthritis or signal joint in front and behind, and (4) one-legged stance with eyes open standing on the leg with knee osteoarthritis or signal joint. All tests were conducted in an upright position looking forward with both hands fixed at the superior iliac crest. After one test trial to become familiar with the procedure, conditions 1 and 2 were taken once, and conditions 3 and 4 were performed twice. The lowest value of each condition was used for analysis. The test duration was 10 seconds for conditions 1, 2, and 3 and 6 seconds for condition 4.

Adherence

Sensor- and app-based log files were read out for each exercise session separately and were used to quantify exercise adherence. Intervention finishers were defined as individuals who participated with >50% of overall exercise session adherence and were still active at weeks 11 and 12 of the intervention phase. Overall exercise session adherence was quantified by calculating the percentage of conducted exercise sessions relative to the overall number of prescribed exercise sessions irrespective of the adherence to the prescribed exercise dosage (number of sets and repetitions). Exercise repetition adherence was determined using the number of valid repetitions of all exercises of a session related to the prescribed repetitions. Percentage data were averaged across all exercise sessions (mean and SD). The active training time of an exercise session was calculated by adding all intervals between the time stamps of successive repetitions of an exercise unless the differences were of >60 seconds. If so, these data were not considered to exclude resting times within the active training time. The active training time was averaged across all exercise sessions (mean and SD) and further differentiated for weeks 1 to 6 and 7 to 12. The daily training time was the gross training time. It was calculated as the difference between the first and last repetition on a training day including all breaks, recalibrations, reviewing the exercise instructions, and the training of the other leg. For analysis of the active training time and gross training time, only cases with an exercise repetition adherence of 100% were considered. In addition, cases were excluded for which the gross training time was of >180 minutes as these cases indicate long breaks during the training or split training sessions and, thus, also possibly falsify pain and intensity data. To monitor perceived exercise intensity, participants were asked to rate their perceived overall exertion at the end of each exercise session. Perceived exertion was measured using the rate of perceived exertion scale from 0 (no exertion at all) to 10 (maximum conceivable exertion). Perceived pain before and after each exercise session was measured using the Faces Pain Scale [49]. Instead of numbers, 6 faces with different facial expressions were used to comment on perceived pain. Each face was associated with a textual reference for the pain intensity, and the faces were scored as 0 (no pain), 2 (little pain), 4 (moderate pain), 6 (much pain), 8 (very much pain), and 10 (highest imaginable pain). In the app, the 6 faces of the original version were replaced by standardized emojis of the iOS platform. For perceived exertion and pain analysis, only cases in which the training session was at least started (exercise repetition adherence of >0) were considered.

Concomitant Care

Concomitant pharmacological care (NSAIDs and analgesics) during the study phase was assessed retrospectively at t3.

Safety

Participants included in the study were asked to document all adverse events (AEs) that occurred during the study period. Participants in the IGs were further instructed to interrupt the training program in case of any suspicious symptoms, fatigue, or severe pain during exercising or wearing the knee brace. Mild AEs had to be reported to the responsible study staff within 1 week (via email, phone, or in-app support chat). AEs that required referral to a physician or other health care professional had to be reported immediately. The decision on how to proceed was up to the study physician as well as the study director (sports scientist and physiotherapist) and referred to the options of complete or temporary discontinuation or modification of the training regime. During data analysis, the reports were classified into AEs and serious AEs (SAEs; events related to death, life-threatening illness or injury, or inpatient hospitalization). They were further classified into expected and unexpected events, and the link to the intervention was differentiated into *sure*, *likely*, *possible*, *unlikely*, or *none*. Actions taken were classified into need or no need for immediate medical care (eg, referral to orthopedist, physiotherapy, or medication) and change in intervention modalities (eg, modification, pausing, stopping, or none).

Sample Size

Sample size was calculated based on an a priori power analysis (PASS 2020; NCSS, LLC). The sample size estimation was related to the primary outcome regarding the comparison of the 2 app-guided IGs (independently of the possible supplementary use of a knee brace in IG AB) versus the CG. Furthermore, the sample size estimation was based on the following assumptions: α level of.05, power of β=.8, and a correlation of pretest-posttest values of r=0.5 [50]. Standardized effect sizes (ESs) were used due to a lack of studies with comparable interventions and measures of dispersion. In this regard, required sample sizes to prove ESs between f=0.2 (equal to Cohen d=0.4) and f=0.4 (equal to Cohen d=0.8) were calculated with n=14 for f=0.2 and n=51 for f=0.4. Under the aforementioned assumptions and an expected dropout rate of approximately 15%, 30 participants should be recruited into each group (IG and CG) to verify a medium ES of f=0.2.

Randomization

Before study start, a randomization list was created using computer-generated random numbers (0 and 1) in 7 blocks with 10 slots each. Subsequently, sealed envelopes were prepared containing sequential numbers corresponding to the group

assignment resulting from the randomization list. Randomization into the IG and CG in a 1:1 ratio took place after baseline testing (t0) in order of appointment (eg, the first patient received the envelope with the first lot and so on). Participants allocated to the IG were then again randomized in a 1:1 ratio to 1 of the 2 intervention subgroups, IG A or IG AB, using the aforementioned procedure, including the prestudy preparation of the randomization list and sealed envelopes as outlined previously. The sealed envelopes were handed over by the study personnel. The randomization list and the sealed envelopes were prepared by a person not involved in the conduction, assessment, or data analysis of the study. Participants were not randomized in case of exclusion before completion of the baseline examination at t0.

Blinding

Participants and study personnel responsible for data collection and data analysis were not blinded to the group assignment or type of study intervention.

Statistical Analysis

Baseline characteristics of the IG (IG A and IG AB) and CG study groups at t0 were described using descriptive statistics, with continuous data being presented as mean and SD or median and IQR and categorical variables being presented as absolute numbers and percentages. Unpaired Student 2-tailed *t* tests or Mann-Whitney *U* tests (in case the normal distribution of the data were violated) and Pearson chi-square tests for categorical data were used to compare baseline characteristics in the IG and CG. The primary outcome was evaluated using an analysis of covariance (ANCOVA) with the dependent variable at t3 (KOOS pain subscale at t3), the fixed-effect group (IG and CG), and the covariate (KOOS pain subscale at t0) to adjust for baseline values. Secondary outcomes for the comparison of the IG and CG were handled accordingly. Mann-Whitney *U* tests using the difference t3–t0 of the variable of interest were calculated as a nonparametric alternative. Imputation of missing data was not foreseen. The α level was set to .05. Adjustments for multiple testing were applied for the tandem stance to account for 2 test conditions using Bonferroni correction (α=.025). Data were analyzed as randomized (intention to treat) following the complete case analysis approach. Sensitivity analyses regarding the evaluations of the 5 KOOS subscales (primary analysis and additional explorative analysis) using the last observation carried forward method and the mean imputation method were conducted to replace missing data and, thus, control for any possible bias due to missing values. In case of no significant deviation compared to the complete case analyses, the analyses were continued as initially intended. Between-group ESs were calculated according to Olejnik and Algina [51], with the differences of the adjusted postintervention values divided by the pooled SD at t3 (original data) and interpreted according to Cohen. Thereby, ESs of 0.2 to <0.5 were interpreted as small, ESs of 0.5 to <0.8 were interpreted as medium, and ESs of ≥0.8 were interpreted as large. Data were analyzed using the software packages Microsoft Excel (Microsoft Corp) and SPSS Statistics (IBM Corp).

Subgroup Analysis

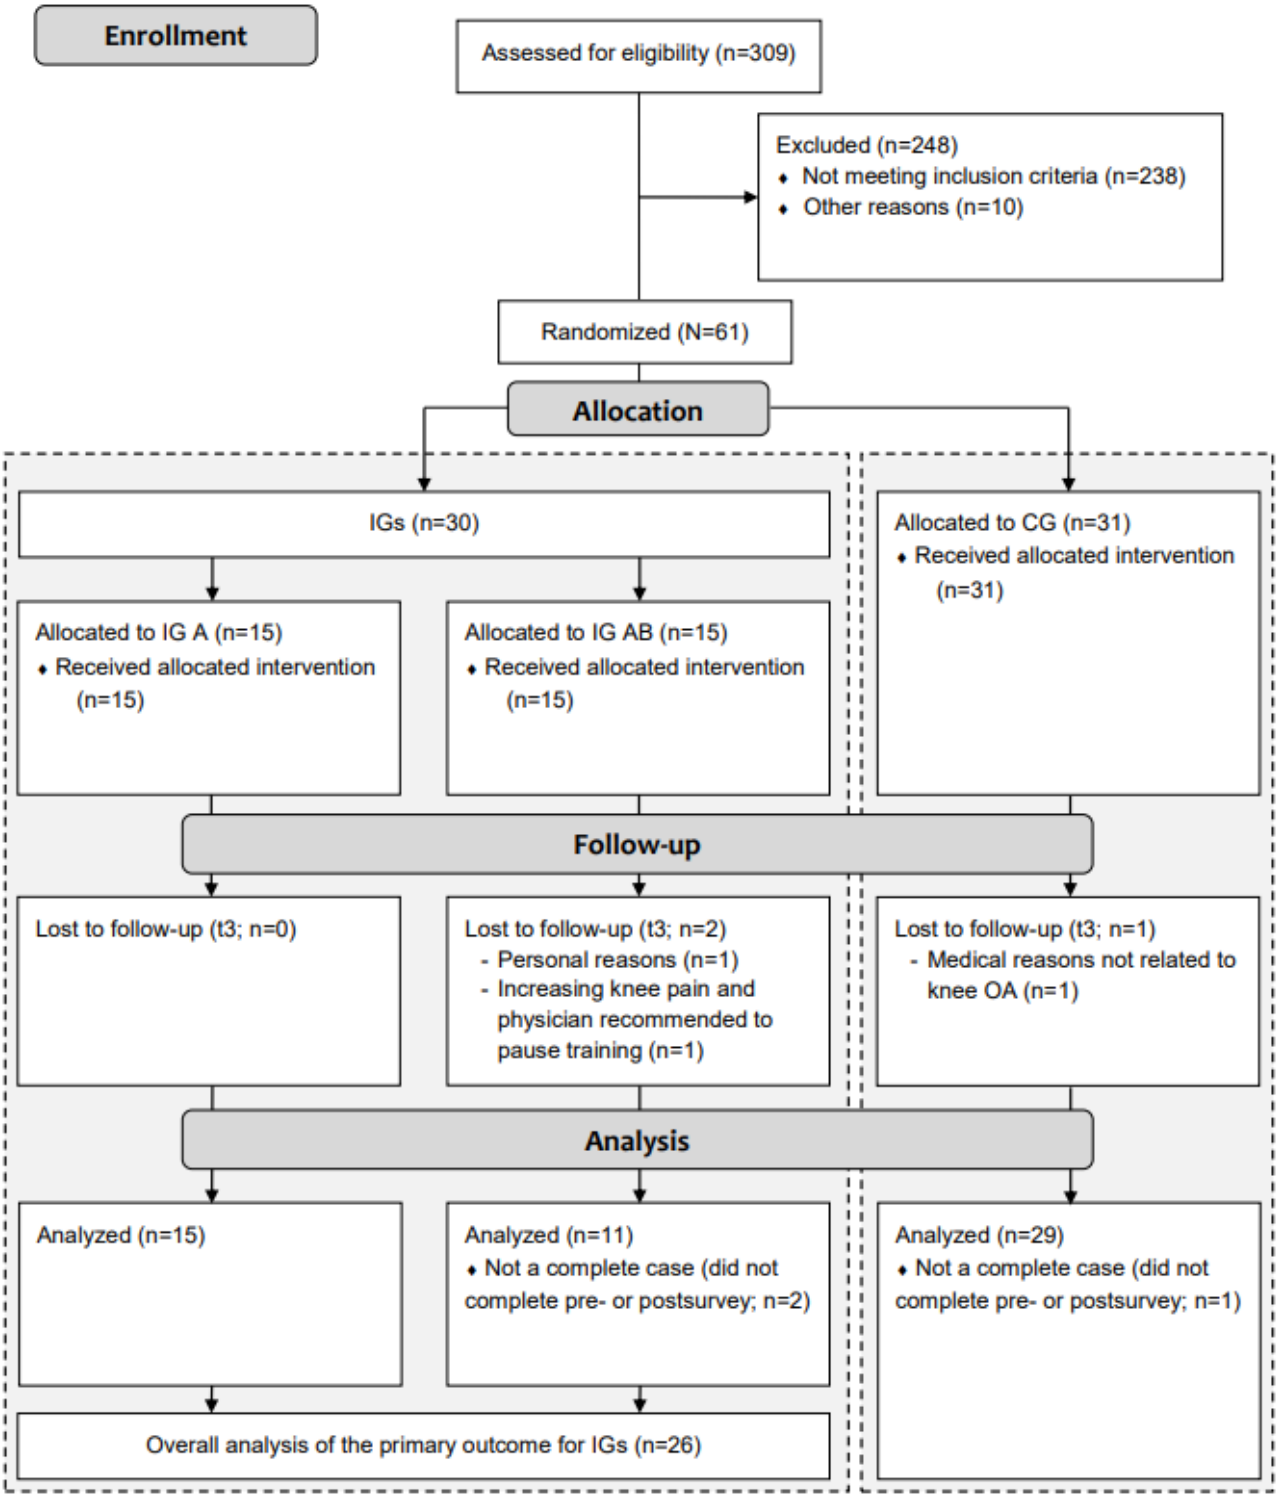
In addition to the aforementioned pooled comparison of the IG versus the CG, explorative separate subgroup comparisons of IG A and IG AB versus the CG as well as comparisons of IG A versus IG AB were conducted for the KOOS at t3. ANCOVA was used according to the procedure described previously.

Results

Participant Flow

Details on participant flow are outlined in Figure 4. Recruitment started on September 21, 2020. All patients were enrolled within 2 weeks, with the first patient included on October 12, 2020. The follow-up after the 12-week intervention period was completed on January 27, 2021. In total, 61 participants were randomized. Thereof, of the 61 participants, 30 (49%) were allocated to the IG (re.flex; n=15, 50% into IG A and IG AB each), and 31 (51%) were assigned to the CG (usual care). Loss to follow-up was 7% (2/30) for the IG and 3% (1/31) for the CG. In addition, 3 complete data sets were excluded from analysis (listwise case exclusion) due to surveys not completed at t0 or t3. Finally, 87% (26/30) of the participants from the IGs and 94% (29/31) of the participants from the CG were considered in the analysis of the primary outcome.

Figure 4. Participant flowchart. CG: control group; IG: intervention group; IG A: app-based training; IG AB: app-based training+brace; OA: osteoarthritis.



Baseline Data

Table 1 reports the sociodemographic and outcome-related baseline values of the participants. At t0, none of the variables showed a statistically significant difference between the IG and CG. Overall, the gender distribution of the participants was balanced (31/61, 51% male and 30/61, 49% female), mean age was 62.9 (SD 8.5) years, and mean BMI was 27.7 (SD 4.5) kg/m^2. However, it has to be noted that the number of male participants was higher in the IG and, on average, the participants in this group were also younger. Most of the participants (58/61, 95%) had never taken part in a hip or knee exercise group before. IG A and IG AB showed statistically significant differences at baseline for the one-legged stance of the signal joint (P=.02), with higher mean values for IG A.

Table 1. Baseline data for the complete case sample in total as well as differentiated according to group assignment (N=61).

Characteristic	Total (N=61)	IG[a] (n=30)	CG[b] (n=31)	*P* value[c]

Primary Outcome

Table 2 and Figure 5 present the primary outcome, the KOOS pain subscale, at 3 months. ANCOVA showed a statistically significant between-group effect ($F_{1,\ 52}$=20.01; *P*<.001; ^{2}=0.278), with greater pain reduction for the IG compared to the CG. The baseline-adjusted mean difference was 13.2 points, demonstrating a medium effect in favor of the IG (ES=0.76).

Table 2. Primary and secondary outcome measures.

Outcome measure and group	Mean (SEM)		Mean difference (IG[a]–CG[b]; 95% CI)[c]	*P* value	ES[d]

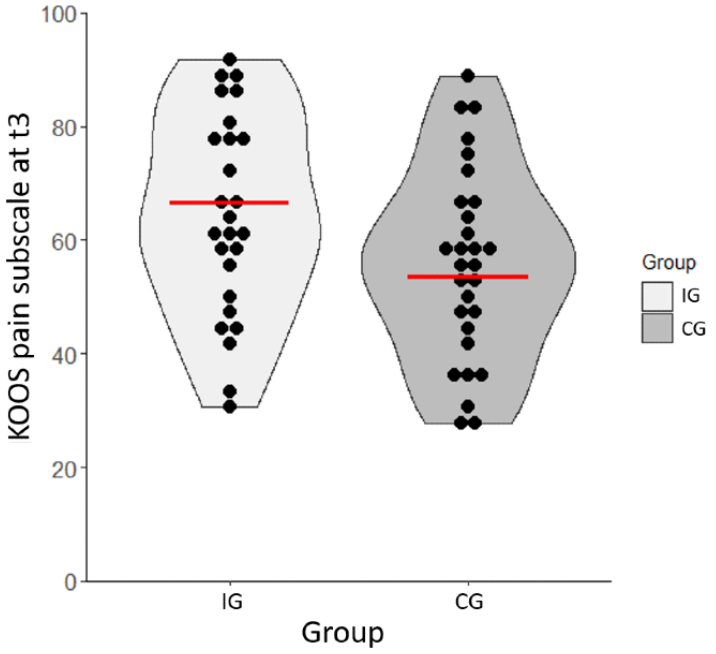
Figure 5. Knee Injury and Osteoarthritis Outcome Score (KOOS) pain subscale at 3 months (t3) of the intervention group (IG) and control group (CG). Violin plots display data distribution (tails are trimmed to the range of the data) and baseline-adjusted means (red line).



Secondary Outcomes

PROMs and Performance Measures

Secondary outcome measures at 3 months are outlined in Table 2. At t3, statistically significant differences between the IG and the CG were observed for all additional KOOS subscales in favor of the IG (symptoms: $F_{1, 52}$=7.01, *P*=.01, and η^2=0.119; physical function [activities of daily living]: $F_{1, 52}$=15.56, *P*<.001, and η^2=0.230; sport and recreation: $F_{1, 52}$=5.98, *P*=.02, and η^2=0.103; QoL: $F_{1, 52}$=19.87, *P*<.001, and η^2=0.277), as well as for the HRQoL PCS ($F_{1, 52}$=13.94; *P*<.001; ^{2}=0.211). Baseline-adjusted mean differences between the IG and CG were between 10.0 and 12.5 points for the KOOS subscales and 6.0 points for the PCS. Interpreted according to the Cohen *d*, the intervention showed a medium treatment effect for improvements in patients' symptoms, physical function, knee-related QoL, and the physical component of the HRQoL and a small treatment effect for sport and recreation activities. No statistically significant differences between groups were observed for any other secondary patient-reported or performance-related outcome measures.

Subgroup Analyses

The exploratory subgroup analyses between IG A and IG AB demonstrated baseline-adjusted mean differences ranging from 4.7 to 12.1 points for the 5 KOOS subscales in favor of the IG AB group. However, between-group differences were not statistically significant. Subgroup analyses for IG A and IG AB separately versus the CG showed superiority of IG AB versus the CG in all KOOS subscales as well as superiority of the IG A versus the CG for pain, physical function, and QoL. Table S1 in Multimedia Appendix 2 provides more details.

Adherence

Of the 30 participants in the IG, 27 (90%) were defined as intervention finishers. During the intervention phase, one participant dropped out due to personal reasons, and another dropped out because of non–device-related increasing knee pain and a subsequent physician-recommended pausing of the training intervention. One participant ceased the intervention from week 8 onward for unknown reasons. Overall, exercise session adherence for intervention finishers was 92.5% (899/972), indicating the percentage of training sessions that were at least started. In total, 7.5% (73/972) of all training sessions were not performed (adherence=0%). The overall mean exercise repetition adherence was 86.8% (SD 28.9%). The average active training time and gross training time in weeks 1 to 12 (total) was 15.5 (SD 4.1) minutes and 31.7 (SD 17.1) minutes, respectively. On average, participants reported a perceived pain score of 0.9 (SD 1.4) points before and 1.1 (SD 1.5) points after the exercise sessions. This was according to the Faces Pain Scale, equivalent to a slight traction or mild pain. The mean difference from after to before exercise sessions was 0.2 points. After the exercise sessions, the participants reported an average intensity value of 3.5 (SD 1.4) points. According to the rate of perceived exertion scale, this indicates a slight to somewhat exhausting load. Further details on adherence, training time, exertion, and pain outcomes are outlined in Tables 3 and 4.

Table 3. Adherence and training time.

Outcome measure	Weeks 1-12	Weeks 1-6	Weeks 7-12
Overall exercise session adherence (%)[a]	92.5	93.0	92.0
Exercise repetition adherence (%), mean (SD)[a]	86.8 (28.9)	87.6 (28.0)	85.9 (29.8)
Active training time (min), mean (SD)	15.5 (4.1)	17.6 (3.3)[b]	13.3 (3.7)[c]
Gross training time (min), mean (SD)	31.7 (17.1)	36.2 (19.3)[b]	27.3 (13.2)[c]

[a]Data refer to 972 exercise sessions (12 weeks with 3 sessions per week; n=27 [n=3 no intervention finishers]).

[b]Data out of 360 exercise sessions.

[c]Data out of 364 exercise sessions.

Table 4. Perceived exertion and pain outcomes.

Outcome measure	Values, mean (SD)	Values, median (IQR)	Range
Perceived exercise intensity after exercise sessions, mean (SD)[a,b]	3.5 (1.4)	3.0 (1.0)	3.5-9.0
Perceived pain before exercise sessions, mean (SD)[b,c]	0.9 (1.4)	0.0 (2.0)	0.9-6.0
Perceived pain after exercise sessions, mean (SD)[b,c]	1.1 (1.5)	0.0 (2.0)	1.1-6.0

[a]10-point scale from 0 (*no exertion at all*) to 10 (*maximum conceivable exertion*).

[b]Data out of 888 exercise sessions.

[c]10-point scale from 0 (*no pain*) to 10 (*highest imaginable pain*).

Concomitant Care

Concomitant pharmacological care data during the study phase were available for 93% (28/30) of the IG participants and 97% (30/31) of the CG participants. Overall, at t3, a total of 14% (4/28) of the IG participants compared to 10% (3/30) of the CG participants reported a daily intake of NSAIDs or analgesics during the study phase, and 7% (2/28) of the IG participants compared to 7% (2/30) of the CG participants reported a weekly intake of NSAIDs or analgesics during the study phase.

Safety and Technical Issues

No SAEs were reported throughout the intervention phase to the study personnel. In summary, 7 AEs were reported. In total, 4 of the AEs were sure to be intervention related (AEs number 11, 21, 40, and 59), of which 3 (75%) required a modification of the training (AEs number 11, 40, and 59) and 1 (25%) required pausing the training intervention (AE number 21). Medical care was necessary in one case (AE number 40). The remaining 43% (3/7) of the AEs were not intervention related (AEs number 29, 44, and 49). Further details are outlined in Table 5.

Table 5. Adverse events (AEs) throughout the study period.

ID	Group	Harm	Type	Expectation	Link to intervention	MC[a]	CoI[b]
11	IG[c]	Increased pain due to device-initiated overload (repetition count failure and range of motion)	AE	UE[d]	Sure	No	Modification
21	IG	Increased pain and feeling of permanent muscle soreness in legs and arms	AE	EE[e]	Sure	No	Pausing
29	IG	Training interruption due to lumbago	AE	—[f]	No	No	Pausing
40	IG	Increased pain (especially for standing exercises on one leg) and activated OA[g]	AE	UE	Sure	Yes	Modification
44 (DO[h])	CG[i]	Dizziness and personal health problems	AE	—	No	Yes	None
49 (DO)	IG	Fall on knee and subsequently irritated and overloaded knee	AE	—	No	Yes	Stopping
59	IG	Increased pain and knee joint unusually warm	AE	UE	Sure	No	Modification

[a]MC: medical care; need for immediate medical care (yes) or no need for medical care (no).

[b]CoI: change of intervention.

[c]IG: intervention group.

[d]UE: unexpected event.

[e]EE: expected event.

[f]Not applicable or no link.

[g]OA: osteoarthritis.

[h]DO: dropout.

[i]CG: control group.

Technical issues reported by participants when using the app were used for minor technical bug fixes during the study period as well as for adjustments after the study period. In the following paragraph, only the summarized incident report of a participant on a specific topic is considered. On the one hand, bug fixes related to failures of the movement sensors, which, in some cases, did not adequately recognize patients' movements and, thus, led to incorrect counting of exercise repetitions. This was the case for the following exercises: wall slide (n=12), knee extension exercises (seated and supine position; n=7), and hip abduction exercises (seated and standing position; n=5). Other problems included the need for multiple recalibrations during an exercise session (n=17), an incorrect representation of the training leg on the app (twisted and no reaction; n=12), and initial problems connecting the sensors (n=7).

Discussion

Principal Findings

Overview

This pilot study aimed to evaluate the efficacy of a 12-week app-based exercise intervention with or without an additional knee brace on symptoms and function in participants with knee osteoarthritis. The results of the study demonstrated small to medium treatment effects with statistically significant reductions in self-reported osteoarthritis-related pain (primary outcome) and other osteoarthritis-specific concerns (KOOS symptoms, physical function, sports and recreation, and QoL subscales), as well as an increase in the PCS of the general HRQoL after the 12-week app training versus the CG. No intervention effects were found for any other of the secondary outcomes. The intervention showed an excellent adherence rate and no SAEs.

Overview of PROMs

Previous studies have shown superiority of exercise interventions guided by fully automated mobile apps versus control to reduce knee-related pain and improve physical function in patients with knee osteoarthritis [22,23,52]. However, in contrast to our results indicating medium ESs of >0.6 for pain and physical function, Bossen et al [52], who focused their intervention primarily on increasing general physical activity, demonstrated much smaller effects of 0.2 for pain and physical function. Regarding the absolute differences between the baseline-adjusted postmeasures of the IG and CG, substantially higher between-group differences (10.0 to 13.2 points) were reported in this study in comparison to other studies with digital interventions (2.9 to 7.7 points), of which only Mecklenburg et al [23] used a similar sensor-assisted and app-based exercise program [22,23,52]. Uesugi et al [53] did not find a significant between-group effect at all.

From a clinical perspective, within-group differences for pain in the IG of our study exceeded the minimal clinically important improvement (MCII) of 8.7 points/100 as reported for patients with knee osteoarthritis who underwent a 12-week rehabilitation intervention with active and passive therapeutic treatments. Reported cutoff values for physical function (13.4 points/100) could not be reached [54]. However, regarding minimal clinically important differences (MCIDs) between the IG and CG, the ESs of our study are within or above reported thresholds for MCIDs [55]. Nevertheless, there are many different calculation methods for determining MCII and MCID, and these values may also differ between population groups and

interventions, leading to a lack of consensus on which cutoff values should be used. Therefore, future studies should apply an own anchor-based approach to be able to define intervention-related MCID and MCII values for pain and physical function.

At present, nondigital interactions are the gold standard for exercise guidance, and novel interventions should not only be compared between each other but also in reference to the standards. Studies on nondigital interactions have reported small to medium effects in terms of pain reduction and improvement in physical function for delivery modes such as one-on-one treatments, class-based programs, and home-based exercises [9,56]. Verhagen et al [57] recently stated that the estimated effects regarding pain reduction of supervised exercising are very robust and no further intervention studies in this domain would change these findings. This is in contrast to cutting-edge results of an individual patient data meta-analysis on exercise therapy in knee and hip osteoarthritis questioning the clinical importance of reported effects versus those of a CG [58]. Accordingly, it seems reasonable to expand the field of application and investigate alternative, innovative ways of delivering exercise therapy that may further increase our knowledge of the effectiveness and mechanisms of action of new treatment delivery opportunities. Considering this, the app-based instruction appears to be a promising evolution of the currently proven standard therapy, especially as the results of this study indicate clinically important ESs. Another possible reason for the larger effects reported in our study may be related to the fact that we only included patients with at least moderate knee osteoarthritis symptoms. This reduced the potential risk of ceiling effects as the possible range of improvements for patients with early or mild disease-specific symptoms was much lower and baseline pain has been described as a moderator for treatment effectiveness [58].

The exploratory subgroup analyses for the KOOS subscales showed superiority of IG AB versus the CG in all KOOS subscales as well as superiority of IG A versus the CG for pain, physical function, and QoL. The direct comparison of both IGs provided a first indication of the superiority of IG AB versus IG A. However, these findings were not statistically significant. This potential trend of superiority of IG AB must be considered with caution due to the small subgroup sample size and should be verified in a subsequent data analysis with a larger sample.

Benefits of exercise therapy on mental and physical HRQoL in patients with knee osteoarthritis have also been reported in a recent meta-analysis with reported standardized mean differences of 0.52 for the PCS and 0.44 for the MCS [59]. Compared with these values, this study showed even greater improvements for the PCS with an ES of 0.74, yet no improvements in the MCS were observed. However, baseline scores for the MCS already exceeded the US population norm of 50 points [60].

When looking at health-psychological measures, participants in the IG had less fear of movement after the intervention in comparison to participants in the CG, although this finding failed to reach statistical significance. Mean values at baseline already indicated a low level of fear of movement in the population under study. As most participants were recruited via newspapers or newsletters, it seems reasonable that only patients who did not have fear of activity-induced worsening of symptoms would have applied to participate. We also investigated whether the self-efficacy and control competence subcompetencies of the physical activity–related health competence model improved after taking part in the stand-alone mHealth intervention. However, no differences between the IG and CG were observed. In the study population, both measures that included the subscales showed ceiling effects at baseline. Thus, the possibility of change after the intervention phase was limited.

Performance Measures

Strength endurance quantified using the 30-second chair stand test increased by 1.7 repetitions for the IG versus the CG. However, this finding was not statistically significant. Therefore, the results are in contrast to those of a study on the effectiveness of a 6-week internet-based exercise intervention against usual care in patients with knee osteoarthritis reporting a statistically significant between-group effect in favor of the intervention. The participants in the IG improved by an average of 4.5 repetitions. The between-group difference after the intervention was 3.4 repetitions [61].

Change in knee extension strength has been described as a mediator for clinical benefit in patients with knee and hip osteoarthritis [62]. Our results showed no improvement in maximum knee extension strength in the IG. This is in contrast to a meta-analysis including results of 10 studies in which low-intensity resistance training reported short-term ESs with a standardized mean difference of 0.5 when compared to the CG. However, there was also a small group of studies that failed to show significant benefits for strength outcomes. The authors of the meta-analysis [63] hypothesized that one reason for the absence of benefit may be related to the low intensity of these exercise programs as too low intensities cannot trigger sufficient muscle activity to promote neuromotor adaptations and hypertrophy to ultimately generate muscle gains [63]. This could also explain the lack of strength improvements in our study as the analysis of the sensor and app log files after the training sessions revealed only a perceived “slight” to “somewhat exhausting” intensity level, and thus, this tends to fall in the subthreshold exercise dose. In the future, patients should be better educated to enable them to independently adjust their training intensity (eg, by choosing a heavier or lighter exercise variation). At the end of an exercise set, a training-effective exercise load in the range of “strenuous” to “very strenuous” should be achieved.

We did not find consistent superiority of the IG versus the CG for postural control outcomes, and we refrain from discussing this further as measurement instruments, postures, and durations differ across trials and the measures used in our study are not part of the recommended set of performance-based measures to assess physical function in people diagnosed with knee and hip osteoarthritis [64].

Adherence

The success of exercise therapy and the associated improvements in pain, physical function, and QoL are highly dependent on the maximization of the adherence to exercise. Therefore, it is recommended to supervise exercise sessions at least in the initial exercise period to enhance adherence before continuing exercise independently [65]. Various factors (eg, motivational level, physical status, personal goals, self-regulation, and several extrinsic factors) can impact exercise adherence [47,66]. To overcome these barriers, especially for nonsupervised training, the field of digital-based exercising may offer a different approach for guidance and motivation as well as an independence from time and location. The particular group of sensor-based apps can additionally supervise the training execution and provide real-time feedback. The impact of supporting features for barrier management in eHealth and mHealth technologies may also be the reason for the high adherence rates of up to 82% to 91% for digital-based home exercise interventions (all sources, not only sensor based) in patients with knee osteoarthritis [67,68]. These numbers correspond to the adherence rate of 92.5% (899/972) in our study and exceed reported rates of 62% to 75% for nondigital home exercise interventions [69,70]. The results of our study only refer to the short term. As adherence to exercise is critical for the long-term benefit of lifestyle interventions [13], future studies may investigate whether better adherence to app-guided interventions can be sustained over a longer period as well.

Limitations

One limitation of our study is related to potential bias due to missing values of the complete case analyses. According to Jakobsen et al [71], a complete case analysis can be applied up to a threshold of approximately 5% missing values. They further report that missing data can be ignored in the analysis if the impact of missing data on the results is negligible. In our study 9.8% of data were missing but no significant differences were observed for the complete case analyses in comparison to the sensitivity analyses (data not shown) for the KOOS subscales. Another limitation is the lack of blinding of participants because of their obvious group assignment. This may have particularly influenced subjective outcome measures in the CG due to a lack of treatment expectations. A major limitation of the study is related to the sample size of the 2 subgroups, IG A and IG AB. Our study was powered for a joint comparison of IG A and IG AB versus the CG. Therefore, subgroup comparisons of IG A and IG AB versus the CG may lack statistical power and generalizability. Due to the relatively small subgroup sample size, additional data are needed to substantiate or revise the findings of a possible additional treatment effect of wearing a knee brace during exercising.

It should also be mentioned that the study design does not allow for clarification on whether the favorable study results of the IGs were the result of app use or just of the fact that participants exercised more than those in the CG. However, the aim of this trial was not to conduct a comparison of different delivery modes of exercise (eg, supervised in person vs stand-alone app) but to obtain first insights into the efficacy of a sensor-based mHealth intervention in comparison to usual care. Further comparative studies are needed to answer the question of which patients respond best to which type of delivery.

Conclusions

Individuals with knee osteoarthritis undergoing a 12-week sensor-assisted app-based exercise intervention program with or without an additional knee brace experienced positive treatment effects with medical benefits regarding pain relief and improvements in physical function as well as other osteoarthritis-specific concerns compared to those in the CG. Adherence to the exercise intervention was high, and the mobile app can be classified as a safe intervention, with no SAEs being reported. To overcome limitations in the generalizability of the results because of the rather small sample size and the joint comparison of IG A and IG AB, a well-powered trial on the effectiveness of re.flex versus a CG is currently being conducted.

Acknowledgments

The authors want to thank all the study participants. They also highly appreciate the involvement of Georg Haupt, who made a significant contribution to the design of the intervention. They also thank scientific assistants Patrick Riedt, Johannes Goller, Milena Hartwig, and colleague Isabel Schubert for their help with data collection and analysis. The study was funded by Sporlastic GmbH. The funding source was not involved in data collection, data analysis, or the report of the study. Sporlastic GmbH provided the digital app and sensors that were used in the clinical trial. Sporlastic GmbH has a contractional relationship with Kineto Tech Rehab SRL. Kineto Tech Rehab SRL is the manufacturer of the product (sensors and app). Sporlastic GmbH is the exclusive distribution partner for the contract area (Germany). The authors acknowledge support from the Open Access Publication Fund of the University of Tübingen and the company Sporlastic GmbH for the funding of the remaining publication fee. The manuscript was submitted to Sporlastic GmbH for review. Sporlastic GmbH approved the manuscript without any request for modification. The University Hospital Tübingen has a basic right of publication of study data. The study protocol and results will be communicated at scientific congresses and in peer-reviewed scientific journals. Sporlastic GmbH has the right to make the study results public as part of corporate communications.

Authors' Contributions

All authors contributed to the conception and design of the study. IK and PJ were responsible for the acquisition of funding. VD and PJ contributed to the collection of data. PJ was the responsible orthopedist. VD and IK were responsible for data management, data analysis, and interpretation of the data and drafting and revising the paper. All authors read and approved the final manuscript.

Conflicts of Interest

This study was an investigator-initiated trial in cooperation with an industrial partner, the financial supporter of the study. The authors declare no further potential conflict of interest.

Abstract

Background: Cardiac rehabilitation (CR) is a safe, effective intervention for individuals with cardiovascular disease (CVD). However, a majority of eligible patients do not complete CR. Growing evidence suggests that home-based cardiac rehabilitation (HBCR) programs are comparable in effectiveness and safety with traditional center-based programs. More research is needed to explore different ways to deliver HBCR programs to patients with CVD.

Objective: We aimed to assess the feasibility and impact of a digital HBCR program (RecoveryPlus.Health) that integrates both telehealth and mHealth modalities on functional exercise capacity, resting heart rate, and quality of life among adults with CVD.

Methods: This 12-week prospective, single-arm remote clinical trial used a within-subject design. We recruited adults with CVD (aged ≥40 years) from the community with a CR-eligible diagnosis (stable angina pectoris, myocardial infarction, and heart failure) between May and August 2023. All enrolled patients referred to the RPH clinic in Roanoke, Texas, were included. The care team provided guideline-concordant CR services to study participants via two modalities: (1) a synchronous telehealth exercise training through videoconferencing; and (2) an asynchronous mobile health (mHealth) coaching app (RPH app). Baseline intake survey, electronic health record, and app log data were used to extract individual characteristics, care processes, and platform engagement data. Feasibility was measured by program completion rate and CR service use. Efficacy was measured by changes in the 6-minute walk test, resting heart rate, and quality of life (12-Item Short-Form Health Survey) before and after the 12-week program. Paired *t* tests were used to examine pre- and postintervention changes in the outcome variables.

Results: In total, 162 met the inclusion criteria and 75 (46.3%) consented and were enrolled (mean age 64, SD 10.30 years; male: n=37, 49%; White: n=46, 61%). Heart failure was the most common diagnosis (37/75, 49%). In total, 62/75 (83%) participants completed the 12-week study and used the telehealth modality with 9.63 (SD 3.33) sessions completed, and 59/75 (79%) used the mHealth modality with 10.97 (SD 11.70) sessions completed. Post intervention, 50/62 (81%) participants' performance in the 6-minute walk test had improved, with an average improvement of 40 (SD 63.39) m (95% CI 25.6-57.1). The average 12-Item Short-Form Health Survey's physical and mental summary scores improved by 2.7 (SD 6.47) points (95% CI 1.1-4.3) and 2.2

(SD 9.09) points (95% CI 0.1-4.5), respectively. There were no changes in resting heart rate and no exercise-related adverse events were reported.

Conclusions: The RecoveryPlus.Health digital HBCR program showed feasibility and efficacy in a group of nationally recruited patients with CVD. The findings add to the evidence that a telehealth and mHealth dual-modality HBCR program may be a promising approach to overcome some of the main barriers to improving CR access in the United States.

Introduction

Cardiovascular disease (CVD) remains the leading cause of morbidity and mortality in the United States, with more than 2 million hospitalizations and 400,000 deaths due to CVD [1,2]. Cardiac rehabilitation (CR) is a grade I guideline-recommended multidisciplinary program intended to reduce the risk of subsequent cardiovascular events and improve quality of life through activities shown to improve physical, psychological, and social functioning, and ultimately reduce associated morbidity among patients with CVD [3,4]. Despite strong evidence regarding its safety and efficacy, CR use rate remains very low, with only about 1 in 4 eligible patients enrolling in CR [5-10]. In addition, disparities in CR uptake with respect to sex, age, race, ethnicity, and geographic locations persist, contributing to the low overall CR participation rate and substantial geographic variations in participation [3,11]. With the initiation of the Million Hearts 2022, a national program aimed at achieving a target of 70% CR participation among eligible patients by 2027 [9], the current 2300 center-based cardiac rehabilitation (CBCR) programs in the United States are unlikely to meet the demand for CR [12,13]. Therefore, new home-based cardiac rehabilitation (HBCR), an alternative to traditional CBCR that allows patients to undergo rehabilitation in their own homes, is urgently needed to expand CR access [3,14].

HBCR alone or in combination (hybrid) with CBCR, has been shown to be a safe and effective option for patients eligible for CR [15-17], with the potential to address some of the key barriers to CR access (eg, time and cost of transportation) [5]. HBCR programs use the same multifaceted approaches (exercise training, education, dietary guidance, and lifestyle modification) as CBCR, providing patients with synchronous or asynchronous delivery of supervised remote exercise training and care management [4,18,19].

While HBCR programs have certain disadvantages compared with CBCR (eg, lack of published clinical standards, lower exercise training intensity, and potential safety concerns for high-risk patients), their key advantages include reduced enrollment delays, expanded capacity, flexible scheduling, minimal travel, and improved access for patients with limited mobility [2,5,20]. The unexpected disruption to CBCR access caused by the COVID-19 pandemic inadvertently accelerated the transition of many in-person CR programs to the home setting and increased the acceptability of HBCR and center-home hybrid CR programs [21]. There is a need for greater engagement in safe and evidence-based CR exercise programming for patients recovering from CVD. Among these new approaches, home-based synchronous remote CR and asynchronous mobile health (mHealth)–based CR modalities, alone or in combination, have the potential to improve access by expanding provider offerings and reduce the time and costs associated with travel to traditional CR centers [22].

The RecoveryPlus.Health digital (RPH-D) HBCR program is an innovative program that combines 2 delivery modalities, a synchronous telehealth modality delivered through videoconferencing by an interdisciplinary care team and an asynchronous mHealth modality delivered through a digital app (RPH app) for individualized exercise therapy. The RPH-D program was developed based on the American Heart Association CR guidelines for delivering tailored, evidence-based CR remotely and on demand.

This study aimed to determine whether the dual-modality RPH-D program is feasible for delivering remote CR to a nationally recruited sample, and to examine its impact on patients' functional exercise capacity (cardiorespiratory endurance), resting heart rate, and quality of life.

Methods

Recruitment

This is a prospective single-arm remote clinical trial using a within-subject design. Between May 1, 2023, and November 30, 2023, a dedicated recruitment website was established to facilitate the sharing of study information for recruitment through 2 primary channels, referrals from cardiology providers in the Dallas-Fort Worth area and through a collaboration with The Mended Hearts, Inc, a national and community-based nonprofit cardiovascular patient support organization. The community partners sent emails to their patients prompting potential participants to visit the study website. Potential participants were screened for eligibility criteria by a secure web-based questionnaire. Patients who passed the initial screening were contacted by the study coordinator by phone to verify eligibility and finalize enrollment.

Participants were included if they were aged 45 years or older; had stable CVD and under medical management; received referral to CR from a provider within 60 days; were able to walk

unassisted; deemed stable with low to moderate risk of a cardiac event; and with a CR eligible diagnosis in previous 12 months as defined by Medicare Part B (stable angina pectoris, myocardial infarction, stable heart failure, and coronary artery bypass graft surgery). Participants were excluded if they were unable to read and speak in English, had a BMI greater than 40 kg/m^2, had hospitalization or significant decline in health, had physical or mental health limitations that prohibit participation in exercise activities, could not use a tablet computer, lack of access to Wi-Fi, or had severe hearing or vision impairment.

Intervention: The RecoveryPlus.Health Digital CR Program

The RPH-D program for patients recovering from a CVD event leverages 2 weekly concurrent remote modalities to engage the study participants: (1) synchronous (telehealth) coaching sessions conducted by an exercise physiologist by Zoom for Healthcare (Zoom Video Communications, Inc); and (2) asynchronous (mHealth) exercise sessions by the RPH app. The telehealth sessions focused on the following core CR services: patient assessment, exercise training, care management, lifestyle counseling, and remote monitoring. The study iPads were preloaded with the RPH app, which offers a library of on-demand exercise videos with varying degrees of difficulty. Wireless heart rate and blood pressure monitors were connected to the iPad by Bluetooth to enable real-time monitoring of patient vital signs and feedback (eg, patient-rated difficulty for each prescribed exercise) and tailor individual patient regimens regularly for safety and fine-tuning the exercise therapy. During the app-based exercise sessions, participants rated the perceived level of difficulty (exertion) of each exercise on a 1-10 scale. If a patient chooses to skip an exercise or exit a session before completing the prescribed exercises, the reasons were documented by the app (Multimedia Appendix 1).

All clinical team members had access to the RPH remote health care provider web portal (HIPAA [Health Insurance Portability and Accountability Act]-complaint) to enter, store, and view participant demographic and clinical information, create fitness assessments, write and update a patient's exercise prescription, and generate reports. The clinicians were trained to use patient feedback along with data derived from heart rate monitors to assess exercise intensity, appropriateness, and adherence to the prescribed exercise program, and, importantly, make adjustments to better personalize the care plan for each patient. The RPH remote CR platform also provided real-time, automated alerts that were sent to the care team for any symptoms or reports of out-of-range heart rate reading to facilitate immediate evaluation to determine the severity of a symptom and which course of action is required for follow-up. In these events, participants were instructed to stop exercising immediately and report any cardiac-related symptoms to their clinician at any time, during or outside of exercise sessions. The clinical care team received and responded to alerts 24 hours a day, 7 days per week.

Outcomes and Measures

The main variables of interest were feasibility and efficacy. Feasibility was measured by program initiation (the proportion of enrolled patients who completed all baseline assessments and completed the initial Zoom teleconferencing session with an exercise physiologist and participation (the proportion of enrolled patients who completed at least 50% or more of prescribed sessions). Feasibility data were captured by the HIPAA-compliant, encrypted, RPH electronic health records. Efficacy was measured by 6-minute walk test (6MWT), resting heart rate, and quality of life. These measures were assessed by the study exercise physiologist and recorded on the RPH electronic health record platform. The 6MWT was measured by the 6WT app, an iOS app validated in 330 volunteers (age range 16-91 years) [23]. Participants were instructed to walk on a flat, hard surface outside of their homes for a period of 6 minutes. The 6MWT is a widely used and well-documented measure of aerobic exercise capacity used to indicate change in fitness [24]. Resting heart rate is positively associated with mortality and is known to decline with regular exercise [25]. Quality of life was measured by the 12-Item Short-Form Health Survey (SF-12, version 2), a validated and commonly used measure of perceived quality of life and functional health among patients with CVD [26]. Individual characteristics included basic sociodemographic variables collected at baseline (age, sex, race, ethnicity, comorbidities, and referring diagnosis).

Sample Size Calculation

Power calculation was based on the primary efficacy measure: 6MWT. At a 5% level of significance, to achieve 85% power in detecting a small to moderate difference of 35 m for the 6MWT before and after the RPH-D program, a sample size of 75 participants was required [24,27]. To account for an estimated 25% attrition rate, a total sample of 100 was set as the enrollment target.

Statistical Analysis

Standard descriptive statistics were used to describe the study sample and compare them by study completion status. For continuous variables, 2-sample *t* test was used, and Fisher exact test was used for categorical variables. To examine the impact of the RPH-D program on the outcome measures, paired *t* tests were used to examine whether there were any within-subject changes post intervention. To quantify the uncertainty surrounding the point estimates of effect sizes, 95% CI was calculated using nonparametric bootstrapping with 5000 repetitions [28]. Statistical analysis was performed in Stata 17 BE (StataCorp).

Ethical Considerations

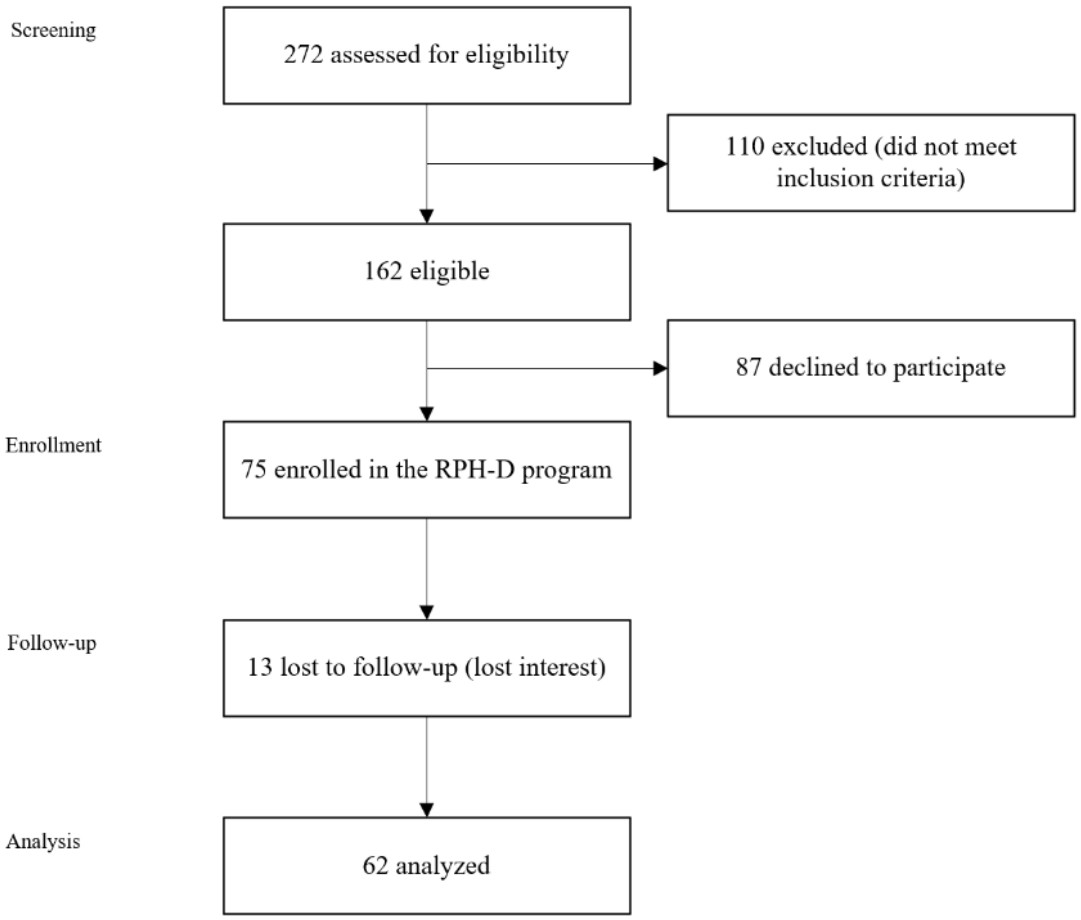
The study protocol was approved by the Advarra Institutional Review Board (Pro00070335) and written informed consent was obtained from all participants.

Results

Overview

Of the 272 individuals screened for eligibility, a total of 162 individuals from 29 states met the study eligibility criteria and 75 (46%) consented to the study and were enrolled in the RPH-D program. In total, 13 participants withdrew from the study and 62 (83%) were included in the analysis (Figure 1).

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram for patient enrollment and follow-up. RPH-D: RecoveryPlus.Health Digital.



Participant Characteristics

Table 1 displays the baseline participants' individual characteristics for the overall sample and by participation rate (less than or greater than 50%). Study participants had a mean age of 64.6 (SD 10.0; range: 45-85 years) and 38 (51%) were female (Table 1). Non-Hispanic White participants made up majority of the sample at 46 (61%), followed by 8 (11%) Black American, 5 (7%) Hispanic, and 16 (21%) other or missing race. The top 5 referring diagnoses were chronic heart failure (n=37, 50%), coronary artery bypass grafting (n=9, 15%), valvular surgery (n=9, 15%), acute myocardial infarction (n=6, 10%), and percutaneous coronary intervention (n=6, 10%). Participants who completed 50% or more sessions were older and more likely to have percutaneous coronary intervention as the referring diagnosis. With the exception of age and BMI, there were no significant differences in the characteristics of the participants who completed the study versus those who did not.

A total of 62 out of 75 (83%) participants completed the 12-week study. Out of 62 participants, 50 (81%) completed at least 50% of CR sessions. All participants were prescribed 12 one-on-one videoconferencing (telehealth) sessions (55 minutes per week, 660 minutes total) and 12 app-based exercise (mHealth) sessions (27.8 minutes per week, 334 minutes total) over 12 weeks. A total of 62 out of 75 (83%) participants used the telehealth modality (9.63, SD 3.33 sessions) and 34 of 62 (55%) participants completed all 12 sessions. A total of 59 out of 75 (79%) used the mHealth modality (10.97, SD 11.70 sessions) and 32 out of 62 (52%) completed all 12 sessions. Among those who completed the study, all participants used the telehealth modality and all but 3 participants used the mHealth modality. Participants completed an average of 654.1 (SD 113.6) minutes of telehealth sessions and 421 minutes (SD 306) of mHealth sessions (Table 2). A total of 12 participants visited the emergency room (15 visits total) and none were related to the RPH-D program.

In total, 3 outcome measures were used to examine the impact of the intervention before and after the 12-week intervention (Table 3). Overall, participants who completed the intervention had an average improvement in 6MWT performance of 40 (SD 63.39) meters (95% CI 25.6-57.1). The average SF-12 physical and mental component summary scores improved by 2.7 (SD 6.47, 95% CI 1.1-4.3) and 2.2 (SD 9.09, 95% CI 0.1-4.5) points, respectively. There was a small nonsignificant improvement in average resting heart rates (mean –1.1, SD 9.05, 95% CI –3.4 to 1.1).

Discussion

Principal Findings

In this remote clinical study, the RPH digital home-based CR program that integrated synchronous telehealth and asynchronous mHealth modalities was tested among a group of nationally recruited individuals with cardiovascular disease. Screening, recruitment, and engagement outcomes showed that while enrollment yield was modest, the great majority of consented individuals were able to complete the program. Adherence to both modalities was high, although there were substantial variations in adherence to the mHealth exercise sessions. Overall, the program was feasible and efficacious in improving functional exercise capacity and quality of life.

Home-based versus center-based cardiac rehabilitation continues to receive much attention, with a recent Cochrane review identifying 24 completed trials and at least 14 more registered. While the extent of evidence suggests that these 2 delivery approaches showed comparable effects on total morality and exercise capacity up to 12 months postintervention, with no significant differences in health-related quality of life for up to 24 months [12], evidence regarding the delivery modality for HBCR is less clear. A recent review of asynchronous and synchronous delivery models for HBCR showed that while most studies of HBCR tested asynchronous approaches before 2016, a growing number of HBCR trials started to incorporate synchronous approaches [14]. The findings of this study add to the growing evidence base supporting the feasibility of a concurrent dual-modality remote CR for individuals with CVD. For example, a study in New Zealand among predominantly male patients with CHD found that 82.9% (68/82) of those assigned to the remote CR program completed the 12-week program. A total of 2 small studies in the United States reported varying completion rates. Misra et al [29] tested a digitally delivered remote CR program among 12 patients with atrial fibrillation who underwent catheter ablation in Charlotte, North Carolina. In total, 92% (11/12) were able to complete the 12-week program, with an average of 2.9 exercise sessions per week. Giggins et al [30] reported a completion rate of 72.7% (8/11) for an 8-week web-based remote CR program among patients with CHD. Taken together, these findings support the feasibility of HBCR programs for individuals with CVD.

The broad geographic reach (29 states) of the RPH-D program conducted from a single clinic shows the promise of digital technology-enabled remote CR programs. As geographic disparities in access to traditional center-based CR have been highlighted as one of the main barriers to CR participation [3,31], asynchronous home-based CR programs like the RPH-D program provide greater flexibility for patients with CVD. The findings indicate that the great majority of eligible

participants-initiated CR with high completion rates. The availability of the asynchronous mHealth modality may help in narrowing the digital divide among patients from rural and remote areas [32]. Participation rate (of 50%) did not differ among participants based on sex and race, suggesting that the program may offer women and minority patients an equitable option for HBCR access.

The findings from this study are also in line with those from multiple systematic reviews concluding that eHealth delivery of cardiac rehabilitation increases patient physical activity and compliance [14,33-35]. As suggested by a recent review of remote solutions for CR, the use of multiple devices for monitoring and communication with their health care team, program personalization, and continuous feedback for users all contributed to the program compliance and feasibility found in this study [20]. This review of 19 different studies of remote cardiac rehabilitation programs noted, as did ours, no intervention-related adverse events, suggesting that remote CR is generally safe.

This study contributes to the literature in several ways. To the best of our knowledge, this is the first study that tested a concurrent telehealth and mHealth dual-modality HBCR program in a group of age and sex-diverse adults in the United States. An Australian-based randomized controlled trial with 24-week (12+12) sequential dual modality HBCR program is currently being tested [36]. It was designed to be pragmatic, with care team members providing remote CR service using existing clinical procedures and electronic medical records system for workflow management. Hybrid, remote, and digitally supported CR services appear to be a safe and effective delivery approach for secondary prevention of CVD with growing evidence [4,37-40]. In addition, the encouraging uptake of remote CR services by women and minority patients may offer new ways to reduce disparities in CR care [41], with the potential to greatly increase the number of patients with CVD engaging in evidence-based CR, an intervention shown to positively impact the health, fitness, and quality of life outcomes for these patients [7,42,43]. Our data demonstrate that patients with CVD will maintain engagement with a platform like RPH remote CR that combines synchronous 1:1 telerehabilitation sessions with an EP with asynchronous exercise sessions longer than they would be traditional in-person CR. In addition, the on-demand exercise feature of the program provides an engaging physical activity option outside of the one-on-one teleconferencing sessions, a promising solution to scheduling and scalability challenges of traditional in-person CR programs. Finally, it is encouraging that this study enrolled a gender, culturally, and geographically diverse patient population, all of which has long been recognized as being underserved by CR services [44-46].

Limitations

Several limitations should be considered when interpreting the findings. This single-arm remote clinical trial did not include a control group, so we cannot rule out the possibility that the changes in the patient outcome measures may be due to factors other than the RPH-D program. This design choice was based on clinical and ethical reasons: CR is a well-established clinical approach to manage CVD; thus, a randomized controlled trial would have required either not offering or delaying the active intervention to half of all eligible patients. Even a randomized controlled trial with an active CBCR arm would have required some patients to access center-based CR, which may not be readily available to this patient population. Second, study participants came from a national convenience sample with heterogeneous CR-eligible diagnoses and the sample size was modest. Therefore, the findings should be replicated in larger national studies that would allow for subgroup analyses (eg, by referring diagnoses, age, or sex) to help inform clinical practice. Third, the 12-week follow-up period was limited and cannot offer evidence regarding longer-term adherence and outcomes. In addition, the participation rate for the mHealth modality was limited, as some participants experienced challenges with using the iPad with wireless monitors due to limited digital literacy. Finally, relying on 2 primary recruitment channels (through community partner referral and web-based advertisement) contributed to the under-recruitment of the study. Future studies should broaden the referral network to include primary and specialty care and include an economic evaluation component to generate evidence regarding the value for payers [47]. Devices that enable coverage beyond traditional Wi-Fi technology (such as those based on 5G mobile phone network or satellite network) can further reduce geographic barriers to HBCR. These limitations notwithstanding, this is the first US study to test an innovative dual-modality remote CR program that combined synchronous and asynchronous approaches to deliver a fully remote home-based CR program.

Conclusion

The results of this study show that a dual-modality home-based CR program can be a feasible option to improve access to home-based CR for improving functional exercise capacity after acute CVD. Future research using randomized controlled design (eg, a preference-based RCT) is needed to test the RPH-D CR program in a larger, more diverse pool of patients. If the long-term impact of this program can be confirmed in a multicenter randomized controlled study, a stronger case can be made to implement HBCR programs in health care systems to increase the uptake of CR and bridge the gap between evidence and practice in secondary prevention of CVD.

Acknowledgments

The authors would like to acknowledge The Mended Hearts, Inc, for assistance with member outreach and recruitment. We also wish to acknowledge all study participants and the staff at Node.Health Foundation and RecoveryPlus.Health, for their contributions to this research project.

Authors' Contributions

TB, NV, RS, SC, and ZL contributed to the conception and design of the project. JM, WZ, CB, RS, and SC contributed to the implementation of the program and acquisition of data. RS, SC, and HM drafted the manuscript. TB, JM, SN, SB, HM, and ZL critically revised the manuscript. All authors gave final approval and agreed to take responsibility for the integrity of the data and the accuracy of the work reported.

Conflicts of Interest

TB, JM, WZ, CB, XC, and ZL are employees of RecoveryPlus.Health.

Abstract

Background: Health care professionals use mobile apps to support patients' rehabilitation after total hip or knee arthroplasty. Understanding patient engagement in such mobile health interventions can help tailor these interventions to better support patients.

Objective: This study aimed to investigate patient engagement in a mobile app–based arthroplasty rehabilitation program and to investigate the association between patient engagement and their characteristics.

Methods: Data were extracted from a pool of 42 participants in the experimental arm of a randomized controlled trial that used a mobile app (WeChat [Tencent Holdings Limited])–based program to support patients' rehabilitation after total hip or knee arthroplasty. The primary outcomes were the number of days the participants accessed the program and completed recommended rehabilitation tasks. Secondary outcomes included data on the participants' posts on a discussion forum, messages sent by the participants, access to the program components, and reading and sharing the program content. Generalized linear models were used to analyze the association between patient engagement and personal characteristics.

Results: The participants reported in a rehabilitation diary accessing the program on a mean of 5.2 (SD 2) days per week and completing recommended rehabilitation tasks on a mean of 6.5 (SD 0.8) days per week. The majority (31/42, 74%) posted on the discussion forum, with a mean of 18.1 (SD 21.2) posts. Most participants (37/42, 88%) sent messages to health care professionals, with a mean of 14 (SD 15.9) messages. The program components were visited for a total of 525 times. The program content was read 898 times and shared 82 times in total. Generalized linear models showed that both primary outcomes, the number of days the participants accessed the program (B=6.46, 95% CI 1.98-15.35; χ^2_1=11.1, *P*=.001) and the number of days they completed rehabilitation tasks (B=2.65, 95% CI 0.45-5.48; χ^2_1=5.7, *P*=.02), were positively associated with having a high school education or above. In addition, the number of posts on the discussion forum was positively associated with living with family, having a high school education or above, undergoing total knee arthroplasty, having comorbidities, and the score of self-efficacy but was negatively associated with age. The number of messages sent by the participants was positively associated with having a high school education or above, having comorbidities, and the score of self-efficacy.

Conclusions: Patient engagement in mobile arthroplasty rehabilitation is associated with their education level, cohabitation status, age, type of surgery, presence of comorbidities, and sense of self-efficacy. Program developers can consider these characteristics and use strategies, such as family involvement, in the design of mobile arthroplasty rehabilitation programs to enhance patient engagement in such interventions.

KEYWORDS

total hip arthroplasty; total knee arthroplasty; rehabilitation; mobile health; social media application; patient engagement

Introduction

Over 3 million total hip arthroplasty (THA) and total knee arthroplasty (TKA) procedures are performed globally each year [1]. Patients after THA and TKA require rehabilitation to relieve pain, enhance muscle strength, improve mobility, optimize functional outcomes such as walking, and improve health-related quality of life [2,3]. However, patients may have difficulty accessing face-to-face rehabilitation services after arthroplasty due to the geographic distance from rehabilitation facilities or lack of local health resources [4]. This is particularly true in China due to the lack of rehabilitation facilities and qualified health care professionals [5]. With technological advancement, health care professionals can use information and communication technologies, such as mobile apps, to complement or as an alternative to face-to-face services, to support patients' rehabilitation after THA and TKA [6]. Studies have investigated the effectiveness of using mobile apps to support patients' rehabilitation after arthroplasty and reported positive effects of app-based rehabilitation on health outcomes such as pain, range of motion, physical function, and health-related quality of life [7,8]. However, more evidence from robust randomized controlled trials based on physical and psychological outcomes is needed to support the implementation of mobile rehabilitation in arthroplasty populations [9].

Mobile apps used to provide arthroplasty rehabilitation interventions include those specifically designed for target populations [7], commercial medical apps [10,11], and social media apps such as WeChat (Tencent Holdings Limited) [8]. Social media apps are used by many health care providers due to their high penetration, good interactivity, ease of use, and low cost [12]. In China, WeChat is the most popular free social media platform [13] and has been used to provide health interventions, such as weight control and hypertension management [14,15]. We developed a mobile app (WeChat)–based program that was based on theories [16,17] and patients' perceived needs [18] to support patients' rehabilitation in 6 weeks after THA and TKA. A randomized controlled trial was conducted to investigate the effectiveness of the program, and the results showed that the program improved patients' self-efficacy, physical function, and health-related quality of life and reduced levels of anxiety and depression [19]. Study participants reported that the program facilitated their access to health care, encouraged their postoperative recovery, supported the relationships with health care professionals and other patients in the program, and facilitated their learning during postarthroplasty rehabilitation [20]. However, the extent to which patients were engaged in the mobile app–based rehabilitation program and how this engagement was associated with patients' characteristics were not investigated.

It is important to understand patient engagement in mobile health interventions because interventions are more efficient and effective when patients are better engaged [21]. In mobile health, patient engagement is defined as "...the ability for apps to enable collaboration, activation and participation, information-sharing, and decision-making in one's own health" [22]. Patient engagement in mobile health is often indicated by the continued use of an app; the intensity of using a function of the app; information dissemination through the app, such as reading and sharing content; and patients' performance, such as reactions and comments on posts in a social media app [23-25]. Collection and analysis of data on patient engagement will facilitate the understanding of patients' preferences for using mobile health programs, disparities among populations, and barriers to engagement, which will further inform the improvements in the design of mobile health programs as well as strategies to enhance patient engagement in mobile health [24,25].

Patient engagement in mobile arthroplasty rehabilitation has not been extensively explored. Previous studies analyzed usage data (eg, log-in frequency) automatically recorded by commercial medical apps [11] or apps specifically designed for arthroplasty populations [7,26] and reported that 11% to 14% of patients did not adhere to the mobile rehabilitation programs recommended by health care professionals. One reason was that patients could not interact with the program because of technical challenges, such as the need to set up sensors and touch the device multiple times to start a session [7,26]. However, a research gap exists in patient engagement in social media–based health interventions, requiring further studies to explore engagement assessment as well as strategies to promote patient engagement [27]. For example, measuring patient engagement in WeChat-based interventions may differ from that based on specifically designed or commercial medical apps that could track log-in data, as WeChat's privacy policy does not allow researchers to access individual data on log-in frequency and duration [28]. A self-reported rehabilitation diary and counting data (eg, number of posts and messages) may provide information about patient engagement in such social media app–based programs [29].

Furthermore, evidence of the association between patient engagement in mobile health and personal characteristics is inconclusive. For example, a study on a mobile program to support medication adherence reported that age was positively associated with the duration of patients' usage of the program, while gender and education level had no association with either duration or intensity of usage [30]. Another study found that age, education level, family monthly income, and employment status were associated with the usage duration and log-in frequency in a mobile breast cancer support program [31]. In mobile arthroplasty rehabilitation, patient engagement may be

influenced by factors such as age, pain, and limited physical function after surgery [32,33]. In addition, surgical procedures, such as THA and TKA, may also affect patients' use of social media for health purposes [34]. Elucidating the association between patient engagement and their characteristics can guide the development of programs that are delivered through social media platforms to make them acceptable to patients and thus effective in supporting patients' rehabilitation [35].

This study aimed to investigate patient engagement in a social media app–based rehabilitation program for THA and TKA by analyzing data that had been collected in a randomized controlled trial. The objectives were to (1) investigate patient engagement in the 6-week mobile arthroplasty rehabilitation program through data collected from a written rehabilitation diary, data on the patient's performance in the program, and data tracked by the app's background system; and (2) examine the association between patient engagement and their demographic and clinical characteristics.

Methods

Study Participants

This study extracted data from the pool of 43 participants in the experimental arm of a single-center, parallel-group, randomized controlled trial conducted at a university hospital in Shanghai, China. All participants were adults (aged ≥18 years) who (1) were discharged home after a unilateral primary THA or TKA and (2) had access to a 6-week, mobile app–based rehabilitation program after hospital discharge. Patients were excluded from this study if they could not practice recommended rehabilitation exercises due to major complications or serious health conditions such as heart failure or had severe vision impairment.

Description of the Mobile App–Based Rehabilitation Program

A 6-week, theory-underpinned rehabilitation program was provided to study participants through the app WeChat, aiming to enhance their self-efficacy during rehabilitation and improve their rehabilitation practice and outcomes. The program provided exercise demonstration videos that were designed for patients after THA and TKA. The participants were suggested to follow the videos and practice for 1 hour per day and at least 5 days per week. In addition, program components were designed to enhance patients' self-efficacy for rehabilitation, such as setting weekly goals for rehabilitation; scheduling progressive rehabilitation tasks; providing short stories and videos to share the experiences of previous patients; holding a discussion forum that involved health care professionals, patients, and researchers through the app; and providing psychological techniques such as relaxation exercises. To facilitate the participants' learning process, educational materials in the program were designed using visual presentations with short text messages, and a paper booklet on the use of the program was provided in addition to verbal explanations. A detailed description of the program has been published [36].

The mobile app–based rehabilitation program was carried out between May 2021 and January 2022. Educational materials such as demonstration videos were uploaded to the app (WeChat) in advance. The participants could learn at home through WeChat installed on their own mobile devices. To improve participants' engagement in the program, the researchers sent an exercise reminder every Monday, and the participants were encouraged to record their usage of the program and completion of recommended rehabilitation tasks in a written rehabilitation diary.

Patient Engagement in the Program

Patient engagement in the mobile rehabilitation program was evaluated using 3 measures. The first measured the number of days the participants accessed the program and the number of days the participants completed recommended rehabilitation tasks. These data were obtained by reviewing the participants' records in their rehabilitation diary. The total number of days and the number of days per week were calculated for each participant. The second measure counted the number of participants' posts on the discussion forum and the number of messages sent by the participants to health care professionals. The percentages of participants posting on the discussion forum and sending messages were calculated, as well as the number of posts and messages for each participant. The third measure focused on the data from the background system of the app, which tracked how many times the content from the program was read and shared by the participants and how often the program components were visited.

The primary outcomes of this study were the number of days the participants accessed the program and the number of days they completed the recommended rehabilitation tasks as recorded in the paper diary. These outcomes reflected individual engagement in the mobile rehabilitation program. Secondary outcomes focused on engagement in a part of the program, including the number of posts made by the participants on the discussion forum, the number of messages they sent to health care professionals through the app, the total number of visits to the program components, and the total number of times the content was read and shared.

Demographic and Clinical Characteristics

Before starting the mobile rehabilitation program, study participants completed a paper questionnaire that collected their demographic and clinical characteristics. Demographic data included age, gender, BMI, residence, cohabitation status, education level, and employment. Clinical data included the type of surgery; reasons for surgery; comorbidities; long-term use of medication; and health assessment outcomes such as self-efficacy, self-reported physical function, severity of pain, levels of anxiety and depression, and health-related quality of life. Self-efficacy was measured using the Chinese version of the Self-Efficacy for Rehabilitation Outcome Scale, a 12-item scale that measures the patient's belief in their ability to perform physical rehabilitation behaviors after hip or knee surgery [37,38]. Patient-reported physical function was measured using the Chinese version of the Hip Disability and Osteoarthritis Outcome Score Physical Function Short Form for THA and the Knee Injury and Osteoarthritis Outcome Score Physical Function Short Form for TKA [39,40]. The severity of pain was measured using the Numeric Rating Scale for Pain [41]. Levels of anxiety and depression were measured using the Chinese version of the

Hospital Anxiety and Depression Scale [42]. The patient's health-related quality of life was measured using the Chinese version of the 5-level EQ-5D version developed by the EuroQol Group [43].

Statistical Analysis

Data were analyzed using IBM SPSS Statistics (version 28.0; IBM Corp) [44]. Numerical data were described using means with SDs and medians with IQRs. Categorical data were described using frequencies and percentages. In association analyses, data on the number of days accessing the program and the number of days completing rehabilitation tasks were categorized as "equal to or greater than 30 days" and "less than 30 days or missing data" since the participants had been suggested to practice rehabilitation at least 5 days per week (30 days in total) with the support from the program.

As the outcome variables were categorical data (eg, 2 categories of the number of days accessing the program) or counting data (eg, the number of posts and messages), generalized linear models were used to analyze the association between patient engagement and their demographic and clinical characteristics. Pearson correlation analysis was performed for explanatory variables, and pairs of variables with correlation coefficients greater than 0.7 (age and employment as well as comorbidities and long-term use of medication) were discussed within the research team. A decision was made to remove 2 variables, employment and long-term use of medication, from the model, as they might be due to highly correlated variables. A collinearity diagnostic was conducted for the remaining explanatory variables. The results showed that the tolerance of the variables was greater than 0.2 and the variance inflation factor was less than 5, indicating that there was no significant collinearity between the variables. Therefore, all remaining explanatory variables (ie, age, gender, BMI, residence, cohabitation status, education level, type of surgery, reasons for surgery, comorbidities, self-efficacy, self-reported physical function, severity of pain, levels of anxiety and depression, and health-related quality of life) were included in generalized linear models. Considering the coprimary outcomes, the statistical significance was set as an α level of .025.

Ethical Considerations

Ethical approval to conduct this study was obtained from the Human Research Ethics Committee of the University of Newcastle in Australia (reference H-2020-0414) and from the study hospital (reference B2021-096R). All participants signed a written informed consent before they were enrolled in the study. The original approval covers secondary data analysis without additional consent.

Results

Participant Characteristics

As 1 patient dropped out from the study within 1 week after group allocation and did not participate in the mobile rehabilitation program, this study included 42 participants in total. Women comprised 74% (31/42) of the participants, and the age ranged from 33 to 83 (mean 66.7, SD 10.4) years. The participants had undergone THA (23/42, 55%) or TKA (19/42, 45%). Most participants underwent surgery because of osteoarthritis (35/42, 83%), followed by acute fractures (5/42, 12%) and other reasons (2/42, 5%). The majority (30/42, 71%) had chronic diseases, such as hypertension (19/42, 45%) and diabetes mellitus (9/42, 21%), and were taking medication for these diseases. Most participants (39/42, 93%) lived with their families after THA and TKA surgery, and 90% (38/42) of the participants were unemployed or retired at the time of the study. In terms of education levels, 24% (10/42) had completed education at university or college, 31% (13/42) had completed high school education or had equivalent learning experience, 29% (12/42) had completed middle school education, and 17% (7/42) had primary school education or lower.

Patient Engagement in the Mobile App–Based Rehabilitation Program

The majority of study participants (26/42, 62%) returned their completed rehabilitation diary to health care professionals. In the diaries, 65% (17/26) reported accessing the program in 30 or more days, and 96% (25/26) reported completing recommended rehabilitation tasks in 30 or more days. The number of days that the participants accessed the rehabilitation program ranged from 1.3 to 7 (mean 5.2, SD 2; median 5.8, IQR 4.1) days per week, and the number of days that the participants completed recommended rehabilitation tasks ranged from 3.5 to 7 (mean 6.5, SD 0.8; median 7, IQR 0.8) days per week. Table 1 presents descriptive statistics on participant-reported access to the program and completion of rehabilitation tasks, and an exploratory analysis of changes in these data over 6 weeks is provided in Multimedia Appendix 1.

As shown in Table 1, the majority (31/42, 74%) posted questions or comments on the discussion forum in the app. The number of posts ranged from 1 to 70 (mean 18.1, SD 21.2; median 10, IQR 22). Most participants (37/42, 88%) sent messages to health care professionals. The number of messages ranged from 1 to 69 (mean 14, SD 15.9; median 10, IQR 11). The app's background system showed that the participants read the educational materials in the program 898 times, with a mean of 21.4 times per person, and shared these materials 82 times, with a mean of 2 times per person. The most frequently visited program components were related to the rehabilitation after arthroplasty, such as exercise demonstration videos (243/525, 46%), precautions after the surgery (100/525, 19%), and follow-up schedules (84/525, 16%). They are followed by the stories and short videos shared by previous patients (55/525, 11%) and psychological support components (43/525, 8%).

Table 1. Patient engagement in the mobile app–based rehabilitation program for total hip or knee arthroplasty during the 6-week intervention.

Patient engagement in the program	Value, min[a]	Value, max[b]	Value, mean (SD; 95% CI)	Value, median (IQR; 95% CI)
Number of days accessing the program (n=26; d/wk)	1.3	7	5.2 (2; 4.4-6.0)	5.8 (4.1; 4.4-6.9)
Number of days completing rehabilitation tasks (n=26; d/wk)	3.5	7	6.5 (0.8; 6.2-6.8)	7 (0.8; 6.7-7.0)
Number of posts on the discussion forum (n=31; times)	1	70	18.1 (21.2; 10.4-25.9)	10 (22; 5-16)

[a]Min: minimum.

[b]Max: maximum.

Association Between Patient Engagement, Demographic, and Clinical Characteristics

Table 2 shows the association between patient engagement in the mobile app–based rehabilitation program and their demographic and clinical characteristics. The number of days that the participants reported accessing the program was positively associated with having a high school education or above (B=6.46, 95% CI 1.98-15.35; χ^2_1=11.1, *P*=.001). The number of days that the participants reported completing rehabilitation tasks was positively associated with having a high school education or above (B=2.65, 95% CI 0.45-5.48; χ^2_1=5.7, *P*=.02). The number of posts that the participants posted on the discussion forum was negatively associated with age (B=–0.09, 95% CI –0.16 to –0.02; χ^2_1=6.6, *P*=.01) but positively associated with living with family (B=2.74, 95% CI 1.42-4.06; χ^2_1=16.6, *P*<.001), having a high school education or above (B=2.46, 95% CI 1.22-3.69; χ^2_1=15.1, *P*<.001), undergoing TKA surgery (B=1.34, 95% CI 0.35-2.33; χ^2_1=7, *P*=.008), having comorbidities (B=2.13, 95% CI 0.32-3.95; χ^2_1=5.3, *P*=.02), and the score of self-efficacy (B=0.33, 95% CI 0.13-0.53; χ^2_1=10.2, *P*=.001). The number of messages sent by the participants was positively associated with having a high school education or above (B=0.90, 95% CI 0.18-1.62; χ^2_1=6, *P*=.01), having comorbidities (B=1.21, 95% CI 0.20-2.23; χ^2_1=5.5, *P*=.02), and the score of self-efficacy (B=0.22, 95% CI 0.05-0.39; χ^2_1=6.2, *P*=.01).

Discussion

Principal Findings

This study investigated patient engagement in a social media app (WeChat)–based arthroplasty rehabilitation program by analyzing data obtained from the app (eg, posts, messages, and reading and sharing of program content) and a written rehabilitation diary (eg, days patients accessed the program and completed recommended rehabilitation tasks). The proportions of patients who accessed the WeChat–based program and who completed recommended rehabilitation tasks are comparable with that reported in previous arthroplasty rehabilitation programs using specifically designed apps or commercial medical apps [7,11,26]. Usage data, such as the number of days per week the patients accessed the program, the average number of posts on the discussion forum, and the average number of messages sent by the patients, are also similar to that in a TKA

rehabilitation program based on a commercial medical app [10]. The previous programs were considered to have high levels of patient acceptance and engagement [10,26]. These findings provide evidence that arthroplasty rehabilitation delivered by WeChat has good patient engagement. Furthermore, the findings from this study suggest that patient engagement in mobile arthroplasty rehabilitation is associated with demographic characteristics such as age, education level, and cohabitation status, as well as clinical characteristics such as type of surgery, presence of comorbidities, and sense of self-efficacy. This adds to the body of evidence about the relationship between patient engagement in mobile arthroplasty rehabilitation and personal characteristics.

Education level was found positively associated with all 4 indicators of patient engagement in this study. This supports the evidence that education levels influence patients' usage of mobile health technologies. A previous study reported that women with higher levels of education had more frequent log-ins and longer usage durations in an app–based breast cancer support program [31]. The authors explained that this was because women with higher levels of education were more receptive to new knowledge and had a greater capacity for understanding health information. In addition to these reasons, patients with higher education levels may be more familiar with the access and use of mobile health technologies, which may have facilitated the engagement of this group of patients in our study. Conversely, patients with lower education levels may need support to facilitate engagement in mobile health care. Program developers could consider using visual presentations, such as videos and pictures, instead of written materials, and plain language instead of medical jargon to improve engagement in mobile health interventions in populations with lower levels of education.

This study found that patients who lived with their families after surgery posted more frequently on the discussion forum held through the app. Because of cultural contexts such as filial piety and kinship, patients after arthroplasty in China tend to live with their families. Family members are usually the primary caregivers of the patients, participating in and influencing the patient's decisions about treatment and care [45]. In our study, family members who lived with the patients may have aided the patients' usage of the mobile app–based rehabilitation program, such as technical assistance, which may have facilitated patient engagement in the program. Patients who have experienced mobile app–based arthroplasty rehabilitation reported that they perceived involving family members would help them better use the programs [20]. Family involvement is also considered important for postarthroplasty recovery in other cultural contexts. One study conducted in 6 European countries recommended the inclusion of family members in health education to fulfill their knowledge expectations and better support patients' postarthroplasty rehabilitation [46]. Therefore, we recommend including family members in mobile arthroplasty rehabilitation programs, such as giving family members access to health information provided in the program and enabling their involvement in discussions. This will help family members understand arthroplasty rehabilitation and support the patients to be more engaged in the rehabilitation program.

In terms of type of surgery, this study found that patients after TKA were more engaged in the discussion forum than patients after THA. It has been reported that THA procedures offer patients better outcomes on pain relief, daily activity performance, expectations met, and overall satisfaction with the surgery than TKA [47]. Approximately 10% (2,754/25,012) of patients undergoing TKA are dissatisfied because of factors such as unmet expectations and persistent pain [48]. Patients after TKA thus may have more concerns and questions than those after THA about their postarthroplasty recovery and need more support during rehabilitation. The discussion forum of the current program enabled patients to obtain timely support from health care professionals and fellow patients undergoing similar procedures. When investigating the effectiveness of the mobile rehabilitation program, this support was confirmed by the patients [20]. Future studies could investigate the specific support required by patients after TKA and solutions to address the requirements so that mobile rehabilitation interventions are tailored for this population.

In our study, patients with comorbidities, such as hypertension and diabetes mellitus, were more engaged in the discussion forum and sending messages. Patients with such chronic diseases may have developed skills to access health information and support and embraced technology to help them understand and manage their chronic conditions [30,49]. These skills may have facilitated their engagement in the current mobile rehabilitation program for arthroplasty. For instance, in a previous study, a patient who underwent THA with systemic lupus erythematosus said that they were familiar with seeking health information about their condition from the internet, but they preferred to use the mobile rehabilitation program that was specifically designed for patients undergoing arthroplasty as they found that the health information provided by health care professionals in the program was more comprehensive and reliable than that available on the internet [20].

Patients' self-efficacy scores were found positively associated with the number of posts they posted on the discussion forum and the number of messages they sent to health care professionals. A systematic review reported that self-efficacy as a predictor of patient engagement in online health interventions was inconclusive, as few studies had explored the relationship [50]. Theoretically, patients with a higher sense of self-efficacy are more confident in accomplishing rehabilitation tasks [16]. These patients may be more inclined to view difficulties arising during rehabilitation as challenges that they should put more effort into or seek support from health care professionals and others [51]. In this study, patients were provided with the opportunity to obtain professional and peer support through the discussion forum held through WeChat and sending messages to health care professionals. This may explain why patients with higher self-efficacy scores were more engaged in these 2 components of the program. Future mobile rehabilitation programs could consider identifying patients with a lower sense of self-efficacy and providing support to facilitate their engagement in the program. The theory of self-efficacy [16] could be used to guide the individualization of mobile rehabilitation interventions.

However, this study found that patient engagement, such as posting on the discussion forum, was negatively associated with age. This is consistent with the findings of a previous systematic review that older age is associated with decreased engagement in mobile technology–based monitoring for TKA [32]. Physiological declines with advancing age, such as decreased visual perception and hearing loss, may hinder using mobile technology–based health interventions in older populations [52]. Low technology proficiency was reported as a barrier to engagement in eHealth in older adults [53], but other researchers have also claimed that advanced age is not a major issue in the use of mobile health technologies if adequate orientation and coaching are provided [54]. Zhu et al [31] found that older women were even more engaged in a mobile app–based breast cancer support program than younger women. The authors believed that user-centered design, technical support, and provision of easy-to-understand information would facilitate older patients' engagement in mobile health interventions [31]. Therefore, age as a predictor of patient engagement in mobile health is inconclusive, and more research is needed to understand the relationship between them and possible mediating factors.

Study Limitations

This study has limitations. Engagement data were extracted from 1 arm of a randomized controlled trial. This may have introduced selection bias in the results as patients who voluntarily participated in the trial might be more familiar with technology and thus better engaged in the program. The results of this study should be interpreted with caution, as the sample size was small, which may have reduced the power of the statistical analysis [55]. Due to the privacy policy of WeChat, the engagement data from the app's background system, such as the times of reading and sharing the program content, are global counts, and the data of each participant cannot be identified. This limits the exploration of individual disparities in program usage. The current program is a 6-week mobile rehabilitation program focusing on acute rehabilitation after arthroplasty, which limits the exploration of how patient engagement in mobile rehabilitation changes with recovery after surgery.

Data collected through the written rehabilitation diary may not fully represent patients' access to and completion of the rehabilitation program. The return rate of the rehabilitation diary was 62% in this study, which is in the middle of the range reported in previous studies where 35% to 86% of patients undergoing THA or TKA returned a written diary to health care professionals [56,57]. However, a large proportion (74% and 88%, respectively) of patients in our study posted and sent messages in the mobile rehabilitation program, suggesting some patients who did not return the diary engaged in the program. App-based electronic diaries have reported high completion rates. For example, a study had 89% to 94% of patients completing the diary [58]. Electronic diaries facilitate the return rate by sending reminders, tracking reports in a real-time way, and collecting data remotely without physical space restriction [59]. However, further investigation is needed on how to incorporate electronic diaries into social media app–based arthroplasty rehabilitation programs. Furthermore, the validity of the written rehabilitation diary may have been reduced if the patients back- and forward-filled in their diaries to meet the expectations of health care professionals [60].

Conclusions

The social media app–based arthroplasty rehabilitation program can support patient engagement. Patient engagement in mobile arthroplasty rehabilitation is associated with their characteristics, such as education level, cohabitation status, age, type of surgery, presence of comorbidities, and sense of self-efficacy. The future design of mobile app–based arthroplasty rehabilitation programs could consider these characteristics and use strategies, such as involving family members, to improve patient engagement with these interventions.

Acknowledgments

We acknowledge all the study participants. We also acknowledge the University of Newcastle in Australia for providing a data storage system and statistical analysis software which were used in this study. This research did not receive any specific grant from funding agencies in the public, commercial, or not-in-profit sectors.

Conflicts of Interest

None declared.

Abstract

Background: Managing noncommunicable diseases effectively requires continuous coordination and monitoring, often facilitated by eHealth technologies like mobile health (mHealth) apps. The end-user version of the Mobile Application Rating Scale is a valuable tool for assessing the quality of mHealth apps from the user perspective. However, the absence of a French version restricts its use in French-speaking countries, where the evaluation and regulation of mHealth apps are still lacking, despite the increasing number of apps and their strong relevance in health care.

Objective: This study aims to translate and culturally adapt a French version of the user Mobile Application Rating Scale (uMARS-F) and to test its overall and internal reliability.

Methods: Cross-cultural adaptation and translation followed the universalist approach. The uMARS-F was evaluated as part through a cohort study using the French mHealth app “MonSherpa” (Qare). Participants were French-speaking adults with Apple or Android phones, excluding those with difficulty understanding French, prior app use, or physical limitations. They assessed the app using the uMARS-F twice (T1 and T2) 1 week apart. Scores for each section and overall were assessed for normal distribution using the Shapiro-Wilk test and presented as mean (SD), and potential floor or ceiling effects were calculated accordingly. Overall reliability was evaluated using intraclass correlation coefficients and internal reliability using Cronbach α. Concordance between the 3 subscales (objective quality, subjective quality, and perceived impact), 4 sections, and 26 items at T1 and T2 was evaluated using the paired *t* test (2-tailed) and Pearson correlation.

Results: In total, 167 participants assessed the app at both T1 and T2 (100% compliance). Among them, 49.7% (n=83) were female, and 50.3% (n=84) were male, with a mean age of 43 (SD 16) years. The uMARS-F intraclass correlation coefficients were excellent for objective quality (0.959), excellent for subjective quality (0.993), and moderate for perceived impact (0.624). Cronbach α was good for objective quality (0.881), acceptable for subjective quality (0.701), and excellent for perceived impact (0.936). The paired *t* tests (2-tailed) demonstrated similar scores between the 2 assessments ($P>.05$), and the Pearson correlation coefficient indicated high consistency in each subscale, section, and item ($r>0.76$ and $P<.001$). The reliability and validity of the measures were similar to those found in the original English version as well as in the Spanish, Japanese, Italian, Greek, and Turkish versions that have already been translated and validated.

Conclusions: The uMARS-F is a valid tool for end users to assess the quality of mHealth apps in French-speaking countries. The uMARS-F used in combination with the French version of the Mobile Application Rating Scale could enable health care professionals and public health authorities to identify reliable, high-quality, and valid apps for patients and should be part of French health care education programs.

Introduction

Noncommunicable diseases (NCDs), such as cardiovascular diseases, diabetes, cancers, and chronic respiratory conditions, represent a major burden for global health systems and account for 74% of all deaths according to the World Health Organization [1]. The management of NCDs is challenging, requiring complex coordination among various medical stakeholders and regular monitoring of treatments and symptoms outside of hospitalization periods [2].

In the context of new global health care challenges such as demographic changes due to an aging population and a shortage of health care professionals (HCPs), particularly in rural areas, the need to implement out-of-hospital assessment and health monitoring systems to ensure continuous and effective communication between patients and HCPs is critical [3]. eHealth technologies, especially mobile health (mHealth) apps, offer promising solutions to address this need [4,5] and can be applied not only to NCDs but also to health determinants (eg, sleep, diet, exercise, and mental health).

In secondary and tertiary prevention, mHealth apps are revolutionizing the way clinicians and researchers monitor and manage the risk of recurrence or complication [6-9], reducing health inequalities by facilitating access to quality health care [10], improving lifestyle behaviors and chronic condition management, lowering health care costs [11], and increasing patient awareness and autonomy [12,13]. In primary prevention, individuals empower themselves to achieve better health conditions. Despite the growing popularity of mHealth apps and their promising outlook, most of them are unregulated and have not been scientifically evaluated in terms of effectiveness, efficiency, cost, and patient acceptability [14]. The 2016 best practice guidelines by the French National Authority for Health (Haute Autorité de Santé) were an important step toward improving the quality of mHealth apps [15]. These guidelines aimed to provide developers with a framework to ensure apps meet certain standards in terms of functionality, data privacy, and safety but without a clinical purpose. However, the guidelines are nonbinding and do not constitute formal regulation [16]. This means that adherence is voluntary, and there are no legal mechanisms to enforce compliance or monitor apps after launch, which creates gaps in quality assurance. Moreover, while the guidelines outline broad principles, they lack specific evaluation criteria or a standardized certification process, making it difficult for health care providers and users to assess whether an app meets the recommended standards. This creates variability in app quality and can lead to the promotion of apps that may not have been rigorously tested or validated. The absence of mandatory oversight means that some apps might pose risks to users, particularly regarding data security and clinical accuracy.

On the other hand, this lack of evaluation significantly impacts on the difficulties encountered by clinicians and end users face in selecting safe and effective apps [3]. The quality of the information is questionable, and the developer's evaluation is not comprehensive enough to help end users, HCPs, and researchers identify the app's quality [17,18].

Publicly available information, star ratings that may be artificially inflated, or downloads are the most common ways to select a mHealth app rather than validated scientific content [19]. Only a few mHealth apps available on the market have undergone a thorough validation process based on high-level evidence [20]. Appropriate quality and efficacy assessment and assurance are therefore needed both during the development and ongoing use of mHealth apps [21].

To objectively evaluate the validity and functionality of mHealth apps, several standardized scales have been developed for HCPs [22]. One of the most widely used of these assessment tools, the Mobile Application Rating Scale, developed by Stoyanov et al [22], is to date considered as the reference scale for HCPs in the scientific literature. However, this scale requires a level of scientific and clinical expertise and training in mHealth, making it almost impossible for its use by end users. Therefore, the same team of authors developed the end-user version of the Mobile Application Rating Scale (uMARS), which is a valid and objective tool that can be used by end users with different levels of education or by researchers working with end users to evaluate and assess the quality of mHealth apps from end-user perspective [23]. This scale is available in English (uMARS) [23], Spanish (uMARS-S) [24], Italian (uMARS-I) [25], Japanese (uMARS-J) [26], Turkish (uMARS-T) [27], and Greek (uMARS-G) [28]. The cross-cultural translation and validation of the original uMARS into the French language have not yet been carried out, limiting its use in French-speaking countries, despite the fact that 321 millions of people worldwide speak French, representing the fifth most spoken language in the world [29]. The aim of this study was (1) to translate and culturally adapt a French version of the uMARS and (2) to test its overall and internal reliability.

Methods

Study Design

This study followed and applied the universalist approach [30] to translate, cross-culturally adapt, and validate the original version of uMARS [23] into French. The reliability of the French version of the user Mobile Application Rating Scale (uMARS-F) was assessed through a prospective, longitudinal cohort study, adhering to the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines (Multimedia Appendix 1).

Description of the uMARS

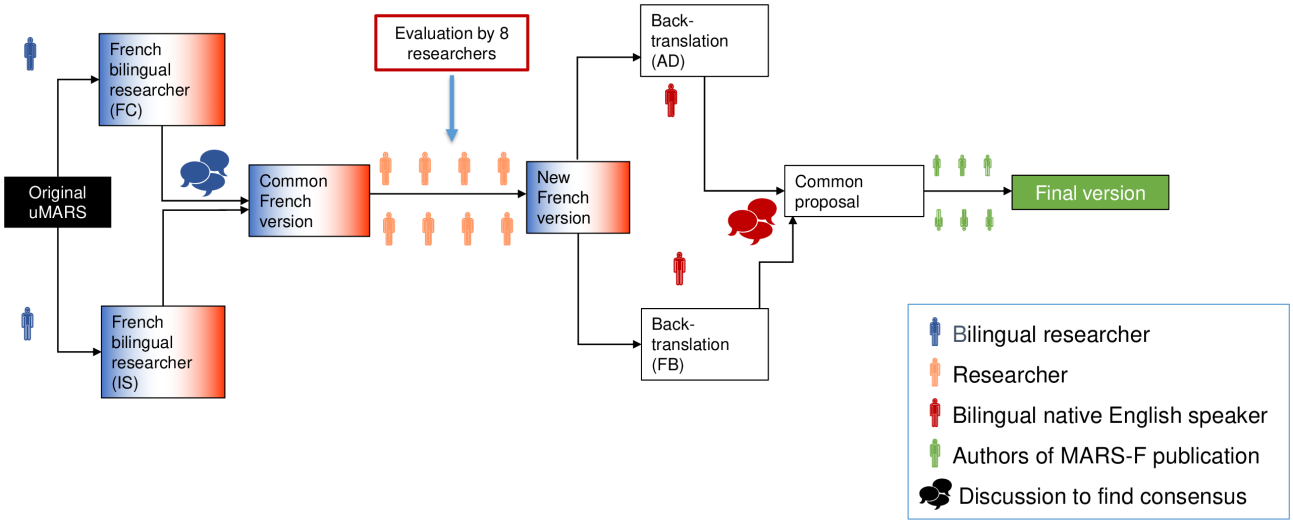
The uMARS is a valid and useful tool designed to allow end users to evaluate the quality of English-language mHealth apps [23]. It consists of 26 items organized into 3 subscales. The first one, the subscale ("objective quality") is divided into 4 sections:

engagement (items 1-5), functionality (items 6-9), aesthetics (items 10-12), and information (items 13-16). The second one, the subjective subscale ("subjective quality") contains 4 items (17-20). The third one, an additional 6-item subscale measuring the app's perceived impact on awareness, knowledge, attitudes, intention to change, help-seeking, and probability of changing the targeted health behavior. Each item of the uMARS is rated on a 5-point Likert scale ranging from 1=poor to 5=excellent. The response "not applicable" (NA) is an additional option included for the information section in case an item may not be applicable. The uMARS scale is both a profile, as each subcategory has a score, and an index, as it provides a final overall score for assessing the quality of mHealth care apps.

Process of Translation and Cultural Adaptation

Figure 1 presents the process of translation and cultural adaptation of the uMARS in the French language. Two native French bilingual researchers (FC and IS) independently translated the original version of the uMARS from English into French. The 2 French translations obtained were compared by the 2 researchers who, in case of discrepancies, discussed to ensure that the meanings were as close as possible to the original English version and proposed a common French version after reaching a consensus. The common version's comprehensibility was then evaluated by 8 researchers (DB, LF, CC, SB, DT, SV, BDSDV, and CD) who, after discussion, agreed on a new consensual French version. This version was blind back-translated in English by 2 native English speakers (AD-B and Felicor Bongolan) independently. Their final common proposal was reviewed and compared with the original English version, which was then read and evaluated by 6 researchers, authors of the French version of the Mobile Application Rating Scale (MARS-F; IS, FC, LF, DB, CD, and DT). Their comments and suggestions were discussed within the research group, and the final version of the uMARS-F was developed.

Figure 1. Translation methodology for uMARS. MARS-F: French version of the Mobile Application Rating Scale; uMARS: user version of the Mobile Application Rating Scale.



Evaluation of Reliability

The reliability of the uMARS-F was evaluated between December 2022 and June 2023 using the French mHealth app "MonSherpa" (Qare). This app, chosen by the research team, is a free psychological support app available in the Google Play and Apple stores, targeting adults (≥18 years) of both sexes.

The sample size for validation of the uMARS-F scale was calculated to ensure sufficient statistical power to assess reliability. Using test-retest reliability with intraclass correlation coefficients (ICCs) in a 2-way random-effects, k-measurement model with consistency, the target was to detect an ICC of 0.75 with 80% power and a 5% significance level, with 2 measures per participant. Based on standard calculations, a minimum of 35 participants was required to achieve this level of reliability.

The recruitment method was based on voluntary participation. Participants were initially enrolled through the established network of research laboratory members, who received an email inviting them to participate. Additionally, social networks such as LinkedIn and Facebook were used to reach a broader audience. A snowball effect was also used, where initial participants were encouraged to refer others who might be interested.

The inclusion criteria were (1) French people aged 18 years and older, (2) persons having access to an Apple or Android phone, and (3) people who did not know the app or had not used it before. The exclusion criteria were people who (1) have difficulty in understanding the French language, (2) already know and used this app personally, and (3) had difficulty using "MonSherpa" for any reason (eg, physical disability).

Eligible participants were asked to download the "MonSherpa" app and use it at least 5 minutes a day for 1 week. On the seventh day, they rated (time 1, T1) this app using a web-based version of the uMARS-F. Then, they were not allowed to use this app for 1 week. Finally, after this washout period, all the participants used this app for only 5 minutes and rated it once again using the same scale (time 2, T2).

Data Analysis

Descriptive Statistics

The distribution of summary scores for each section and for all sections was evaluated for normal distribution using the

Shapiro-Wilk test. For the normal distribution, means and SDs were calculated. Floor or ceiling effects were present when more than 15% of responses were rated as the minimum or maximum scores, respectively [31].

Evaluation of the Validity and Reliability of the uMARS-F

Intraclass Correlation Coefficient

The ICCs were calculated to assess the interrater reliability of the sections and subscales. A random-effects average measures model with absolute agreement was used for this calculation. ICC values were interpreted as follows: less than 0.50 indicated poor reliability, 0.51-0.75 indicated moderate reliability, 0.76-0.89 indicated good reliability, and greater than 0.90 indicated excellent reliability.

Cronbach α

The internal consistency of the uMARS-F questionnaire was evaluated using Cronbach α. A high Cronbach α indicates that the items within the scale are well correlated, suggesting that the scale is reliable. The interpretation of the Cronbach α coefficient was as follows: excellent (≥0.90), good (0.80-0.89), acceptable (0.70-0.79), questionable (0.60-0.69), poor (0.50-0.59), and unacceptable (<0.50) [31].

Pearson Coefficient

The test-retest reliability was evaluated using Pearson *r* coefficients with 95% CIs. The correlation coefficient ranges between –1 and 1, with values closer to 1 indicating a strong positive linear relationship between the subscales, sections, and items, and values closer to –1 indicating a strong negative linear relationship. The significance of the correlations was assessed to determine the strength of the association.

Paired *t* Test

The paired *t* test (2-tailed) was used to compare the means of the 2 times and evaluate the test-retest reliability. This test assesses whether the mean difference between paired observations is significantly different from 0. A *P* value less than .05 indicates that there is a statistically significant difference between the paired means.

Statistical Software

The statistical analysis was carried out using Python (version 3.10; Python Software Foundation), with scipy.stats for statistical calculations and matplotlib along with seaborn for data visualization.

Ethical Considerations

This study did not involve research with access to health data and, therefore, falls outside the scope of the French Jarde law on research involving humans (Law 2012 - 300 of March 5, 2012). Participants gave their consent by completing the web-based questionnaire, and they could withdraw from the study at any time by logging out. Data were completely anonymous, as no identifying data were collected. The platform Claroline Connect from the University Claude Bernard Lyon 1 used for the web-based questionnaire was in accordance with the Regulation EU 2016/679 of the European Parliament and the Council of April 27, 2016, on the protection of individuals with regard to the processing of personal data and on the free movement of such data. Participants received no compensation.

Results

Cross-Cultural Adaptation and Translation Process

Both the conceptual analysis and the translation were considered relevant and appropriate to French culture. No major differences were found between the 2 independent translations of the uMARS into French. The back-translated version of the uMARS-F was equivalent to the original uMARS except for softening changes. The final version of the uMARS-F was produced after review by the authors and mutual agreement on any discrepancies (Multimedia Appendix 2).

Participant Characteristics

In total, 167 participants assessed the app at both time 1 and time 2 (100% compliance). Among them, 49.7% (n=83) were female, and 50.3% (n=84) were male, with a mean age of 43 (SD 16) years. In terms of education level, 21.6% (n=36) of participants did not have the baccalaureate, 25.1% (n=42) had education levels ranging from the baccalaureate to 2 years postbaccalaureate, and 53.3% (n=89) had education levels higher than 2 years postbaccalaureate.

Descriptive Results of the uMARS-F Assessment

All the participants have filled out the uMARS-F questionnaire twice, 7 days apart. They answered all the questions. The mean uMARS-F objective quality score was 4.08 (SD 0.77), whereas the subjective quality score was 2.95 (SD 1.20), and the perceived impact score was 3.42 (SD 0.96). There were no missing values among the responses.

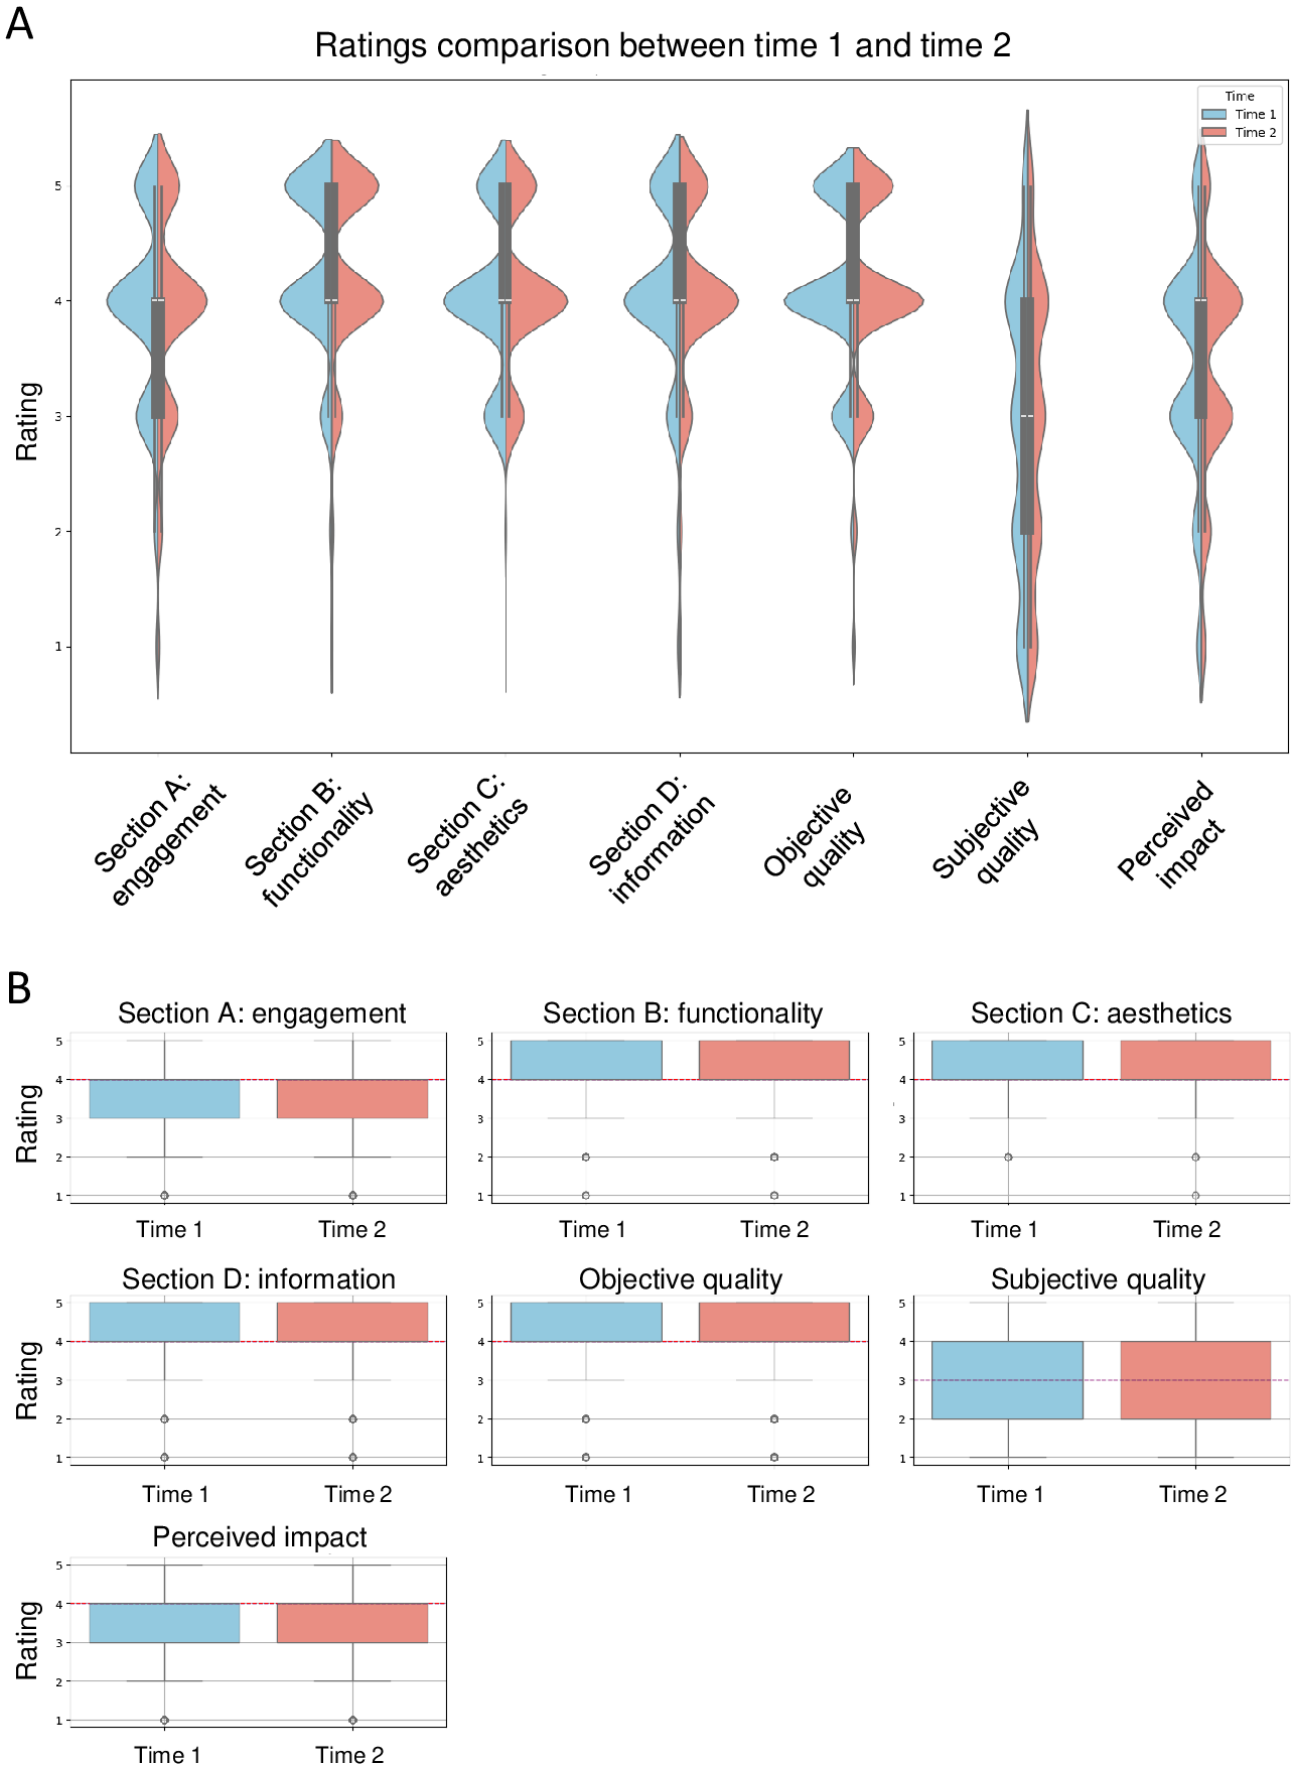
The descriptive analysis of the evaluation is presented in Table 1. A high ceiling effect was observed for the objective quality and its 4 sections (engagement, functionality, aesthetics, and information), suggesting that respondents tended to give higher ratings, indicating overall satisfaction. No floor effect was observed except for the subjective quality (n=26, 15.6%). The Shapiro-Wilk test showed a lack of fit to the normal distribution in subscales and sections.

The distribution of scores across the uMARS-F subscales and sections presented in Figure 2 indicates high consistency between the 2 evaluation times (T1 and T2), as evidenced later by the strong Pearson correlations (all *P*<.001). The objective quality subscale and its sections generally exhibited scores concentrated between 3 and 5, suggesting a favorable evaluation of the app quality. However, the subjective quality subscale showed a wider range of scores from 0 to 5, indicating more variability in user perceptions. For the perceived impact section, scores were predominantly grouped between 3 and 4, reflecting a moderate perceived impact of the app.

Table . Descriptive statistics.

		Ceiling effect, n (%)	Floor effect, n (%)	Shapiro-Wilk, *P* value	Mean (SD)
Objective quality		50 (29.9)	2 (1.2)	<.001	4.08 (0.77)
	Section A (engagement)	38 (22.8)	3 (1.8)	<.001	3.88 (0.87)
	Section B (functionality)	70 (41.9)	1 (0.6)	<.001	4.28 (0.73)
	Section C (aesthetics)	44 (26.3)	0 (0.0)	<.001	4.07 (0.69)
	Section D (information)	47 (28.1)	3 (1.8)	<.001	4.07 (0.80)
Subjective quality		13 (7.8)	26 (15.6)	<.001	2.95 (1.20)
Perceived impact		16 (9.6)	8 (4.8)	<.001	3.42 (0.96)

Figure 2. Descriptive results of the uMARS-F evaluation. (A) Violin plots of the uMARS-F subscales and section scores. (B) Box plot of the uMARS-F subscales and section scores. uMARS-F: French version of the user Mobile Application Rating Scale.



Evaluation of the Validity and Reliability of the uMARS-F

Evaluation of Interrater Reliability Using ICCs and Internal Consistency Using Cronbach α Coefficients

The results for the ICC and Cronbach α are described in Table 2. The ICC was excellent for the objective quality subscale (0.959, 95% CI 0.93-0.98), excellent for the subjective quality subscale (0.993, 95% CI 0.98-1.0), and moderate for the perceived impact (0.624, 95% CI 0.32-0.92). The engagement, aesthetics, and information sections obtained an excellent ICC score, whereas the functionality section obtained a moderate ICC score.

The Cronbach α was good for the objective quality subscale (0.881), acceptable for the subjective quality subscale (0.701), and excellent for the perceived impact subscale (0.936).

Table . Interrater reliability using the intraclass correlation coefficients (ICCs) and internal consistency using the Cronbach α coefficients for the French version of the user Mobile Application Rating Scale.

		ICC (95% CI)	Cronbach α (95% CI)
Objective quality		0.959 (0.93-0.98)	0.881 (0.862-0.899)
	Section A (engagement)	0.975 (0.93-1.0)	0.732 (0.683-0.775)
	Section B (functionality)	0.771 (0.43-0.98)	0.795 (0.757-0.829)
	Section C (aesthetics)	0.914 (0.72-1.0)	0.777 (0.732-0.816)
	Section D (information)	0.926 (0.78-0.99)	0.734 (0.684-0.777)
Subjective quality		0.993 (0.98-1.0)	0.701 (0.646-0.751)
Perceived impact		0.624 (0.32-0.92)	0.936 (0.924-0.946)

Paired t Test and Pearson Coefficient

The paired *t* test (2-tailed) and Pearson coefficient are presented in Table 3. The results from paired *t* tests (2-tailed) indicated no significant differences ($P>.05$) between T1 and T2 between the 20 items and overall subscale scores, highlighting a high test-retest reliability over time in end users' perceptions.

Table . Paired *t* test (2-tailed) and Pearson correlation for the French version of the user Mobile Application Rating Scale.

	Paired *t* test			Pearson correlation	
	Mean score at T1 (SD)	Mean score at T2 (SD)	*P* value	*r*	*P* value
Objective quality	4.06 (0.80)	4.06 (0.80)	.12	0.84	<.001
Section A (engagement)	3.89 (0.86)	3.87 (0.87)	.33	0.84	<.001
1. Entertainment	3.83 (0.79)	3.86 (0.79)	.56	0.78	<.001
2. Interest	3.89 (0.66)	3.89 (0.71)	>.99	0.76	<.001
3. Customization	3.30 (1.01)	3.34 (0.97)	.28	0.88	<.001
4. Interactivity	3.99 (0.76)	3.93 (0.87)	.13	0.81	<.001
5. Target group	4.42 (0.65)	4.33 (0.73)	.05	0.79	<.001
Section B (functionality)	4.27 (0.74)	4.28 (0.73)	.44	0.81	<.001
6. Performance	4.14 (0.77)	4.16 (0.75)	.55	0.87	<.001
7. Ease of use	4.33 (0.67)	4.31 (0.69)	.62	0.76	<.001
8. Navigation	4.21 (0.82)	4.26 (0.81)	.18	0.84	<.001
9. Gestural design	4.40 (0.67)	4.41 (0.64)	.87	0.74	<.001
Section C (aesthetics)	4.05 (0.69)	4.09 (0.69)	.06	0.81	<.001
10. Layout	4.22 (0.63)	4.25 (0.64)	.43	0.81	<.001
11. Graphics	3.86 (0.71)	3.93 (0.70)	.05	0.79	<.001
12. Visual appeal	4.07 (0.68)	4.10 (0.68)	.27	0.81	<.001
Section D (information)	3.95 (0.80)	3.96 (0.77)	.81	0.89	<.001
13. Quality of information	3.95 (0.75)	3.96 (0.73)	.67	0.88	<.001
14. Quantity of information	3.99 (0.75)	3.97 (0.70)	.62	0.79	<.001
15. Visual information	3.93 (0.91)	3.95 (0.89)	.41	0.95	<.001
16. Credibility of source	3.95 (0.80)	3.96 (0.77)	.81	0.89	<.001
Subjective quality	2.94 (1.21)	2.96 (1.20)	.43	0.90	<.001
17. Would you recommend	2.93 (1.06)	2.97 (1.08)	.41	0.81	<.001
18. How many times	3.43 (1.02)	3.43 (1.00)	.89	0.85	<.001
19. Would you pay	1.69 (0.77)	1.74 (0.81)	.15	0.82	<.001
20. Overall (star) rating	3.72 (0.82)	3.69 (0.85)	.51	0.85	<.001

Pearson correlations between T1 and T2 are consistently high (ranging from 0.74 to 0.95), indicating strong positive relationships and high reliability of responses across both time points. These correlations are significant (P<.001), reinforcing the reproducibility of end users' evaluations over time.

Discussion

Principal Results and Comparison With Prior Work

The widespread use of mHealth apps over the last few years has led to a significant revolution in the treatment of lifestyle-related disorders and NCDs, which are now an inevitable part of our modern society [12]. The mHealth apps are an effective health care approach, and their number increased dramatically, accentuated since the COVID-19 crisis [32]. By the end of 2023, there were over 100,000 mHealth apps on the global market, and this number is constantly growing [33]. The French mHealth sector has followed this trend with a growing number of mHealth apps and a high level of interest in their importance for health care over the last 5 years [34]. Therefore, it is crucial to have a standardized and reproductible evaluation scale to identify those that are effective and comply with medical standards [34]. These evaluations must be conducted at 2 main levels: by HCPs, who can assess the quality of the content and its alignment with medical recommendations using the MARS-F;

and by end users using the uMARS-F to evaluate the usability, acceptability, and impact on their engagement in care [7,35,36].

To date, only the MARS-F scale for HCPs [21] is available in French. The aim of this study was to translate, culturally adapt, and validate the French version of the uMARS to enable end users to assess the quality of mHealth apps. For this, a methodology similar to that used for the uMARS-J [26], uMARS-S [24], uMARS-I [25], uMARS-T [27], and uMARS-G [28] scales was followed.

The number of participants completing the questionnaires at T1 and T2 (n=157) was far higher than the calculated minimum sample size (n=35). Consequently, as similar studies have included between 35 [26] and 216 participants [24], it was decided to include all participants and analyze their data to increase the power of the results.

The validation process showed high ceiling effects for objective quality and its 4 sections, with many participants giving high scores, limiting the scale's ability to distinguish top performers. In contrast, subjective quality had a floor effect, indicating dissatisfaction with the personal appeal of the app. The ceiling or floor effects were only observed in the Japanese version [26] and demonstrated no effect.

The reliability of the measures was primarily indicated by the ICC values. The excellent ICC values for most of the sections reflected strong interrater reliability, ensuring that the repeated measures are consistent. The uMARS-F demonstrated higher ICC values for both the objective and subjective quality subscales compared to the English, Spanish, Italian, and Japanese versions [23-26]. The comparison with Turkish and Greek versions was not possible due to unavailable ICC values [27,28].

The higher ICC values observed in the French version of the uMARS compared to the other versions may stem from cultural differences in how users rate apps. Another factor could be the translation and adaptation process of the uMARS into French which can involve, or not, careful attention to linguistic nuances and cultural relevance, contributing to more consistent ratings. This is particularly relevant for the English and Spanish versions, where there are significant linguistic disparities between countries. Additionally, the demographics and characteristics of the study samples (eg, educational levels) may differ across countries, influencing how participants engage with the tool.

These differences have important implications. Higher ICC values in the French version suggest stronger internal consistency, making it a reliable tool for evaluating mHealth apps in French-speaking populations. However, it also highlights the need for localized validation efforts, as the reliability and applicability of the uMARS may vary depending on cultural and linguistic contexts. Future research could explore how these factors impact app evaluations across different regions to ensure the tool is robust and adaptable globally.

Additionally, the results highlight a significant correlation between repeated measures (T1 and T2) using paired *t* test (2-tailed) and Pearson correlation coefficients for all subscales, sections, and items. Paired *t* tests (2-tailed) were uniquely conducted in the Italian version [25] and, similar to this study, showed no statistically significant difference in each answer or group of answers between times 1 and 2 ($P>.05$). Pearson correlation coefficients were evaluated in the Italian [25] and Japanese [26] versions, showing similarly high reliability of responses across both time points (ranging from 0.74 to 0.95).

The validity of the measures is inferred from Cronbach α values, which indicates the internal consistency and the correlation between subscales. High Cronbach α values for objective quality and perceived impact suggested strong internal consistency. The internal consistency across the sections supports the validity of the measures, as it suggests that the subscales are appropriately correlated. For the objective quality subscale, the uMARS-F's Cronbach α (0.881) was similar to that of the original uMARS and other versions, including Italian, Japanese, Spanish, Turkish, and Greek [23-28]. For the subjective quality subscale, the uMARS-F's Cronbach α (0.701) was acceptable and comparable to the original uMARS and Japanese versions [23,26], but higher than the Spanish, Greek, and Turkish versions [24,27,28], though lower than the Italian version [25].

Limitations

This study presents several limitations. First, only 1 mHealth app, MonSherpa, was assessed to validate the study. Further investigations are required to test or retest the uMARS-F on other mHealth apps targeting populations more representative of the general French population. Second, the uMARS-F was developed by native French speakers living in France, and its metric properties must be taken into consideration because French speakers worldwide may have different cultures with different varieties of French depending on their country, and further adaptation may be required [21].

Conclusions

The uMARS-F is a valid tool with adequate metric properties for evaluating the quality of mHealth apps in French-speaking countries. It offers a valuable framework for both developers and researchers to assess and enhance mHealth app quality from an end-user perspective prior to market launch or after the introduction of new functionalities. Therefore, the uMARS-F serves as a cornerstone of the French mHealth field, providing opportunities to identify reliable, high-quality, and valid apps for the benefit of end users.

The integration of the uMARS-F into existing health care systems could significantly enhance mHealth app selection by HCPs and public health authorities, enabling the recommendation of high-quality mHealth apps tailored to patient needs. Moreover, incorporating the u-MARS-F into health care education programs could help future professionals make informed decisions about mHealth tools, potentially improving patient outcomes.

From a regulatory perspective, the uMARS-F could play a key role in establishing standardized quality benchmarks for mHealth apps in French-speaking regions. Developers may also use the tool to align with best practices, ensuring that apps meet both clinical and user-experience standards.

Further research should explore the use of uMARS-F alongside MARS-F in clinical and public health settings to better assess the impact of mHealth apps on patient care. Future studies could also investigate how these tools influence app development, regulation, and long-term health care integration across various French-speaking health care systems.

Abstract

Background: Accurately assessing an individual's diet is vital in the management of personal nutrition and in the study of the effect of diet on health. Despite its importance, the tools available for dietary assessment remain either too imprecise, expensive, or burdensome for clinical or research use. Image-based methods offer a potential new tool to improve the reliability and accessibility of dietary assessment. Though promising, image-based methods are sensitive to adherence, as images cannot be captured from meals that have already been consumed. Adherence to image-based methods may be improved with appropriately timed prompting via text message.

Objective: This study aimed to quantitatively examine the effect of prompt timing on adherence to an image-based dietary record and qualitatively explore the participant experience of dietary assessment in order to inform the design of a novel image-based dietary assessment tool.

Methods: This study used a randomized crossover design to examine the intraindividual effect of 3 prompt settings on the number of images captured in an image-based dietary record. The prompt settings were control, where no prompts were sent; standard, where prompts were sent at 7:15 AM, 11:15 AM, and 5:15 PM for every participant; and tailored, where prompt timing was tailored to habitual meal times for each participant. Participants completed a text-based dietary record at baseline to determine the timing of tailored prompts. Participants were randomized to 1 of 6 study sequences, each with a unique order of the 3 prompt settings, with each 3-day image-based dietary record separated by a washout period of at least 7 days. The qualitative component comprised semistructured interviews and questionnaires exploring the experience of dietary assessment.

Results: A total of 37 people were recruited, and 30 participants (11 male, 19 female; mean age 30, SD 10.8 years), completed all image-based dietary records. The image rate increased by 0.83 images per day in the standard setting compared to control (P=.23) and increased by 1.78 images per day in the tailored setting compared to control (P≤.001). We found that 13/21 (62%) of participants preferred to use the image-based dietary record versus the text-based dietary record but reported method-specific challenges with each method, particularly the inability to record via an image after a meal had been consumed.

Conclusions: Tailored prompting improves adherence to image-based dietary assessment. Future image-based dietary assessment tools should use tailored prompting and offer both image-based and written input options to improve record completeness.

(JMIR Mhealth Uhealth 2024;12:e52074) doi:10.2196/52074

Introduction

Accurate assessment of dietary intake is an essential component in the study of nutrition, energy balance, and interventions for obesity and diabetes. Current tools to measure dietary intake are either too imprecise, or they are precise but too expensive, to provide an accurate assessment for clinical use or large population studies [1].

An increasingly popular tool for measuring dietary intake is image-based dietary assessment. Image-based methods are characterized by images rather than text as the main form of data input and have been reported as a preferred method, particularly among children and adolescents [2]. Image-based

dietary assessment tools, such as Easy Diet Diary, MealLogger, and MyFitnessPal, are increasingly being adopted for clinical, research, and personal use [3-5]. The accuracy of image-based methods is comparable to traditional text-based methods; in a meta-analysis by Ho et al [6], image-based methods underreported energy intake by 20% compared to doubly labeled water, the gold standard for measuring energy intake. For comparison, Burrows et al [7] showed that text-based food records underreported energy intake by 11% to 41% compared to doubly labeled water.

Innovations in phone cameras and computer vision, alongside widespread smartphone ownership, provide an opportunity to advance image-based dietary assessment [8]. For image-based methods to achieve high accuracy, they must improve how users capture the content and portion sizes of the foods they eat. The most basic challenge is that users must remember to record in real time, for the simple reason that they cannot photograph food that has already been eaten. Reminding users to capture images using customized text prompts immediately before a meal has previously been shown to improve adherence to an image-based method [9].

This mixed methods study used a randomized crossover trial to examine if the timing of customized text prompts affected the completeness of dietary recording using an image-based method; we also performed a qualitative study of participant attitudes toward image- and text-based dietary assessment methods and text prompting. This study and its findings will inform the design of a novel dietary assessment application.

Methods

Recruitment

Participants were recruited through a circulating poster on university staff and student email lists, social media sites, and word of mouth. Potential participants contacted the researchers, who then provided information about the study. Individuals were eligible if they met the following inclusion criteria: they (1) were aged ≥18 years, (2) had access to a smartphone with a camera, (3) had internet access on their mobile device, and (4) could speak and read English. There were no additional exclusion criteria.

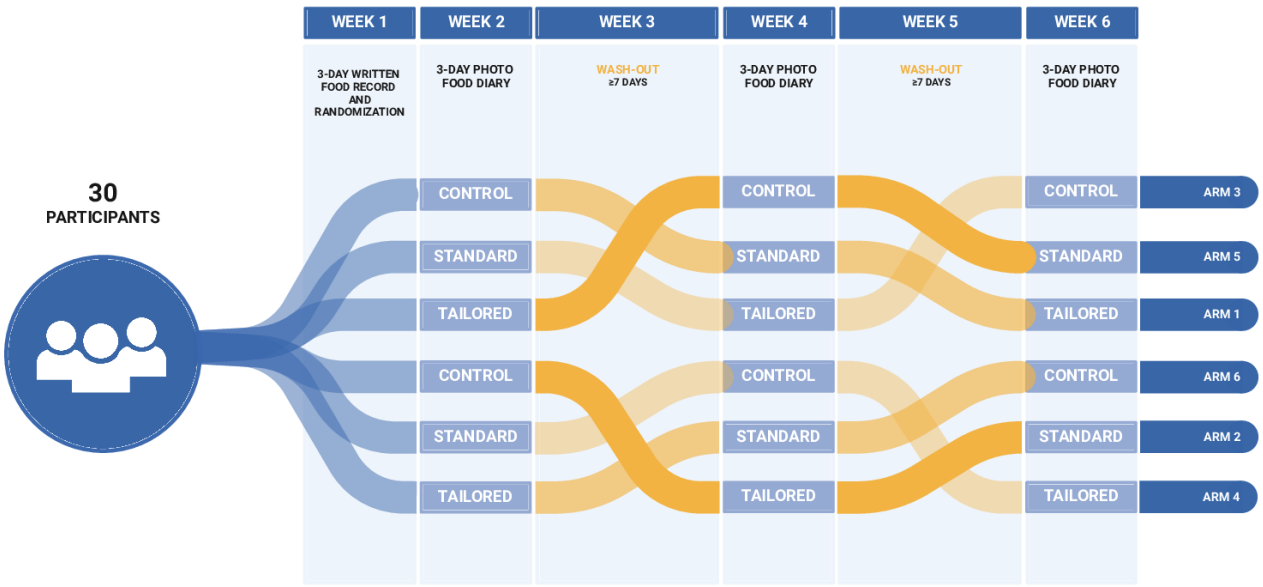
Ethical Considerations

This study was approved by the University of Otago Human Ethics Committee (H21/049). Informed consent was required to participate in the study and was gained at the screening visit. Participants could opt out at any time during the study and were not required to provide a rationale. All participant data were deidentified. Each participant was compensated with a NZ $50 (US $30) supermarket voucher.

Randomized Crossover Trial

The randomized crossover trial compared standard and tailored text prompts to a control period without prompts while completing an image-based dietary record. The study design is shown in Figure 1. Participants attended a screening visit at the research center at the University of Otago, Wellington, New Zealand. After providing written informed consent, eligible participants completed baseline measurements: (1) height in meters using a wall-mounted stadiometer to the nearest 0.5 cm, (2) weight in kilograms to the nearest 0.1 kg using an electronic scale (TBF-300; Tanita Corporation), and (3) resting metabolic rate in kilojoules per day using a ventilated hood (PromethION High-Definition Room Calorimetry System; Sable Systems International). Participants were shown how to use the Easy Diet Diary app (Xyris Software) for the text-based dietary record and image-based dietary record and given the opportunity to ask questions. Easy Diet Diary is free to download from the iOS and Android app stores. Participants then recorded all dietary intake and meal times for 3 days in a text-based dietary record using the text-based features of Easy Diet Diary. Participants were contacted by a researcher if no food was recorded that day to confirm the accuracy of the text-based dietary record. The meal times from this first text-based dietary record were used to calibrate the timing of tailored text prompts for use in the subsequent randomized part of the trial.

Figure 1. Overview of randomized crossover trial design of text prompt settings. Control setting: no prompts received; standard setting: prompts received at 7:15 AM, 11:15 AM, and 5:15 PM; tailored setting: prompts received at times specific to participants' typical meal times as recorded with a text-based dietary record.



After recording the text-based dietary record, participants were randomized into 1 of 6 arms, each arm having a unique order of the 3 text prompt conditions, as described in Figure 1. Participants were reminded to begin their 3-day image-based dietary records using a text message that required confirmation. Each of the image-based dietary records was recorded over 2 weekdays and 1 weekend day. After each 3-day image-based dietary record, participants underwent a washout period of at least 7 days of no recording to mitigate fatigue or training effects. This process was repeated until each participant completed recording under all 3 conditions.

Under the control setting, participants received no prompts. For the standard condition, text prompts were sent at 7:15 AM, 11:15 AM, and 5:15 PM. Data on the typical meal times in New Zealand were unavailable, so these times were chosen to capture participants who might have early meal times. Individually tailored text prompts were determined based on the meal timing provided during the initial text-based dietary record. Each meal time in the text-based dietary record was recorded via the Notes feature of Easy Diet Diary using the following format: "[Time of eating] – [Description of food item consumed]," for example, "1.50 PM – Salmon bagels." Tailored text prompts were set according to the following guidelines: (1) prompts were sent 15 minutes before the earliest recorded eating episode and (2) a prompt for snacks was sent if snack intakes occurred within 1 hour of each other on 2 of 3 days during the text-based dietary record. Both standard and tailored text prompts read, "This is a reminder to record your photo food diary using the Easy Diet Diary app."

Image Rate

The number of images per participant per day was counted across the predefined recording dates. Images generated by the user were automatically uploaded to Easy Diet Diary Connect (Xyris Software) for image rate analysis at the end of each image-based dietary recording period. No analysis or interpretation of nutritional content in the image was performed.

Qualitative Methods

The objective of the qualitative component of the study was to explore the participant experience with each text prompt setting, with the purpose of informing the design of future image-based dietary assessment tools. The qualitative component was composed of interviews and questionnaires. All participants were invited to semistructured open-ended interviews that were conducted one-on-one by a single researcher face-to-face or via video conference (Zoom Video Communications, Inc) after the completion of the image-based dietary records. Interviews lasted for 30 to 60 minutes and focused on (1) the experience of diet monitoring, (2) attitudes toward the Easy Diet Diary app, (3) attitudes toward text prompting, and (4) discussing the participant's "ideal diet monitoring tool." Transcripts of the interviews were coded and thematically analyzed using NVivo Qualitative Data Analysis (QSR International). Additional online questionnaires hosted on Survey Monkey (Momentive Inc) explored the same topics using Likert scales and rankings to identify participant preferences for dietary assessment methods and text prompt settings.

Statistical Analysis

Overview

Statistical analyses were conducted using R (version 4.2; R Foundation for Statistical Computing). Linear mixed effects analysis of the impact of prompt setting on image rate was conducted using the *lme4* package (Bates, Mächler, Bolker, and Walker). Prompt setting and order were fixed effects within the model—order was included to account for uneven sizes in the 6 different orders. Participants were accounted for as random effects (random intercept model), accounting for repeat observations under each prompt setting and correlation of

participant responses across conditions. *P* values for the fixed effect of prompt setting order were obtained using the Wald type 3 test. Q-Q plots were visually inspected and a histogram of the model residuals was checked for homogeneity of variance or any obvious deviations from normality.

Power

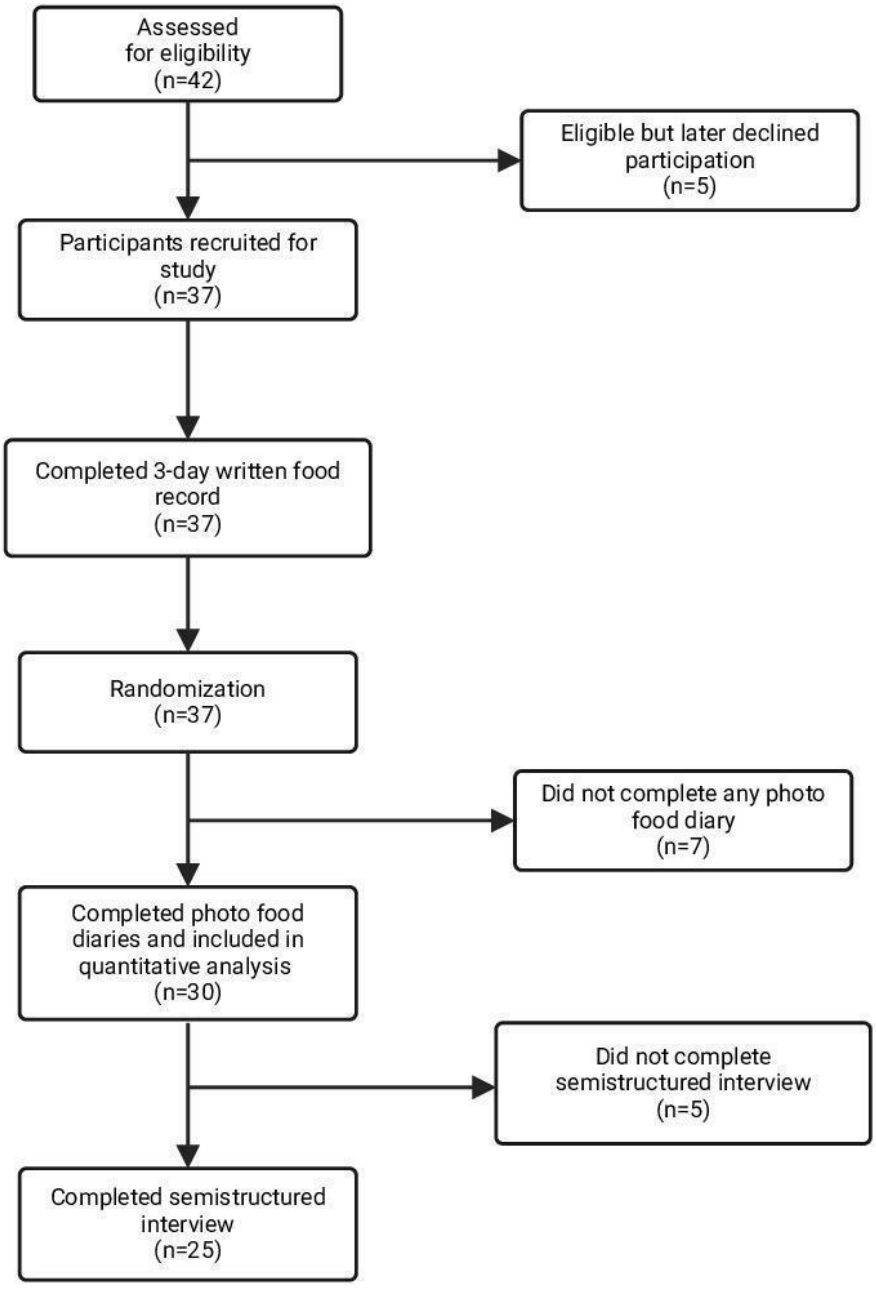
Previous use of image-based dietary records has seen an image rate of 1.4 images per 2.6 meals: a rate of 54% [10]. From this, we estimated under the control setting a mean of 1.6 images per day (54% capture rate applied across 3 meals per day, excluding snacks). With our intervention, we aimed to be able to detect 2.4 images per day (representing 80% coverage) of meals. A sample size of 20 in each of the 3 measurement conditions had over 80% power to detect this difference in rates with a 2-sided α of 5%. The crossover design improved power to detect differences in adherence rates compared to a between-subjects design.

Results

Participants

A total of 42 people were screened for eligibility: 37 met the inclusion criteria and were enrolled, 30 completed the food records, and 25 participated in the qualitative interviews. Seven participants were lost to follow-up and could not be contacted. Five participants did not wish to participate in interviews because of time. A flow diagram of participation is shown in Figure 2.

Figure 2. Flow diagram of participants throughout the study.



The number of participants in each arm and their baseline characteristics are shown in Table 1. The prompt setting order can be seen in Figure 1. Arm population sizes were uneven due to asymmetrical loss to follow-up after randomization; each of

these participants were categorized as lost to follow-up after failing to respond to 3 emails sent to confirm their ongoing participation in the study prior to starting the active part of the intervention. Only those participants completing all 3 image-based dietary records were included in the analysis.

Table . Characteristics of participants who completed the image-based dietary records (n=30).

Characteristics		Values
Age (years), mean (SD)		30 (10.8)
BMI (kg/m^2), mean (SD)		24.6 (5.6)
Sex, n (%)

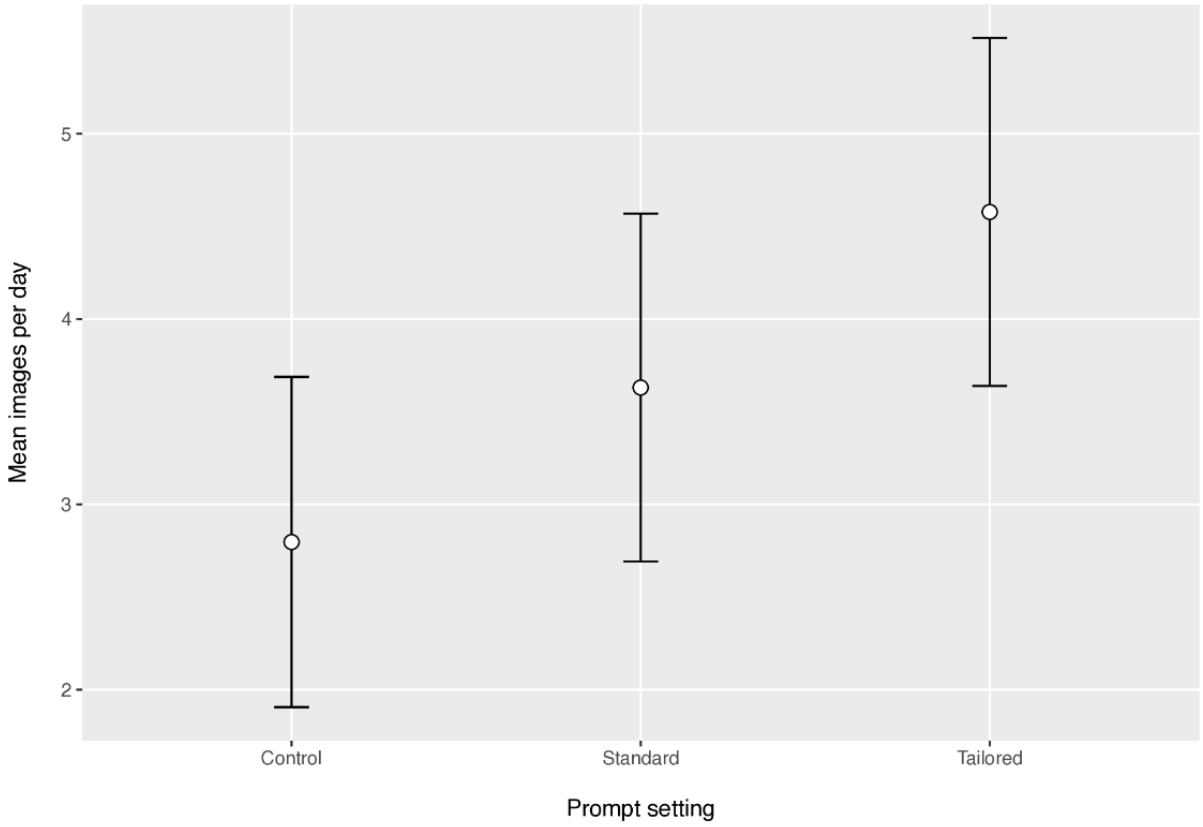
Image Rate

The image rate, that is, the mean number of images per day recorded on the image-based dietary record, under each prompt setting is shown in Figure 3 with 95% CIs. In the control setting, participants took a mean of 2.8 (95% CI 1.91-3.69) images per day, 3.6 (95% CI 2.69-4.56) images in the standard prompt setting, and 4.6 (95% CI 3.64-5.52) images in the tailored prompt setting. This represents an increase in image rate of 0.83 (95% CI 0.2-2.58) in the standard setting compared to control and an increase of 1.78 (95% CI 1.15-5.51) in the tailored setting compared to control. The order within the sequence of prompt settings had a significant effect *(P*<.001), where the second recording period had 0.82 fewer images per day and the third recording period had 1.19 fewer images per day compared to the first recording.

Figure 3. Interval plot of mean image rate (whiskers represent the 95% CI) under each prompt setting.



Interviews and Questionnaires

Twenty-five participants took part in the interviews (characteristics in Multimedia Appendix 1). Themes that emerged from the interviews were attitudes toward (1) the image-based dietary record, (2) the text-based dietary record, and (3) text prompts. Illustrative quotes relating to these themes can be found in Table 2.

Table . Themes, subthemes, and illustrative quotes from interviews.

Theme and subtheme		Illustrative quote
Attitudes toward text-based dietary records		
	High level of input required	• "… the extra time involved, and finding all the random little bits that you've put in to make a meal, and then trying to put the quantities in that you've eaten… it's just the time, even though it's only a minute or two… it's enough to be a barrier"
	Convenience of retrospective recording	• "Because often it would be like you'd get a text to remind you to take a photo, and then you'd forget straight away and with a photo, you can't eat your food… whereas like, with a written record, that you still know what you've eaten. It could just be like, you can write it the end of the day, or like, whenever you remember" • "As annoying as it was to kind of write everything out, it meant that I could do it at the end of the day and didn't have to remember at the time I was eating. For the most part would write it as I was eating to make sure I was… capturing everything that I was eating, but often actually, by the end of the day, I'd be like, I actually had this snack at this time. So I'll check that in now… it gave me a bit more freedom. But then the picture one was really easy, because you just took a picture… but relied on you to remember at the time you're eating"
	Challenges with the available database and portion input options	• "That's my main complaint… [not having New Zealand brands]… because then you have to manually put it in" • "It would be like in grams or mLs or whatever. And I just kind of put like a handful of something or a scoop of something… kind of tedious trying to be like how many grams would that have been? Or what was it, half a cup or a cup? I guess it's just because I'm not used to it" • "… but in something like Weetbix, it's fine… to quantify how much how much milk I was using in terms of mLs, which is something that I'm not used to measuring… and even Weetbix, because if I had an odd, an odd number of WeetBix, you can only put everything into two sets of Weetbix. So if you had five, you're going to put six or four"
Attitudes toward image-based dietary records		
	Convenience	• "I found photos quite easy, because you just… take a photo and it's done"

Theme and subtheme		Illustrative quote
	Less useful data output	• "… the fact that you just take a photo of it, but it doesn't come up with any information… would it be nice if like, you take a photo and all the information comes out and you can kind of track it" • "… but I don't feel like it did anything really? For like purpose of losing weight. … because I took the picture and didn't tell me like how many calories I was eating… like that cheese and garlic twist, wagyu patty thing… I take picture and think it's not too bad but not realizing it was 1700 calories"
	Difficulty with habit formation	• "Because I wasn't doing it consistently throughout the whole period, it was a lot harder to do than I think would have been"
	Perceived as more accurate than the text-based dietary record	• "[On photo food diaries] … more accurate. You know, this is literally what I'm eating. Whereas doing [the written food record] is sort of like… 'yeah about a cup of raspberries and I don't know what the bun was…' but was that the right one? Or was it like twice as much was this"
	Perceived as less accurate than the text-based dietary record	• "I might've had 12 eggs. You can't really tell in my pictures" • "There was sometimes where that I'd only had about half my muesli in the morning… I was in a rush, but I would have taken a photo of the whole thing. That would have been half the amount of calories"
Attitudes toward text prompts		
	Helpful	• "I think that the reminders definitely helped me to remember to take photos. But I think if it was coming from the app, it would have been less annoying"
	Annoying	• "They were annoying. The first couple were fine. But towards the end, I literally just ignored all of them" • "The days where they were just not at all related to when I usually ate they weren't really helpful at all, because I would just forget again by the time it came to actually take a picture of my food"

Theme 1: Text-Based Dietary Record

Participants reported that the text-based dietary record required a high level of input; this produced detailed food logs with per-item and daily calorie counts, which participants viewed as more useful than the simple image output of the image-based dietary record. Another benefit was the ability to retrospectively record food items; participants often filled in the text-based dietary record at the end of the day—an impossibility with the image-based dietary record. However, participants found completing the text-based dietary record burdensome due to the level of input required: searching and selecting food items, estimating quantities, and reconciling differences between the food item and the database available. The database was often missing food items that were consumed, forcing the participants to input similar but not identical food items. The options available to input portion sizes were also a challenge—participants not knowing the weight of their food in grams, for instance.

Theme 2: Image-Based Dietary Record

Participants preferred to use the image-based dietary record; on a Likert scale with 0 indicating preference for text-based dietary records and 100 indicating preference for image-based dietary records, the average response was 60 (SD 32). Most participants found adhering to the image-based dietary record challenging; 83% of interviewed participants reported difficulty in remembering to capture an image of the entire meal. Most cited simple forgetfulness, though some noted difficulty forming the habit of recording with only 3 days of recording interrupted by

washout periods. Participants reported difficulty with the image-based dietary record if they had partially or entirely consumed the meal before recording, as they could not capture the consumed meal. Participants reported that the images were simple and convenient to capture but provided no calorie counts or dietary information.

Theme 3: Prompts

Attitudes toward the text prompts covered the spectrum from "helpful" to "annoying." Sending prompts via text messaging was reported as an annoyance by all interviewed participants. These notifications, although welcome in the context of text communication, were intrusive as image-based dietary record reminders; "in-app" reminders were preferred. Despite these annoyances, participants generally found the prompts helpful, with tailored prompts viewed as more helpful.

Discussion

Principal Results

This randomized controlled crossover trial demonstrated that text prompts tailored to an individual's typical meal times improved the completeness of image-based dietary records. This suggests that individual tailoring of prompts will improve accuracy of energy intake assessments. Any prompting was better than no prompts, and tailored prompts were the most effective.

These findings are consistent with work shown in Martin et al [9], where standard and customized prompts were compared in a 2-arm study without crossover or a no-prompt arm. Prompt timing could be improved further by longer calibration periods to determine the individual's usual meal time and by recording the time of imaging, which was unavailable using Easy Diet Diary. Automated methods of determining prompt timing may provide pragmatic and scalable methods for tailored prompting [11]. Prompting is not unique to dietary assessment, however, and a diverse range of fields use prompts and study their effectiveness [12]. Previous work has identified that an individual's responsiveness—that is, the likelihood an individual will interact with a prompt or notification—varies based on the characteristics of the person and the prompt [13,14]. Specifically, varying responsiveness to prompts over the course of the day reflects our finding that the timing of a prompt affects the likelihood of interaction. Variable responsiveness poses a particular problem for dietary assessment, where the objective is not only response with a dietary record, but for that response to be accurate. Accuracy of recall has been shown to improve when the recall event is closer to the eating event; that is, recall accuracy decreases with time [15,16]. A prompt must therefore balance the chance of an individual responding to the prompt and the decaying accuracy of the prompted response. Our findings suggest that most individuals in this study were more responsive to dietary assessment prompts closer to meal times, although previous work on prompt responsiveness suggests that this varies from person to person [17]. For some individuals, tailored prompting may reduce the responsiveness of a dietary record. Regular meal times are not the only method to tailor prompts. The use of geolocation to detect likely eating locations, such as restaurants, accelerometers to detect eating or cooking motions, or acoustic sensors to detect chewing noises, among other "context-aware" methods, could also improve prompt timing and appear to be socially acceptable [18-20]. These methods should be selective in their implementation to avoid an excessive number of prompts to participants.

Our findings indicate that prompting tailored to an individual's food intake pattern improves image-based dietary record completeness. An alternate explanation to consider is that the number of prompts, rather than the timing, improves the image rate. This was not supported by these data. Participants in the tailored setting received a mean of 3.1 prompts per day, while all those in the standard setting received 3 prompts. The effect of tailored prompts on image rate therefore should be attributable to the timing, rather than the number, of prompts. The observed increase of 1.78 images per day with tailored prompts (vs control) is important because this represents mean capture of almost 2 meals across a day that would otherwise have been missed and therefore increases accuracy of dietary intake assessment.

Image recording during the second and third instance of the 3-day image-based dietary record decreased by 0.82 and 1.19 images per day, respectively, compared to the first diary in the sequence. This suggests a fatigue effect that was not mitigated by the 7-day washout period and is of concern where ongoing use of a prompted image-based dietary record is desired in a clinical or research setting. Decreasing energy intake over a recording period has previously been identified in national nutrition surveys such as the United Kingdom's National Diet and Nutrition Survey. The average decrease from day 1 to 4 was small at 164 kJ, though this may reflect a true decrease in energy intake under observation [21,22]. This fatigue effect has also been found to apply to prompts themselves, with one study of a diet app finding decreasing responsiveness to push notifications over time [17].

Participant Experience

Participant attitudes toward the image-based dietary record and text-based dietary record contrasted each other. Recording with the image-based dietary record was more convenient at the cost of less useful output in the absence of caloric or macronutrient data. Useful nutritional data can potentially be generated from image-based methods using computer vision–machine learning software, a rapidly advancing field [23]. Text-based dietary records and automated recognition both rely on a representative nutritional database. An incomplete database was highlighted as a barrier to participants providing complete and accurate information. Missing food items or specific brand-name items and inflexible or unfamiliar portion options were challenging. Ensuring that nutritional databases reflect modern and traditional diets, as well as local and culturally relevant foods, should be a priority for current and future dietary assessment tools.

Participants highlighted the convenience of retrospective recording with text-based dietary records, which is not possible with image-based dietary records. The higher number of days with at least 1 entry in the text-based dietary record is suggestive of this retrospective recording, noted in participant interviews and illustrated in Table 2.

Overall, participants reported preference for the image-based dietary record compared to the text-based dietary record, a finding consistent with prior work [24-26]. This preference is notable, as the image-based dietary record did not provide nutritional feedback, and the app was not designed to use images as the primary input method. Participants highlighted that even simple image-based recordings that lack energy or macronutrient intake data provide benefit in the self-assessment of dietary intake, a benefit unique to image-based input that has been identified previously [27,28]. These findings suggest that image-based dietary assessment apps should feature both text and image inputs, providing users the convenience of both simple image-based recording and retrospective text-based recording. Finally, participants preferred tailored prompts and indicated a preference for in-app prompting versus text message prompts.

Strengths

This study had several strengths. The crossover design allowed for intraindividual assessment. Instructing participants to only record images during the image-based dietary records in the absence of automation to provide numeric caloric or macronutrient data means that this information was not available to participants, but this does more closely reflect participant behavior using an automated image-based dietary assessment tool. The diversity of participants included in this study is a strength, with representation of Māori and Pacific views on dietary assessment, which is particularly important in New Zealand.

Limitations

This study had a number of limitations. A 3-day text-based dietary record and rudimentary guidelines were used to generate tailored prompt timing; future studies should use more sophisticated methods—such as machine learning techniques—and expanded timeframes to generate tailored prompt timing. The 3-day time frame for the text-based dietary record and each of the image-based dietary records is brief, and future studies should ideally extend to longer time frames; however, extending these time frames must be balanced against the decreasing accuracy over time. This study placed an artificial dichotomy on the method of dietary assessment. In reality, individuals are free to alternate between image-based and text-based input; a key finding of this study is the importance of offering both, and there are many platforms that provide both methods. We did not directly compare the accuracy of image-based versus text-based input using manual or automated analysis of the images to determine if one method produces more reliable energy intake, macronutrient, or micronutrient estimates, which would affect the interpretation of dietary assessment data from platforms that use both methods.

Conclusions

Individualized tailoring of prompts to match likely meal times improved the completeness of image-based dietary record entries. This is important to improve the accuracy of dietary intake assessments in both clinical and research settings. Although participants preferred the image-based diary, they also identified the need to be able to retrospectively enter data for meals that they had missed recording with an image. The accurate analysis of nutritional composition of a meal from an image requires interpretation of the volume and composition of a meal and integration with nutrient data. Currently available nutritional databases have limitations in the items included, particularly in certain population groups and for culturally specific foods. Therefore, we propose 3 recommendations for future iterations of image-based dietary assessment apps: (1) allowing options for both image-based and written input, (2) publishing and continually updating a nutritional database relevant to the population under study, and (3) the use of tailored in-app prompting for both prospective recording and retrospective recording of missed food items.

Abstract

Background: People living with and beyond breast cancer can face internal barriers to physical activity (eg, fatigue and pain). Digital interventions that promote psychological acceptance and motivation may help this population navigate these barriers. The degree to which individuals (1) adhere to intervention protocols and (2) reflect on and internalize intervention content may predict intervention efficacy.

Objective: The objective of this study was to characterize the nature of reflective processes brought about by an 8-week acceptance- and mindfulness-based physical activity intervention for insufficiently active survivors of breast cancer (n=75). Furthermore, we explored the potential utility of a metric of reflective processes for predicting study outcomes.

Methods: Of the intervention's 8 weekly modules, 7 (88%) included an item that asked participants to reflect on what they found to be most useful. Two coders conducted directed content analysis on participants' written responses. They assessed each comment's depth of reflection using an existing framework (ranging from 0 to 4, with 0=*simple description* and 4=*fundamental change with consideration of social and ethical issues*). The coders identified themes within the various levels of reflection. We fit multiple linear regression models to evaluate whether participants' (1) intervention adherence (ie, number of modules completed) and (2) the mean level of the depth of reflection predicted study outcomes.

Results: Participants were aged on average 57.2 (SD 11.2) years, mostly non-Hispanic White (58/75, 77%), and mostly overweight or obese (54/75, 72%). Of the 407 responses to the item prompting personal reflection, 70 (17.2%) were rated as reflection level 0 (ie, *description*), 247 (60.7%) were level 1 (ie, *reflective description*), 74 (18.2%) were level 2 (ie, *dialogic reflection*), 14 (3.4%) were level 3 (ie, *transformative reflection*), and 2 (0.5%) were level 4 (ie, *critical reflection*). Lower levels of reflection were characterized by the acquisition of knowledge or expressing intentions. Higher levels were characterized by personal insight, commentary on behavior change processes, and a change of perspective. Intervention adherence was associated with increases in self-reported weekly bouts of muscle-strengthening exercise (B=0.26, SE 0.12, 95% CI 0.02-0.50) and decreases in sleep disturbance (B=−1.04, SE 0.50, 95% CI −0.06 to −2.02). The mean level of reflection was associated with increases in psychological acceptance (B=3.42, SE 1.70, 95% CI 0.09-6.75) and motivation for physical activity (ie, integrated regulation: B=0.55, SE 0.25, 95% CI 0.06-1.04).

Conclusions: We identified a useful method for understanding the reflective processes that can occur during digital behavior change interventions serving people living with and beyond breast cancer. Intervention adherence and the depth of reflection

each predicted changes in study outcomes. Deeper reflection on intervention content was associated with beneficial changes in the determinants of sustained behavior change. More research is needed to investigate the relations among digital behavior change intervention use, psychological processes, and intervention efficacy.

Introduction

Background

There were an estimated 4.1 million people living with and beyond breast cancer in 2022 [1]. This number is estimated to reach nearly 5 million by 2030 [2]. This population can encounter long-term challenges related to health and quality of life, including fatigue, anxiety and depressive symptoms, breast cancer–related lymphedema, metabolic dysregulation, bone loss and osteoporosis, and cancer recurrence [3,4]. Physical activity may protect people living with and beyond breast cancer from these problems [5-7]. However, most people who have been diagnosed with breast cancer do not meet nationally recommended physical activity guidelines [8,9].

Psychotherapy-informed digitally delivered acceptance- and mindfulness-based approaches may facilitate physical activity promotion for people living with and beyond breast cancer. People living with and beyond breast cancer commonly cite uncertainty, frustration, cancer-related fatigue, and pain to be barriers to physical activity [10-13]. Interventions that can help people to better navigate the uncomfortable thoughts and sensations that can act as impediments to physical activity may support their efforts to be more physically active. Authoritative entities recommend acceptance- and mindfulness-based interventions for people living with and beyond cancer; strong evidence supports their efficacy for reducing anxiety and depressive symptoms in this population, and they have been shown to reduce cancer-related fatigue [14-17]. Furthermore, physical activity interventions that simultaneously target both health-related behaviors and quality-of-life issues are more effective at achieving sustained physical activity outcomes than interventions that only promote physical activity for this population [18]. Emerging evidence suggests that acceptance- and mindfulness-based physical activity interventions can be feasible and effective at promoting physical activity [19-21] and that digitally delivered approaches can be acceptable and potentially effective for people living with and beyond cancer [22,23].

The degree to which participants meaningfully engage with and internalize health promotion content may determine the efficacy of digital behavior change interventions (DBCIs). However, achieving high levels of engagement can be a marked challenge for DBCIs [24]. Participants often exhibit low adherence to digital physical activity interventions and poor study retention [25]. Accordingly, researchers have tended to prioritize measuring and optimizing intervention use (eg, optimizing metrics such as the number of modules completed and time spent in an app) [26]. However, using system use data alone as a proxy for engagement is problematic. First, the relationship between these metrics and intervention efficacy is not always straightforward. Although there is sometimes a positive linear relationship between DBCI use and intervention efficacy, this is not always the case [25,27,28]. DBCIs may tend to have certain thresholds of engagement that confer the majority of the benefits, or intervention components may interact with one another. Furthermore, engagement with a DBCI may be expected to taper over time and even be supplanted by engaging in the desired behavior itself [29]. Second, focusing exclusively on quantitative use metrics affords only limited insight into the psychological aspects underpinning participants' experiences with DBCIs. This precludes achieving a full understanding of the DBCI's mechanisms of action. Thus, researchers have called for broadening our conceptualization of DBCI engagement [28].

A growing literature highlights the importance of understanding the psychological processes that occur when participants engage with DBCI content; this includes supplementing system use metrics with additional aspects of DBCI engagement that pertain to affect, attention, interest, immersion, flow, and reflection [26,29,30]. Researchers of human-computer interaction have discussed engagement in similar terms, parsing engagement according to notions of behavioral adherence, behavioral effort (eg, discussing emotions, thoughts, and behaviors in intervention), cognition, and affect [31]. Researchers with an educational perspective have provided similar definitions of engagement with digital systems, noting that the cognitive and affective aspects of engagement are largely neglected [32]. Yang et al [25] have contributed a framework specific to physical activity promotion in mobile health in which they conceptualize engagement as being determined by breadth, depth, interaction, and length of engagement. These broad conceptualizations are useful for helping to orient researchers toward the many and varied facets of engagement. Rather than attempting to establish a universal conceptualization, it may be advantageous to tailor the conceptualizations of engagement based on context [33]. Using qualitative and mixed methods to investigate the nature of participants' engagement with DBCIs may be particularly useful to this end [24,26,29].

Reflection is an essential process for self-improvement and making lasting behavior changes in the context of DBCIs [34]. As applied to health-related education, reflection and reflective processes connotate deliberate critical analysis of knowledge and experiences to achieve a fuller understanding [35]. The process of reflecting on the outcomes of past and ongoing efforts or newly acquired information helps individuals integrate knowledge and skills into practice and overcome persistent barriers to behavior change [35,36]. Reflection may be particularly relevant in the context of DBCIs because it may allow people to gain meaningful insights from their personal

health-related data that can support lasting behavior change [34]. In the education literature, reflective thinking and writing are commonly used strategies to prompt personal reflection, and it is a common practice to evaluate written responses to determine to what degree an individual has considered and applied didactic content in the context of their own lived experiences [37-39]. Fleck and Fitzpatrick [40] present a framework that operationally defines 5 levels of reflection. This framework has been shown to be particularly useful for evaluating the levels of reflection promoted by the design features of DBCIs [34]. In this study, we sought to extend this literature by characterizing the reflective processes engaged in by people living with and beyond cancer who experienced a digital acceptance- and mindfulness-based physical activity intervention.

Objectives

It may be possible to help people living with and beyond breast cancer reframe some of the unpleasant internal sensations that can act as barriers to physical activity (eg, pain, fatigue, and frustration). Understanding the degree to which participants reflect on and internalize digital intervention content targeting these psychological processes may be useful for understanding how best to support this population. This study answers calls to investigate the deeper psychological aspects involved in engagement with DBCIs to provide insight into the interplay among intervention use, individual experiences, and intervention efficacy. The aims of this study were to (1) characterize the nature of reflective processes brought about by a DBCI designed to increase physical activity in insufficiently active people living with and beyond breast cancer and (2) explore the potential utility of a metric of reflective processes in DBCIs within an acceptance- and mindfulness-based physical activity intervention.

Methods

Study Design

We conducted a secondary analysis on data obtained from a 1-group pilot study. The purpose of the parent study was to evaluate the acceptability of an acceptance- and mindfulness-based intervention to increase physical activity in survivors of breast cancer [23]. This study is an investigation of the use of the intervention. Participants were female adults (aged ≥18 y) who had been diagnosed with breast cancer but were not actively preparing for surgery or undergoing chemotherapy or irradiation treatment (n=75). Eligibility criteria included that participants reported engaging in <150 minutes of moderate-intensity aerobic physical activity per week. We recruited participants using a large listserve of individuals who were interested in receiving information about breast cancer–related research studies. Study staff contacted interested individuals via telephone to assess eligibility.

Ethical Considerations

Study procedures were approved by the University of Texas School of Public Health Committee for the Protection of Human Subjects (HSC-SPH-18-1025). All participants provided informed consent for participation.

Intervention Description

The intervention has been described in detail elsewhere [23]. Briefly, the ACTive program was an 8-week DBCI designed to help insufficiently active survivors of breast cancer increase moderate-intensity aerobic and muscle-strengthening physical activity. It was centered on increasing physical activity acceptance (ie, cognitive acceptance and behavioral commitment) and autonomous motivation for physical activity (ie, enjoyment, values, interest, and identification). It was grounded in acceptance and commitment therapy (ACT) principles (ie, values, committed action, acceptance, defusion, and contacting the present moment). It consisted of 8 modules (along with a brief introductory module), each of which was delivered electronically via a weekly REDCap (Research Electronic Data Capture; Vanderbilt University) survey. The modules included didactic content and experiential exercises targeting core ACT principles. They were presented in brief videos, audio files, images, and other documents. Participants were prompted to input information periodically (eg, physical activity levels and reactions and thoughts on experiential exercises). Branching logic within REDCap was used to remind participants of their responses to items from previous modules as well as provide feedback on their responses within modules (eg, an emoji appeared if responses indicated that the participant had met her physical activity goal for the week). The modules contained a repository of additional optional content (eg, muscle-strengthening physical activity videos for survivors of cancer, videos with yoga classes for survivors of breast cancer, and a video on proper walking posture for survivors of cancer).

At the end of modules 1 to 7, an item asked participants, “What is one important, personal take-away point from this session?” This item was included to identify specific aspects of the intervention that were perceived as the most *useful* by participants because usefulness is an important component of acceptability. Participants were presented with an open-text box to provide a reply. Providing participants with the opportunity to reply to open-ended items such as this can help contribute to a more in-depth understanding of participants’ engagement and experience with DBCI content [26].

Measures

Physical Activity Behaviors

The Godin Leisure-Time Exercise Questionnaire was administered to obtain pre- and postintervention estimates of participants’ average weekly leisure time aerobic physical activity over the past month [41,42]. To obtain estimates of participants’ muscle-strengthening physical activity levels, we included an item derived from the Godin Leisure-Time Exercise Questionnaire [43,44]. This item asked, “In a typical week, outside of your job or work around the house, how many days do you do leisure-time physical activities specifically designed to strengthen your muscles such as lifting weights, circuit training, or resistance bands? (Do not include cardio/aerobic types of exercise).” Response options ranged from 0 to 7.

Physical Activity Acceptance

The ACTive program was centered on increasing physical activity acceptance. This was defined as one’s willingness to

experience the negative internal experiences that can sometimes be associated with physical activity, rather than avoiding them. This was operationalized by the Physical Activity Acceptance Questionnaire (PAAQ) [45]. The PAAQ consists of two 5-item subscales. The *cognitive acceptance* subscale measures one's propensity to accept the reality of unpleasant sensations associated with physical activity, whereas the *behavioral commitment* subscale pertains to persisting in committed action despite the occurrence of challenging thoughts or sensations. Responses on items of the PAAQ range from 1=*never true* to 7=*always true*. For scoring, the items on the *cognitive acceptance* subscale are reverse coded, and the items of each subscale are summed (range 5-35). This questionnaire was administered before and after the intervention.

Motivation for Physical Activity

The ACTive program also aimed to increase motivation for physical activity as conceptualized by self-determination theory (SDT). SDT parses motivation conceptually based on the degree to which it is autonomous in nature. SDT posits that changes in more autonomous motivations (eg, integrating a behavior into relevant self-narratives) will yield longer-lasting behavior changes than changes in less autonomous motivations (eg, receiving a *badge* as reinforcement for performance). We operationalized motivation for physical activity before and after the intervention using the Behavioral Regulation for Exercise Questionnaire-3 (BREQ-3). The BREQ-3 consists of six 4-item subscales (*amotivation*, *external regulation*, *introjected regulation*, *identified regulation*, *integrated regulation*, and *intrinsic regulation*). The *intrinsic regulation* subscale captures a highly autonomous form of motivation, defined by the degree to which one engages in a behavior because one finds it inherently interesting or enjoyable. The *integrated regulation* subscale captures another highly autonomous form of motivation, an extrinsic form of motivation defined by the degree to which an individual has fully internalized the reason for action owing to finding it concordant with their values. The *identified regulation* subscale captures a somewhat less autonomous form of motivation (although still relatively autonomous overall), defined by the degree to which an individual consciously values a reason for action. For scoring, the mean scores for each set of items are calculated (range 0-4).

Health-Related Outcomes

For exploratory purposes, we administered measures of quality of life and physical functioning before and after the intervention. To operationalize these constructs, we used the National Institutes of Health–funded Patient-Reported Outcomes Measurement Information System (PROMIS)-29 profile measure (version 2.1) [42]. The PROMIS-29 consists of 8 subscales: *physical function* (eg, "Are you able to run errands and shop?"), *anxiety* (eg, "In the past 7 days...I felt fearful"), *depressive symptoms* (eg, "In the past 7 days...I felt worthless"), *fatigue* (eg, "In the past 7 days...I felt fatigued"), *sleep disturbance* (eg, "In the past 7 days...I had a problem with my sleep"), *ability to participate in social roles and activities* (eg, "I have trouble doing all of my regular leisure activities with others"), *pain interference* (eg, "In the past 7 days...How much did pain interfere with your day to day activities?"), and *pain intensity* (eg, "How would you rate your pain on average?"). All subscales except the *pain intensity* subscale have 4 items and 5-point Likert-type responses ranging from 0 (*not at all*) to 4 (*very much*). The *pain intensity* subscale has 1 item and an 11-point scale ranging from 0 (*no pain*) to 10 (*worst pain imaginable*). Scores are coded, summed, and converted to T-scores such that higher scores indicate more of the concept being measured (eg, range for *physical functioning* subscale: 22.5-57.0).

Reflection Framework

Reflection levels were based on the reflection framework presented by Fleck and Fitzpatrick [40]. This framework emerged from research conducted in the context of the design of digital technologies and human-computer interaction. It defines 5 levels of reflection intended to serve as a resource for thinking about, and designing for, reflection. Reflection level 0 (revisiting) is defined as "Description or statement about events without further elaboration or explanation. Not reflective." Reflection level 1 (reflective description) is defined as "Description including justification or reasons for action or interpretation, but in a reporting or descriptive way. No alternate explanations explored, limited analysis and no change of perspective." Reflection level 2 (dialogic reflection: exploring relationships) is defined as "A different level of thinking about intervention content. Identifying or exploring relationships between relevant concepts. Applying experience or knowledge, providing evidence of cycles of interpreting and questioning, consideration of different explanations, hypotheses and/or other points of view." Reflection level 3 (transformative reflection: fundamental change) is defined as "Revisiting an event or knowledge with intent to re-organize and/or do something differently. Asking fundamental questions and challenging personal assumptions leading to a change in practice or understanding." Finally, reflection level 4 (critical reflection: wider implications) is defined as "Social and ethical issues are taken into consideration. Generally considering the (much wider) picture."

Data Analysis

Qualitative Data Analysis

MCR and EJL conducted 2 phases of directed content analysis on participants' written responses to the open-ended item asking, "What is one important, personal take-away point from this session?" [46]. First, the coders independently rated the reflection level of each individual response by evaluating the response against the reflection framework presented by Fleck and Fitzpatrick [40]. Throughout this process, they produced descriptors to extend and apply the definitions presented by Fleck and Fitzpatrick [40] of the various reflection levels to our study context. The 2 coders first coded all the responses from 1 module independently. Next, they met to discuss the functional definitions and descriptors of reflection levels in our study context and resolve coding discrepancies. The coders then evaluated the rest of the responses independently. After doing so, they met to reconcile discrepancies. The coders created a table, based on the reflection framework presented by Fleck and Fitzpatrick [40] as well as supplemental descriptors and illustrative examples from this study, to further clarify their conception of the various reflective levels as they might be

applied in the context of DBCIs. For the second phase of directed content analysis, MCR sorted responses by reflection level and MCR and EJL coded responses using inductive codes that were informed by principles of behavioral science (eg, behavior change techniques) and ACT [46]. MCR coded all responses first and provided a list of inductive codes to EJL. Next, EJL coded all responses using the list of inductive codes provided by MCR and adding additional codes as needed. The 2 coders then met to discuss codes and reconcile differences.

Quantitative Data Analysis

We computed descriptive statistics for participant demographics, study outcome variables, intervention adherence, and each participant's mean level of reflection (ie, each individual's mean score of the items scored via the qualitative procedures detailed in the previous subsection). We defined intervention adherence as the number of modules that each participant completed; this is a commonly used measure of engagement with DBCIs [26]. We then conducted multiple linear regression analyses with maximum likelihood estimation. The independent variables were (1) the number of modules completed and (2) participants' mean level of reflection. The dependent variables (in separate models) were the follow-up measures of self-reported aerobic and muscle-strengthening physical activity, the PAAQ, the BREQ-3, and the PROMIS-29 subscales described previously. All analyses adjusted for the baseline value of the dependent variable and, given our interest in parsing the possible effects of the breadth versus the depth of engagement, the other independent variable of interest (ie, both intervention adherence and the mean level of reflection were included in all models). All analyses also adjusted for sociodemographic and cancer-related factors that we identified a priori as potentially confounding variables. Specifically, we adjusted for age (years), education level (no bachelor's degree, bachelor's degree, or graduate school), ethnicity (Hispanic or not Hispanic), race (American Indian or Alaska Native or other, Asian, Black or African American, or White), BMI category (underweight, normal, overweight, or obese), time since cancer diagnosis (years), and stage at diagnosis (1, 2, or 3/4). Missing data were handled using full information maximum likelihood. We set our nominal α level to .05 for all analyses. All statistical analyses were performed using R (version 4.0.3; R Foundation for Statistical Computing).

Results

Participant Demographic Characteristics

The average age of the participants was 57.2 (SD 11.2; range 31-78) years. The median time since breast cancer diagnosis was 8.2 (IQR 3-12) years. The participants were relatively well educated, mostly non-Hispanic White (58/75, 77%), and mostly overweight or obese (54/75, 72%; Table 1).

Table 1. Participant characteristics.

Characteristic and category	Participants, n (%)
Education level (n=75)	
High school diploma or GED[a]	0 (0)
Some college	16 (21)
Bachelor's degree	34 (45)
Graduate school degree	25 (33)
Stage of breast cancer at diagnosis (n=71)	
1	32 (45)
2	28 (39)
3	9 (13)
4	2 (3)
Race (n=75)	
American Indian, Alaska Native, or other	1 (1)
Asian	4 (5)
Black or African American	7 (9)
White	63 (84)
Ethnicity (n=74)	
Hispanic	7 (10)
Non-Hispanic	67 (91)
Marital status (n=74)	
Single	11 (15)
Married	54 (73)
Living with significant other	1 (1)
Divorced	5 (7)
Widowed	3 (4)
Employment status (n=68)	
Employed full-time	38 (56)
Employed part-time	10 (15)
Retired	20 (29)
BMI status (n=74)	
Underweight	1 (1)
Normal	19 (26)
Overweight	32 (43)
Obese	22 (30)

[a]GED: General Educational Development Test.

Intervention Adherence

The median number of the 8 modules completed was 8 and the first quartile value was 4 modules (IQR 4). The minimum number of modules completed was 1 (7/75, 9%).

Coding the Levels of Reflection

The coders created a table while going through the process of coding the reflections based on the reflection framework presented by Fleck and Fitzpatrick [40]. We added descriptors and illustrative examples from this study to further clarify our conception of the various reflective levels as they might be applied in the context of DBCIs (Table 2).

Table 2. Levels of reflection with relevant descriptors and illustrative examples.

Reflection level[a] and additional descriptors	Illustrative examples
Reflection level 0. Description: revisiting (description or statement about events without further elaboration or explanation; not reflective)	
Repeating or paraphrasing intervention content	• "That exercise makes you less tired but also helps you sleep Better." [SID[b] 157, 47 years]
Superficial imperative statements	• "[G]et up and move." [SID 95, 49 years]
Surface-level comments	• "I thought the extended mindfulness video was helpful." [SID 100, 37 years]
Platitudes	• "Life is hard sometimes." [SID 99, 68 years]
Not responsive to the prompt	• "Bad weather." [SID 117, 64 years]
Reflection level 1. Reflective description: revisiting with explanation (description including justification or reasons for action or interpretation but in a reporting or descriptive way; no alternate explanations explored, limited analysis, and no change of perspective)	
Elaborating upon intervention content	• "On our sickest days, there is more going right in our bodies than going wrong. I need to appreciate this. And celebrate this." [SID 113, 50 years] • "[T]hat the uncomfortable feel of exercise is actually good for me. I just need to embrace it." [SID 140, 60 years]
Imperative statements (including justification or reasons or descriptive strategy)	• "I need to get moving, so I will feel better." [SID 79, age not given]
Personal insight	• "[T]hat I'm good at putting things off." [SID 134, 60 years] • "I am totally the kid looking out the window—I try to make everything an adventure and to look at the positive mental attitude." [SID 103, 45 years]
Skill building or learning a technique	• "I've learned how to focus away from the chatter in my brain." [SID 99, 68 years] • "[T]hat I can 'pick up' internal barriers which relieves some of the feeling of frustration and feeling like a failure." [SID 98, 53 years] • "I liked the shear stress explanation. I can picture that while I exercise." [SID 100, 37 years]
Reflection level 2. Dialogic reflection: exploring relationships (a different level of thinking about intervention content; identifying or exploring relationships between relevant concepts; applying experience or knowledge, providing evidence of cycles of interpreting and questioning, and consideration of different explanations, hypotheses, and other points of view)	
Applying intervention content to one's own life	• "My old excuse of saying 'I just don't want to exercise,' is not a good enough reason. I know the reasons are that it's uncomfortable and inconvenient, but that's really not true. Also, I know I can adapt and it won't cause pain in my hip with bursitis." [SID 145, 48 years]
Commentary on the nature of the relationships between disparate concepts	• "If I am going to change my fitness habits, I must see how they relate to my values." [SID 124, 42 years]
Taking a different perspective	• "[T]hat I'm being invited, not required to experiment with activity and that I can choose how to do it. I liked the line about experimenting with what we're being told the benefits are in our own bodies. That makes me feel more in control and interested." [SID 137, 53 years]
Applying new skills or knowledge and reflecting on this	• "In the almost 14-minute extended mindfulness exercise, I found that it did relax me even though that wasn't the objective. I kept my eyes closed during the entire exercise. At first, my other thoughts included anxiety over today's election. One of the suggestions was to look at yourself from outside yourself. I find I'm usually able to do that anyway...as it enables me to be more compassionate and understanding of others' pain because of what I've experienced. For me, the only distraction, as I kept my eyes closed, was hearing the/your voice telling me things. I had no problem with pushing away thoughts because the only thing I was seeing was inside my eyes as they were closed. Once opened, everything becomes a distraction." [SID 133, 70 years]
Reflection level 3. Transformative reflection: fundamental change (revisiting an event or knowledge with intent to reorganize and do something differently; asking fundamental questions and challenging personal assumptions leading to a change in practice or understanding)	

Reflection level[a] and additional descriptors	Illustrative examples
Perspective significantly altered	• "[T]hat I and many other people get very wrapped up in goals and disguise them as values. We find that we're not measuring up and we get disappointed in ourselves and give up working at them. Looking at goals as finite and values as infinite and guiding principles that shape goals puts them in a different perspective. It gives me hope that I won't judge myself too harshly if I don't fulfill my goals, that I'll realize that maybe that goal wasn't right for me and didn't fit in well with my values." [SID 137, 53 years]
A change in practice or understanding resulting from personal insight	• "I am stronger than the spoiled, damaged, hurt child inside me. I don't have to listen to her. Just put her plump pouty face in my backpack and carry on." [SID 82, 64 years]
Reflection level 4. Critical reflection: wider implications (social and ethical issues are taken into consideration; generally considering the wider picture)	
A transformative reflection that weaves in broader social or ethical considerations	• "My essential Self is still there...I am alive, the tiny kernel of me, the spark, though almost extinguished, has to be nurtured above all else now...or I am extinguished by the grotesque cancer industry conveyor belt." [SID 110, 74 years]

[a]From Fleck and Fitzpatrick [40].

[b]SID: study identification number.

Levels of Reflection

Overall

There were 407 total responses from the 75 participants over the course of the 7 modules that featured the open-ended item for reflection (the item was not included in module 8). Participants submitted an average of 5.4 (SD 2.2) out of 7 possible responses. Of the 407 responses, we rated 70 (17.2%) as reflection level 0 (ie, *description*), 247 (60.7%) as level 1 (ie, *reflective description*), 74 (18.2%) as level 2 (ie, *dialogic reflection*), 14 (3.4%) as level 3 (ie, *transformative reflection*), and 2 (0.5%) as level 4 (ie, *critical reflection*).

Reflection Level 0 (Description: Revisiting)

Responses that were rated as reflection level 0 were judged to be not reflective and often emphasized one's desire or intention to increase one's physical activity levels, simply repeated or paraphrased subject matter content, or provided commentary on the delivery of the subject matter itself. The themes we identified for reflection level 0 responses related to (1) *making a resolution*, (2) *knowledge of subject matter*, and (3) *appreciation or distaste for intervention content*.

Participants often made short imperative statements concerning a general need to increase physical activity or mindfulness (ie, *making a resolution*), but at this level of reflection, they did not demonstrate sufficient explanation to extend their response beyond merely revisiting intervention content (eg, "Just start!" [study identification number (SID) 148, 64 years]).

The theme related to *knowledge of subject matter* characterized a subset of responses that were descriptive paraphrases of didactic intervention content related to physical activity or ACT principles; for example, a participant wrote, "Even 10 minutes of activity is better than none" (SID 152, 54 years).

Responses that spoke to an *appreciation or distaste for intervention content* generally provided commentary on the intervention content without evidencing deeper reflection:

> *No real huge "ah ha" moments from this since it was all review. I had some problems with technology this time and got booted out twice before saving my answers so fewer long responses this week.* [SID 103, 45 years]

Reflection Level 1 (Reflective Description: Revisiting With Explanation)

Responses that were rated as reflection level 1 were judged to provide more justification than reflection level 0 comments, but this additional substance was generally descriptive in nature and without evidence of a deeper change in perspective. This reflection level made up the majority of responses (247/407, 60.7%). These comments commonly emphasized one's desire or intention to increase one's physical activity levels with some action-oriented or attitudinal elaboration. The themes we identified for reflection level 1 responses related to (1) *making a resolution*, (2) *personal application or action planning*, and (3) *kindness*.

Making a resolution was also a common theme for the level 1 responses. These responses were generally centered on the importance of increasing physical activity levels and provided a more nuanced explanation than the level 0 responses (eg, "[T]hat fitness in itself is a value that I should prioritize for overall happiness and well-being, not just when I want to lose weight and achieve a summer body" [SID 84, 32 years]).

Responses related to *personal application or action planning* tended to apply information from the intervention to the participant's own life. This was often related to engaging in physical activity (eg, "One of the important takeaways for me is the proper way to stand and walk which allows our back to be straight...and assist with our posture" [SID 87, 64 years]). This theme also applied to using acceptance- and mindfulness-based techniques (eg, "Practical Action idea: Pausing to 'unpack' the negative thoughts, physically remove them" [SID 110, 74 years]).

Finally, the *kindness* theme captured responses that included an emphasis on being kind to oneself in the course of gradually

increasing physical activity levels. This theme was also evident in comments that spoke to an appreciation of intervention content that normalized the reality of challenges experienced in the course of engaging in physical activity and cancer survivorship:

> *Life is hard and challenging and that is NORMAL. A rich full life is one that consists of a variety of emotions.* [SID 93, 56 years]

Reflection Level 2 (Dialogic Reflection: Exploring Relationships)

Responses that were rated as reflection level 2 were judged to exhibit reflection on more complex conceptual relationships than responses rated as reflection level 1. These responses often evidenced a change of perspective or a more nuanced consideration of the intervention content and its application to one's own life. Reflection level 2 responses commonly displayed many of the themes presented previously (eg, *making a resolution* and *personal application or action planning*) but were further characterized by the themes of (1) *personal insight* or (2) *discussion of personal facilitators or mechanisms of behavior change*.

The theme of *personal insight* characterized comments that involved elements of personal introspection and reflection on oneself or one's own thought and behavioral patterns:

> *It got me to thinking about what the negative thought might be. Why do I not want to exercise if I know it's good for me? Somewhere way, way deep down I don't think I believe it. That's helpful to realize and good to see in print. Now to figure it out.* [SID 120, 78 years]

Other participants shared candid observations about the difficulties involved with satisfying perceived needs:

> *Need to refocus on what has been important, can be again but with physical limitations like a nagging injury, isolation due to the pandemic, restrictions where I live, too comfortable with aloneness now.* [SID 139, 76 years]

The theme of *discussion of personal facilitators or mechanisms of behavior change* applied to responses that evidenced reflection on what might help increase physical activity or how being more physically active might in turn support a valued aspect of the participant's life:

> *I need to learn how to separate the thought from who I really am. I realize that I am overwhelmed by the "starting point," that place where I am required to overcome the law of inertia in all the things I want or need to do. Once I get started I am generally able to complete the task.* [SID 98, 53 years]

Reflection Level 3 (Transformative Reflection: Fundamental Change)

This level of reflection was relatively rare (14/407, 3.4%). Responses determined to represent reflection level 3 were characterized by substantively deeper reflection than responses determined to represent reflection level 2—additionally marked by evidence suggestive of more profound *personal insight* and a fundamental *change in perspective*. In reflections that attained this level of depth, individuals often intimated that they revised personally held beliefs in ways that were empowering and conducive to enduring change:

> *I think about "the body keeps the score" and how some of the problems and thoughts and feelings I have are programmed into my DNA just like my propensity towards cancer. Some, but not all. I need to look at those moments where I am able to distract myself and notice the little victories. I'll never be perfect—never have a perfect body a perfect kid a perfect life, but there are moments every day where I feel I'm doing it right and I need to notice those moments. Last week i ran 2 miles without stopping. Not much—I used to run 5 without stopping—but that was a great feeling. Last week I carved pumpkins with my son and my neighbor came over and we talked for over an hour. Thoughts of being unlovable and depressed faded during those moments. Also I'm trying to stay away from situations where I feel this loneliness and unlovable-ness... staying off the dating site I paid so much for hurts in one way but since nobody was calling me anyways it's better just to not open the app up.* [SID 104, 50 years]

Participants evidencing this level of reflection often reframed challenges that related to their cancer journey or spoke about appreciating life from a different perspective:

> *I love the point just made: "Even if we fail at our goals, if we act in a way that's consistent with our values we are successful." I didn't do as much walking this week, but I did add strength training this week and it's amazing how much more I felt. And that's not a typo. I don't know how else to describe it than I just felt "more."* [SID 113, 50 years]

Reflection Level 4 (Critical Reflection: Wider Implications)

Responses reaching reflection level 4 were very rare (2/407, 0.5%). These responses were judged to meet the level of intrapersonal depth characteristic of reflection level 3 as well as to incorporate some of the wider social and ethical contexts in which the participants' experiences were situated. The responses spoke to a pressing tension the participants experienced as survivors of cancer in navigating social and community-level factors (1 quote is presented herein, and another quote is presented in Table 2):

> *Dr. Harris' video was great to hear. When I was going through chemo some people would say, "Keep a positive attitude" and I didn't always want to. I wanted to withdraw or rage sometimes. I think it's easier for others to see you happy, it relieves their tension about what is happening to you. It does not mean you are not living a rich and fulfilling life and I was HAPPY to hear him say that.* [SID 120, 78 years]

Intervention Adherence Predicting Outcomes

We observed associations between intervention adherence and change in 2 outcomes of interest (Table 3). Higher intervention adherence was associated with higher weekly bouts of muscle-strengthening physical activity at follow-up, adjusting for baseline levels, age, time since diagnosis, stage at diagnosis, race, ethnicity, education level, BMI category, and mean reflection level (B=0.26, SE 0.12, 95% CI 0.02-0.50; Cohen *d*=2.17). Participants in the fourth quartile of intervention adherence (21/75, 28%) averaged an increase of 0.38 bouts of muscle-strengthening physical activity in a typical week from baseline to follow-up, whereas those in the first quartile (40/75, 53%) averaged an increase of 1.43 bouts in a typical week. Similarly, higher intervention adherence was associated with less sleep disturbance at follow-up, adjusting for baseline levels and other covariates (B=−1.04, SE 0.50, 95% CI −2.02 to −0.06; Cohen *d*=2.08). Participants in the fourth quartile of intervention adherence averaged a decrease of 2.31 in the PROMIS-29 sleep disturbance score from baseline to follow-up, whereas those in the first quartile averaged a decrease of 4.68 in the PROMIS-29 sleep disturbance score. We did not observe statistically significant associations between intervention adherence and other outcomes of interest.

Table 3. Results from multiple linear regression analyses with independent variables regressed on intervention adherence and mean reflection level (n=75).

Outcome variable	Intervention adherence[a]	Mean reflection level[b]
	Estimate (SE; 95% CI)	Estimate (SE; 95% CI)
Self-reported weekly physical activity		
Aerobic moderate to vigorous exercise (min)	11.75 (8.08; −4.09 to 27.59)	−30.84 (31.50; −92.58 to 30.90)
Muscle-strengthening exercise (bouts)	0.26 (0.12; 0.02 to 0.50)	0.11 (0.49; −0.85 to 1.07)
BREQ-3[c]		
Identified regulation	0.01 (0.04; −0.07 to 0.09)	0.06 (0.16; −0.25 to 0.37)
Integrated regulation	0.00 (0.06; −0.12 to 0.12)	0.55 (0.25; 0.06 to 1.04)
Intrinsic regulation	0.01 (0.06; −0.11 to 0.13)	0.28 (0.25; −0.21 to 0.77)
PAAQ[d]		
Cognitive acceptance	−0.07 (0.41; −0.87 to 0.73)	3.42 (1.70; 0.09 to 6.75)
Behavioral commitment	0.07 (0.32; −0.56 to 0.70)	0.93 (1.33; −1.68 to 3.54)
PROMIS-29[e]		
Physical functioning	0.37 (0.41; −0.43 to 1.17)	−1.77 (1.65; −5.00 to 1.46)
Anxiety	0.82 (0.49; −0.14 to 1.78)	−1.19 (2.07; −5.25 to 2.87)
Depressive symptoms	−0.03 (0.41; −0.83 to 0.77)	2.45 (1.72; −0.92 to 5.82)
Fatigue	−0.18 (0.65; −1.45 to 1.09)	0.84 (2.66; −4.37 to 6.05)
Sleep disturbance	−1.04 (0.50; −2.02 to −0.06)	1.16 (2.07; −2.90 to 5.22)
Social roles	−0.28 (0.37; −1.01 to 0.45)	−0.83 (1.54; −3.85 to 2.19)
Pain interference	0.47 (0.60; −0.71 to 1.65)	-0.12 (2.62; −5.26 to 5.02)
Pain intensity	0.11 (0.13; −0.14 to 0.36)	0.09 (0.58; −1.05 to 1.23)

Mean Level of Reflection Predicting Outcomes

We observed associations between participants' mean reflection level and change in 2 outcomes of interest (Table 3). Higher mean reflection level was associated with higher integrated regulation at follow-up, adjusting for baseline levels, age, time since diagnosis, stage at diagnosis, race, ethnicity, education level, BMI category, and intervention adherence (B=0.55, SE 0.25, 95% CI 0.06-1.04; Cohen *d*=2.20). Similarly, higher mean reflection level was associated with higher cognitive acceptance of physical activity at follow-up, adjusting for baseline levels and all other covariates (B=3.42, SE 1.70, 95% CI 0.09-6.75; Cohen *d*=2.01). We did not observe statistically significant

associations between mean reflection level and other outcomes of interest.

Discussion

Principal Findings

This study was a secondary analysis of data from a digitally mediated intervention centered on applying principles and techniques from ACT to help people living with and beyond breast cancer overcome internal barriers to physical activity (eg, pain, fatigue, and frustration). We applied the framework presented by Fleck and Fitzpatrick [40] to gauge the depth of reflection evident in participants' written responses to prompts encouraging reflection on the intervention's weekly modules. We conducted content analysis to characterize participants' responses and multiple linear regression analyses to explore to what extent intervention adherence and participants' mean level of reflection were associated with study outcomes (ie, physical activity behaviors, motivation for physical activity, physical activity acceptance, and health-related quality of life). There were 407 written responses from the 75 participants over the course of 7 modules. Most of the responses were rated as either reflection level 0 (ie, *description*; 70/407, 17.2%) or level 1 (ie, *reflective description*; 247/407, 60.7%). Of the 407 responses, 90 (22.1%) demonstrated evidence of deeper levels of reflection. Intervention adherence was associated with more muscle-strengthening physical activity and better sleep outcomes. Mean reflection level was associated with more integrated motivation for physical activity and higher willingness to experience the full range of sensations that may accompany physical activity.

Comparison With Previous Literature

This study extends previous literature that has highlighted the importance of the cognitive and experiential aspects of DBCI engagement. To date, these aspects of DBCI engagement have largely been inferred from behavioral data (ie, system use metrics). In their review of methodologies for measuring engagement with DBCIs, Short et al [26] suggested that researchers should investigate how intervention content affects the cognitive and experiential aspects of DBCI engagement via the inclusion of open-ended items. We took this approach and found that participants' responses to open-ended items could be evaluated using the reflection framework presented by Fleck and Fitzpatrick [40]. This approach is consistent with research in the education literature that has found reflective writing samples to be amenable to the quantitative assessment of the depth of reflection [35].

Our findings regarding the breakdown of reflection levels evident in this study were consistent with reviews that have evaluated reflective writing in the context of health-related education [39,47]. Even among graduate students, the great majority of reflective processes tend to occur at the descriptive level, and transformative and critical reflections are consistently rare [39,47]. There is limited literature applying these or similar techniques to better understand programs for health education and health promotion [39,47]. In this study, we observed considerable variation in the reflective depth of responses within and between individuals. This suggests that depth of reflection may be modifiable in this context. Indeed, reflection is a common goal of educational interventions, and it seems to be modifiable in other contexts [35]. Providing appropriate scaffolding, fostering collaboration in learning, and using varied exercises to stimulate reflection have been identified as techniques that may increase learners' depth of reflection [35,39]. Time constraints, conflicting values, a lack of feedback, and a lack of trust have been identified as barriers to learning in the context of educational interventions promoting student reflection [35,39]. Future research is needed to identify how DBCIs might be designed to facilitate meaningful reflection and most effectively target the psychosocial determinants of lasting behavior change.

The themes identified in our qualitative analysis provided some insight into the variability of cognitive processes occurring in participants who experienced the digital physical activity intervention. Common themes in the lower levels of reflection generally suggested that participants had acquired new knowledge and endorsed intentions to change their physical activity behaviors (eg, *making a resolution* and *knowledge of subject matter*). These are important antecedents of successful behavior change [48]. However, they are generally not sufficient for realizing physical activity adherence goals; nearly half of the people who indicate that they intend to change their physical activity patterns do not do so [49]. The themes that characterized higher levels of reflective comments are concordant with processes that have been shown to moderate this *intention-behavior gap* [50]. *Discussion of personal facilitators or mechanisms of behavior change* and experiencing *personal insight* or a *fundamental change in perspective* conceptually align with the self-regulatory processes and notions of physical activity identity that tend to moderate the relationship between intention and physical activity adherence [50]. Encouraging personal reflection may be an autonomy-supportive approach to health promotion [34,51,52]. More research is needed to better understand if and how engaging in deep reflection may influence the conscious (eg, affective attitude) and automatic (eg, identity) processes that underlie successful behavior change.

Reflection may be a type of cognitive engagement uniquely suited to supporting knowledge transfer into other domains and contexts [36,53,54]. Schon [55] provides detailed commentary on reflective processes and distinguishes *reflection-on-action* (critical retrospective analysis) from *reflection-in-action* (conscious awareness of real-time behavioral modification). The author emphasizes the primacy of the latter as a determinant of sustained change and suggests that *reflection-on-action* may serve as a prerequisite for implementing change in real time. We found participants' average depth of retrospective reflection to be associated with more integrated regulation for physical activity and cognitive acceptance in the context of physical activity but not with other outcomes of interest. It is encouraging that deeper levels of reflection on intervention content were associated with beneficial changes in motivation and physical activity acceptance, given that these were the theory-informed psychosocial constructs that the DBCI targeted [23]. The cognitive acceptance of physical activity has been shown to be associated with long-term changes in objectively measured physical activity, and integrated regulation is similarly predictive

of physical activity [45,56]. However, in this study, we did not observe evidence that the depth of reflection was associated with physical activity–related outcomes or other outcomes of interest. Simple intervention adherence was associated with increases in muscle-strengthening physical activity and reductions in sleep disturbance. This may be due to the intervention's inclusion of practical resources for muscle-strengthening physical activity and mindfulness exercises. Our findings suggest that designing DBCIs to encourage reflective processes may help target some theory-supported mechanisms of action but may not always be necessary to engender changes in desired end points. More research is needed to investigate whether deep reflection mediates changes in key long-term behavioral and health outcomes and to what degree it should be prioritized in DBCIs.

Considering the depth of reflection may be a useful lens through which to evaluate participants' cognitive engagement with the didactic components of DBCIs. At present, DBCIs are commonly oriented toward maximizing participant engagement as measured by system use. However, rather than simply attempting to maximize DBCI system use, it may be beneficial to target aspects of *effective* engagement [29]. In this study, participants' depth of reflection was associated with 2 key study outcomes. It may be possible to design dynamic interventions that optimize psychological processes such as critical reflection. This endeavor would be supported by the ability to derive metrics that reliably reflect underlying psychological processes from participants' verbal output. We demonstrated that applying the reflection framework presented by Fleck and Fitzpatrick [40] is a promising approach to quantifying participants' qualitative data. Emerging technologies such as large language models may be applied to this end to make this process more expedient and conducive to just-in-time adaptive interventions. Digital health promotion efforts centered on optimizing psychological processes such as critical reflection may supplement or supplant approaches that are narrowly oriented toward maximizing system use.

Reflective writing can serve as a means of self-expression and have therapeutic effects [57]. However, it can also be perceived as burdensome by some individuals. Perski et al [30] emphasized the role played by participants' subjective experiences, characterized by attention, interest, and affect, in DBCI engagement. There are likely important trade-offs that occur in optimizing for cognitive versus affective aspects of DBCI engagement. Participants' comments in this study suggested that although many enjoyed the introspective aspects of the intervention, some did not. This observation is concordant with high ratings of acceptability in the parent study for those who completed the study but a less-than-ideal dropout rate (23.7%) [23]. Achieving deeper levels of reflection may have a dynamic and, in some contexts, diametrically opposed relationship with affective or subjective experiences. Particularly given the importance of affect in physical activity behavior [58], future research should investigate the interrelationships among these aspects of DBCI engagement and how to strike the right balance for different individuals in different contexts.

Limitations

The findings from this study must be considered in the context of its limitations. A small sample size, possible selection bias, and high attrition limit the generalizability of the findings of this study; the analytical sample was a convenience sample that was relatively well educated and had limited racial and ethnic diversity. Short et al [26] highlight that the use of qualitative methods to assess DBCI engagement is inherently limited by a lack of generalizability. The application of the reflection framework presented by Fleck and Fitzpatrick [40] along with directed content analytic methods may facilitate comparison in future studies; however, it is important to note that there may be other dimensions of reflection. We were primarily interested in assessing the vertical dimension of reflection (ie, the depth of reflection), but reflection has also been characterized as having an iterative process-oriented dimension that can be nonlinear and cyclic [39]. Given this prospect and the sometimes cyclical nature of behavior change itself [59], it may be beneficial to longitudinally investigate reflective processes and their bidirectional relationships with physical activity behaviors and determinants. Likewise, there are other ways to define intervention adherence. A limitation of this study is that we did not obtain other metrics that might characterize adherence, such as time spent in the modules. In future studies, obtaining more granular data concerning system use may be advantageous. Given that the study was conducted during the COVID-19 pandemic, history was a threat that may have influenced participants' reflective processes and physical activity–related constructs. Reliance on the self-reported assessment of physical activity patterns also has well-documented limitations. Finally, we conducted multiple statistical tests and, although this investigation was explicitly exploratory in nature, the study findings are prone to an inflated chance of type I error.

Conclusions

In this study, we sought to explore a novel method for understanding critical reflection occurring in a DBCI designed to increase physical activity in insufficiently active people living with and beyond breast cancer. We found the application of qualitative content analysis based on the reflection framework presented by Fleck and Fitzpatrick [40] to be a useful tool for helping to gauge the extent to which participants engaged in reflective processes. Furthermore, we found that deeper reflection levels tended to be associated with changes in the targeted psychosocial constructs. Reflecting on newly acquired information is a critical process in integrating relevant insights for sustained behavior change. Encouraging personal reflection is an autonomy-supportive approach to promoting physical activity, and more research is warranted to investigate this approach in DBCIs serving people living with and beyond cancer.

Abstract

Background: ChatGPT by OpenAI emerged as a potential tool for researchers, aiding in various aspects of research. One such application was the identification of relevant studies in systematic reviews. However, a comprehensive comparison of the efficacy of relevant study identification between human researchers and ChatGPT has not been conducted.

Objective: This study aims to compare the efficacy of ChatGPT and human researchers in identifying relevant studies on medication adherence improvement using mobile health interventions in patients with ischemic stroke during systematic reviews.

Methods: This study used the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. Four electronic databases, including CINAHL Plus with Full Text, Web of Science, PubMed, and MEDLINE, were searched to identify articles published from inception until 2023 using search terms based on MeSH (Medical Subject Headings) terms generated by human researchers versus ChatGPT. The authors independently screened the titles, abstracts, and full text of the studies identified through separate searches conducted by human researchers and ChatGPT. The comparison encompassed several aspects, including the ability to retrieve relevant studies, accuracy, efficiency, limitations, and challenges associated with each method.

Results: A total of 6 articles identified through search terms generated by human researchers were included in the final analysis, of which 4 (67%) reported improvements in medication adherence after the intervention. However, 33% (2/6) of the included studies did not clearly state whether medication adherence improved after the intervention. A total of 10 studies were included based on search terms generated by ChatGPT, of which 6 (60%) overlapped with studies identified by human researchers. Regarding the impact of mobile health interventions on medication adherence, most included studies (8/10, 80%) based on search terms generated by ChatGPT reported improvements in medication adherence after the intervention. However, 20% (2/10) of the studies did not clearly state whether medication adherence improved after the intervention. The precision in accurately identifying relevant studies was higher in human researchers (0.86) than in ChatGPT (0.77). This is consistent with the percentage of relevance, where human researchers (9.8%) demonstrated a higher percentage of relevance than ChatGPT (3%). However, when considering

the time required for both humans and ChatGPT to identify relevant studies, ChatGPT substantially outperformed human researchers as it took less time to identify relevant studies.

Conclusions: Our comparative analysis highlighted the strengths and limitations of both approaches. Ultimately, the choice between human researchers and ChatGPT depends on the specific requirements and objectives of each review, but the collaborative synergy of both approaches holds the potential to advance evidence-based research and decision-making in the health care field.

ChatGPT; systematic reviews; medication adherence; mobile health; mHealth; ischemic stroke; mobile phone

Introduction

Background

Artificial intelligence (AI) is the field of computer science that studies and develops systems that can perform tasks, typically requiring human intelligence, such as reasoning, learning, decision-making, natural language processing (NLP), computer vision, and speech recognition [1]. AI is a rapidly evolving field with applications in various domains, for example, health care, education, business, and entertainment [2]. One of the subfields of AI is NLP, which deals with analyzing and generating natural language texts [3]. Chatbots, a type of NLP system, can interact with humans using natural language, either through text or speech. Chatbots can be used for various purposes, including customer service, entertainment, education, and information retrieval [3]. However, developing chatbots that can engage in natural and coherent conversations with humans is a challenging task that requires advanced NLP techniques and large-scale data.

One of the recent advances in NLP is the development of GPT models, which are neural network models that can generate natural language texts based on a given input or context [4]. GPT models are trained on large corpora of text from various sources, such as books, websites, news articles, and social media posts [4]. GPT models have been used to create chatbots that can generate realistic and diverse responses to human queries or messages [4]. Although GPT models have been developed by various research groups and companies (ie, OpenAI, Google, Facebook, and Microsoft), the first one was introduced by OpenAI in 2019 [5]. Since then, ChatGPT has been improved and refined by researchers and developers, who have applied it to various tasks and scenarios, such as customer service, education, entertainment, and social media [5]. ChatGPT models aim to provide engaging, informative, and coherent dialogues with users across different domains and tasks [4].

ChatGPT has been applied in the medical field in various ways. For instance, in medical practice, it has the ability to help streamline the clinical workflow, enhance diagnostics, and predict disease risk and outcome [6]. For medical education, ChatGPT can be useful in tailoring education and enabling powerful self-learning [6]. In terms of medical research, a previous study reported that ChatGPT has the potential to advance understanding, identify new research questions, and improve data analysis and interpretation [7]. In addition, ChatGPT extends to involve in writing articles through improvement in language and communication of result findings [6]. In particular, in the literature review process, which is time and effort consuming, ChatGPT has a promising advantage because of its potential ability to analyze large amounts of data, particularly in scientific articles [8]. Furthermore, ChatGPT was reported to have the potential to generate effective Boolean queries for systematic review literature searches [9].

Although ChatGPT has several advantages in medical research, it has limitations that could impact the quality of research, particularly in the literature review and search strategies processes. Citation inaccuracies, insufficient references, and references to nonexistent sources were reported as current problems [6]. Moreover, ChatGPT has a limited knowledge period based on the data sets used in ChatGPT training, which limits the reliability of the updated source of the literature review [6]. In a previous study, researchers were advised to consider the potential for incorrect MeSH (Medical Subject Headings) terms and the varying effectiveness of search queries with multiple requests when devising search strategies for a systematic review [9]. However, ChatGPT has a high potential to be used in medical research in the future. Therefore, it is imperative to explore and develop to improve and use it effectively.

Despite the significant benefits and limitations of using ChatGPT, the evaluation of the quality and performance of ChatGPT models in the review process remains unclear. Therefore, this study aims to compare the efficacy of ChatGPT and human researchers in identifying relevant health-related studies, such as research on medication adherence improvement using mobile health (mHealth) interventions in patients with ischemic stroke. The review will use systematic methods to search, select, appraise, and synthesize to address the following questions: (1) How does ChatGPT's performance compare to that of human researchers in terms of accuracy in identifying relevant studies? (2) What challenges and limitations arise from using ChatGPT versus human researchers for identifying relevant studies in systematic reviews? (3) What are the implications of using ChatGPT to enhance the efficiency of systematic reviews? The results of this review will provide crucial insights into the potential of ChatGPT as an innovative tool for conducting systematic reviews.

Objectives

This study aims to compare the efficacy of using ChatGPT and human researchers in identifying relevant studies on medication adherence improvement using mHealth interventions in patients with ischemic stroke during systematic reviews.

Methods

Identify Relevant Studies

In this study, we used the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) [10] guidelines to identify the relevant studies. Overall, 4 electronic databases, including CINAHL Plus with Full Text, Web of Science, PubMed, and MEDLINE, were searched to identify articles published from inception until 2023 on using mHealth interventions for improving medication adherence in patients with ischemic stroke. We used search terms based on MeSH using Boolean phrases generated by human researchers and ChatGPT version 3.5 to identify relevant studies. The reference lists of the included studies, generated by human researchers and ChatGPT, were separately stored and screened in EndNote (EndNote X7 reference management software package). A PRISMA flow diagram was created to present the results of the search and screening process.

Study Selection

The authors independently screened the titles and abstracts of the studies identified through separate searches conducted by human researchers and ChatGPT to determine their relevance. Subsequently, the full text of the selected articles was also assessed to ensure they met the predetermined inclusion criteria. A consistent set of inclusion criteria was applied to ensure that only studies relevant to the review's objective were included. In contrast, the same exclusion criteria were used to eliminate literature unrelated to the review (Textbox 1).

Textbox 1. Study inclusion and exclusion criteria.

Inclusion criteria

- Studies that aimed to use mobile health interventions for improving medication adherence
- Studies that primarily included adults with ischemic stroke or transient ischemic attack (TIA) aged ≥18 years (if the study included other stroke types, such as hemorrhagic stroke, it is acceptable, but the study population must include adults with ischemic stroke or TIA)
- Studies in English
- Studies that were published from inception until 2023

Exclusion criteria

- Studies that included children or adolescents aged <18 years
- Conference proceedings, abstracts, review articles, protocols, dissertations, letters to the editor, brief reports, or statement papers
- Studies that involved animal samples

Data Extraction

A separate summary table for data extraction is presented in Multimedia Appendix 1 [11-20], consisting of the following data for each study: reference, year, country, study design, sample size, target population, intervention and objective, and main findings. This table will be used to compare the included studies obtained through the *Identify relevant studies* phase conducted by human researchers versus ChatGPT. The primary outcome of interest is medication adherence among patients with ischemic stroke. Medication adherence can be measured using various methods, such as drug level measurement, pill count, electronic databases, self-report questionnaires, and electronic monitoring systems [21]. The findings from studies that aimed to use mHealth interventions for improving medication adherence but did not measure medical adherence directly will be evaluated based on how they operationalized medication adherence according to their study design.

Data Analysis

In this study, we will assess the accuracy of both human researchers and ChatGPT in identifying relevant studies from electronic databases by measuring precision. Precision is a performance metric that measures the accuracy of a model's positive predictions. It focuses on the proportion of correctly identified positive instances (true positives) out of all the cases that the model predicted as positive (true positives+false positives) [22]. Precision is calculated using the following formula: precision=true positives/(true positives+false positives).

A high precision value close to 1 indicates that the model has a low rate of false positives. This means that when the model predicts an instance as positive, it will likely be correct. In contrast, a low precision value close to 0 indicates that the model has a high rate of false positives. This means that when the model predicts an instance as positive, it often needs to be corrected [22]. In the context of this study, precision will help evaluate the ability of both human researchers and ChatGPT to accurately identify relevant studies from electronic databases during the systematic review process. We will compare their precision scores to determine which approach yields a higher proportion of true positives and a lower rate of false positives.

In addition, as the human researcher will still need to conduct the screening, eligibility, and inclusion phases, we will also calculate the percentage of relevance using the formula ([true positives/total studies identified from the search]×100). This approach will be chosen to ensure a fair assessment, as relying solely on a formula based on true and false positives (precision) might only reflect human variability and accuracy during the screening, eligibility, and inclusion phases.

Ethical Considerations

This study considers nonhuman research according to the "Self-Assessment form whether an activity is human subject

research which requires ethical approval" recommended by Mahidol University Central Institutional Review Board. Therefore, ethics approval from the research ethics committee was not required.

Results

Search Term

Human Researcher

In the search phase, we used search terms based on MeSH using Boolean operators. The searched topic was related to using mHealth interventions for improving medication adherence in patients with ischemic stroke: (Ischemic Stroke* OR Cryptogenic Ischemic Stroke* OR Cryptogenic Stroke* OR Cryptogenic Embolism Stroke* OR Wake up Stroke* OR Acute Ischemic Stroke* OR Embolic Stroke* OR Cardioembolic Stroke* OR Cardioembolic Stroke* OR Thrombotic Stroke* OR Acute Thrombotic Stroke* OR Lacunar Stroke* OR Lacunar Syndrome* OR Lacunar Infarction* OR Lacunar Infarct*) AND (Medication Adherence OR Medication Nonadherence OR Medication Noncompliance OR Medication Persistence OR Medication Compliance OR Medication Non-Compliance) AND (Tele-Referral* OR Virtual Medicine OR Tele Intensive Care OR Tele ICU OR Mobile Health OR mHealth OR Telehealth OR eHealth OR Remote Consultation OR Teleconsultation* OR Telenursing OR Telepathology OR Teleradiology OR Telerehabilitation* OR Remote Rehabilitation* OR Virtual Rehabilitation*).

ChatGPT

To compare with the search by human researchers, we asked ChatGPT [23] on June 23, 2023, at 1:30 PM EST to provide a search term for conducting a systematic review of the same topic as follows: "Hello ChatGPT, we are researchers and currently conduct a systematic review titled: Using m-health interventions for improving medication adherence in ischemic stroke patients. Can you provide Medical Subject Headings (MeSH) search terms and combine them using Boolean operators for a search process?" The following search terms resulted from ChatGPT, which we used in the search phase and then compared the results with those from human researchers: (Mobile Applications OR Cell Phone OR Smartphone OR Telemedicine OR Text Messaging OR Internet) AND (Medication Adherence OR Patient Compliance OR Medication Systems, Intelligent) AND (Stroke OR Ischemic Attack, Transient OR Cerebrovascular Disorders). The search term (generated by human researchers and ChatGPT) was adjusted according to the database searching requirement before searching, but the original keyword was not changed.

Search Results

We compared the ability of humans and ChatGPT to retrieve all relevant studies. A higher recall indicates a better ability to capture all the relevant literature. Figure 1 shows the flowchart diagram of the selection of included studies based on search terms generated by human researchers. An initial literature search yielded 61 articles, including 30 from PubMed and MEDLINE, 21 from Web of Science, and 10 from CINAHL Plus Full Text. No additional records were found through other sources. After deduplication (n=7 studies), the researchers screened 54 studies, of which 47 (87%) were excluded based on the inclusion and exclusion criteria following the title and abstract screening phase. This left 7 articles for full-text screening, during which 1 article was excluded as it did not include any mHealth-related intervention. Therefore, 6 articles were included in the final analysis. It should be noted that human researchers conducted the identification, screening, eligibility, and inclusion phases.

Figure 1. The flowchart diagram displays the selection method of qualified studies searched by a human researcher. mHealth: mobile health.

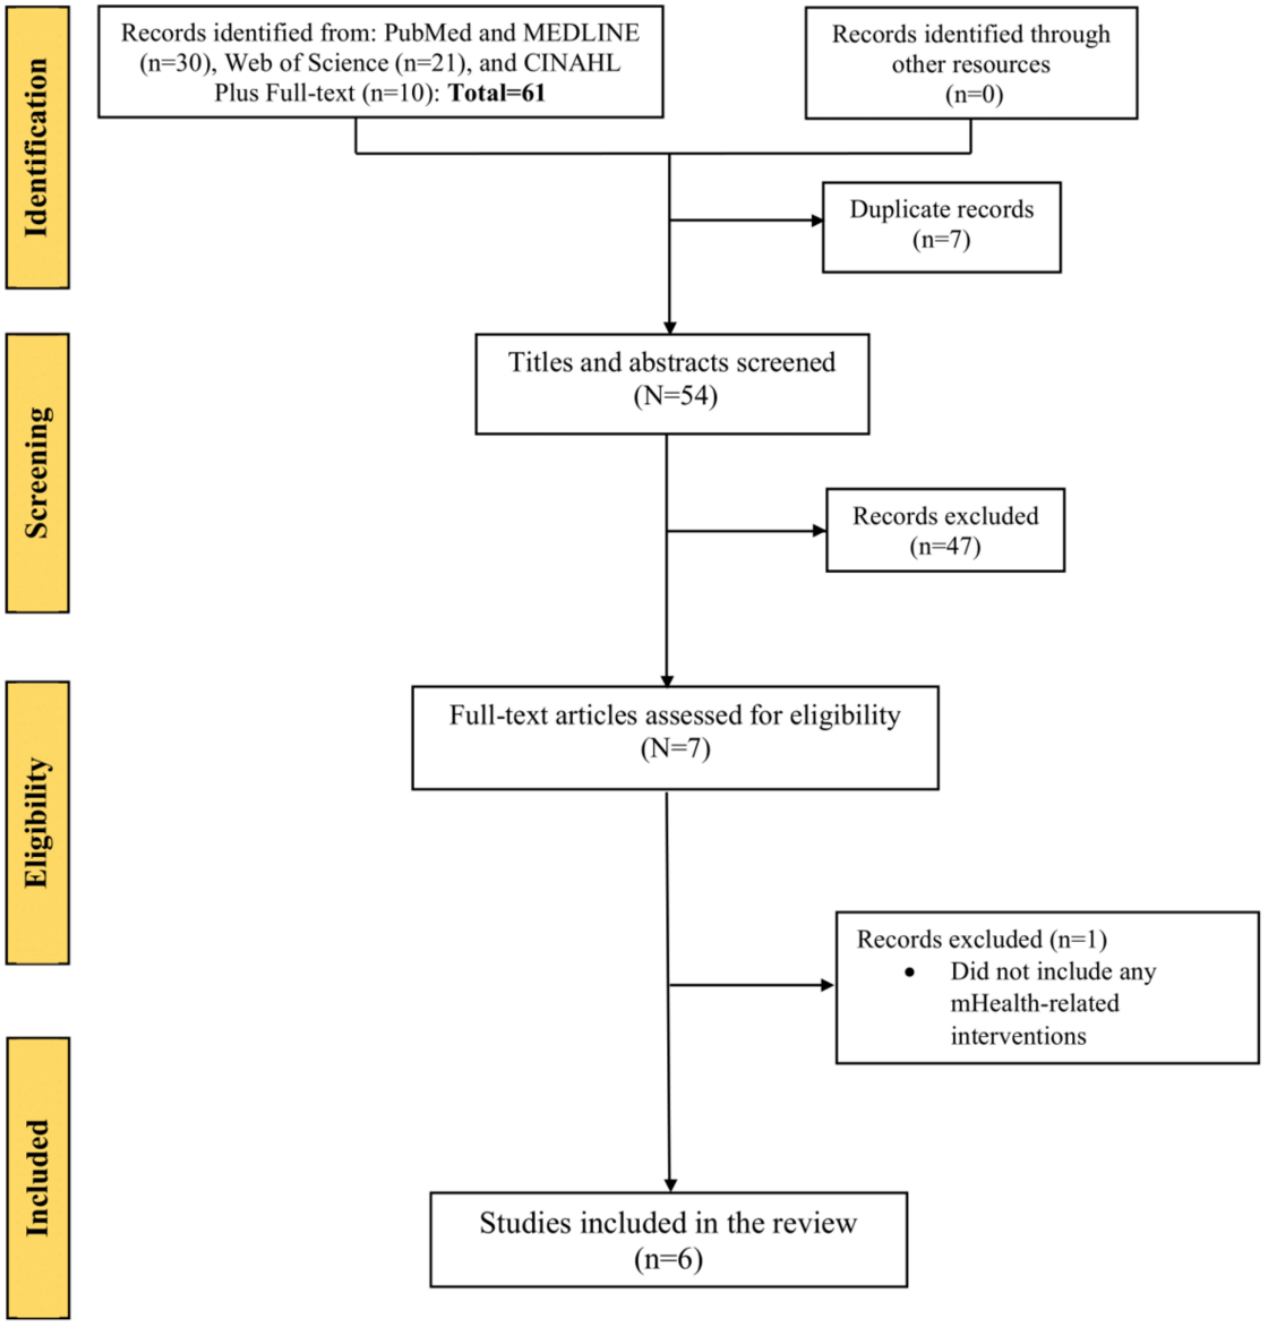

Figure 2 shows the flowchart diagram of the selection of included studies based on search terms generated by ChatGPT. An initial literature search yielded 334 articles, including 146 from PubMed and MEDLINE, 130 from Web of Science, and 58 from CINAHL Plus Full Text. No additional records were found through other sources. After deduplication (n=104 studies), the researchers screened 230 studies, of which 217 (94.3%) were excluded based on the inclusion and exclusion criteria following the title and abstract screening phase. Of the 13 articles that underwent full-text screening, 3 studies were excluded because the intervention was irrelevant (n=1, 33%), the publication was not in English (n=1, 33%), and it was a letter to the editor (n=1, 33%). Finally, 10 articles were included in the final analysis. It should be noted that ChatGPT has been used only in the identification phase. The human researcher conducted the screening, eligibility, and inclusion phases.

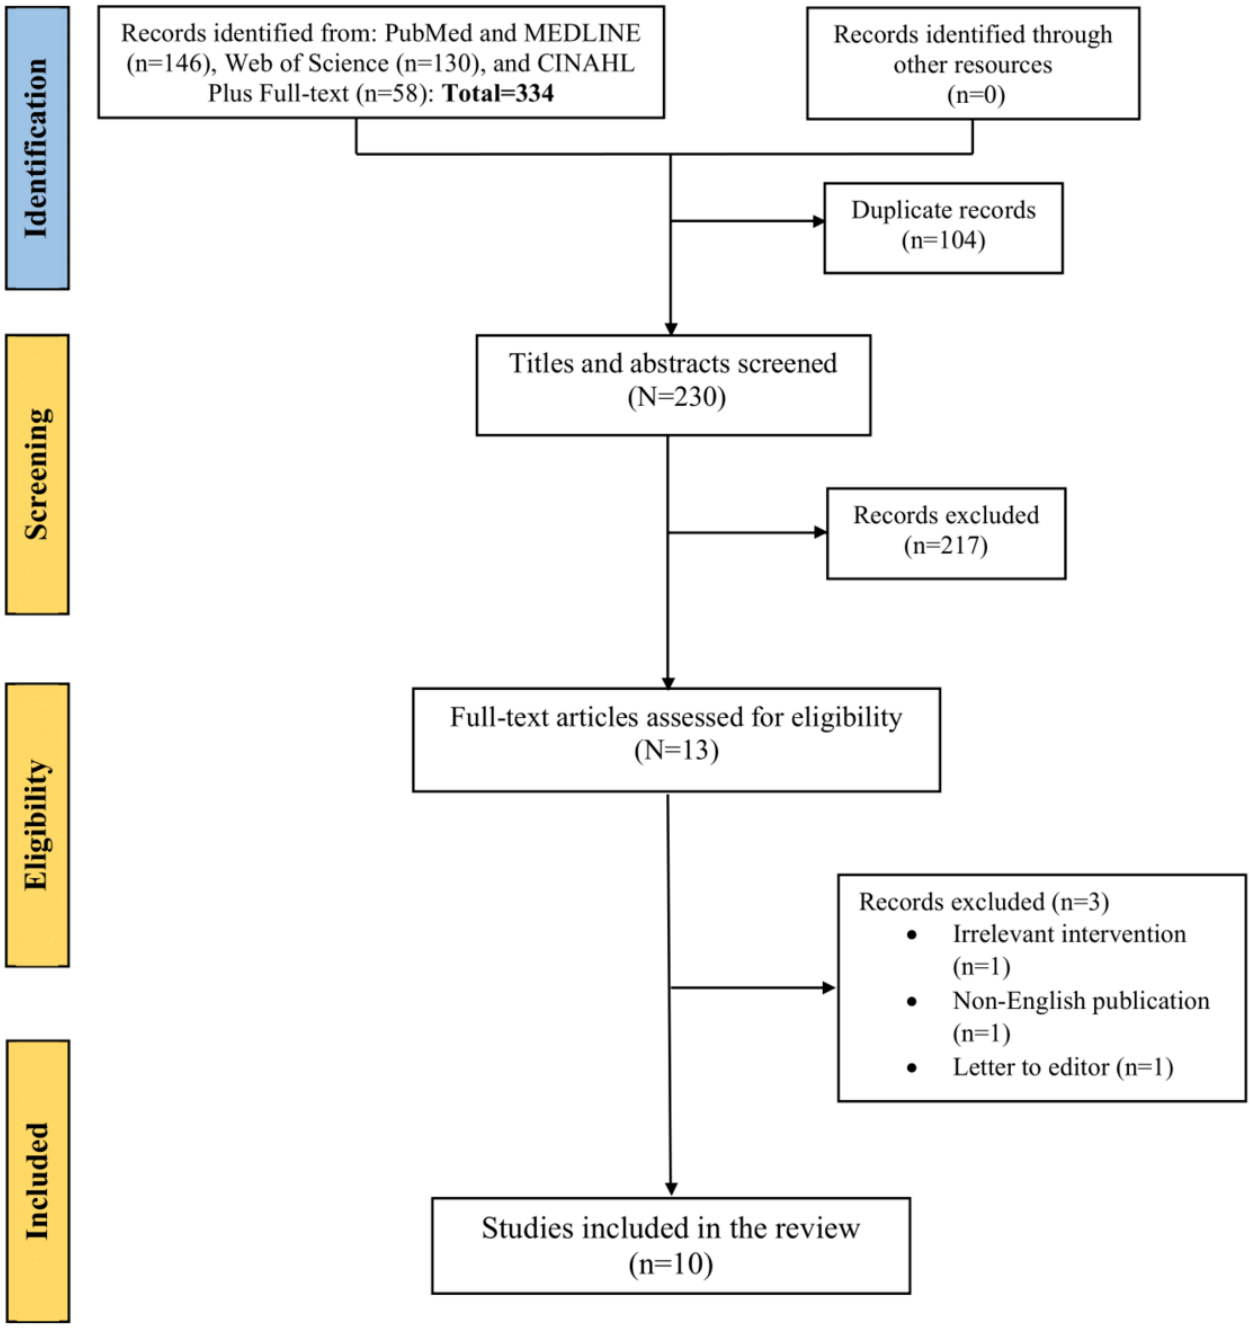
Figure 2. The flowchart diagram displays the selection method of qualified studies searched by ChatGPT.



Description of the Included Studies

Studies Included From Human Searches

The analysis included 6 studies obtained from the human search (Multimedia Appendix 1). Most of these studies (3/6, 50%) were published in 2020. Among the countries where the studies were conducted, 50% (3/6) were from China, whereas 17% (1/6) of the studies each originated from Belgium, the Republic of Korea, and Sweden. In terms of study design, of the 6 studies, 3 (50%) were cohort studies, 2 (33%) were randomized controlled trials (RCTs), and 1 (17%) was a non-RCT. The sample sizes varied, with 50% (3/6) of the studies having a sample size ranging from 1 to 300 and the other 50% (3/6) of the studies having a sample size of >300. Regarding the impact of mHealth interventions on medication adherence, most included studies (4/6, 67%) reported improvements in medication adherence after the intervention [11-14]. However, in 33% (2/6) of the included studies, it was not clearly stated whether medication adherence improved after the intervention [15,16].

Studies Included From ChatGPT Searches

A total of 10 studies were obtained from the ChatGPT search, of which 6 (60%) studies overlapped with the human searches (Multimedia Appendix 1). Most of these studies (4/10, 40%) were published in 2020. Among the countries where the studies were conducted, 50% (5/10) of the studies were from China, whereas 10% (1/10) of the studies each originated from Belgium, the Republic of Korea, Sweden, the United States, and Pakistan. In terms of study design, most were RCTs (6/10,

60%), with 30% (3/10) of the studies being cohort studies, and 10% (1/10) of the studies being a non-RCT. The sample sizes varied, with 70% (7/10) of the studies having a sample size ranging from 1 to 300 (70%), and the other 30% (3/10) of the studies having a sample size of >300. Regarding the impact of mHealth interventions on medication adherence, most included studies (8/10, 80%) reported improvements in medication adherence after the intervention [11-14,17-20]. However, in 20% (2/10) of the included studies, it was not clearly stated whether medication adherence improved after the intervention [15,16].

Accuracy

In our study, we used precision as a metric to assess the accuracy of both human researchers and ChatGPT in identifying relevant studies from electronic databases during the systematic review process. By comparing their precision scores, we aimed to determine which approach yielded a higher proportion of true positives (correctly identified relevant studies) and a lower rate of false positives (incorrectly identified irrelevant studies). The precision calculation formula used was as follows: precision=true positives/(true positives+false positives).

Moreover, the human researcher conducted identification, screening, eligibility, and inclusion phases, as illustrated in Figure 1. In contrast, ChatGPT was used only during the identification phase, and the human researcher conducted the screening, eligibility, and inclusion phases, as depicted in Figure 2. Therefore, we also calculated the percentage of relevance using the formula ([true positives/total studies identified from the search]×100). This approach was chosen to ensure a fair assessment, as relying solely on a formula based on true and false positives might only reflect human variability and accuracy during the screening, eligibility, and inclusion phases.

For human researchers, the precision in accurately identifying relevant studies from electronic databases was calculated as 6/(6+1)=0.86, where 6 is the number of studies included in the review (true positive) and 1 (false positive) represents the study that was incorrectly identified as relevant for inclusion in the review (did not include any mHealth-related intervention; Figure 1). This means that out of the studies deemed relevant by human researchers, 86% (6/7) were indeed appropriate for inclusion in the review, whereas 14% (1/7) were falsely identified as relevant. The percentage of relevance for the human researcher was calculated as follows: (true positives/total studies identified from the search)×100=(6/61)×100=9.8%.

Regarding ChatGPT, its precision in accurately identifying relevant studies from electronic databases was calculated as 10/(10+3)=0.77, where 10 is the number of studies included in the review (true positive) and 3 (false positive) represents the studies that were incorrectly identified as relevant for inclusion in the review (irrelevant intervention, non-English publication, and a letter to the editor; Figure 2). This indicates that out of the studies identified by ChatGPT as potentially relevant, 77% (10/13) were indeed relevant and suitable for inclusion in the review, whereas 23% (3/13) were mistakenly identified as relevant. The percentage of relevance for ChatGPT was calculated as follows: (true positives/total studies identified from the search)×100=(10/334)×100=3%.

According to our findings, the precision of human researchers was higher (precision=0.86) compared to ChatGPT (precision=0.77). This is consistent with the percentage of relevance, where human researchers (9.8%) demonstrated a higher percentage of relevance than ChatGPT (3%). These results indicate that human researchers were more effective in identifying relevant studies during the systematic review process. However, it is noteworthy that despite the lower precision and percentage of relevance, ChatGPT's initial search yielded a significantly larger number of studies (n=334) compared to human researchers (n=61), and ultimately resulted in more studies included in the final analysis (n=10 for ChatGPT vs n=6 for human researchers). This suggests that ChatGPT's performance was more efficient in terms of study retrieval and inclusion, although there was a 60% overlap in the studies included between both approaches.

Efficiency

As reported in the Accuracy subsection, human researchers demonstrated higher precision in identifying relevant studies compared to ChatGPT. However, the efficiency and ability of ChatGPT to retrieve relevant studies could still hold value in the systematic review process. When considering the time required for both humans and ChatGPT to identify relevant studies, from the beginning (search term generation) to the outcome (identification of relevant studies before screening), our study found that ChatGPT substantially outperformed human researchers. ChatGPT took approximately 10 minutes, whereas human researchers spent an hour in the search term identification process using MeSH and Boolean operators before obtaining the relevant study.

In our study, we used ChatGPT to generate search terms for conducting the systematic review based on our research topic. This substantially reduced the time and effort required for initial study identification. However, it is important to note that ChatGPT's current capabilities are limited to providing search terms, and human researchers are still required to conduct the screening of titles, abstracts, and full texts of the identified studies, using refined inclusion and exclusion criteria.

Discussion

Principal Findings

According to our findings, the precision of human researchers was higher compared to ChatGPT, indicating that human researchers were more accurate in identifying relevant studies during the systematic review process. Our findings are congruent with a previous study [24], which reports inaccuracies of using ChatGPT in research that requires an in-depth understanding of the literature. Likewise, Zhao et al [25] reported that the factual accuracy of ChatGPT cannot be ensured, although it has massive resources such as Microsoft and Google. In addition, a case study of using ChatGPT to conduct literature searches indicated that ChatGPT does not provide an answer to the queries that researchers ask for [26].

Despite the lower precision of ChatGPT compared to human search, a previous study reported that ChatGPT has more accurate and comprehensive relevance judgments than all other

types of NLP models or techniques [27]. Moreover, our findings show that ChatGPT's initial search yielded a significantly larger number of studies compared to human researchers and ultimately resulted in more studies being included in the final analysis despite its lower precision. This suggests that ChatGPT's performance was more efficient in terms of study retrieval and inclusion, although there was a 60% overlap in the studies included between both approaches. Similarly, a study of ChatGPT's insights on the future of scientific publishing reports it as a valuable resource for initiating discussions [28]. However, a previous study using ChatGPT for retrieval of clinical, radiological information reported that ChatGPT provided only two-thirds of correct responses to questions [29].

Regarding the efficiency issues of using ChatGPT in identifying relevant search terms, the results of this study suggest that ChatGPT can be a useful tool for generating search terms for systematic reviews, as it can save time and effort for human researchers and potentially retrieve more relevant studies. The previous study on the use of ChatGPT Boolean query construction and refinement for systematic review showed that ChatGPT can generate queries with high precision [9]. Therefore, ChatGPT could be a valuable tool, especially for rapid reviews where time is limited and high precision is preferred over high recall [9].

Some researchers may argue that as ChatGPT has lower precision and may generate irrelevant or inaccurate terms, human researchers still need to carefully screen the studies that ChatGPT identified and verify the quality and validity of the evidence [30]. ChatGPT should be used with caution and verification and supplemented with other methods and sources to ensure the validity and rigor of the literature search [9]. Furthermore, ChatGPT's performance may vary depending on the research topic, data availability, and input quality. Thus, future studies are needed to evaluate ChatGPT's generalizability and reliability across different domains and contexts.

Using ChatGPT to generate search terms for systematic reviews raises some ethical questions regarding the quality and validity of the research process. Although ChatGPT may offer some advantages in terms of efficiency and comprehensiveness, it may also introduce some biases and errors that could affect the reliability and reproducibility of the systematic reviews. For example, ChatGPT may generate search terms that are irrelevant to the research topic or too broad or narrow, resulting in either missing or including studies that do not meet the inclusion criteria [31]. Moreover, ChatGPT may generate search terms that are based on its own internal knowledge and information, which may not reflect the current state of the art or the best available evidence in the field [31]. Therefore, human researchers need to carefully evaluate and validate the search terms generated by ChatGPT and document their rationale and methods for using them. In addition, human researchers need to disclose the use of ChatGPT as a tool for generating search terms and report its strengths and limitations and any potential ethical implications in their systematic review reports [31]. This would ensure that the systematic review process is transparent, accountable, and trustworthy and that the results are credible and useful for informing decision-making.

As we embark on a comparative analysis between ChatGPT and human researchers in the pursuit of identifying relevant studies within systematic reviews, particularly focused on mHealth interventions for improving medication adherence in patients with ischemic stroke, it becomes evident that several challenges and limitations underscore the intricate nature of this exploration. These challenges offer insight into the complex interplay between cutting-edge technology and the established domain expertise of human researchers, shaping the landscape in which this study unfolds.

First and foremost, the outcomes of our study are intrinsically linked to the performance of ChatGPT, an AI-driven tool that relies on its current capabilities to generate search terms. As an entity in constant evolution, ChatGPT's performance may undergo shifts over time, potentially influencing the accuracy and efficiency with which it generates relevant search terms. Moreover, replicating the search in subsequent studies is essential due to ChatGPT's intrinsic unpredictability. The lack of such repetition presents challenges in determining whether the observed phenomenon reflects an inherent trait of the model or is simply a random incident.

This dynamic underscores the need to interpret our findings in the context of the tool's state during the study period. Within the realm of medical research, the intricate and evolving nature of terminology poses a formidable challenge. Although ChatGPT exhibits language generation prowess, the intricate nuances of medical terminology—constantly adapting and expanding—could potentially pose challenges to its accurate formulation of search terms. The complexity inherent to medical concepts demands a level of contextual understanding that might be challenging for an AI system.

Another pivotal consideration revolves around the potential biases embedded within ChatGPT's training data. Drawing insights from vast data sets, ChatGPT-generated search terms might inadvertently inherit biases present in the underlying data sources. This potential bias, albeit unintentional, introduces an element of caution when relying solely on AI-generated search terms for systematic reviews. A crucial aspect of our study's execution pertains to refining search terms. Although ChatGPT serves as a catalyst for initial search term generation, human researchers play a pivotal role in the subsequent validation and fine-tuning of these terms. This collaborative process introduces an additional layer of complexity, as human intervention becomes essential to ensure the relevance and accuracy of the generated search terms. Moreover, the resources available and the access to ChatGPT's capabilities could introduce variability in the study's outcomes. Depending on factors such as subscription tiers or institutional resources, the extent of ChatGPT's contributions and, subsequently, its comparative assessment against human researchers may exhibit nuances that warrant consideration. The study's defined scope, focused on mHealth interventions for medication adherence improvement in patients with ischemic stroke, provides a specific lens through which insights are garnered. However, this specificity inherently limits the direct transposability of findings to other medical domains or broader systematic review topics. The nuances of different research contexts might yield distinct results. Language and geographic considerations further amplify the complexity.

The study predominantly engaged with studies in English, potentially omitting valuable research published in other languages or regions. This limitation underscores the need for meticulous attention to language diversity and inclusion in systematic reviews. Human researcher variability introduces a layer of subjectivity into the study. With multiple researchers contributing to search term generation, variations in expertise and individual approaches could impact the study's outcomes. The potential for differing interpretations and formulations of search terms necessitates careful management. Publication bias, a well-known challenge in research, extends its influence into our study's design. Both ChatGPT and human researchers might inadvertently be swayed by publication bias, where certain types of studies are more likely to be published, potentially influencing the pool of studies considered in this review.

External factors beyond the purview of our study could exert unanticipated influence. Variables such as changes in database availability, updates to search algorithms, or shifts in the research landscape might subtly shape the study's design and outcomes, introducing an element of unpredictability. The study's designated time frame for data collection and inclusion introduces potential time constraints and selection bias. Studies published after the search period might be inadvertently omitted, potentially impacting the completeness of the review. Although the study provides valuable insights within its specific scope, the generalizability of findings to other systematic review topics or research questions requires cautious interpretation. The intricate interplay between technology and human expertise forms the cornerstone of our study, emphasizing the necessity for a balanced and nuanced approach when leveraging ChatGPT for systematic reviews.

The Implications of Using ChatGPT to Improve the Efficiency of Systematic Reviews

The integration of ChatGPT into the systematic review process for identifying relevant studies on mHealth interventions holds several noteworthy implications for research methodology, efficiency, and the advancement of evidence-based practices. This section explores the key implications that arise from incorporating ChatGPT as a tool to expedite and enhance the systematic review process.

One of the most immediate and impactful implications of using ChatGPT is its ability to significantly expedite the systematic review process. Traditionally, the generation of search terms for identifying relevant articles is a time-intensive task that requires meticulous crafting and refinement by human researchers. ChatGPT's capacity to swiftly generate search terms offers an innovative solution to this bottleneck, reducing the time invested in this preliminary phase. This acceleration holds the potential to expedite the overall timeline of systematic reviews, enabling researchers to allocate more time to critical appraisal, synthesis, and analysis of selected studies.

The inherent nature of ChatGPT's language generation capabilities allows a more diverse and expansive range of search terms. By tapping into its capacity to comprehend and generate natural language, researchers can explore a broader spectrum of keyword variations and synonyms. This expanded search scope can lead to the inclusion of studies that might have been overlooked using traditional search methods. As a result, the systematic review process becomes more comprehensive, encompassing a wider array of relevant literature.

ChatGPT's ability to generate novel and contextually relevant search terms introduces a valuable avenue for exploratory research and hypothesis generation. Researchers can leverage ChatGPT to identify emerging trends, novel terminologies, or unconventional associations that may inform the direction of their systematic reviews. This capacity to extract insights from the vast expanse of existing literature can potentially lead to the formulation of innovative research questions and avenues for investigation.

Although ChatGPT demonstrates remarkable efficiency in generating search terms, its use necessitates a collaborative approach with human researchers. The synergy between ChatGPT's speed and human researchers' expertise in refining and validating search terms ensures a balanced and accurate outcome. Human researchers play a pivotal role in critically evaluating the generated search terms, refining them to align with the specific objectives of the review, and subsequently verifying the relevance of the identified articles. This collaborative interplay mitigates the risk of introducing erroneous or irrelevant studies into the review process.

In research environments with limited resources, such as time and personnel, ChatGPT offers a solution to address scalability challenges. Its ability to rapidly generate search terms can prove invaluable in scenarios where timely completion of systematic reviews is imperative. Researchers operating within resource-constrained contexts can leverage ChatGPT to conduct preliminary searches efficiently, thus optimizing the allocation of limited resources to subsequent stages of the review.

In summary, the integration of ChatGPT into the systematic review process introduces a transformative approach to enhancing efficiency and enriching the scope of literature exploration. Although its speed and breadth of search terms hold the promise of expediting the review timeline and uncovering hidden associations, the collaborative involvement of human researchers remains pivotal for ensuring accuracy, relevance, and the meticulous execution of subsequent review stages. The strategic use of ChatGPT in conjunction with traditional research practices paves the way for a new era of evidence synthesis and knowledge advancement in the field of health care interventions.

Conclusions

Our study compares the accuracy and efficacy of human researchers and ChatGPT in providing search terms to identify articles during a systematic review on mHealth interventions for improving medication adherence in patients with ischemic stroke. Although human researchers achieved greater precision, ChatGPT's search results exhibited lower accuracy. However, ChatGPT excelled in efficacy, taking less time to generate search terms compared to human researchers, who required more time to identify appropriate search terms. In addition, ChatGPT's search yielded a higher number of articles compared to human researchers. Following exclusions, human researchers were left with 6 articles, and ChatGPT resulted in 10 articles after

screening, 6 (60%) of which overlapped with the findings of human researchers. The use of ChatGPT in creating search terms can significantly accelerate the systematic review process, although human researchers are still essential to carry out the selection process and ensure accuracy.

Acknowledgments

The authors would like to express their gratitude to Mahidol University, Thailand, for covering the article publishing charge. During the preparation of this work, the authors used ChatGPT (version 3.5, 2024; OpenAI [23]) to improve language and readability, which the study group further reviewed and revised.

Abstract

Background: Mobile health (mHealth) interventions that promote healthy behaviors or mindsets are a promising avenue to reach vulnerable or at-risk groups. In designing such mHealth interventions, authentic representation of intended participants is essential. The COVID-19 pandemic served as a catalyst for innovation in remote user-centered research methods. The capability of such research methods to effectively engage with vulnerable participants requires inquiry into practice to determine the suitability and appropriateness of these methods.

Objective: In this study, we aimed to explore opportunities and considerations that emerged from involving vulnerable user groups remotely when designing mHealth interventions. Implications and recommendations are presented for researchers and practitioners conducting remote user-centered research with vulnerable populations.

Methods: Remote user-centered research practices from 2 projects involving vulnerable populations in Norway and Australia were examined retrospectively using visual mapping and a reflection-on-action approach. The projects engaged low-income and unemployed groups during the COVID-19 pandemic in user-based evaluation and testing of interactive, web-based mHealth interventions.

Results: Opportunities and considerations were identified as (1) reduced barriers to research inclusion; (2) digital literacy transition; (3) contextualized insights: a window into people's lives; (4) seamless enactment of roles; and (5) increased flexibility for researchers and participants.

Conclusions: Our findings support the capability and suitability of remote user methods to engage with users from vulnerable groups. Remote methods facilitate recruitment, ease the burden of research participation, level out power imbalances, and provide a rich and relevant environment for user-centered evaluation of mHealth interventions. There is a potential for a much more agile research practice. Future research should consider the privacy impacts of increased access to participants' environment via webcams and screen share and how technology mediates participants' action in terms of privacy. The development of support procedures and tools for remote testing of mHealth apps with user participants will be crucial to capitalize on efficiency gains and better protect participants' privacy.

KEYWORDS

user testing; user participation in research; COVID-19; remote testing; intervention design; mobile phone

Introduction

Mobile health (mHealth) interventions, which use mobile technology such as smartphone apps to promote healthy behaviors or mindsets [1], are a promising avenue to reach vulnerable groups [2]. Meaningful user involvement is critical for such interventions [3] to ensure that end user needs and perspectives are adequately represented in the design process [4]. Conducting such feedback and evaluations with users face to face (local testing) [5-7] involves efficiency drawbacks, particularly travel, time, and cost [8]. Researchers and practitioners have thus experimented with remote testing and research [9,10] using both specialized tools (eg, UserTesting and Lookback) and videoconferencing (eg, Zoom, Hangout, and Teams). Studies comparing local and remote research practices have concluded comparable results in the quality of the research output [11]. However, before the COVID-19 pandemic, local testing was the usual practice in research and among practitioners [4,6]. Reasons may include network variance, poor audio or video quality, unfamiliarity with remote technology, and the lack of contextual information or nonverbal cues inherent in remote methods. Local testing, by contrast, removes users from the intended context of use; this is significant for user involvement in the design of mobile solutions such as mHealth interventions.

Traditional research methods tend to involve users from high socioeconomic backgrounds, who are easy to reach and have the means to participate, including resources of time, transport, and social support [12]. Human-computer interaction research calls for adequate reach and engagement with the people affected by the design to ensure an alignment of needs and, ultimately, an effective program [13,14]. This can be challenging when working with community groups who are marginalized or experience social disadvantage, such as racial or ethnic minority groups, individuals who have low income and who are unemployed, people with disabilities [15], or those with gender or sexual diversity [14,16]. This risks diminishing the validity of the findings to the target population and reduces the authenticity of engagement. While mHealth interventions may be particularly relevant for these groups, the suitability of remote practices for user involvement should be explored. More evidence is needed to support the appropriateness and effectiveness of remote user-centered research methods when engaging with vulnerable participants.

Accelerated by the pandemic, remote research and participation tools have become more available and ready-to-hand [17]. Researchers expedited the incorporation of remote methods that allowed for project continuity, highlighting the research community's resilience and researchers' and participants' willingness to experiment with technology. A recent meta-analysis found that one of the most significant effects of the pandemic on user involvement in design was shifting to web-based platforms [11]. At the community level, the increased use of telehealth services across populations to provide continuity of health care and education [18] has increased familiarity and comfort with videoconferencing and other web-based tools.

While the COVID-19 pandemic was a catalyst for innovation and creativity in remote user design methods, now that the pandemic has resolved [19], the opportunity to learn and adopt effective remote methods remains. Conducting meta-research to capture these experiences is important for future research applications. Some examples of such research exist: Hill et al [20] reviewed practical approaches for remote user testing in older adults. Other researchers have compared findings between remote and nonremote methods [21] or discussed specific aspects of the testing, including moderator and observer roles [5,22]. However, few studies have detailed the implementation of user-centered design in mHealth [3] or reflected on the researcher and participant experiences [23] in intervention design targeting vulnerable or diverse population groups.

Thus, the research question addressed by this qualitative and retrospective study is as follows: what are the opportunities and considerations emerging from involving vulnerable user groups remotely in mHealth intervention design? This study will highlight what was learned by adapting to agile remote user involvement during COVID-19 to inform future applications of such involvement with vulnerable user groups. Research practices from 2 projects, which applied remote inclusion of vulnerable population groups to designing and developing mHealth interventions within child health (parental feeding) and social psychology (mindset), were used as cases.

This study is structured as follows: an overview of the research projects and the methodology of this study is provided, followed by case descriptions and lessons learned before the analytical findings and implications are presented.

Methods

Research Context

The 2 research projects in this study used human-centered design (HCD) methodology [24] to design and develop web-based mHealth interventions targeting vulnerable populations. The project aims were to create digital health interventions collaboratively with and for end users and then evaluate these as part of ongoing research. The Responsive Feeding in Tough Times (RFiTT) project in Australia aimed to develop and evaluate a parenting program to promote responsive feeding practices in parents with young children in low-income families. The Career Learning App (CL-APP) project in Norway aimed to design, develop, and test positive psychology intervention apps targeting unemployed adolescents and young adults to promote job-seeking mindset and behaviors. These projects from different contexts have shared characteristics, including transdisciplinary work across design and health and applying an HCD process where users' ideas and feedback were central to the final intervention designs. Both project outcomes were web-based interventions designed for self-administered use on users' mobile phones, and remote user testing was applied with research participants from vulnerable groups.

In the 2 projects, the respective authors (IJS and KAB) developed user-centered design approaches, which were predominantly formative user-based evaluation [4,6] in the form of qualitative, moderated early testing [25] and feedback on

intervention prototypes. This included conducting the posttest analysis of the collected data. From March 2020 to December 2022, a total of 38 sessions were conducted across the 2 research projects. Participants were recruited intentionally with the characteristics of potential end users of the interventions to include their input into the designed outcome.

The projects' remote user engagement timing aligned with different phases of the COVID-19 pandemic. The Norway project experienced acute disruption during user testing (March 2020-April 2021), coinciding with the initial COVID-19 response. In contrast, the Australian project conducted user testing (November 2022-December 2022) during a more stable "living with" COVID-19 phase.

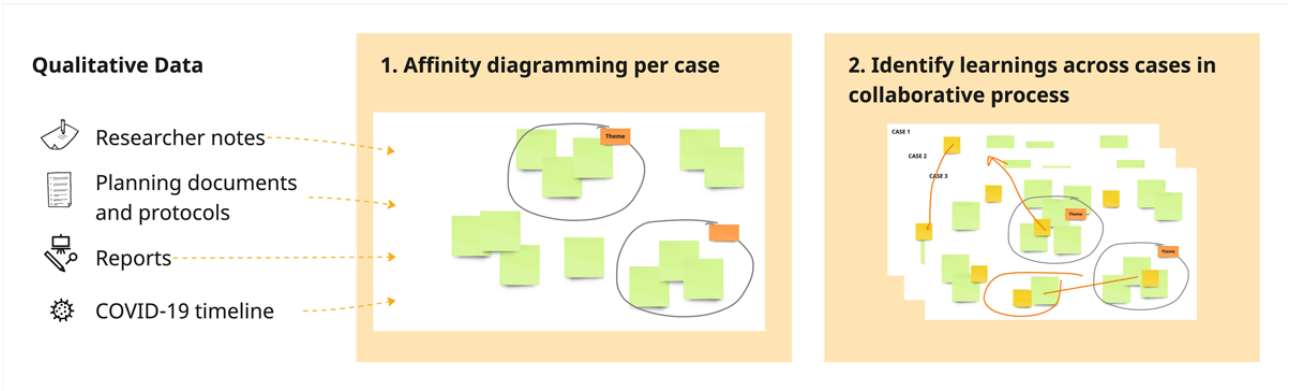
Research Design

Given the unprecedented COVID-19 pandemic during user testing, the retrospective reflection-on-action approach [26,27] was selected to explore the remote research setting. This study's research question and topic were explored [28,29] through "reflecting on action" [26]. Reflection was both internal and in dialogue between the authors and fellow researchers. This approach enabled researchers to reflect on the cases after the upheaval period of the pandemic had receded to uncover knowledge through analyzing and integrating experiences and practices.

We conducted a descriptive and retrospective examination of the research practices and experiences across the 2 projects. This was done through an iterative process using visual mapping (ie, affinity mapping or KJ-method) to sort findings visually [30] in Miro [31]. Affinity mapping builds upon abductive thinking and is commonly used by user experience practitioners [32,33]. This method was selected because of our heterogeneous data set [32] and the need to synthesize ideas from unstructured data. Our data included multiple sources: protocol documents, user test setups and documentation, researcher notes and reflections, postanalysis reports, and photos and screenshots from recordings.

We took a constructivist approach to our analysis, where synthesis and connections are formed through the researchers' critical reflection, and learnings are identified through active engagement and "discussions with the data" [34,35]. Our analysis was conducted stepwise (Figure 1), where we first added our data to the diagrams and started making clusters and groupings of findings relevant to the research question and labeling these on a case-by-case basis. Second, we identified learnings across cases in a collaborative process by regrouping our initial categories and findings of interest into broader categories or constructed themes [34] that represent the opportunities and considerations from different cases.

Figure 1. Stepwise analysis process based on visual diagramming, such as affinity mapping.



Participants

The participants included in this study are considered potentially "vulnerable" due to socioeconomic factors such as unemployment, low income, and economic hardship. *Vulnerability* is viewed as an inclusive term in line with the study by Culén and van der Velden [36], assuming that all users may be "vulnerable" at some point. The 2 research projects had different participant groups and ethical considerations; therefore, we describe them separately below. Table 1 summarizes participants across projects.

Table 1. Description of participants across cases: demography, recruitment channel, and format of the user testing.

	Participants
Case 1	
Target group (inclusion criteria)	• Unemployed or dropped out of school • Aged 18-29 y • Living in Rogaland, Norway • Speaking Norwegian
Recruitment channel	• Invitation via NAV[a] or IPS[b] program • Self-signup on website or via SMS text messaging or mail
Participants	• 12 participants aged 18-27 y; 7 females, 5 males[c]; 2 from ethnic minority groups (immigrant or BIPOC[d])
Format user test	• 3 in-person sessions • 9 remote of which 3 Discord, 5 Zoom, 1 other (Whereby); 2 used mobile phone device to connect to Zoom
Case 2	
Target group (inclusion criteria)	• Unemployed or dropped out of school • Aged 18-29 y • Living in Rogaland, Norway • Speaking Norwegian
Recruitment channel	• Invitation via NAV or IPS program • Self-signup on website or via SMS text messaging or email
Participants	• 13 participants • Aged 18-29 y; 6 female, 7 male[c]; 1 ethnic minority group (immigrant or BIPOC)
Format user test	• 0 in person (not possible) • 13 remote of which 12 Zoom, 1 other (Teams), and 1 used a mobile device to connect to Zoom but switched to computer during session
Case 3	
Target group (inclusion criteria)	• Parent or caregiver of a child aged 6 mo-3 y • Aged >18 y • Self-reported economic hardship
Recruitment channel	• Expression of interest list
Number of participants	• 12 participants • Average age 30 (range 26-36) y; 10 female, 2 male; 9 Australian, 1 Aboriginal Torres Strait Islander, 1 Indian, 1 Cambodian
Format user test	• 12 Zoom • 10 used mobile phone devices to connect to Zoom

[a]NAV: Norwegian Labour and Welfare Administration.

[b]IPS: Individual Placement and Support program.

[c]On the basis of observation, not self-reported.

[d]BIPOC: Black, indigenous, and people of color.

Ethical Considerations

Norway: Participants, Ethical Considerations, and Approval

Participants recruited to the Norwegian project were 18 to 29 years old and either registered as unemployed at the Norwegian Labour and Welfare Administration (NAV) or participating in a regional Individual Placement and Support program. Furthermore, they needed to speak Norwegian because of the in-app language. All participants provided explicit and written consent to participate in the study and were compensated for their time with a gift card of US $30 per session. The study was evaluated and approved by the Norwegian Centre for Research Data (approval number 131074).

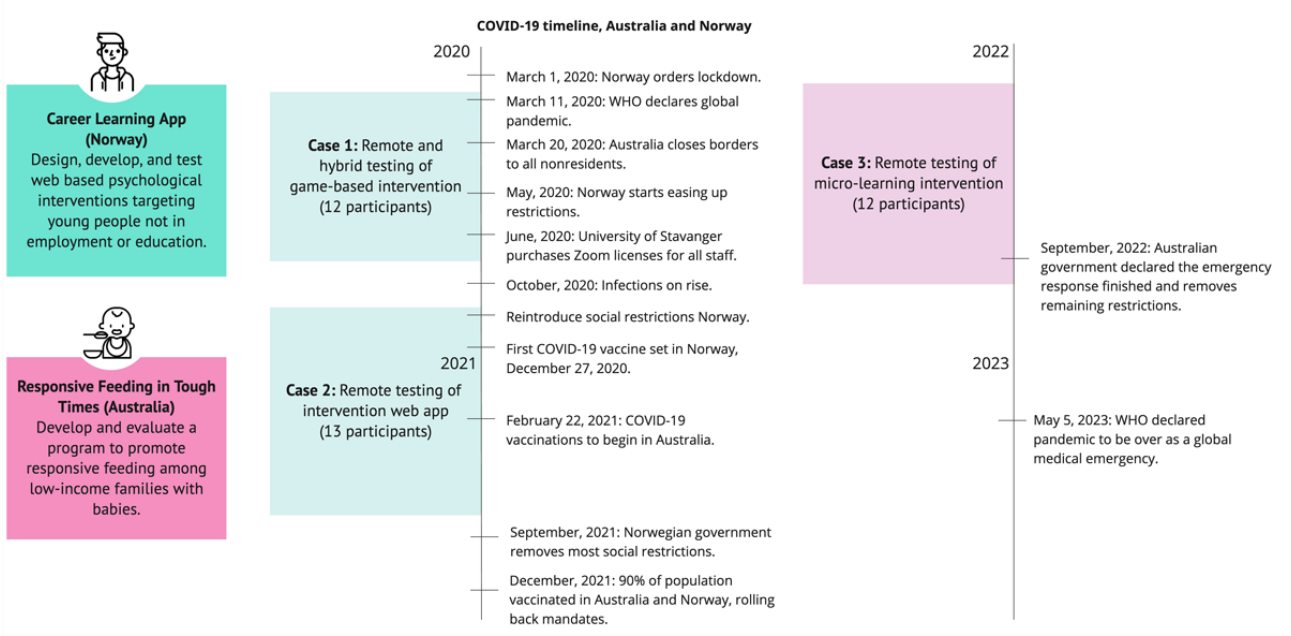
Australia: Participants, Ethical Considerations, and Approval

Participants were recruited Australia-wide and self-identified as experiencing economic hardship during screening. All participants were aged >18 years and caregivers of a child between 6 months and 3 years of age. Individuals were recruited from a pool of potential participants who had previously taken part in a web-based survey and had expressed interest in being contacted about other research activities. Participants were given an electronic gift voucher worth US $18 to thank them for their time. The Children's Health Queensland Hospital and Health Service Human Research Ethics Committee (LNR/21/QCHQ/72314) and the Queensland University of Technology Human Research Ethics Committee (2021000193) approved the study.

Case Descriptions

This section outlines the 2 research projects and details the user involvement protocols. The Norwegian project included 2 instances of user involvement; the Australian project involved 1. Hence, 3 cases are presented across the 2 research projects (Figure 2). Each case is divided into *case description*, *pandemic restrictions*, *test setup*, *participants*, and *case-specific reflections.*

Figure 2. Overview of user involvement conducted in the 2 research projects during the pandemic.



Case 1: Remote and Hybrid Testing of a Game-Based Intervention Concept, Norway

Case Description

The CL-APP project explored an interactive gaming concept to make a positive psychology intervention more engaging and relevant to unemployed young adults. The intervention design explored a 3D-based game. The development work was planned and executed in 3 sprints, with end users involved in formative user testing toward the end of each sprint. Further elaboration of the game concept and user feedback can be found in the study by Straand et al [37], with screenshots provided in Figure 3.

Figure 3. Screenshots from 3D game intervention VitaNova.

Pandemic Situation

On March 12, 2020, the Norwegian government ordered a nationwide lockdown, closing nonessential workplaces, schools, and child care centers. Schools and child care reopened with reduced hours for younger children toward the end of the following month. In May 2020, social and mobility restrictions were eased or replaced with mask mandates and sanitation requirements. However, in September 2020 and October 2020, infections again peaked, and in late October, new restrictions were announced, returning nonessential workers such as university staff to home offices.

Participants

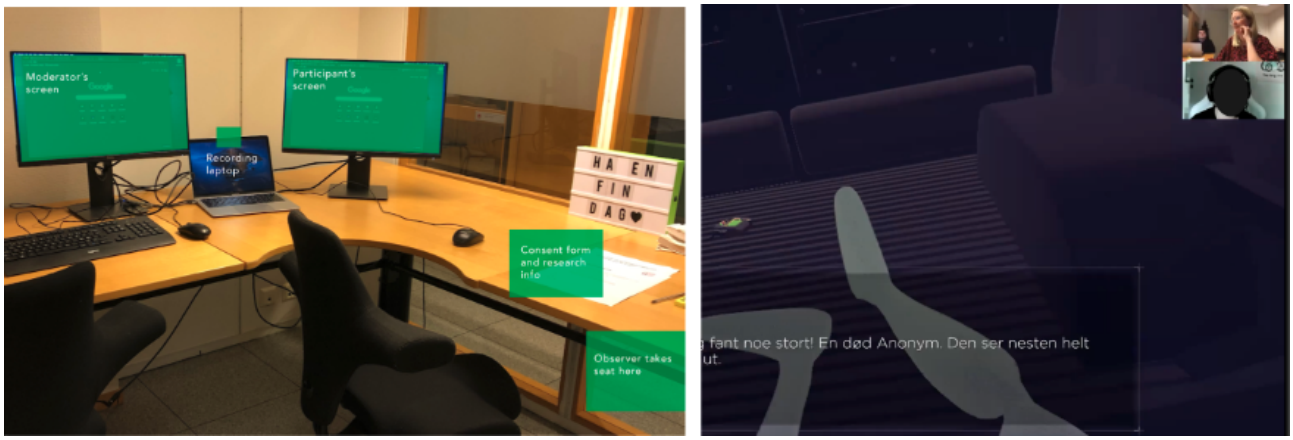
A total of 12 participants (female participants: 7/12, 58%; male participants: 5/12, 42%), aged 18 to 27 years, participated in the study.

Test Setup

In mid-March 2020, amidst pandemic uncertainty and lacking established remote protocols, plans for moderated, in-person usability testing were improvised. Discord, chosen for its familiarity among young gamers, served as the platform for remote testing. The test setup involved several manual operations due to the lack of functionality in Discord, including scheduling, consent, and provision of gift cards. The moderator and observer met a few minutes before and then added the participant to a group call once the participant had logged in to Discord. Despite its suitability for gamers and developers, approximately half of the users encountered startup issues due to unfamiliarity with the software. External software (Apple QuickTime) was used for recording, and this lack of a built-in recorder led to missing audio for some sessions. Platforms designed for usability testing or videoconferencing were rejected at the time from the premise of introducing complexity for the team and the participant users for a relatively short time of need.

As the team transitioned toward testing a functional prototype, concerns over network variance and load time prompted plans for face-to-face testing once restrictions eased in May 2020. A single participant signed up who had been involved in early-stage interviews. The test was conducted with strict sanitation and social distancing. However, with only 1 participant, it had limited value. A subsequent round of testing was planned for October 2020, when COVID-19 restrictions were expected to ease. This time, participants self-enrolled via a website and received SMS text messaging confirmation and reminders. We set up a testing space within the NAV offices. The team adapted its research strategy to allow participants to choose between in-person and remote testing on Zoom on the enrollment website. Remote participants signed digital consent forms and received digital gift cards, while in-person participants completed forms upon arrival and received physical gift cards (see Figure 4 for the hybrid test setup). The team completed tests with 7 participants, with the majority (5/7, 70%) opting for Zoom sessions.

Figure 4. Hybrid test setup: a total of 2 participants used local testing (left), while the remaining users opted for Zoom meetings (right).



Case-Specific Reflections

This case involved improvisation to enable continuity of the research, both with software and tools and with testing procedures. This iteration allowed us to observe how the videoconferencing software impacted the interaction with the participant, creating a new setting for the interaction depending on the software used. In the first rounds of testing using Discord, we all had our camera off. Discord users mostly use illustrations or avatars for their profile pictures and audio-only calls. Thus, although it is possible to share a camera view, none of the sessions using Discord had the participants with camera on; this included our webcams as researchers in the role of moderator and observers. The sessions done via videoconferencing software always had the camera-on mode for the moderator and nearly always for the participants, offering a richer data set for later analysis.

The "hybrid" strategy toward the end of the study meant the moderator and observer were usually in the same room, calling in as 1 user on Zoom. After the first session, it became the established practice for the moderator and observer to join in as individual users; the observer would mute the camera and microphone after a brief introduction at the beginning. This improved the interaction of the session, as the participant did not have to address 2 people. This remote setup allowed the observer to "disappear" into the background, overcoming the issue with the silent notetaker in a face-to-face session.

Some tasks were more challenging to deliver in the remote setup since the test tasks were designed for in-person sessions rather than remote participation. For instance, idea cards were created

that participants could sort according to their preferences. When the testing was on the web, we had to send them a copy of the cards in PDF format; this made the task less engaging and cumbersome. After preliminary user-derived findings, the development of the gaming-based intervention app presented in case 1 was discontinued.

Case 2: Remote Testing of mHealth Intervention Web App Concept, Norway

Case Description

Building on case 1, the CL-APP project redirected the design and development process to a mobile phone web app based on user preferences. The intervention target was foremost to promote a "growth mindset." A growth mindset [38-40] encourages a different interpretation of challenges faced by the young unemployed, normalizing struggles and setbacks to offer a more positive and flexible view of one's intelligence and ability to learn new things. The key objective of engaging with end users was to explore users' motivation to enhance reach and adherence. HCD methods ensured that the intervention was relevant, user-friendly, and motivating (see Figure 5 for screenshots of the app). In this process, researchers collaborated with designers, developers, and stakeholders, including end users, from October 2020 until the app's completion in December 2022. The user testing took place between November 2020 and April 2021.

Figure 5. Intervention web app concept shaped as learning modules.

Pandemic Situation

On October 26, 2020, the Norwegian government announced new health restrictions to reduce social interaction at work and home, strongly recommending that people return to home offices where possible [41].

Participants

Participants were recruited for 4 rounds of testing. A total of 13 participants (female participants: 6/13, 46%; male participants: 7/13, 54%) aged 18 to 29 years participated in the study.

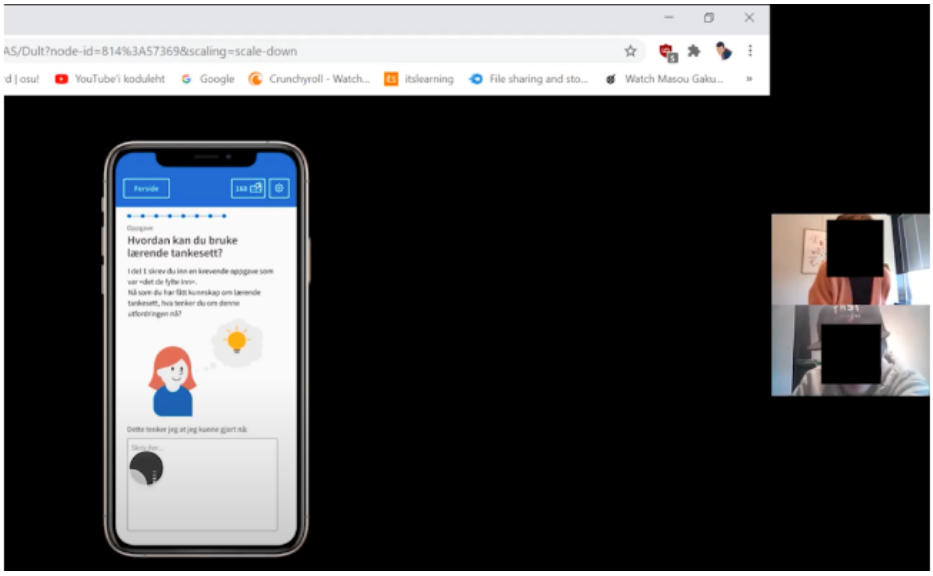
Test Setup

Given the work-from-home directive at the time, the design process, including interaction with end users, was planned remotely via Zoom. During the design process, 4 rounds of testing were performed: the initial test to understand what should be altered in the existing intervention (November: 4 participants) and 3 instances to get feedback on new designs with increasing levels of fidelity as the design progressed (January: 5 participants, February: 2 participants, and March-April: 4 participants). Prototypes were tested using the design tool Figma. The sessions were completed at times that were suitable to the participant. There was 1 session in the evening, but most participants opted for midday sessions (around 11 AM-2 PM).

Case-Specific Reflections

Our main challenge was that the prototype was designed for mobile use, and screen sharing from devices was troublesome in Zoom. Thus, for most of the tests on the new designs, we relied on desktop use and screen sharing from the browser (Figure 6). When a participant dialed in from their phone, the prototype view became unreadable, and we had to ask the participant to switch over to a device with a larger screen. All participants and moderators had their cameras switched on (unprompted). After an initial round of introductions, we continued switching the camera off for the observer or notetaker to reduce their presence in the user-researcher interaction.

Figure 6. Remote test setup in Zoom. The moderator has the camera on; the observer has the camera and microphone muted, therefore hidden from view.



Case 3: Remote Testing of an mHealth Microlearning Concept−Australia

Case Description

The RFiTT research program aimed to develop and evaluate an intervention to promote optimal child-feeding practices among low-income families. The secondary aims were to determine the feasibility, satisfaction, and acceptability of the mode of delivery. Families experiencing socioeconomic disadvantages face challenges feeding their children and following optimal feeding guidelines. The early years are crucial for establishing optimal feeding practices among parents and developing healthy child eating behaviors [42]. Therefore, the target of the intervention was parents or caregivers of children aged 6 to 24 months.

An mHealth digital microlearning concept was developed in response to parent engagement during the project's development phase [43]. Project constraints dictated a technology platform that required no software engineering or development phase and could be generated within a 4- to 6-month time frame. Web-based no-code technologies were researched and piloted to determine a suitable platform.

A learning technology platform (7taps), which used microlearning education, was selected. This platform enabled researchers to create contents that included videos, images, text, and interactions without external input from software engineers or app developers. This platform had a mobile-first design and learning management capability where modules could be delivered with preset timing in customized SMS text messages. Functional prototypes could be created and tested with users using this platform with little to no moderation. A total of 3 test modules that would form part of a microlearning responsive feeding parenting intervention were created (Figure 7).

Figure 7. Eat, Learn, Grow intervention: examples of digital module content and SMS text messaging delivery system.

Pandemic Situation

The RFiTT research program commenced in April 2020. The first case of COVID-19 was confirmed in Australia on January 25, 2020 [43]. On March 18, 2020, the federal government declared a biosecurity emergency, and all Australian States and Territories subsequently implemented lockdown measures [44]. Australia only fully opened its international borders to visitors in February 2022.

During the data collection and engagement phase of RFiTT (2021-2022), recruitment was impacted by the COVID-19 pandemic, and face-to-face data collection attempts were challenging. These recruitment challenges led to experimentation with remote research methods (telephone, web-based survey, noncontact equipment drop-offs) for research activities. By the time of the user testing sessions (November to December 2022), the RFiTT research program had adopted a complete remote research methods approach, and the scope of the population target for the intervention had shifted from a local context (Brisbane, Queensland) to Australia-wide.

Participants

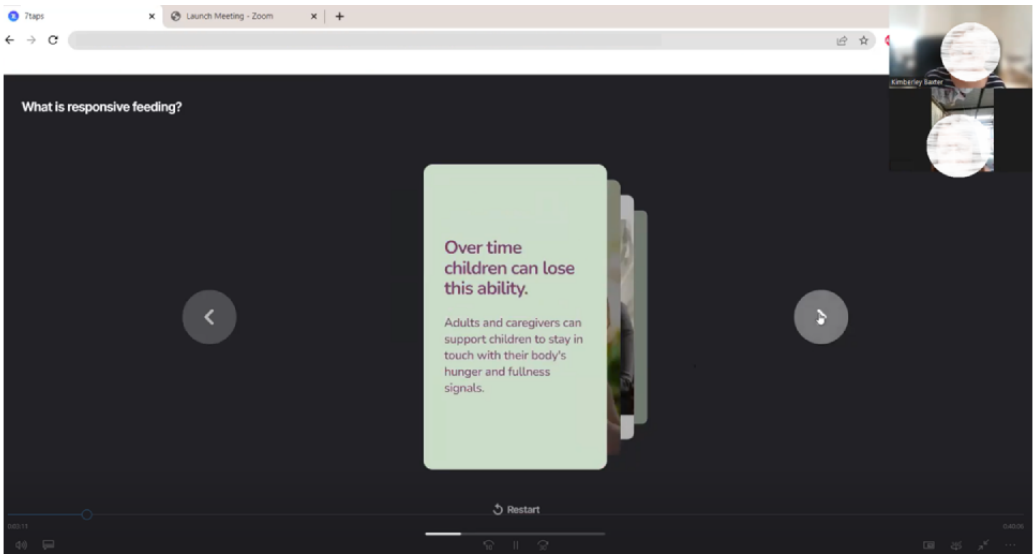
A total of 12 participants tested the prototypes. Of the group, 42% (5/12) had a university degree, and 3 individuals expressed that they had neurodiversity, which impacted their ability to learn and process information (attention-deficit/hyperactivity disorder, dyslexia, and aphantasia). Further details are available in Table 1.

Test Setup

Potential participants were telephoned to invite them to participate in the user testing sessions. Interested participants were sent a digital web link to the Participant Information Statement, a web-based consent form, and a short demographic survey. The web-based form and survey were hosted on REDCap (Research Electronic Data Capture; Vanderbilt University), a secure web application for building and managing web-based surveys [45]. The aim of the testing was twofold: (1) to test the acceptability, readability, and accessibility of 3 examples of microlearning content and (2) to co-design aspects of the content and structure of the intervention.

The sessions were completed at times suitable to the participant, including out-of-hour sessions from November 7, 2022, to December 1, 2022. Most participants joined the session using their mobile phones (10/12, 83%). A total of 3 modules were designed to present different styles of videos, content, and imagery to elicit feedback on the different formats and parents' preferences. The module web links were sent via mobile phone SMS text messaging to participants on the day of the arranged session. Parents viewed the content unmoderated. A Zoom session with the lead researcher (KAB) was arranged on the same day to capture parents' impressions and feedback. All Zoom sessions were video and audio recorded. During the sessions, the researcher shared a preview screen of the digital modules and guided the parent through a talk-out-loud walkthrough of the content (Figure 8). Open-ended questions regarding the usability, accessibility, and satisfaction of the modules were asked. Perspectives from parents were sought on recruitment and retention strategies, the language of key intervention messages, structure, and program timing. The parent intervention was renamed to "*Eat, Learn, Grow*" to reflect parents' feedback.

Figure 8. Screenshot of a remote user testing session conducted on Zoom.



Case-Specific Reflections

Remote inclusion of participants allowed for representation across Australia and of employed parents, who indicated that they would not have been able to participate if the session had been in person. The Zoom platform was effective; no participants had difficulty downloading or using the software. Most of the group (10/12, 83%) used a mobile phone. The mobile phone screen size restricted viewing the content via screen share (see Figure 8). However, it was acceptable, as participants had just engaged with the content. There were minimal connectivity or audio difficulties, but given the participants' home environment, there were interruptions from young children being supervised during sessions. These disruptions did not reduce the effectiveness of the sessions and are a common occurrence in research with parents, where young

children need to accompany parents. The researcher (KAB) is experienced with children and conducting research with families.

The most significant downside noted for the remote sessions in this case was that the parents engaged with the digital modules unmoderated; therefore, researchers did not observe parents interacting with the content for the first time. In the remote user setup, moderated sessions of parents viewing the content on their mobile device were not possible, given that the device needed to be used for videoconference for the feedback session. Moderating the session may have provided helpful information about parents' responses to the digital content. However, given that the platform used (7taps) was a purpose-built learning technology designed for first-time users, this was not the aim of the user testing sessions. This was mitigated by conducting the follow-up Zoom session the same day the digital content was sent to parents.

Results

Overview

We identified opportunities and considerations of conducting remote research with vulnerable users by reflecting on action and through visual diagramming across cases. These are represented as *reduced barriers to research inclusion, digital literacy transition, contextualized insights: a window into people's lives, seamless enactment of roles*, and *increased flexibility for researchers and participants.*

Reduced Barriers to Research Inclusion

During the user testing, the need to quickly design procedures for remote and hybrid research was necessitated by the evolving COVID-19 pandemic. Across the 3 cases, we found that remote research methods effectively engaged the targeted population groups of unemployed young adults and parents experiencing economic hardship. Enabling participants to participate in their home environment removed some systemic barriers to engaging in traditional research. For both groups, there were barriers to meeting face to face beyond the practicalities of travel, time, and capacity. Young people and parent participants displayed increased comfort with digital technologies and remote interactions, facilitating their participation in these research programs.

Remote and agile research methods enabled a broader and more diverse participant pool. RFiTT (case 3) widened the recruitment pool to Australia-wide rather than a small geographical area focus. In the Norway project, the recruitment pool was not widened geographically. However, remote methods enabled continued research during the acute response phase of COVID-19. Toward the end of our testing of the gaming concept (case 1), in-person participation was planned since restrictions had been lifted. However, recruitment was difficult, and participants who did consent failed to attend booked appointments despite a monetary incentive. Through this recruitment period, the population group expressed a high concern about the pandemic to researchers. This experience was confirmed in discussions with stakeholders such as welfare administration staff. Shifting to remote testing via web-conferencing (Zoom) facilitated continued participation.

Remote methods mitigated accessibility barriers and eased participants' potential fear, whether related to the pandemic or the unknown of being involved in a research project. Furthermore, many tests were conducted in the evening to adapt to the needs of parent participants (case 3). Across our populations, catering for continued remote participation was relevant even after restrictions were relaxed and was demonstrated by participants' strong preference for remote methods.

Digital Literacy Transition

Initially, the tools used for remote research were improvised, and methodological planning took an iterative approach. As the pandemic unfolded, users and researchers gained experience with relevant digital technology, reaching greater technology awareness and control. The different time frames in which the case studies were conducted during the COVID-19 pandemic provided a context to explore this trend of what we may refer to as a transition to digital literacy.

Initially, researchers and project stakeholders were reluctant to transition to remote participation (cases 1 and 2), whereas users seemed to prefer remote modes. The preferences of researchers and project stakeholders partly grew out of a desire to conduct the research "as planned" and to use established methods. There was also uncertainty about whether users had the necessary skills to use videoconferencing. Researchers had concerns about the limited opportunity for rapport building through informal conversation before the session started. However, the research team underestimated how digitally literate the participants were. This is unsurprising given the amount of time spent on the internet and the degree of web-based communication and collaboration in both groups across many aspects of life [46,47]. This was coupled with COVID-19 pandemic–driven increases in the use of technology for communication and services, such as telehealth [48-51] and work-from-home needs [52,53].

Contextualized Insights: A Window Into People's Lives

Despite our target participants' familiarity with web-based communication, the rapid adoption of these technologies also required sensitivity in protecting participants' privacy. Contrary to our perception of poorer conversations with the loss of face-to-face conversation, we experienced *more* entry into users' lives than participation at a research site. The recording was done easily as a part of the natural flow of conversation with the participant on the web in Zoom. In contrast, introducing video recording devices into physical meetings is cumbersome and can make people uncomfortable. Furthermore, it was found that the type of software used either increased or reduced the likelihood of data sharing due to its internal logics, customs, or *vibe* [54]. With Discord, it is not customary to use a real profile photo; in most instances, people use an avatar, and it did not feel natural to turn the webcam on. Therefore, this channel collected much less personal information than Zoom. Zoom encourages turning webcams on and recording seamlessly and unobtrusively. The tools used for supporting the research, such as Discord and Zoom and systems for issuing electronic gift cards, required collecting more personal data (such as name, email, phone number, and usernames) than in-person research methods.

Web-based and remote methods were a more natural and relevant environment for the user, revealing more contextual information than expected and providing a temporal window into people's lives. Sometimes, this may include unintended information, such as username, browsing history, or open tabs when participants were screen sharing. The less professional nature of the Zoom session also meant some participants were less formal. In one instance, a participant wore a bath robe, while others had babies crying in the background, pets, or others who entered the conversation. This provided a richer contextual backdrop to who the participants were and sparked informal conversation and trust building. At the same time, this contextualized information from the user tests does introduce privacy concerns.

Seamless Enactment of Roles

It is sometimes necessary to have observers during user testing. For face-to-face sessions, 2-way mirrors or screencasting to another location may be used to enable observation. Additional observers may also be needed in a physical space to take notes; this can be disruptive. The user may feel uncomfortable talking to 2 people, not knowing who to look at when talking and when someone is writing intensively. Remote user sessions may require fewer observers, and they may be less intrusive when they are present.

In the Norway cases, the observer's role as a notetaker was improved by videoconferencing. The observer and interviewer would have the camera on for the start of the testing. Then, after introductions, the observer could mute the camera and microphone and continue taking notes without impacting the session. If the observer wanted to ask follow-up questions, it was easy and natural to either bring the observer back into the conversation or allow the observer to post questions via a chat channel for the interviewer to follow up. With this more silent observer role, there was little disturbance to the flow of the conversation. It was easy and natural to switch roles during the session, which was done in case 2, where the author (IJS) moderated most of the session, and one of the designers ran through the prototype with the participants. In the Australian case, no person other than the author (KAB) was present for the testing.

Increased Flexibility for Researchers and Participants

Remote-only testing was found to be more streamlined and flexible compared with both in-person and hybrid models. Research participation, which is planned to be hybrid (case 1), requires booking and setting up the room. This introduces limitations on the remote research imposed by the physical meetings, such as the timeline and availability of physical space.

Remote testing (cases 2 and 3) allowed for more flexibility; meetings could be conducted in the evenings or during weekends or holidays to accommodate participants, with minor disruption to researchers who could dial in from home but with great benefits to participants. Without the booking and timeline constraints of physical space, sessions could take place over time (case 2), allowing revision and adaptation of design prototypes that could be tested again. This maximized the data collection capacity of the sessions and led to a more agile approach to our research and engagement with participants.

For RFiTT (case 3), most participants (10/12, 83%) engaged with the remote user testing sessions via mobile phone. Participants did not have access to a working computer, and using a mobile device enabled participants to perform essential tasks such as supervising young children. This suggests that flexibility and convenience to do other things may contribute to the preference for remote participation. For CL-APP (cases 1 and 2), nearly all participants connected to the remote testing sessions on their computers (23/25, 92%). Participants had good access to both computers and smartphones. The preference for remote participation in this project was considered to be convenience factors, social anxiety, and COVID-19–related concerns. Further research is needed to verify the reasons for preferring digital and remote engagement with research across different populations.

Discussion

Principal Findings

The global pandemic necessitated the reevaluation of traditional research methodologies, compelling researchers across disciplines to adapt to the changing environment and adopt agile approaches. This study explored opportunities and considerations from involving vulnerable user groups remotely to provide lessons learned for future research. We did this by reflecting on research practices that involved user-centric evaluation of interactive behavioral and psychological intervention designs. A total of five topics emerged from our analysis: (1) reduced barriers to research inclusion; (2) digital literacy transition; (3) contextualized insights: a window into people's lives; (4) seamless enactment of roles; and (5) increased flexibility for researchers and participants.

Across the 3 cases, remote participation contributed to a more accessible inclusion of users in design. The emerging technology on modern mobile phones offers the potential to engage with participants effectively across digital platforms such as Zoom. Mobile smartphones are prolific, and with the declining cost of data [55], remote methods that seamlessly integrate with mobile devices are becoming more accessible and equitable for user engagement. Low-income user groups may have limited access to working laptops or home computers, as was the situation in case 3 of this study. Adequate provision or access to suitable digital devices is important in digital equity and research in vulnerable groups [56].

Remote methods mitigate accessibility barriers such as travel costs and logistical challenges, which may deter participation from vulnerable groups. In countries such as Australia and Norway, with a diverse and "spread out" geographical landscape, this was highly valuable in the intervention development phase, enabling wider recruitment reach. This also has significant implications for scalability and implementation. A broader recruitment scope may make it easier to include more participants who are less represented in research, such as those living in rural areas [14]. Web-based and remote methods of research engagement, such as social media, may facilitate

engagement with vulnerable groups not connected with organizations, workplaces, or other services [12].

With an increased focus on digital health interventions and programs delivered remotely, remote user methods align with the design process of such programs. The benefits of a wider recruitment pool and efficiency gains, such as reduced travel time or inconvenience, were expected from past studies on remote research methods [15,20,57]. In past research, these gains are often contrasted against other shortcomings of being remote [58], such as lack of contextual insight, connection problems, audio or video problems, low digital literacy, and the like. Emerging from the technological leap through the COVID-19 pandemic, these shortcomings are diminishing, while the perception of benefits for researchers and participants is increasing. The research teams' initial reservations were that remote research would be complex for potentially vulnerable user participants and could increase stress or fatigue [59]. There were also reservations that remote participation would not provide rich enough user data; however, in the cases presented here, it was found that this method did provide contextualized insights and increased ecological relevance.

Implications

This study provides insight into the broader learnings from adapting to remote research practices during the COVID-19 pandemic and beyond. From the findings, we have extracted 4 significant implications for future research and practice.

Potential for More Agile Research

Remote research practices may come closer to the ideal of an agile approach to testing ("microtesting"), involving briefer and more frequent evaluation sessions with users. This has also been recommended by other recent publications within mHealth [3,60]. For researchers to take advantage of this potential for mHealth apps and interventions, it will bring mHealth research closer to agile user experience practice [61-64] and continuous testing of minimum viable products or prototypes as a form of hypothesis testing [65]. Remote methods facilitate fast cycle iterations and testing in a research design process of sensemaking through trial and error [66].

Remote Research Increases Ecologic Relevance

The interventions developed in these research programs were designed to be used within the context of users' lives, usually the home. Thus, a remote testing method was more ecologically relevant than a traditional face-to-face user test in an office setting. We evaluated the interventions using remote methods in the user's home and on their devices. This enables contextual inquiry and enhances the representativeness of research findings and the applicability of the designed solution. Screen sharing from a mobile device has also improved [67] compared with during our data collection; this will reduce the problems of remote testing of mHealth interventions, enabling testing and feedback sessions with users in their own contexts and on their devices with direct interaction on the app [68].

Technology Impacts Privacy and Human Action

Our research found that there is a risk of capturing more personal data than planned through the ease of recording and screen sharing when engaging with participants through web-based modes. As the participant joins from home, their home context is recorded, including background information and activity. Screen sharing from the participant's device may enable accidental capturing of on-screen activity, such as open tabs and browsing history, which may be unintentional on the participant's part. Digital ethnographers have highlighted this factor in previous studies [69]. This highlights the need to safeguard participants' privacy, as participants may not fully grasp the need to protect their privacy [70]. Throughout the research, participants became more aware of how to protect their privacy, which is represented by the increasing use of video filters such as blurred backgrounds, muting cameras, or strategically placing the webcam. However, some participants perhaps showed unintended details of their personal lives. Researchers should be aware of the ethical considerations of recording videos of participants in their home environment and take care to protect their privacy. Consenting protocols, which include preparing participants for digital interactions, are essential so that participants are adequately informed and aware. As researchers, we may also incorporate practices from web-based counseling and telehealth. Researchers in telehealth also call for revisiting ethical guidelines and procedures following the "ongoing natural experiment" of the pandemic [71].

Our research suggests that when selecting technologies for remote research, it is necessary to consider their functionality regarding privacy protection and the mediating role of technology [58] on human action [72,73]. For instance, when we choose Zoom, Discord, or any other technology, we should consider the norms of how these technologies are being used in other contexts, how these patterns might influence researchers and participants, and how this may influence the data collected.

Remote Research Leads to User Involvement on Participants' Terms

Researchers were concerned by the limited opportunity that remote methods present for informal conversation and rapport building. This interaction style enables trust building and may make research participation more comfortable and less intimidating. However, we found that remote methods shifted control to participants and offered greater comfort than attending unfamiliar institutional settings for face-to-face sessions. Remote methods have the potential for enhanced anonymity as participants have more control over what they share. This may be particularly pertinent for research that involves sensitive or taboo topics, allowing individuals to feel more at ease sharing their experiences and perspectives [74,75].

It was our experience, during work-from-home COVID-19 mandates, that power imbalances were diminished as both researchers and participants were dialing in from a home setting. Thus, there was a more equal grounding and reduced power differential [76]. This is worth considering for future research, specifically setting up the research so that participants and researchers are in similar settings during interaction. When 2 researchers dial in from the same physical location, that introduces a new imbalance, and future research should consider applying the principle of "one remote, all remote" [77,78] when

there is a need to do hybrid remote research to ensure equal participation.

Limitations

For the cases in this study, participants were involved in design processes to capture their experience with iterative designs and provide feedback on design revisions. This took place at different time points during the pandemic. The original research was not designed to answer the research questions of this study. Instead, this topic *emerged* [28] through practice and through reflecting on practice [26]. Retrospective studies have limitations since they may depend on a review of data not planned for research use [79], and information may be missing. This has been mitigated by the participation of the 2 lead authors who conducted the original research. However, our interpretation may be biased despite taking a critical stance on our reflections and interpretations.

The cases and findings presented spark conceptual development and analytical discussion [80] on remote user design methods. However, there are also limitations regarding participants and to whom the findings are relevant. Across cases, specific inclusion criteria and requirements related to recruitment likely impacted our ability to recruit participants. For instance, in cases 1 and 2, we could not advertise for participants and relied on third parties to share information about the research project with potential participants. There was also a requirement to speak Norwegian fluently due to the in-app language. These factors may have reduced the number of people with minority or immigrant backgrounds who registered for the research in the Norway project. Bearing in mind that the young unemployed are twice as likely as other young people to have come to Norway as migrants, this is a weakness. Both projects called for narrow recruitment strategies to target specific population groups. Findings from this study reflect the experiences of the population groups that were involved and may not be generalizable. Further research should explore the applicability and benefit of remote user methods across other population groups.

Conclusions

The COVID-19 pandemic has reshaped the research landscape in many ways, driving rapid innovation and the adoption of remote research methods. These methods proved crucial in overcoming recruitment challenges and enabling researchers to engage with diverse participant groups across geographical areas. Applying remote methods within hard-to-reach groups reduced participation barriers, facilitated recruitment, and cultivated a more inclusive and comfortable research environment. As researchers and designers navigate the evolving research landscape, the lessons learned underscore the enduring value of remote research methods in promoting user participation in the design of mHealth interventions. Furthermore, they may serve as a reminder to question persistent assumptions about technological competence and access in vulnerable populations.

Acknowledgments

The authors would like to thank the participants who took part in the study and gave their feedback on the different prototypes. Furthermore, the authors thanks researchers at the University of Stavanger (UiS) who contributed to the Career Learning App (CL-APP) project: Venke F Haaland, Espen Sagen, Mari Rege, Hilde Ness Sandvold, Jone Bjørnestad, and Wenche Ten Velden Hegelstad. They would also like to thank the Norwegian Labour and Welfare Administration in Sandnes and Skole- og Jobbresept at the University Hospital of Stavanger. CL-App is funded by The Norwegian Research Council (grant number 296390).

They would also like to thank the researchers at the Queensland University of Technology (QUT) who contributed to the Responsive Feeding in Tough Times (RFiTT) project: Rebecca Byrne, Smita Nambiar, Danielle Gallegos, Jeremy Kerr, Robyn Penny, and Rachel Laws. RFiTT is funded by the Queensland Children's Hospital Foundation thanks to the generosity of Woolworths customers and team members. They further acknowledge the QUT Design Lab for organizing a research seminar that allowed authors 1 and 2 to meet and share ideas in March 2023, which resulted in this study.

Abstract

Background: ViSi Mobile has the capability of monitoring a patient's posture continuously during hospitalization. Analysis of ViSi telemetry data enables researchers and health care providers to quantify an individual patient's movement and investigate collective patterns of many patients. However, erroneous values can exist in routinely collected ViSi telemetry data. Data must be scrutinized to remove erroneous records before statistical analysis.

Objective: The objectives of this study were to (1) develop a data cleaning procedure for a 1-year inpatient ViSi posture dataset, (2) consolidate posture codes into categories, (3) derive concise summary statistics from the continuous monitoring data, and (4) study types of patient posture habits using summary statistics of posture duration and transition frequency.

Methods: This study examined the 2019 inpatient ViSi posture records from Atrium Health Wake Forest Baptist Medical Center. First, 2 types of errors, record overlap and time inconsistency, were identified. An automated procedure was designed to search all records for these errors. A data cleaning procedure removed erroneous records. Second, data preprocessing was conducted. Each patient's categorical time series was simplified by consolidating the 185 ViSi codes into 5 categories (Lying, Reclined, Upright, Unknown, User-defined). A majority vote process was applied to remove bursts of short duration. Third, statistical analysis was conducted. For each patient, summary statistics were generated to measure average time duration of each posture and rate of posture transitions during the whole day and separately during daytime and nighttime. A k-means clustering analysis was performed to divide the patients into subgroups objectively.

Results: The analysis used a sample of 690 patients, with a median of 3 days of extensive ViSi monitoring per patient. The median of posture durations was 10.2 hours/day for Lying, 8.0 hours/day for Reclined, and 2.5 hours/day for Upright. Lying had similar percentages of patients in low and high durations. Reclined showed a decrease in patients for higher durations. Upright had its peak at 0 - 2 hours, with a decrease for higher durations. Scatter plots showed that patients could be divided into several subgroups with different posture habits. This was reinforced by the k-means analysis, which identified an active subgroup and two sedentary ones with different resting styles.

Conclusions: Using a 1-year ViSi dataset from routine inpatient monitoring, we derived summary statistics of posture duration and posture transitions for each patient and analyzed the summary statistics to identify patterns in the patient population. This analysis revealed several types of patient posture habits. Before analysis, we also developed methodology to clean and preprocess routinely collected inpatient ViSi monitoring data, which is a major contribution of this study. The procedure developed for data cleaning and preprocessing can have broad application to other monitoring systems used in hospitals.

Introduction

Monitoring the level of mobilization and its changes over time provides critical health information on hospitalized patients. For example, timing of resuming certain postures after surgery can reflect the pace and quality of recovery [1,2]. A traditional method for tracking posture is direct observation, which can be done by a nurse who directly observes and records the patient's posture manually. However, this is time-consuming and resource-intensive, especially when the observers are tracking multiple patients on a ward [3]. Other limitations of direct

observation are subjective reports and intermittent recordings, which may also suffer from bias and random human error [1,4].

To overcome these limitations, some hospitals utilize monitoring systems that use sensors (eg, accelerometer, infrared, and radio frequency identification sensors) to collect measurements for tracking a patient's posture or movement [1,3,5-7]. The collection of measurements by these sensors is continuous and automated. A trained algorithm in the device converts the collected sensor data to a patient's posture objectively. The output reports the patient's postures and activities instantaneously. These data can be used to derive the amount of time a patient spends on bed rest. Moreover, posture monitoring records before and after surgery could be compared to identify whether a patient is having a smooth recovery or a poor one that requires intervention.

Statistical analyses of large datasets collected from many patients using these monitoring systems can further reveal patterns in patients' condition and behavior that can be useful for medical research and operational guidance. There have been preliminary results in connecting hospital sensor observations and patients' condition statistically. For example, recent accelerometer-based studies found that inpatients with acute illness were highly inactive, spending 93%-98.8% of their stay sedentary [5]. Researchers have also used posture monitoring to capture changes in a patient's mobility over the course of their hospital stay and use it as an indicator of recovery rate. In a study of inpatients aged 60 years or older admitted from the emergency room, Theou et al found that those patients classified as less mobile upon admission experienced an increase in their upright time during their hospital stay, possibly corresponding to an improvement in their health condition [8].

A real-time monitoring system that has demonstrated promise in the hospital setting is ViSi Mobile (Sotera Wireless) [9-12]. This device continuously monitors a patient's vital signs and posture. It can be used to capture walking periods, as well as more subtle movements, such as getting out of bed or changing posture in bed. To the best of our knowledge, there are only 3 published studies analyzing ViSi posture data of hospitalized patients. Restrepo et al tested the accuracy of ViSi posture measurements by comparing them to those from direct observation [3]. This study found that ViSi can accurately classify certain static postures, such as lying down and sitting. However, it can have systematic errors in classifying the activity of walking. In an analysis of 2 randomized trials with patients recovering from abdominal surgery, Rivas et al examined the relationship between self-reported pain score and ViSi-measured mobility [1]. The authors estimated the decreasing rate of change in mobility with increasing pain score, and they also found that lower mobility was associated with more postoperative complications. In a study of ViSi data from noncardiac surgery patients, Turan et al found that increased mobility in the 48 hours postoperation was associated with fewer postoperative complications and shorter length of hospital stay [13].

This study sought to characterize posture habits in a large hospitalized patient population, including both surgery and nonsurgery patients. Another purpose of the study was to conduct quality control of the ViSi posture data because the routine hospital measurements originally collected for operational purposes contain different types of errors that require careful treatment. Overall, the study objectives were to (1) develop a data cleaning procedure for a large inpatient ViSi posture monitoring dataset with a duration of 1 year, (2) consolidate posture codes into categories, (3) derive concise summary statistics from the continuous monitoring data, and (4) study types of patient posture habits using summary statistics of posture duration and transition frequency.

Methods

Ethical Considerations

This study used a deidentified dataset and was approved by the Wake Forest School of Medicine Institutional Review Board (IRB00051033). No patient consent was required. No compensation was provided.

Data Description

Since 2015, real-time posture data have been collected routinely using the ViSi Mobile System for patients on postoperative surgical wards and acute medical inpatient wards at Atrium Health Wake Forest Baptist Medical Center in North Carolina, United States of America. The starting point of ViSi monitoring is at admission to the hospital ward. The ViSi device has a wrist module, upper arm module, and chest module, each of which contains a 3-axis accelerometer [14]. Posture is estimated using data collected by the accelerometer sensors. In addition, other sensors on the ViSi device simultaneously measure blood pressure, heart rate, pulse rate, respiratory rate, and oxygen saturation.

This study focused on the ViSi posture data collected at Atrium Health Wake Forest Baptist Medical Center in 2019 from both surgery and medicine services. The ViSi Mobile system converts accelerometer measurements into 15 categories of posture using a proprietary algorithm developed by Sotera Wireless. Each category is presented by a code (Multimedia Appendix 1). A code can describe a single activity, such as walking (WLK). Some codes may combine more than one position or situation into one posture category. For instance, code U90 for upright can be sitting or standing. Code U45, representing a reclined position, may correspond to sitting in a reclined chair or lying when the bed is in a reclined position. On the other hand, for lying down, multiple codes are used to distinguish different postures, such as supine (LSP), prone (LPR), right side (LRS), and left side (LLS). FALL indicates that a patient may have fallen (this code was not observed in the 2019 ViSi posture dataset). UNK indicates that the patient's posture could not be determined by the proprietary algorithm and was categorized as unknown. The ViSi Mobile system also allows the user (patient, nurse, provider) to self-report the patient's posture. Self-reported posture follows the same code pattern, prefixed by an "S-." For instance, self-reported upright is "S-U90."

The ViSi Mobile system outputs a posture recording every 15 seconds. A timestamp is used to identify the time of a given recording. A recording can be a single posture code (eg, "WLK"), or it can be a permutation of 2 or more codes (eg, "U45 U90") if the patient performed multiple postures during

the 15-second window. In the latter case, the permutation of codes is listed in the order that the postures were performed. For example, "U45 U90" indicates that the patient changed their position from reclined to upright, which is an outcome beyond the original 15 categories. Therefore, the permutation of 2 or more codes can generate many other possible outcomes of a patient's posture recording. In the dataset, there were 185 different outcomes in the posture recordings.

A patient's ViSi posture data are saved in several files. All files for a given patient can be identified by the patient's medical record number (MRN). Each file usually contains data from several ViSi devices because each device needs to be charged daily and replaced with another one for continuous observation [11,12]. Within each file, each posture recording is labeled by its timestamp and the device serial number. The files vary in length, including the number of posture recordings and the number of ViSi devices.

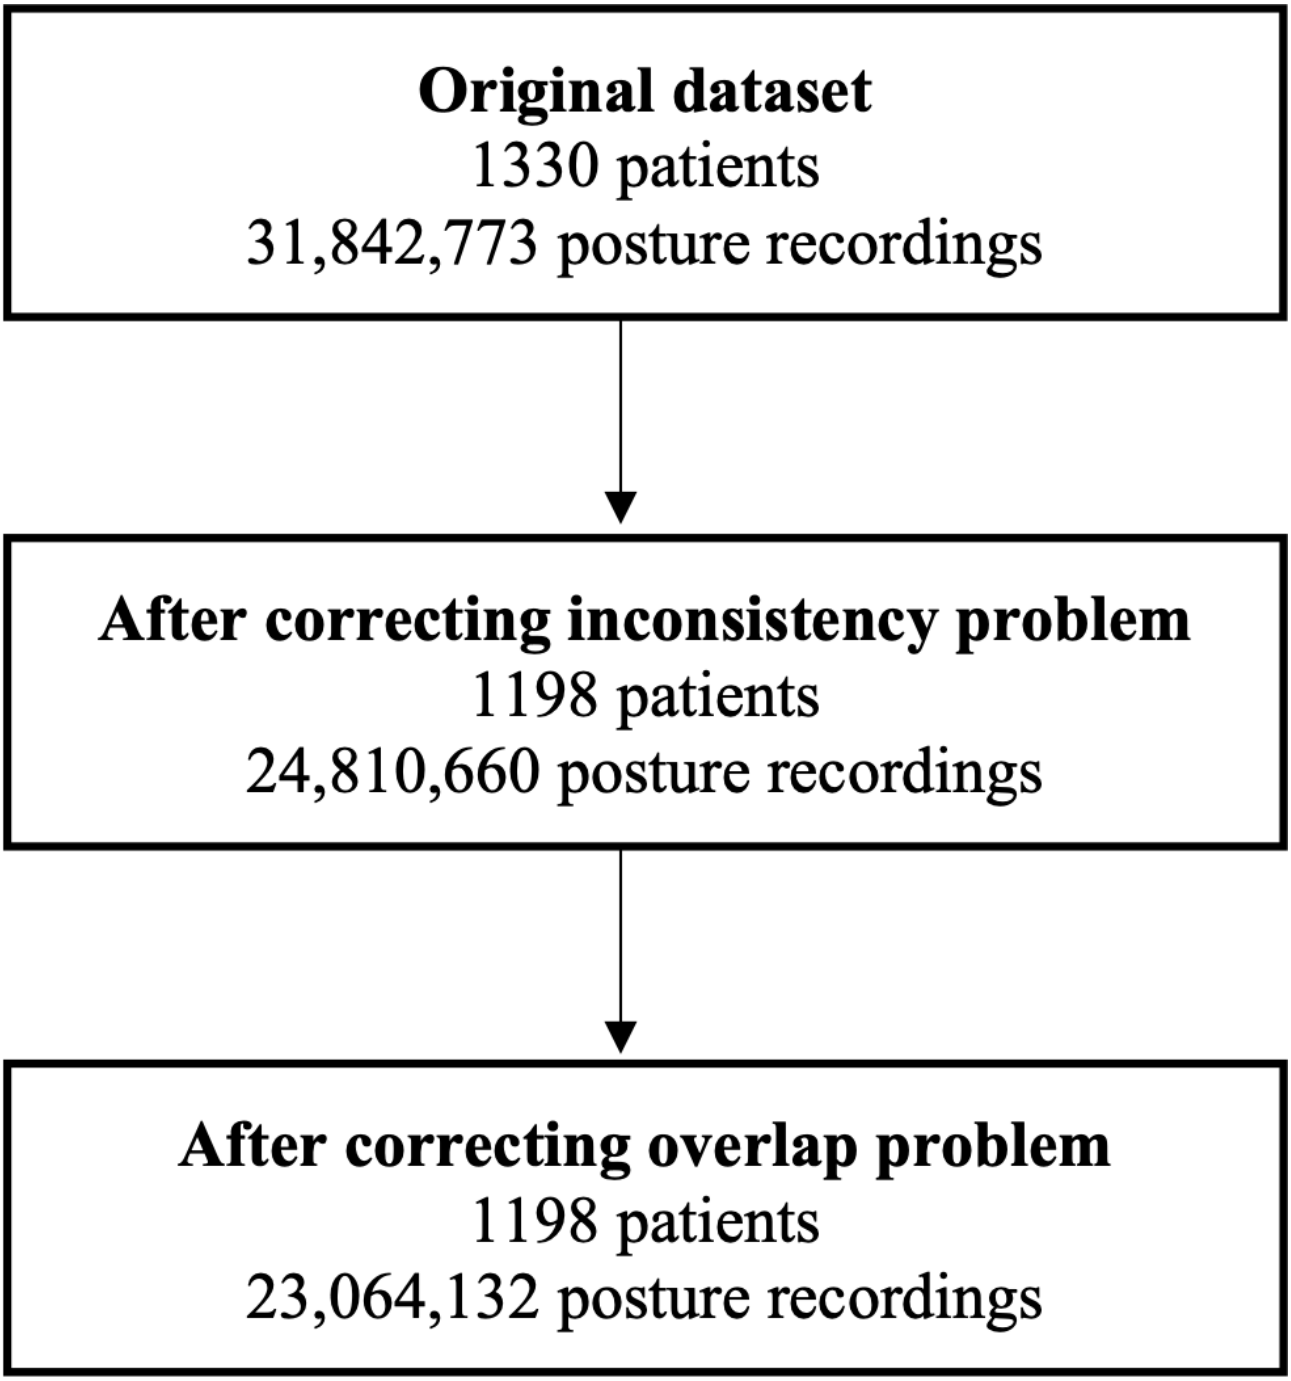
Data Cleaning

The study team conducted a thorough check of the data, which led to the identification of 2 problems. First, "overlap" of posture data was noted for some patients. As described previously, a given patient's records are contained in several files identified by their MRN. For some patients, some data recordings contained in one file overlap with recordings contained in another file. These overlapping recordings have the same timestamps but different readings. They usually come from ViSi devices with different serial numbers. We call this the "overlap problem." About 10% of patients in the dataset exhibited this problem. The overlap period can be long, up to days. Since a patient cannot wear multiple ViSi devices at the same time, overlap should not occur. We speculate that overlap could happen when a recharged ViSi device is reassigned to another patient without updating the MRN. Therefore, when overlap occurs, some data from another patient has likely been misassigned to the given patient.

Second, we identified an inconsistency between the time of hospital stay and the period of ViSi measurements for some patients. For each patient, we compared the ViSi posture data to the admission and discharge times to confirm that the patient's data fell within this time window. However, some patients had ViSi data before their admit time or after their discharge time, which will be referred to as the "inconsistency problem." The mismatch could be large in some cases, up to days. We believe that there are 3 possible reasons for mismatch. One possibility is that the admit and discharge times are not exact. Another is that ViSi data are sometimes collected before admission, resulting in data before the admit time. A third possibility is that the data may have come from another patient. The first 2 situations are benign, while the third situation is problematic and needs to be addressed. Based on the available information, it is not possible to determine which situation has occurred.

The following strategies were used to address these 2 problems. For the overlap problem, all overlapping records were flagged in all files for each individual patient. Data were not immediately discarded, given that one of the data streams could actually be correct. However, following discussion with in-hospital data managers and the device provider, there was no objective method to identify which data stream was correct. Therefore, this study excludes all records flagged as overlapping. A similar approach was used to address the inconsistency problem. Any data before the admission time or after the discharge time was flagged. The statistical analysis in this paper does not include flagged data. Figure 1 shows the sample size before and after we removed the flagged records for the inconsistency and overlap problems. Overall, the 2 procedures excluded 9.9% (132/1330) of patients and 27.6% (8,778,641/31,842,773) of posture recordings.

Figure 1. Flow diagram of data cleaning procedure. Data cleaning included two stages: (1) corrections for the inconsistency problem, and (2) corrections for the overlap problem. We show the number of patients and number of posture recordings remaining after each stage.



Data Preprocessing

Before data analysis, 2 steps of preprocessing were performed to consolidate the possible posture outcomes and to remove short inconsequential fluctuations. First, we consolidated the 185 possible posture outcomes into a more manageable set of 5 groups. These five groups are Upright, Reclined, Lying, User-defined, and Unknown. Compared to the original 185 outcomes, we believe these 5 groups are more easily interpretable and useful to clinicians and analysts. In this consolidated system, each original posture recording (single code or permutation of codes) falls into 1 of the 5 groups. Table 1 provides the definitions of the posture groups, including their connections with the original posture recordings. Essentially, any posture recording that includes a self-reported code goes to the group User-defined. Any recording that includes the UNK code is classified into group Unknown. The group Lying contains posture recordings that are composed of lying codes only (ie, codes beginning with L). Of the remaining recordings, any that has a “WLK” or “U90” is put in the group Upright. The rest of the recordings must contain a “U45” and fall into the group Reclined. The third column of Table 1 shows examples of posture recordings in each group.

Table . The 5 posture groups.[a]

Posture group	Definition	Example recordings in posture group
User-defined	Any posture recording that includes "S - …"	"UNK LSP S-LSP," "UNK LSP S-U45," "UNK S-LLS LSP," "UNK U90 S-U90," "UNK U90 U45 LLS S-U90"
Unknown	• Any posture recording that includes "UNK" (no "S - …"). • Posture recordings that were blank were also classified as Unknown.	"UNK," "UNK LSP"
Upright	Any posture recording including "U90" or "WLK" (no "S - …" or "UNK")	"U90 U45," "U90 U45 WLK," "U90 U45 LLS," "U90 U45 LLS WLK," "U45 LSP WLK"
Reclined	Any posture recording including "U45" (no "S - …," "UNK," "U90," or "WLK")	"U45," "U45 LLS," "U45 LPR," "U45 LPR LRS," "U45 LRS," "U45 LRS LLS," "U45 LSP"
Lying	"LLS," "LRS," "LPR," "LSP," or permutations of these	"LLS," "LPR," "LPR LLS," "LRS," "LRS LLS," "LSP," "LSP LRS"

[a]LLS: lying left side; LPR: lying prone; LRS: lying right side; LSP: lying supine; UNK: unknown; WLK: walking.

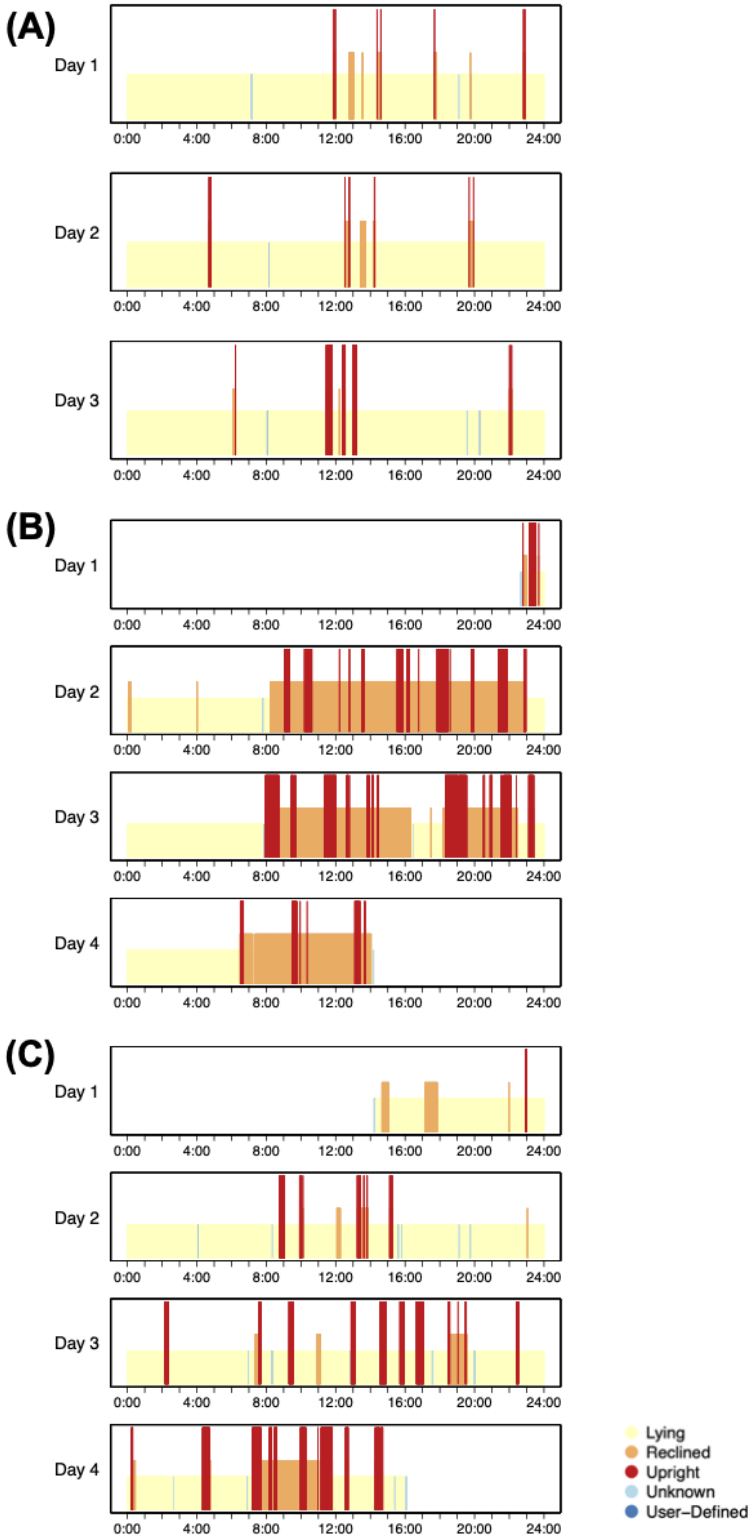
Note that the Upright group combines walking with sitting and standing, rather than treating walking as a separate group. This choice was made because the ViSi device may classify the activity of walking as U90 (the same ViSi code for sitting and standing) instead of WLK, the code for walking [3]. In addition, we set User-defined as its own group, rather than assigning individual user-defined postures to their corresponding categories (eg, "S-LSP" was not assigned to Lying). This was because it is difficult to determine whether the user-defined postures were inputted intentionally. In the rest of the paper, we focus on these 5 posture groups, instead of the 185 posture outcomes. Hereafter, the term "posture" indicates posture group.

After converting the raw posture recordings to posture groups, data smoothing was performed to reduce noise. This was the second step of data preprocessing. Here, noise is defined as an isolated posture of 1 timestamp in between 2 timestamps with the same posture. For example, for a sequence of 3 postures of Lying, Reclined, Lying, the middle one is considered as noise. We removed noise through data smoothing. For each timestamp, we used the following majority vote process to remove the noise. A majority vote was taken, considering the timestamp in question and the 2 adjacent timestamps (ie, 15 seconds before and 15 seconds after). Based on the 3 votes, whichever posture appeared most frequently would be the winner. For example, if there were 2 votes for Lying and 1 vote for Reclined, the posture at the timestamp in question was taken to be Lying. If there was no winner in the majority vote (eg, the three timestamps all had different postures), then the posture at the timestamp in question was left unchanged. This process is analogous to taking a moving average using a sliding window with 3 consecutive timestamps [15], except the mode is taken instead of the average.

Figure 2 presents 3 examples of cleaned and preprocessed posture data, which illustrate how the patterns of posture can vary from 1 patient to another. The first example (Figure 2A) shows long periods of Lying, interspersed with short Reclined and Upright segments. This patient is considered inactive. The second example (Figure 2B) shows a patient who was in the Upright and Reclined postures during the daytime hours and the Lying posture during the nighttime hours. One may infer that this patient was trying to maintain day/night routine behavior during the hospital stay. Figure 2C plots data from a cancer patient postsurgery. The patient spent days 1 and 2 mostly in the Lying posture. Increased activity was observed from day 2 to 3, with more frequent Upright and Reclined periods. On day 4, the patient stayed in Upright and Reclined postures for longer periods than previous days. This shows the patient's process of postsurgery recovery.

The analyses described in the rest of the Methods section used the cleaned and pre-processed data.

Figure 2. Example cleaned and preprocessed data from 3 patients. The short yellow bars correspond to Lying. The taller orange bars correspond to Reclined. The tallest red bars correspond to Upright. The light and dark blue bars correspond to Unknown and User-Defined, respectively.



Summary Statistics

In all, 20 summary statistics were calculated for each patient, using their cleaned and preprocessed data. The purpose was to translate the large amount of data into a concise set of interpretable statistics. The 20 summary statistics can be divided into 3 categories. The first category (data quantity) examines the length of ViSi posture data available for the patient. The second (posture duration) finds the patient's average time spent in each of the 5 postures. The third category (posture transitions) measures the frequency of posture changes in the patient's data.

For data quantity, 2 measures were generated. First, we recorded the total number of days that the patient had any ViSi posture data taken (total days). Total days includes days with complete data (ie, all 24 hours), as well as days with only a short data segment starting from a single recording. Second, we counted

the number of days where the patient had extensive ViSi posture monitoring, defined as at least 22 hours of recordings per day, which we used for further analysis. Hereafter, we refer to these days as analysis days. Since ViSi provides 1 posture recording every 15 seconds, each analysis day contains at least 5280 recordings. The statistics for posture duration and posture transitions, which are described below, were calculated using analysis days only. Thus, any patients who did not have any analysis days have been excluded from this analysis. Based on this criterion, 508 of 1198 patients (42.4%) were excluded. There are 690 patients included in this analysis.

For each patient, the posture duration statistics were defined as the average time spent in each of the 5 posture groups for the whole day (WD), daytime (DT), and nighttime (NT). Thus, there are 15 posture duration statistics from the 5 posture groups for WD, DT, and NT. The unit of measurement for the average time is hours per day. DT is defined as the 12-hour window from 7:00 AM-6:59 PM and NT as the opposite 12-hour window from 7:00 PM-6:59 AM. These definitions match the shift schedule at Atrium Health Wake Forest Baptist. The naming convention for the posture duration statistics is summarized in the first row of Table 2. The WD statistics provide the average number of hours per day that the patient spent in each posture. We calculated the WD statistics using the following procedure. Let k denote the number of analysis days for the patient (k≥1). Consider a posture group (eg, Lying). On each analysis day, we found the proportion of ViSi recordings that fell into the given posture. The average proportion across the k days was calculated, and the resulting value was multiplied by 24 to convert it to the unit of hours per day. This procedure was applied separately to each of the 5 posture groups, yielding a set of 5 WD statistics. Next, we calculated 2 more sets of statistics, one for DT and the other for NT. The purpose was to examine diurnal changes of the patient's posture pattern. To calculate the DT and NT statistics, we applied the same procedure described above to the data collected during the specific 12-hour time block, except changing the conversion factor from 24 to 12. In future work, DT and NT statistics, along with WD statistics, could be used in prediction models for patient outcomes.

Table . List of statistics for posture duration and posture transitions.

	Whole day (WD)	Daytime (DT)	Nighttime (NT)
Posture duration	• Lying-WD • Reclined-WD • Upright-WD • Unknown-WD • UserDefined-WD	• Lying-DT • Reclined-DT • Upright-DT • Unknown-DT • UserDefined-DT	• Lying-NT • Reclined-NT • Upright-NT • Unknown-NT • UserDefined-NT
Posture transitions	FPT-WD[a]	FPT-DT	FPT-NT

[a]FPT: frequency of posture transitions.

The third group, posture transitions, provides the frequency of posture transitions (FPT). We define that a posture transition occurs when a patient's posture group changes from one timestamp to the next. The change is also limited among Lying, Reclined, and Upright only. Based on this definition, there are 6 types of transitions: Lying to Reclined, Lying to Upright, Reclined to Upright, and vice versa. Neither Unknown nor User-defined are considered in posture transitions. This is because whether a physical transition occurs in this case is not clear. The FPT measures the rate of posture transitions including all 6 types described above, with the unit of transitions per hour (tph). As before, we calculated FPT for WD, DT, and NT separately. The naming convention of the statistics is shown in the bottom row of Table 2. The calculation of the FPT-WD statistic is as follows. For each analysis day of the patient, we tallied the number of transitions present and divided this count by the actual number of hours of data in that day. This provided a rate of tph for this specific analysis day. The FPT-WD is the average tph across all k analysis days. The calculation of FPT-DT (or FPT-NT) uses the same procedure, except that the number of transitions and their corresponding hours are from the DT (or NT) window. Overall, 3 statistics are obtained on FPT.

Cluster Analyses

We sought to identify the distinct subtypes of posture habits present in the dataset. For this purpose, a cluster analysis was conducted in which the patients were divided into nonoverlapping clusters, using the posture duration and posture transition statistics. These clusters can be used to identify the different subtypes of posture habits objectively. The cluster analysis was performed using the k-means clustering algorithm [16,17]. The number of clusters, k, must be specified a priori. We tested a range of values for k from 2 to 10 and selected the value of k that maximized the average silhouette width [18,19]. In total, 4 sets of cluster analyses were performed, with different input data. The first set, which we call WD cluster, used the WD statistics (Table 2, column 2). The second set (DT cluster) used the DT statistics (Table 2, column 3). The third set (NT cluster) used the NT statistics (Table 2, column 4). The fourth set (combined cluster) used the combined DT and NT statistics, which doubles the inputted data sample. In the 4 sets, we excluded posture duration statistics corresponding to the User-defined category because patients' values for these statistics were all approximately 0, so they were not useful for differentiating between patients. Before applying the k-means algorithm, each statistic was standardized to have mean 0 and SD 1. For each of the 4 cluster analyses, average silhouette scores were computed across all patients and separately within each of the k clusters.

Analyses were performed using the R programming language (version 4.2.2; R Foundation for Statistical Computing).

Results

Summary Statistics

Table 3 shows the age and sex distributions of the original 1330 patients before data exclusion, and the 690 patients after data exclusion. The age and sex distributions showed little change before versus after data exclusion (Table 3). The number of patients included in the analysis was 690, comprising 407 males and 283 females, with an average age of 60 years.

Table . Age and sex distributions before and after data exclusion.

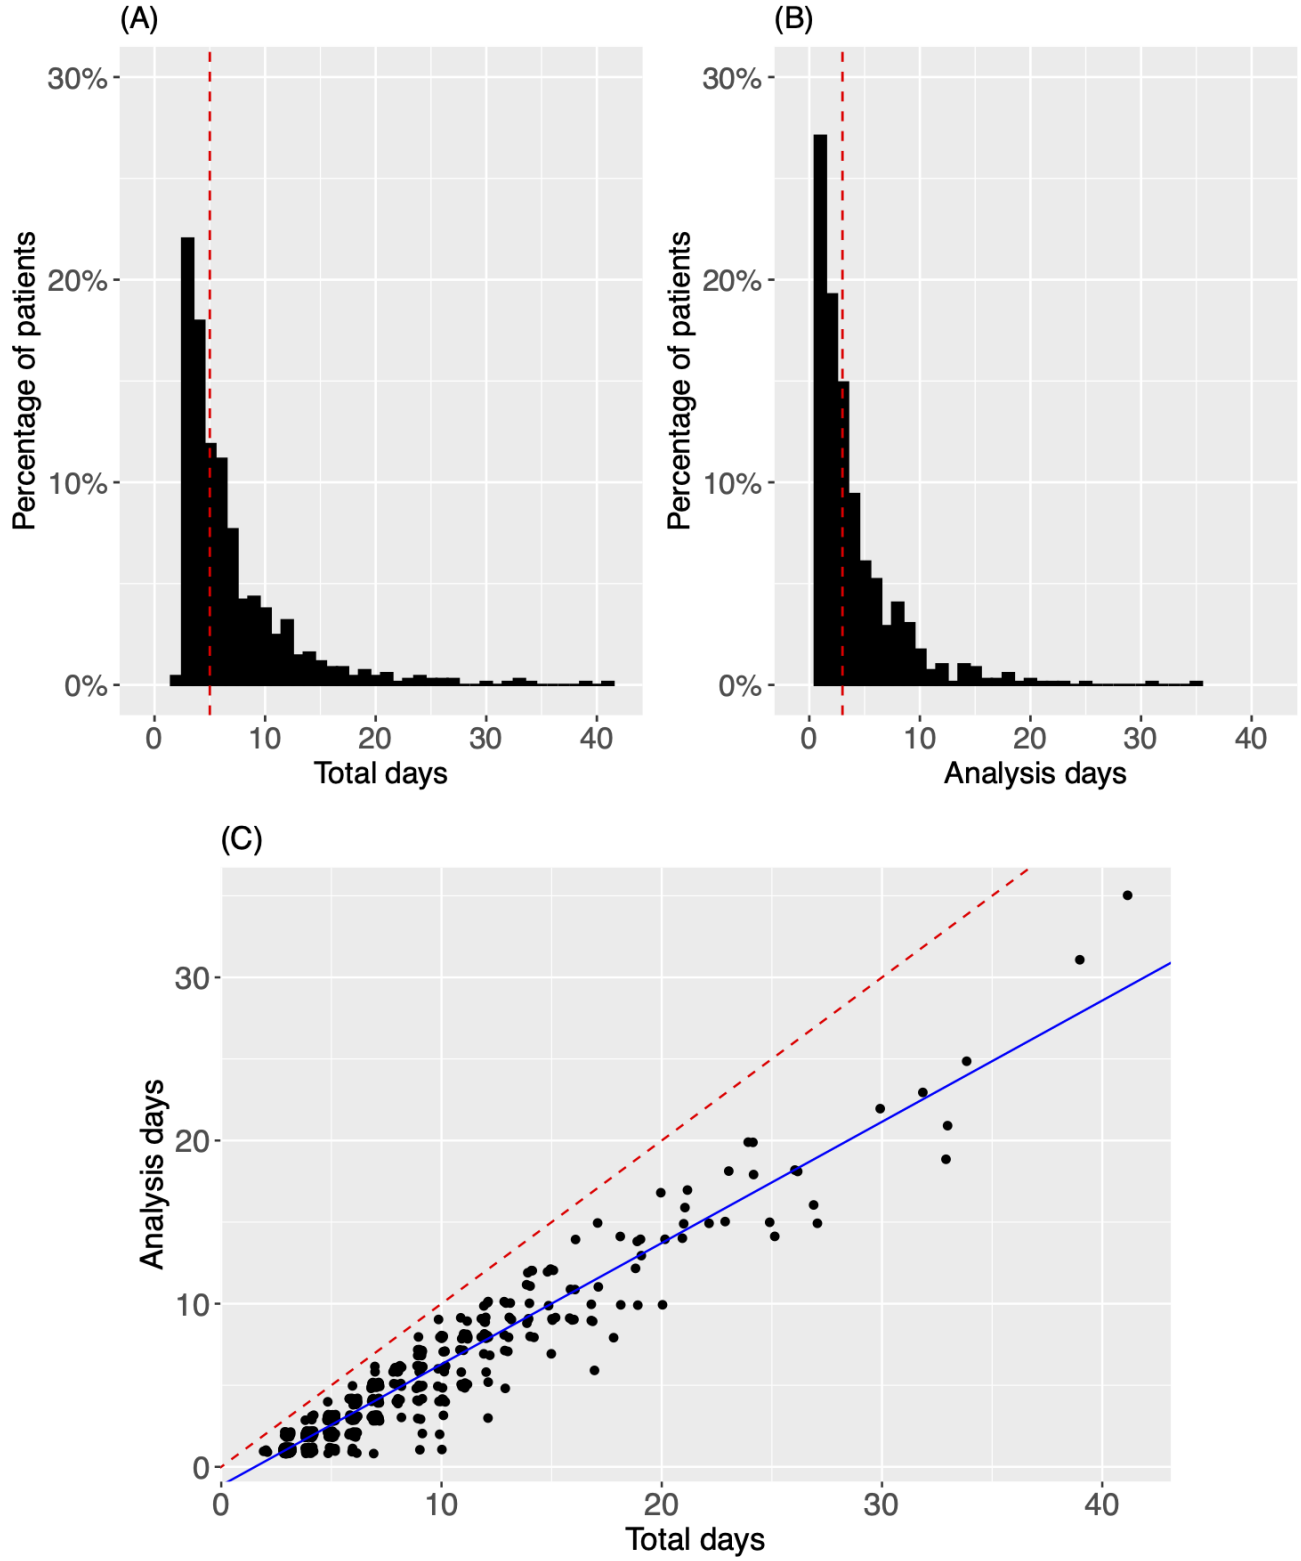
	Before data exclusion (n=1330)	After data exclusion (n=690)
Age [a] (years)		
Mean (SD)	60.5 (15.5)	60.3 (15.0)
Median (IQR)	62.5 (52.0-71.8)	62.4 (52.0-71.4)
Sex		
Male, n (%)	772 (58)	407 (59)
Female, n (%)	557 (41.9)	283 (41)
Unknown, n (%)	1 (0.1)	0 (0)

[a]Age is the subject's age on January 1, 2019.

The univariate distribution of each summary statistic was analyzed for the sample of 690 patients. Figure 3 shows the histograms of total days and analysis days, the summary statistics for data quantity. Both measures exhibit right-skewed distributions, with a higher range for total days than analysis days. The median (red dashed line) was 5 total days per subject and 3 analysis days per subject. The 2 measures are highly correlated with one another (Figure 3C). The scatter plot shows a linear relationship between total days and analysis days, estimated as:

$$\text{AnalysisDays} = -1.14 + 0.74\,\text{TotalDays}$$

Figure 3. Data quantity. (**A**) The histogram for total days per subject. (**B**) The histogram for analysis days. In both (A) and (B), the dotted red line is the median of the distribution. (**C**) A scatter plot of total days versus analysis days. A linear regression fit is overlaid on the points (solid blue). For comparison, the identity line (y=x) is provided (dotted red), which represents the ideal scenario that analysis days=total days. To allow visibility of overlapping points, random noise from a uniform distribution has been added to each point in the horizontal and vertical directions.



As described in the Methods section, only analysis days were considered when calculating the other summary statistics reported hereafter. Approximately 85% (586/690) of patients had between 1 and 7 analysis days, including 27% (187/690) with 1 analysis day, 34% (236/690) with 2 - 3, and 24% (163/690) with 4 - 7 analysis days. The other 15% (104/690) had more than 7 analysis days. The maximum number of analysis days was 35.

Figure 4 presents histograms of the WD statistics for posture duration, including Lying, Upright, Reclined, and Unknown. Table 4 provides the quartiles of the posture duration statistics. The histogram of User-defined is not presented in Figure 4 since

it is concentrated as an isolated peak at near 0 hours/day, consistent with the median of 0.008 hours/day (Table 4). This indicates a very small fraction of User-defined posture among all patients. The distribution of Lying-WD (Figure 4A) is approximately uniform from 2-20 hours near the 9% level, with a decline after 20 hours to 2.5%. There is also a peak from 0-2 hours at 15%. This shows a wide range of time duration spent in Lying across patients. The median for Lying-WD is 10.2 hours/day. Reclined-WD shows a roughly uniform distribution from 0-14 hours at around 12%. The distribution then tapers off on the right side (Figure 4B). The median is 8.0 hours/day (Table 4). In contrast, the distribution of Upright-WD (Figure 4C) is highly right skewed, with a peak at 0 - 2 hours/day accounting for about 45% (305/690) of patients. The interval from 2 - 4 hours/day includes 25% (175/690) of patients. Thus, 70% (480/690) of patients spent between 0 - 4 hours/day Upright. The median is 2.5 hours/day. Unknown-WD (Figure 4D) also shows a right-skewed distribution but with a sharp peak at 0 - 2 hours, accounting for about 80% (548/690) of patients. The median is 0.6 hours/day. This suggests that only a small fraction of patients were characterized in the Unknown category.

Figure 4. Posture duration for whole day. The histograms of the posture duration statistics are shown for whole day. The columns indicate the posture: (A) Lying, (B) Reclined, (C) Upright, and (D) Unknown. User-defined is not shown because this category was rarely observed. In each histogram, the x-axis ranges from 0 to 24 hours, and the y-axis shows the percentage of patients. The red dotted line indicates the median.

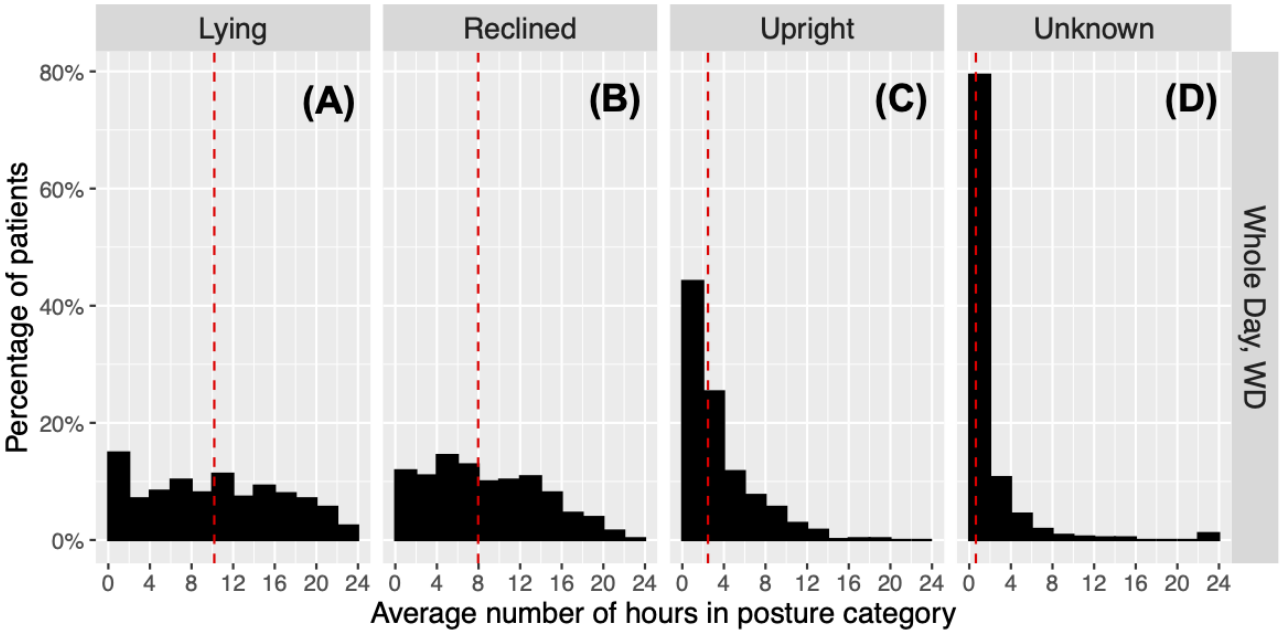


Table . Quartiles for posture duration and posture transition statistics.

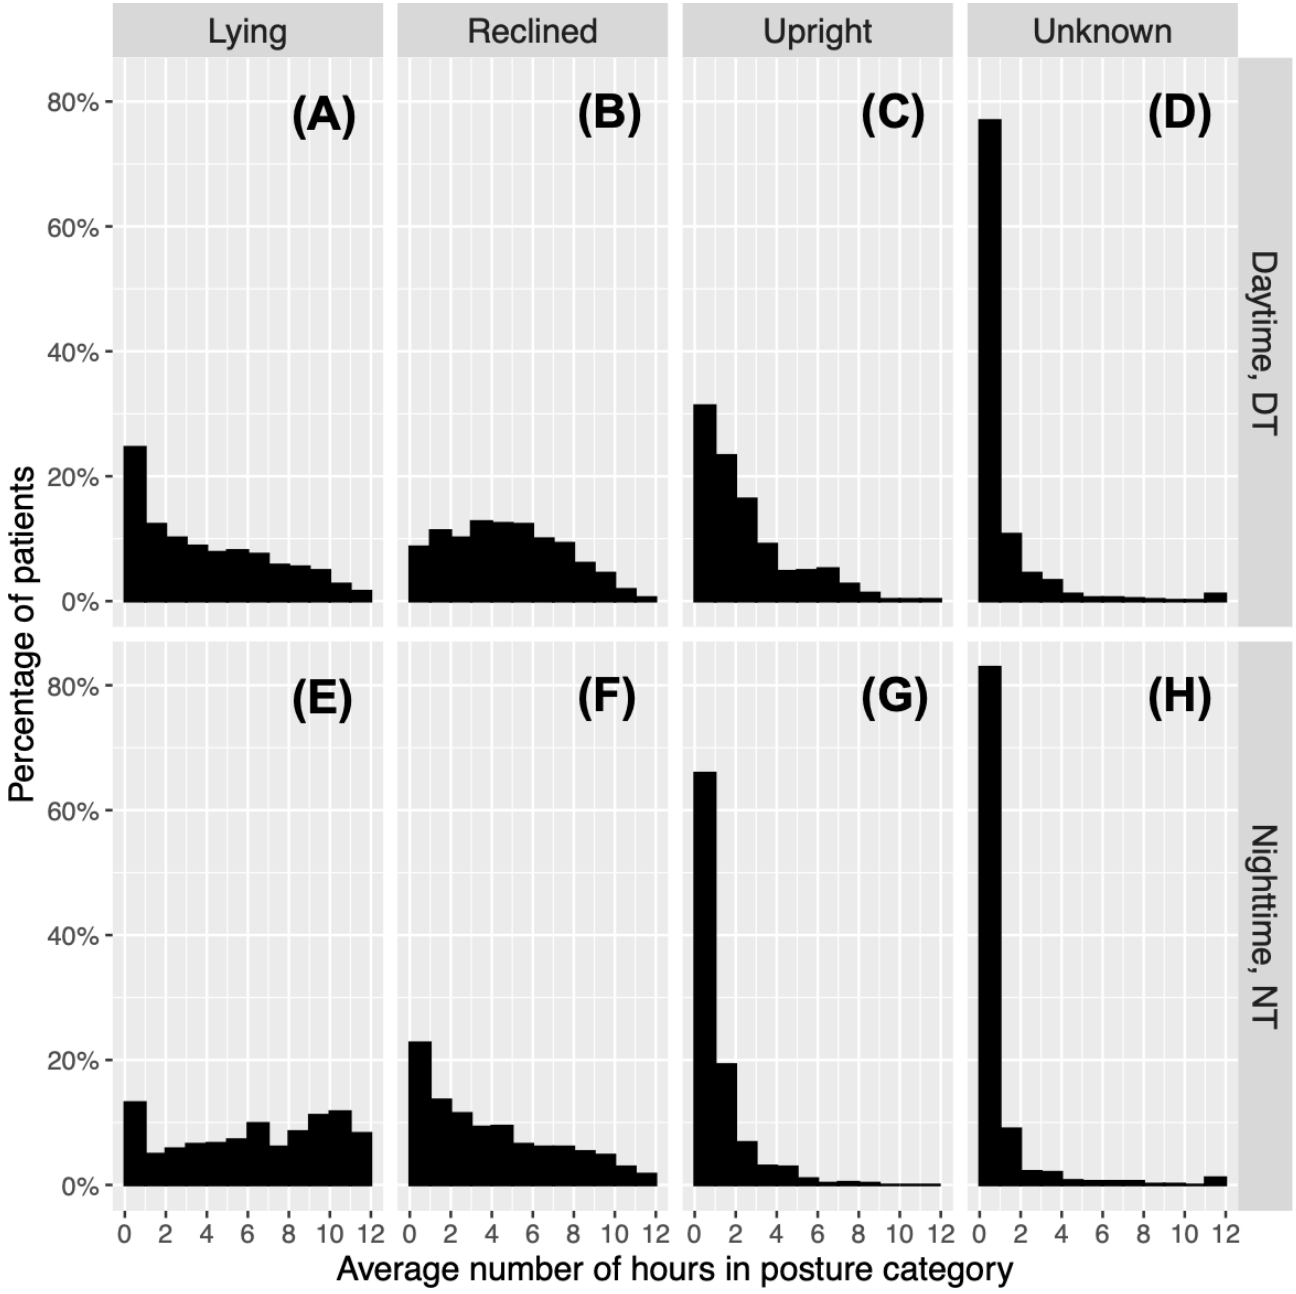
	Posture duration					Frequency of posture transitions (transitions/hour)
	Lying (hours/day)	Reclined (hours/day)	Upright (hours/day)	Unknown (hours/day)	User-defined (hours/day)	
Whole day, median (IQR)	10.2 (4.5 - 15.6)	8.0 (4.1 - 12.7)	2.5 (1.1 - 4.7)	0.6 (0.2 - 1.6)	0.008 (0.007 - 0.009)	2.8 (1.9 - 4.3)
Daytime, median (IQR)	3.3 (1.1 - 6.4)	4.5 (2.4 - 6.7)	1.7 (0.8 - 3.4)	0.3 (0.1 - 0.9)	0.004 (0.004 - 0.005)	3.5 (2.3 - 5.3)
Nighttime, median (IQR)	6.6 (3.1 - 9.6)	3.3 (1.1 - 6.3)	0.6 (0.3 - 1.3)	0.2 (0.04 - 0.6)	0.004 (0.003 - 0.004)	2.1 (1.3 - 3.5)

Figure 5 presents histograms of the DT and NT statistics for posture duration. Table 4 shows the quartiles of these statistics. For the Lying posture, both the DT and NT distributions were substantially different from the pattern of the WD distribution, signifying the diurnal changes of this posture. The DT distribution (Figure 5A) peaked at 0 hours at the 25% level, and then decreased monotonically from 0-12 hours. In contrast, the NT histogram (Figure 5E) increased from 1-11 hours. As expected, there is a substantially higher percentage of patients with longer Lying times during NT than during DT. Consequently, the median for NT (6.6 hours) is higher than that for DT (3.3 hours), as shown in Table 4. However, there is a noticeable peak at 0 - 1 hours for NT, comprising about 13% (91/690) of patients. The Reclined distributions showed a diurnal change from roughly symmetric in DT (Figure 5B) to strongly right skewed in NT (Figure 5F). Although they had different shapes in their distribution, the median of DT (4.5 hours) was only slightly higher than that of NT (3.3 hours). The diurnal change could be explained by a certain percentage of patients changing their posture from Reclined in DT to Lying in NT,

but there remained some patients who continued in Reclined from DT to NT. For Upright, the distributions for DT and NT, like that of WD, were right skewed with a peak starting at the left end. The distribution for DT has its peak of 31% at 0 - 1 hours, followed by a slow decrease (Figure 5C). In comparison, the distribution of NT started from a higher peak of 66% at 0 - 1 hours, followed by a sharp decrease (Figure 5G). A noticeable proportion of people spent a substantial amount of time Upright in DT. For example, 18% (123/690) of patients spent between 4 - 8 hours Upright in DT, compared to 5% (32/690) in NT. The medians for DT and NT were 1.7 hours and 0.6 hours, respectively. The Unknown posture did not show a significant diurnal change.

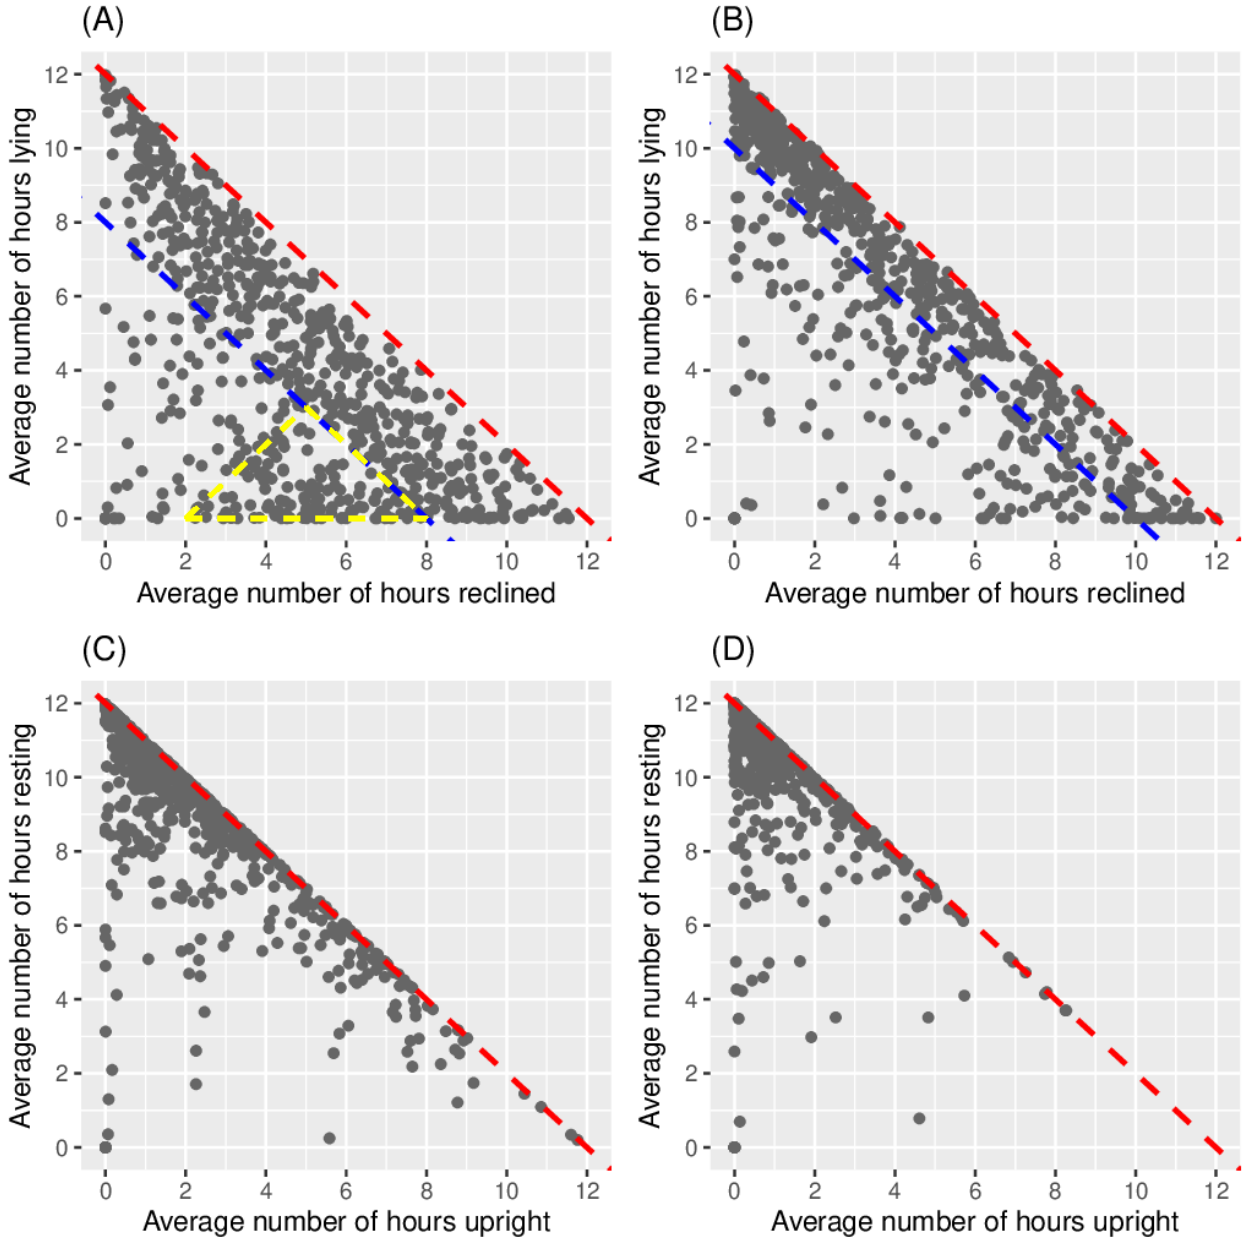
Figure 5. Posture duration for daytime and nighttime. This figure presents histograms of the posture duration statistics for (A-D) DT and (E-H) NT. The rows give the time of day as DT or NT. The columns indicate the posture (Lying, Reclined, Upright, Unknown). For any given row and column pair, the histogram shows the distribution of the average number of hours in the given posture during the given time of day, across the 690 patients. The x-axis of each histogram ranges from 0-12 hours. DT: daytime; NT: nighttime.



Interconnections between the summary statistics were also studied. Figure 6A presents a scatter plot of Reclined-DT versus Lying-DT. All points are contained inside the lower triangle of the square plot because the length of daytime is 12 hours and thus Lying-DT + Reclined-DT ≤ 12. The red dotted line (Lying-DT + Reclined-DT = 12) is the upper boundary of the triangle. Inside the triangle, points are spread out across the domain, but with a concentration at the strip between the upper boundary and lower boundary (blue dotted line) at Lying-DT + Reclined-DT = 8. This strip represents the subgroup that spends at least 8 hours Lying or Reclined during daytime. Another subarea of concentrated samples is the yellow triangle with vertices at (5, 3), (2, 0), and (8, 0). This represents a subgroup that mainly takes the Reclined posture for rest. Their

total resting time is less than those in the strip. They are likely the group with more activities in daytime. Last, the subgroup in the lower left corner is sparser, with only isolated points scattered around. Figure 6B gives the scatter plot of Reclined-NT versus Lying-NT, also with a red dotted line at the upper boundary. It shows a marked change in the relationship between these two postures from daytime to nighttime. Specifically, the strip near the upper boundary of the triangle described in daytime (Figure 6A) narrows during nighttime (Figure 6B), with the lower boundary moving upward to 10 hours (blue dotted line). Most of the study population was concentrated in this strip, and the triangle mentioned previously disappeared. This is consistent with the general behavior that most people rest during the night.

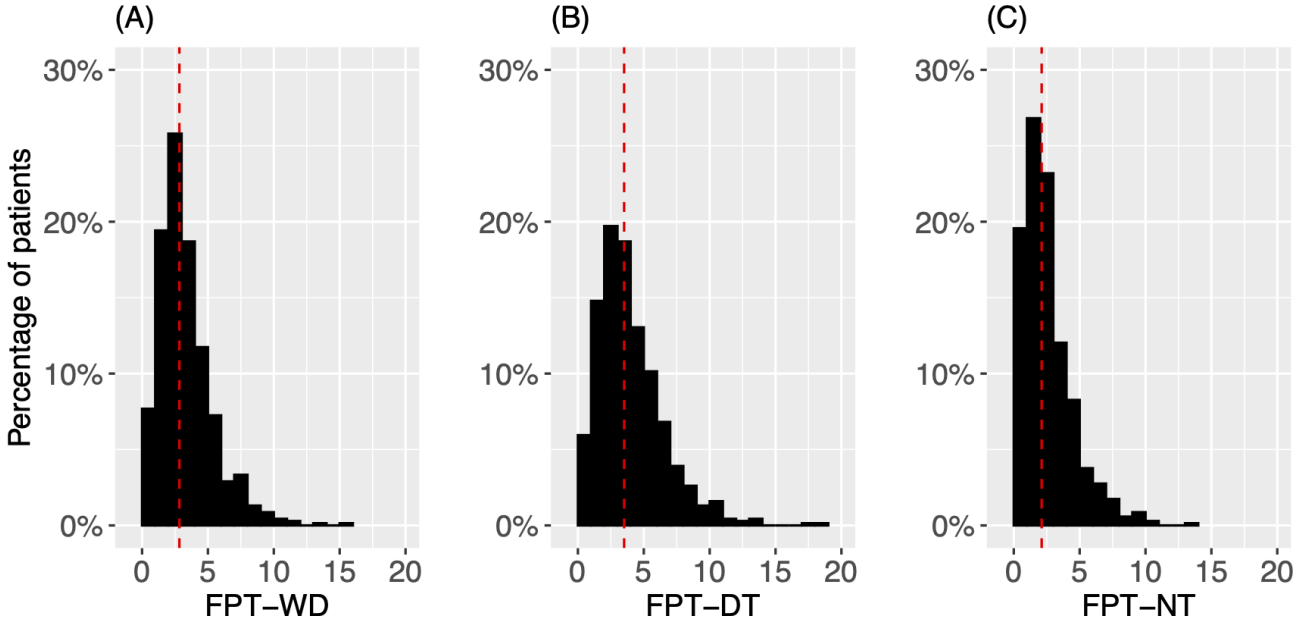
Figure 6. (A) Daytime: Reclined versus Lying. (B) Nighttime: Reclined versus Lying. (C) Daytime: Upright versus Rest. (D) Nighttime: Upright versus Rest. Scatter plots of time spent Lying versus Reclined (first row) and time spent Upright versus in Rest (second row). The left (right) column is for daytime (nighttime). Rest is defined as the sum of Lying and Reclined.



For a more simplified view, Reclined and Lying can be combined into a single category called Rest, defined as the sum of these 2 postures. Figure 6C and D show the relationship between Rest and Upright in DT and NT, respectively. Most of the points are near the upper boundary (red dotted line) because patients spend most of the time in either Rest or Upright postures. In both plots, points are concentrated in the upper left corner of the triangle. The majority are in an Upright posture between 0 - 4 hours and at Rest between 8 - 12 hours. A diurnal change occurs since there is a concentration of points near the upper boundary with Upright between 4 - 8 hours in DT (Figure 6C), while this largely disappears at NT (Figure 6D). In both plots, a small subgroup is well below the upper boundary. These points correspond to patients with higher levels of Unknown, previously shown in the right tail of Figure 5D and H.

Posture transitions were analyzed in addition to posture duration. Figure 7 shows histograms of the FPT for WD, DT, and NT. Table 4 provides the quartiles of each FPT statistic. The distribution of FPT-WD showed a prominent peak at 2 transitions per hour, accounting for 26.7% (184/690) of patients (Figure 7A). The distribution decayed quickly on both sides but with a skew to the right, shown by the long right tail extending to 15 transitions per hour. The distributions of FPT-DT (Figure 7B) and FPT-NT (Figure 7C) were also right-skewed, but showed different characteristics, reflecting a distinct diurnal change of FPT. In comparison to DT, NT had a sharper peak near 27% shifted closer to 0. About 50% (345/690) of people had 1 or 2 transitions per hour in NT. For DT, the peak was at a lower level of 20% and it decayed slower on both sides. About 35% (233/690) of people had 1 or 2 transitions per hour in DT. Moreover, the percentage of patients with higher transition rates (5 - 10 transitions per hour) decreased substantially from DT to NT, demonstrated by the higher weight in the range from 5 to 10 transitions per hour in DT. Both factors contributed to the higher median for FPT-DT compared to FPT-NT (Table 4).

Figure 7. Posture transitions. (A) Histogram for FPT-WD. (B) Histogram for FPT-DT. (C) Histogram for FPT-NT. In each plot, the dotted red line indicates the median for the corresponding statistic. The unit of measurement for the FPT variable is transitions per hour. DT: daytime; FPT: frequency of posture transitions; NT: nighttime; WD: whole day.



Cluster Analyses

Each of the four cluster analyses divided the 690 patients into a small number of clusters. Using the criterion of average silhouette width, the number of clusters k was selected to be 5 for DT, and 4 for WD, NT, and combined. Table 5 gives the cluster averages and number of patients per cluster for WD, DT, and NT. Multimedia Appendix 2 provides the average silhouette scores across all patients and within each cluster, individually for each cluster analysis.

Table . Cluster analyses using the k-means clustering algorithm for WD cluster, DT cluster, and NT cluster. The first k rows for each cluster analysis show the k clusters in order from the largest cluster to the smallest cluster. The last column indicates the number and percentage of patients assigned to the given cluster. The other columns provide the cluster averages for the summary statistics. The last row for each cluster analysis shows the average values across all 690 patients to provide a reference point for comparing the cluster-specific means.

	Lying (hours)	Reclined (hours)	Upright (hours)	Unknown (hours)	Frequency of posture transitions (transitions/hour)	Participants (n=690), n (%)
WD cluster						
W1	16.7	4.3	1.7	1.3	2.5	287 (42)
W2	5.3	14.7	2.9	1.1	2.8	219 (32)

N4	2.2	1.2	0.6	8.0	1.2	26 (4)
Average	6.3	4.0	1.1	0.7	2.6	—

[a]Not applicable.

In the WD cluster (Table 5), the two largest clusters (W1 and W2) spend most of the day in Rest and have low Upright time. W1 prefers the Lying posture for Rest, while W2 prefers Reclined. In both clusters, the average FPT is between 2 - 3 transitions per hour. On the other hand, W3 is the most active, with the highest average Upright time (7.6 hours) and posture transition frequency (5.7 transitions per hour) among the clusters. W4 is the smallest cluster, comprising 3% (23/690) of the patients. Unknown is the dominant category in W4, with 16 hours/day Unknown on average.

The DT cluster (Table 5) identified 5 clusters using the DT statistics. Clusters D1 and D2 spend the daytime hours in Rest. D1 takes Rest mostly through Reclined at 7.4 hours on average, while D2 takes Rest mostly through Lying at 7.8 hours on average. D1 and D2 both have low levels of Upright, at 1.8 and 1.0 hours on average, respectively. D1 and D2 are close in size, accounting for 35% (241/690) and 33% (226/690) of patients, respectively. In comparison, D3 and D4 are more active during DT. D3 has an average Upright time of 3.6 hours, and it prefers Reclined (5.0 hours) over Lying (2.8 hours). D4 has a higher average Upright time (6.7 hours). It also spends more time in Reclined (3.8 hours) than Lying (1.0 hours). D3 and D4 each account for 14% of patients (99/690 and 95/690, respectively). D5 has Unknown as its dominant category and includes 4% (29/690) of patients.

The NT cluster (Table 5) found 4 clusters using the NT statistics. N1 and N2 are the two largest clusters, accounting for 52% (358/690) and 28% (190/690) of the patients, respectively. N1 has Lying as the dominant nighttime posture at 9.2 hours on average, followed by Reclined (1.8 hours). N2 prefers Reclined (8.0 hours) over Lying (2.6 hours) at nighttime. N3 has an average Upright time of 3.1 hours, which is higher than the other clusters. It also has a higher average FPT of 5.4 transitions per hour. N3 accounts for 17% (116/690) of patients. N4 has mostly Unknown posture of 8.0 hours on average.

In the combined cluster (Table 6), the traits of the clusters resemble those from the WD cluster. C1 prefers Lying, C2 favors Reclined, C3 is active in daytime, and C4 is dominated by Unknown. The sizes of C1, C2, C3, and C4 are also similar to the sizes of W1, W2, W3, and W4, respectively. Unlike the WD cluster, the combined cluster analysis revealed further details about changes in the patients' behaviors from daytime to nighttime. For example, cluster C1 spends most of the daytime in Lying (7.0 hours), followed by Reclined (2.9 hours) then Upright (1.3 hours). At nighttime, Lying becomes more

dominant (9.6 hours), with less time spent in Reclined (1.4 hours) and Upright (0.5 hours).

Table . Cluster analyses using the k-means clustering algorithm for the combined cluster.

	Lying (hours)		Reclined (hours)		Upright (hours)		Unknown (hours)		Frequency of posture transitions (transitions/hour)		Participants (n=690), n (%)

Discussion

Principal Results

This study examined a year-long, routine hospital ViSi posture dataset to study patterns in patient posture habits, with the following results. The dataset required substantial preprocessing before statistical analysis. Two errors in the dataset were identified: overlap and inconsistency. Overlap was highlighted because it mixes data from multiple patients, which can alter the derived summary statistics. This problem could be easily overlooked in analyses of massive amounts of data. Overlap may have resulted from shared use of a ViSi monitoring device between multiple patients and lack of reliable timestamps of device handoff. In data preprocessing, we also consolidated the ViSi posture codes to target the most meaningful postures of Lying, Reclined, and Upright, and removed high frequency noise from the posture recordings. The preprocessing treatments improved the data quality, manageability of the data, and interpretation of results.

Using the preprocessed dataset, summary statistics were generated for each patient and probability distributions of the summary statistics were constructed using all 690 patients. This analysis showed that the 3 main postures (Lying, Reclined, Upright) had distinctive distribution patterns. For the whole day statistics, Lying had a flatter distribution, while Reclined showed a decrease in the longer hours. Upright had its peak at 0 - 2 hours, with a quick monotonic decrease. Thus, Lying and Reclined are more dominant postures. These findings are consistent with known clinical observations of inpatients. Pattern changes from daytime to nighttime were observed for Lying, Reclined, and Upright. The distribution of Lying was decreasing during daytime but relatively flat with a slow increase during nighttime. Although this pattern change may be partly explained by the fact that more patients take longer Lying periods during night, the flat distribution during nighttime still needs explanation. Combined with the similarity of the daytime Lying and nighttime Reclined, we speculate that a certain number of patients take Reclined as their resting posture at night. It is also noted that over one-third of patients show a preferred duration of 3 - 6 hours for Reclined posture during daytime. As expected, Upright shows a sharper decrease from daytime to nighttime.

Last, *k*-means clustering analyses were performed to objectively identify subtypes of patient posture habits. We found that 3 of the 4 analyses each identified 4 unique subtypes. These subtypes included 2 sedentary subgroups with different resting styles, one that prefers Lying and the other Reclined. There is an active subgroup that spends relatively more time Upright and has more frequent posture transitions. The fourth subtype includes a small percentage of patients that have Unknown as the dominant ViSi-measured posture during their hospital stay.

Limitations

This study has the following limitations. First, there may still be some irreversible errors left in the data (eg, incorrect placement of ViSi device on the body, battery failure causing discontinuity), which are beyond the scope of this analysis. The postures from the ViSi device can also differ from the ground-truth postures because the ViSi postures are estimated from accelerometer data. We did our best to mitigate the issue of inaccurate posture recognition. For example, because ViSi may classify walking as U90 instead of WLK, the activities of walking, standing, and sitting were combined into the same category of Upright [3]. The difficulty in classifying walking is possibly because the ViSi algorithm, previously trained from certain data, may not fit individual patients' mobility well. This implies that the ViSi algorithm needs to be calibrated to the individual patient, or more customized algorithms can be used to improve the accuracy of walking (eg, [20]). Second, our study does not consider postoperative pain or postoperative medications, but these two factors could affect a patient's posture after surgery. An area of future work is to examine the effect of postoperative pain and medications on ViSi posture statistics for various types of surgery.

Third, the amount of data excluded due to overlap or inconsistency was substantial, accounting for 9.9% (132/1330) of patients and 27.6% (8,778,641/31,842,773) of posture recordings. Our study took a conservative approach of dropping

suspicious data that exhibited the overlap or inconsistency problems. Although this reduced the available sample size, the number of patients included in the analysis remained high (n=690). We believe that the overlap and inconsistency problems occur randomly instead of systematically for certain types of patients. Thus, the data cleaning procedure, which removed these problems, should not cause bias. The data problems that we faced are associated with data collection, storage, and integration with the medical record. The current ViSi system is designed to provide real-time data for the nurse and clinician, rather than for long-term use. Therefore, data cleaning is an inevitable step for retrospective analyses of routinely collected ViSi data. However, some further improvements of the system could make the data more accessible for retrospective analyses. This could be done by creating standardized data models and specifications for measuring patient movement.

Conclusions

Using ViSi posture data collected from routine inpatient monitoring, we derived summary statistics for each patient and analyzed the summary statistics to find patterns in the patient population. Probability distributions, generated from the large sample size of 690 patients, provided quantitative measures of posture durations and transitions, with respect to their median and interquartile range. We considered both surgery and nonsurgery patients in the dataset to provide a baseline measure of these quantities, which sets a basis to study more specific clinical situations. In future work, we will build on this work to study distributions for patients with specific types of disease, as well as distributions of patients before versus after surgery. After these distributions are established, they can serve as useful reference distributions to measure a future patient's recovery trajectory or condition.

ViSi data collection increases work efficiency in the hospital. For the 690 patients analyzed in this study, the cumulative hours of ViSi posture collection amounted to 90,308 hours taken over 4847 patient-days. As an alternative, direct observation requires a nurse spending 2 hours per patient-day to conduct posture monitoring and documentation at a 30-minute frequency. Therefore, ViSi monitoring saved 9694 hours (4847 × 2) of nurses' effort, which could be devoted to other more pressing clinical responsibilities. This corresponds to a saving of labor cost of US $401,138, based on the median hourly rate of US $41.38 per hour for registered nurses, according to the US Bureau of Labor Statistics [21]. Moreover, the digitized inpatient measurements with automated collection and storage provide a vast and valuable database for retrospective analysis, which has not been fully tapped by clinical researchers.

A major contribution of this study is development of methodology to clean and preprocess routinely collected inpatient ViSi monitoring data. The procedure we used for cleaning the ViSi posture data can have broader application in cleaning other routine hospital datasets. The preprocessing treatments for consolidating posture codes and removing high-frequency noise can also improve manageability and interpretability of ViSi posture data. Thus, this study lays groundwork for future studies on examining the associations of clinical data with posture statistics derived from cleaned, preprocessed ViSi data. In future studies, we plan to study the associations of patients' medical condition and treatment (including diagnosis, surgical procedure, medications, sedatives, and pain level) with posture duration and posture transitions. Based on our experience with ViSi analysis, we believe that examining data quality will be the first step to ensure that clinical variables are accurately linked to the cleaned ViSi data records for each patient.

Abstract

Background: Gait speed is a valuable biomarker for mobility and overall health assessment. Existing methods to measure gait speed require expensive equipment or personnel assistance, limiting their use in unsupervised, daily-life conditions. The availability of smartphones equipped with a single inertial measurement unit (IMU) presents a viable and convenient method for measuring gait speed outside of laboratory and clinical settings. Previous works have used the inverted pendulum model to estimate gait speed using a non–smartphone-based IMU attached to the trunk. However, it is unclear whether and how this approach can estimate gait speed using the IMU embedded in a smartphone while being carried in a pants pocket during walking, especially under various walking conditions.

Objective: This study aimed to validate and test the reliability of a smartphone IMU–based gait speed measurement placed in the user's front pants pocket in both healthy young and older adults while walking quietly (ie, normal walking) and walking while conducting a cognitive task (ie, dual-task walking).

Methods: A custom-developed smartphone application (app) was used to record gait data from 12 young adults and 12 older adults during normal and dual-task walking. The validity and reliability of gait speed and step length estimations from the smartphone were compared with the gold standard GAITRite mat. A coefficient-based adjustment based upon a coefficient relative to the original estimation of step length was applied to improve the accuracy of gait speed estimation. The magnitude of error (ie, bias and limits of agreement) between the gait data from the smartphone and the GAITRite mat was calculated for each stride. The Passing-Bablok orthogonal regression model was used to provide agreement (ie, slopes and intercepts) between the smartphone and the GAITRite mat.

Results: The gait speed measured by the smartphone was valid when compared to the GAITRite mat. The original limits of agreement were 0.50 m/s (an ideal value of 0 m/s), and the orthogonal regression analysis indicated a slope of 1.68 (an ideal value of 1) and an intercept of −0.70 (an ideal value of 0). After adjustment, the accuracy of the smartphone-derived gait speed estimation improved, with limits of agreement reduced to 0.34 m/s. The adjusted slope improved to 1.00, with an intercept of 0.03. The test-retest reliability of smartphone-derived gait speed was good to excellent within supervised laboratory settings and unsupervised home conditions. The adjustment coefficients were applicable to a wide range of step lengths and gait speeds.

Conclusions: The inverted pendulum approach is a valid and reliable method for estimating gait speed from a smartphone IMU placed in the pockets of younger and older adults. Adjusting step length by a coefficient derived from the original estimation of step length successfully removed bias and improved the accuracy of gait speed estimation. This novel method has potential applications in various settings and populations, though fine-tuning may be necessary for specific data sets.

Introduction

Gait speed, often considered the sixth vital sign, is a meaningful health indicator that is routinely assessed within clinical and research settings [1-4]. As a biomarker, gait speed is an integrated and reproducible measure of mobility that helps to identify the risk of falls, disability, hospitalization, and even mortality [5,6]. It is also responsive to intervention and is often used to evaluate the effectiveness and progression of rehabilitation programming [3,7]. Within clinical settings, gait speed is most commonly measured by using a stopwatch to record the time taken to walk a short distance [8]. This approach, while validated, requires another person's assistance and is often inaccurate due to human error or bias. Within the laboratory, gait speed is typically measured using motion capture systems or instrumented walkways. This approach increases measurement accuracy yet requires trained personnel and expensive equipment, limiting its accessibility and feasibility for frequent, longitudinal monitoring. Moreover, neither of these clinical or laboratory-based approaches is well-suited for monitoring changes over time via higher-frequency assessments, and neither approach affords the assessment of gait speed assessment under unsupervised conditions during daily life activities. There is thus a need to develop new methods for the low-cost, easy, and accurate measurement of gait speed for use within both clinical and remote, unsupervised settings.

Smartphones, now widely used by younger and older adults and equipped with a high-quality inertial measurement unit (IMU), present a viable and convenient opportunity to objectively measure gait speed outside of laboratory and clinical settings. Previous studies have demonstrated that gait speed can be accurately estimated using multiple IMUs attached to various parts of the body (eg, the trunk and ankles) [9-11]. However, this approach requires specialized equipment that may be difficult to don and doff. Alternatively, studies have attempted to estimate gait speed using a single, research-grade IMU attached to the trunk of the body. In this case, the inverted pendulum model was used to determine gait speed by estimating stride distance and dividing it by stride time, determined by acceleration peaks induced by consecutive heel strikes [12-15]. This approach, while promising, still requires trained personnel for equipment setup and may introduce bias in gait speed estimation, especially at a faster or slower gait speed [13-15]. In this study, we examined the validity and reliability of deriving gait speed from a smartphone IMU with the phone being carried in the individual's front pants pocket when walking.

This study aimed to validate and test the reliability of a smartphone IMU–based gait speed measurement placed in the user's pants pocket in both healthy young and older adults during normal and dual-task walking. The validity of the smartphone-based approach was determined by comparing the estimated step length and gait speed to measurements taken by gold standard instrumentation. Based on initial results, we further examined the use of improving gait speed estimations using a coefficient relative to the estimation of step length as determined by the smartphone. The test-retest reliability of adjusted and unadjusted estimations was examined within both laboratory and unsupervised, real-life home settings. This study is expected to provide valuable insights applicable to a wide range of clinical and everyday gait monitoring scenarios.

Methods

Study Participants

We conducted a design control verification and validation study enrolling younger (aged 20 - 50 years) and older (aged 65 - 90 years) adults between 2016 and 2018. As part of our comprehensive assessment at baseline, we measured key demographic characteristics of the participants, including sex, age (in years), height (in meters), body weight (in kilograms), and ethnicity. We included those who had active Wi-Fi service in their homes and who were able to use the smartphone app by themselves after training. Assistive devices were allowed if participants normally used them when walking. Individuals were excluded if they were hospitalized within the last 6 months; were unable to walk without assistance; self-reported major neuromuscular, cardiovascular, or metabolic disease; had lower-extremity ulcers or amputations; or self-reported pain significantly affecting their gait.

Ethics Approval

This study was approved by the Hebrew SeniorLife Institutional Review Board (approval IRB-2015 - 40).

Smartphone App

Our team previously created an iOS smartphone–based application (app) that uses the phone's IMU sensor to record movements while walking freely at a self-selected speed (ie, normal walking condition) and while walking and concurrently performing a serial-subtraction task (ie, dual-task walking condition) with the phone placed in the user's pants pocket [16]. The app was designed to recreate a commonly used dual-task gait assessment that is typically performed in a laboratory setting. The initial development process involved a detailed analysis of requirements, followed by iterative design and user feedback–driven enhancements, ensuring both user-friendliness and adherence to clinical standards. The app includes a series of instructions for the participants to help ensure assessment reliability. Once the participant presses the "Start" button and places the phone in their preferred front pocket, the app provides auditory instructions for each walking trial via the iPhone speaker, including a randomly generated starting number for the serial-subtraction task for dual-task trials, and cues for the start and end of the trial. These cues trigger the acquisition of 3-axis accelerometer, gyroscope, and magnetometer data at a 100-Hz sampling rate. The data sets are saved on the phone's internal storage and automatically transmitted via Wi-Fi to a remote, cloud-based data server for offline analysis. The validity and reliability of the smartphone app, especially in temporal information (ie, stride time), have been established [16-18]. Additionally, its applicability extends to various populations, including individuals with Parkinson disease and older adults diagnosed with blood cancer [18-21].

Study Procedures

Overview

Each participant completed 2 laboratory visits separated by at least 1 week. Between these visits, participants were asked to complete the walking assessment using the app at home once a day on 3 separate days. Participants were instructed to wear comfortable pants or shorts with front pockets for each visit. Our previous work indicated that stride time estimations were unaffected by pocket tightness [16].

Laboratory Assessments

The same procedures were used on both laboratory visits. Within each visit, participants completed the walking assessment using the app 3 times, that is, 3 pairs of normal and dual-task walking trials. For each walking trial, participants walked around an oval-shaped, 24-m indoor track. The GAITRite mat (CIR Systems, Inc) was placed along one long side of the track. Each trial began with participants standing just behind the beginning of the mat to ensure that the first footfall of each trial was captured by the mat. Participants were instructed to use the app to start and finish each trial. Stride time, step length, and gait speed obtained from the first pass over the GAITRite mat were considered the gold standard and aligned the data sets to enable direct comparison of GAITRite and smartphone app data for each identified step.

Home Assessments

At home, participants were instructed to use the app to complete 1 normal walking and 1 dual-task walking on 3 separate days in between the 2 laboratory visits. The app provided the same instructions as given during the laboratory visit. The participants were instructed to walk continuously along the longest hallway or unobstructed path in their home, making 180-degree turns at each end, throughout the trial. We believe this setup can be effective in remote settings, provided that a flat and consistent walking surface is available, external interference is minimal, and stable Wi-Fi is present.

Data Analysis

Gait Speed Estimation

All data analyses, graphics generation, and statistical analyses were performed using programs developed in-house within MATLAB (R2022b, MathWorks) and SPSS (version 20; SPSS Inc).

For the data obtained from the smartphone, the raw time series 3-axis accelerometer and gyroscope data were transformed from the smartphone local coordinate system to an earth global coordinate system using a quaternion rotation matrix. This transformation ensured that the z-axis of the data aligned with the vertical line of gravity. After the transformation, each z-axis time series was filtered using a Butterworth filter [16,22], chosen for its smooth frequency response and minimal signal distortion, which worked well in our previous published study [16]. The time series data obtained from the accelerometer and gyroscope sensors contained alternating peaks of high and low amplitude that corresponded to the heel-strike and toe-off events [16]. Stride time was defined as the time between 2 consecutive heel strikes of the same foot, which was calculated by determining the number of data points between 2 heel strikes and dividing by 100-Hz sampling frequency. The step length was estimated using a simple inverted pendulum model, which uses the participant's leg length (l) and the change in height of the smartphone's vertical position over each step (h) as the following equation:

$$(1)\text{Step length}=2*2*h*l-h2$$

In particular, the vertical position was derived by doubly integrating the vertical acceleration data (z-axis) and high-pass filtering the outcome using a fourth-order zero-lag Butterworth filter with a 0.11-Hz cutoff frequency to remove any integration drift [12,23]. The fourth order of the filter ensures effective attenuation of frequencies below 0.11 Hz, substantially reducing low-frequency drift caused by noise in the acceleration data. Additionally, the zero-lag design of the Butterworth filter preserves the temporal accuracy of the signal, ensuring precise alignment of the filtered output with the real-time events being measured. Gait speed for each stride was then calculated by dividing stride length (ie, step length multiplied by 2) by the corresponding stride time. Gait variables thus included step length and gait speed from both GAITRite mat and smartphone app data were used for the statistical analyses.

The Step Length Adjustment Process

After calculating the validity of the gait speed and step length derived from the smartphone app and GAITRite (see Statistical Analysis section), we observed a bias between smartphone app and GAITRite measurements for both gait speed and step length across all participants, walking conditions, and laboratory trials. That is, as the step length (average of the smartphone app and GAITRite mat measurement) increased, the step length derived from the app became increasingly greater than the corresponding values derived from the GAITRite mat. This trend was independent of the walking condition and study visit order (Figures 1A and 2A). To address this, we systematically tested various intervals, starting from 0.1, 0.15, 0.2 m, and all the way up to 0.5 m, with a 0.05-m increment, for adjusting the step length. Our analysis revealed that an interval of 0.3 m consistently produced the best validity, evidenced by a slope of 1 and an intercept close to 0 m in the relationship between our adjusting measurements and those from the GAITRite mat. These findings indicate a robust linear correlation and minimal systematic bias. This method was designed for its ability to adjust the step length estimation, aiming to align more closely with the gold standard GAITRite measurements, particularly addressing the identified bias across different step lengths. The intervals were chosen based on a detailed stepwise iterative approach, where each interval was evaluated for accuracy and precision. This approach allowed us to capture the nonlinear relationship between the app-derived and GAITRite-derived step lengths across the range of observed values (Table 1).

$$(2)\text{Adjustedsteplength}=\text{coefficients}*\text{steplength}$$

Figure 1. The solid lines are the average difference, and the dashed lines are the limit of agreements (SD 1.96).

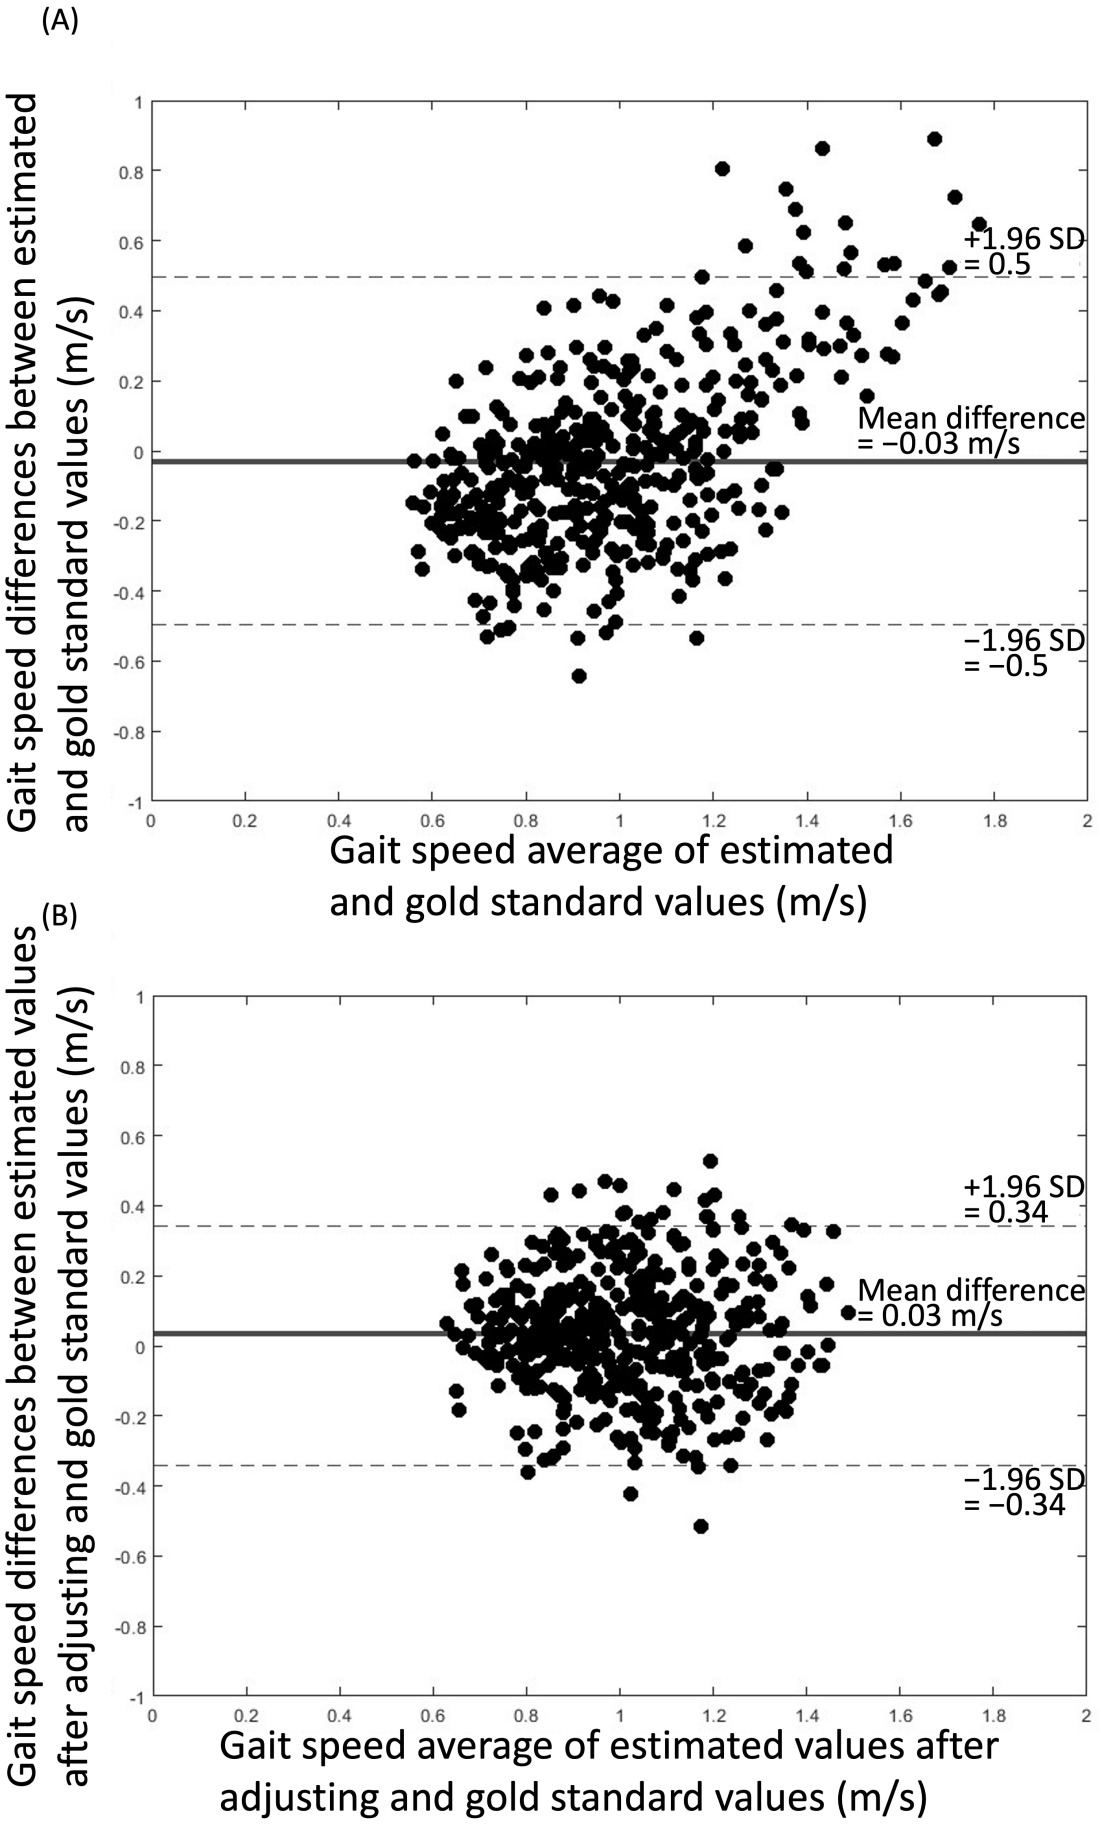

Figure 2. Bland-Altman plot for step length when using the smartphone app–based assessment compared to GAITRite mat before (A) and after (B) adjusting by coefficients relative to the original estimation of step length. The solid lines are the average difference, and the dashed lines are the limit of agreements (SD 1.96).

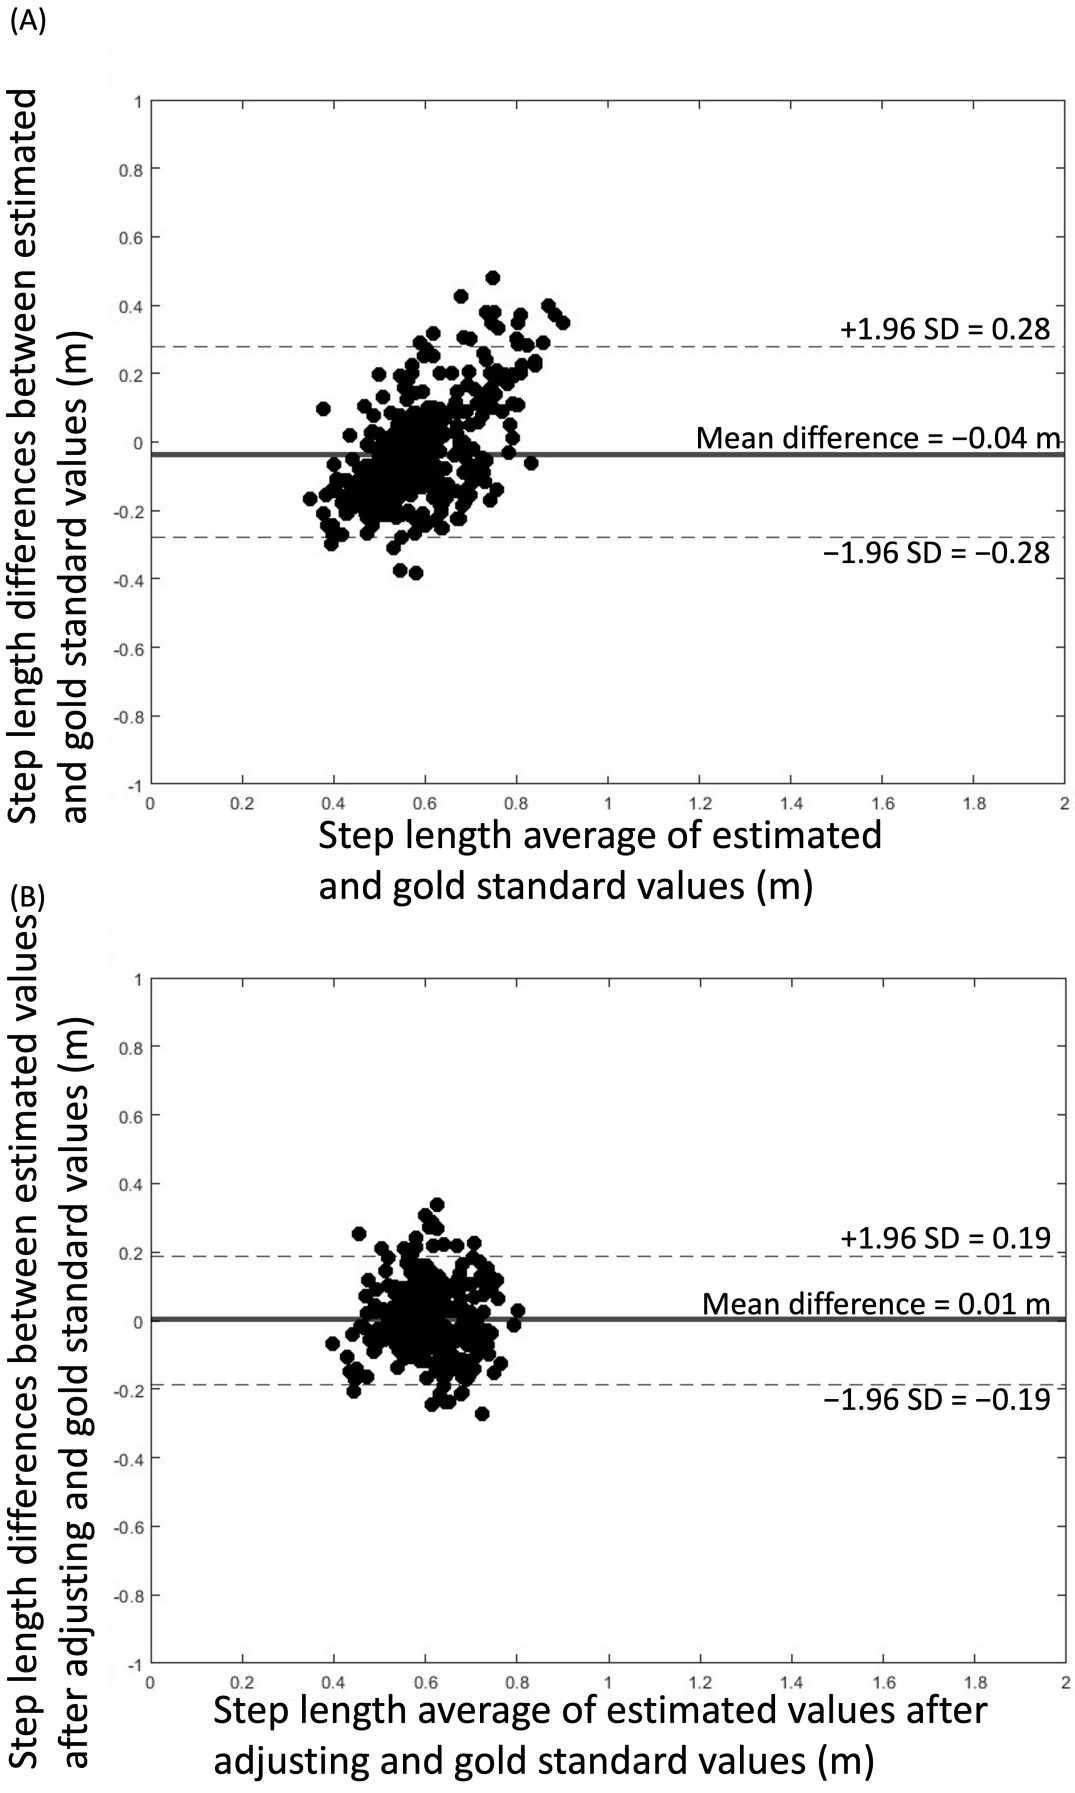

Table . Coefficients that were used to adjust step length and gait speed.

		Step length 0.2 - 0.5 m	Step length 0.5 - 0.8 m	Step length 0.8 - 1.1 m
Coefficients				
	All data points	1.37	1.02	0.74
	Only normal walking data points	1.40	1.04	0.74
	Only dual-task walking data points	1.36	1.01	0.73

Statistical Analysis

The validity of app-derived gait speed and step length was examined by estimating their agreement with corresponding gait data derived from the gold standard GAITRite mat using a Passing-Bablok orthogonal regression model, which is suitable for comparing different measurement methods while acknowledging measurement error [24]. This statistical method was chosen for its robustness in comparing methods with measurement error, providing a more accurate assessment of agreement between different measurement systems. Initial sources and seminal works on the Passing-Bablok regression model highlight its suitability for medical and biomechanical research applications [24]. The magnitude of error between the gait data from the app and the GAITRite mat was calculated for each stride, and a Bland-Altman plot was produced to visualize this error as a function of gait data, which was the average of the gait speed calculated by the app and the GAITRite mat. Test-retest reliability was assessed for all derived gait parameters from both the smartphone app and GAITRite mat using several intraclass correlation coefficients (ICCs). For each of the following two conditions, we computed ICC separately for normal and dual-task walking trials: (1) across trials within each laboratory assessment, and (2) across trials over the 3 home assessments. The unit of interest was the average gait speed in strides derived from each trial of the same condition (ie, normal or dual-task walking; ICC (1, 1)). We considered ICC values greater than 0.75 as excellent reliability, 0.6 - 0.75 as good reliability, 0.4 - 0.6 as fair reliability, and less than 0.4 as poor reliability [25].

Results

Overview

In total, 12 healthy young adults (6 female adults and 6 male adults; age: mean 29.1, SD 4.4 years; height: mean 168.7, SD 13.1 cm; and body mass: mean 74.0, SD 13.9 kg) and 12 healthy older adults (8 female adults and 4 male adults; age: mean 72.0, SD 6.4 years; height: mean 165.6, SD 9.0 cm; and body mass: mean 71.6, SD 16.3 kg) participated in the study.

A total of 24 participants completed 96 passes over the GAITRite mat with the phone placed in their pocket during the laboratory visits. Each session comprised 2 normal walking trials and 2 dual-task walking trials, yielding 4 - 5 strides per trial for each participant. This resulted in a data set comprising a total of 442 strides for direct comparison of gait speed, step length, and stride time estimations between the GAITRite mat and smartphone app approaches. Average normal and dual-task gait speeds for the younger and older groups are presented in Table 2.

Table . Means (SDs) and minimum (min)-maximum (max) of the spatiotemporal parameters during normal and dual-task walking in the younger and older groups.

Validity and Reliability of the Original Estimated Gait Speed and Step Length

Average normal and dual-task gait speeds within each group, as estimated from the smartphone app, were largely similar to those derived from the GAITRite mat (Table 2). Smartphone-derived gait speed and step length demonstrated good validity as compared with the GAITRite mat. The close-to-zero average magnitude of biases for gait speed and step length was −0.03 m/s and −0.04 m, and the limits of agreement were 0.5 m/s and 0.28 m, respectively (Figures 1A and 2A). Orthogonal regression analysis revealed that the slope and intercept of the gait speed and step length derived from the app were 1.68 (intercept=−0.70) and 2.37 (intercept=−0.86), respectively (Figures 3A and 4A).

Figure 3. Relationship between gait speed as derived from a smartphone app–based assessment and from a GAITRite mat before (A) and after (B) adjusting by coefficients relative to the original estimation of step length. The Passing-Bablok orthogonal best-fit line of these data had a slope of approximately 1 and an intercept of 0 after adjusting.

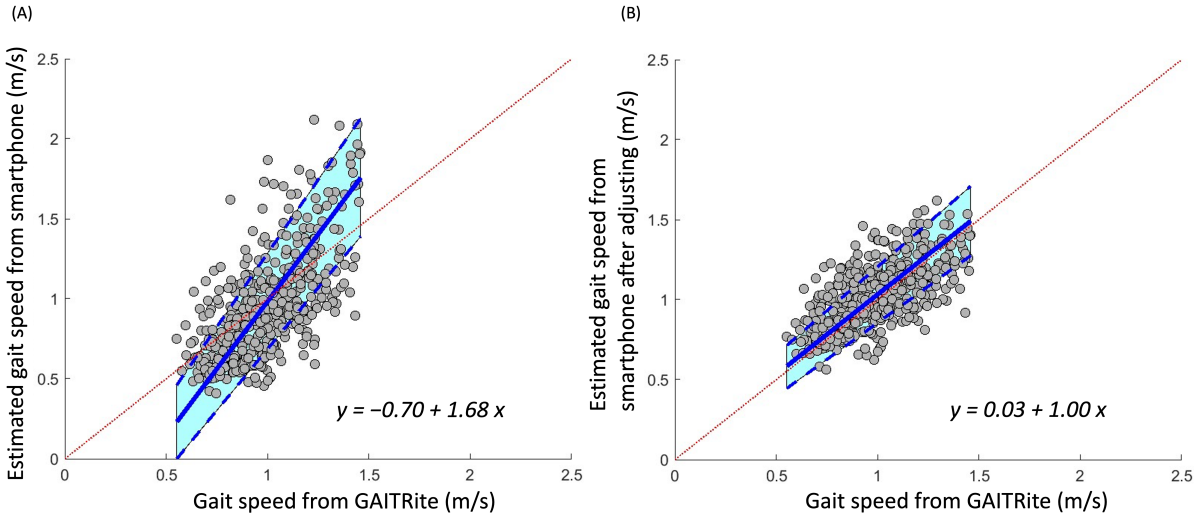

Figure 4. Relationship between step length as derived from a smartphone app–based assessment and from a GAITRite mat before (A) and after (B) adjusting by coefficients relative to the original estimation of step length. The Passing-Bablok orthogonal best-fit line of these data had a slope of approximately 1 and an intercept of 0 after adjusting.

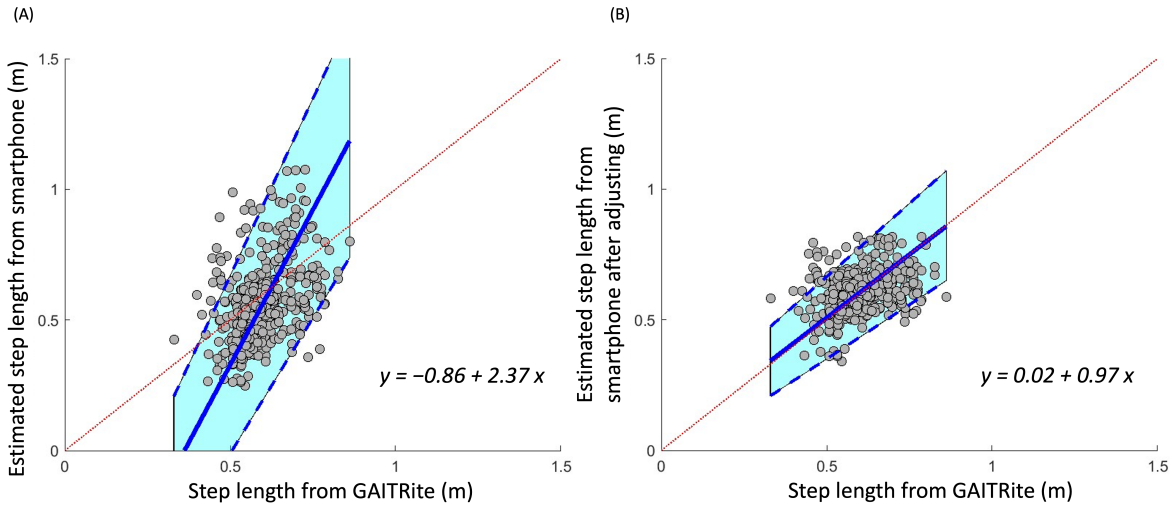

Good to excellent test-retest reliabilities (0.64 - 0.86) were demonstrated for the average app-derived gait speed across trials within each laboratory assessment, as well as over the 3 home assessments, for both normal and dual-task walking in young and older adults (Table 3).

Table . Test-retest reliability of the laboratory- and home-based assessments of average gait speed in strides.

Validity and Reliability of Smartphone-Derived Gait Speed After Adjusting Step Length by a Coefficient Relative to the Original Estimation of Step Length

After iteratively calculating the validities and reliabilities of the different step length zone thresholds as intervals, results indicated that 0.3 as an interval appeared to produce the best validity (Table 4). After adjusting step length with this coefficient relative to the original estimation of step length, the average gait speed in the younger group during normal and dual-task walking was 1.13 (SD 0.12) and 1.01 (SD 0.14) m/s, respectively; and the average gait speed in older group during the 2 conditions was 1.04 (SD 0.11) and 1.01 (SD 0.11) m/s, respectively (Table 2). These adjusted estimations of gait speed and step length derived from the smartphone app demonstrated a considerably smaller bias trend compared to the original estimated data (Figures 1 and 2). For gait speed and step length, mean differences were 0.03 m/s and 0.01 m, and limits of agreement were 0.34 m/s and 0.19 m, respectively (Figures 1B and 2B). Orthogonal regression analysis revealed that the validity of gait speed and step length derived from the app were higher with those measured by the GAITRite mat after adjusting, as indicated by one and close-to-one slopes, which were 1.00 (intercept=0.03) and 0.97 (intercept=0.02), respectively (Figures 3B and 4B).

Table . The slope and intercept for the Passing-Bablok orthogonal best-fit line after adjusting using stepwise iterative approach to define different step length zones by dividing the original estimation of step length using multiple zone thresholds as intervals from 0.1 to 0.5.

Intervals	Slope	Intercept
0.10	0.97	0.23
0.15	0.86	0.16
0.20	0.91	0.12
0.25	1.00	0.04
0.30	1.00	0.03
0.35	1.13	−0.09
0.40	1.23	−0.18
0.45	1.35	−0.28
0.50	1.40	−0.34

In general, the test-retest reliability of adjusted estimations of gait speed was good to excellent (0.62 - 0.76) between laboratory assessments, and between home assessments, for both normal and dual-task walking in the younger and older groups (Table 3).

Discussion

This study indicated that using a smartphone app placed in the front pocket of an individual's pants or shorts can produce valid estimates of gait speed under both normal and dual-task walking conditions in healthy younger and older adults. Moreover, we demonstrated that the accuracy of gait speed estimation using the inverted pendulum model approach can be improved by adjusting the estimated values with coefficients determined by the gold standard measurement of step length. This improved smartphone app–based approach provided high test-retest reliability within a supervised laboratory environment and within the unsupervised home setting.

The current results revealed that the pendulum model approach to calculating gait speed from a single IMU placed in the pocket overestimated step length and therefore gait speed if the step length derived from the GAITRite mat was greater than 0.8 m, yet underestimated both values if the step length was less than 0.5 m. Through visual inspection of published work, it appears that this observed bias in step length estimation is common, even when the IMU is secured to the participant's trunk [13,15]. To our knowledge, however, no one has reported this observation, and no adjustment has been made to correct the bias.

Our work suggests that a simple adjustment of step length for those steps that are relatively short, or relatively long, removes the observed bias and improves the accuracy of gait speed estimation. The current results suggested that the original estimated step length from the smartphone app between 0.5 and 0.8 m may not need to be adjusted as its coefficient was close to 1. Comparing our smartphone app with gold standard measurements, it is evident that in scenarios involving normal or dual-task walking, the app maintains robust performance with small bias across younger and older groups, different walking conditions, and different testing settings (laboratory and home). This implies that the described method can be used accurately within numerous applications. The simple inverted pendulum model requires only 2 pieces of information, namely, the participant's leg length and the change in height of the smartphone's vertical position during each step (from heel strike to contralateral heel strike). We suspect that several factors may contribute to the observed bias. There may be nonlinear relationships between step length and the combinations of changes in the height of the smartphone's vertical position and leg length. This could indicate inherent limitations in the inverted pendulum model. Exploring these factors further may thus offer insights into optimizing the model for different IMU locations and gait patterns, enhancing the applicability of our method across diverse populations and conditions.

The results from this study not only reinforce the reliability of the approach to estimate gait speed under different walking conditions in ambulatory older adults without overt disease but also suggest its applicability to all IMU data. Good to excellent test-retest reliability of results was observed across younger and older groups, different walking conditions (normal walking and dual-task walking), and different testing settings (laboratory and home). This implies that the described method can be used effectively within numerous applications. Moreover, the test-retest reliability observed in this study was noticeably higher than a previous report that used the pendulum model without adjustment [15]. Incorporating a wide range of ages from young to old in this study allowed us to encompass a broader spectrum of gait speeds and step lengths, which enhanced the generalizability of our findings. The observed consistency in the adjustment coefficients across these age groups suggests that the pendulum model approach we used is robust and applicable across a diverse age demographic. This inclusivity in our research approach enriches its relevance and widens its potential impact, thus making our findings more applicable in real-world scenarios where age-related variations in gait are common.

The coefficients established from our cohort may be applicable to other data sets where the populations and the settings of the devices (smartphone), including sampling rate, are similar; yet, the coefficients may need to be fine-tuned for different populations and devices, especially when a gold standard measurement is available. Our coefficients performed well in our data set, which involved a wide range of step length and

gait speed in both healthy young and older populations. In terms of future application to other data sets, this method holds significant potential for various areas. For data sets where a gold standard method is unavailable, our coefficients are worth trying to adjust the original estimated value. If the population (ie, healthy young and healthy older adults) and tool (ie, a smartphone app in the pants pocket) are similar to that tested and used in this study, implementing this type of adjustment is expected to improve the accuracy and reliability of the estimates. For data sets where a gold standard is available, researchers are recommended to develop their own coefficients based on the unique characteristics of each data set, thereby improving the method's precision and applicability to specific contexts.

Further research is required to determine the generalizability of our method to broader populations, especially in cases where a gold standard method is not available. The original step length estimations in this study were classified into 3 categories, which may decrease the test-retest reliability of those step length data close to the margin of categories. To address this, larger data sets are needed to establish a continuous adjustment approach without the need to classify the data into categories. Additionally, refining the inverted pendulum model to better accommodate the nonlinear relationship between step length and smartphone vertical displacement could enhance accuracy. The applicability of the method to individuals with abnormal gait patterns should also be explored. Despite these limitations, this study provided evidence that gait speed can be accurately and reliably estimated with minimum information (leg length) in young and older adults during normal and dual-task walking based upon a single IMU-embedded smartphone placed in the pocket.

Abstract

Background: A distal radius fracture (DRF) is a common initial fragility fracture among women in their early postmenopausal period, which is associated with an increased risk of subsequent fractures. Gait assessments are valuable for evaluating fracture risk; inertial measurement units (IMUs) have been widely used to assess gait under free-living conditions. However, little is known about long-term changes in patients with DRF, especially concerning daily-life gait. We hypothesized that, in the long term, the daily-life gait parameters in patients with DRF could enable us to reveal future risk factors for falls and fractures.

Objective: This study assessed the spatiotemporal characteristics of patients with DRF at 4 weeks and 6 months of recovery.

Methods: We recruited 16 women in their postmenopausal period with DRF as their first fragility fracture (mean age 62.3, SD 7.0 years) and 28 matched healthy controls (mean age 65.6, SD 8.0 years). Daily-life gait assessments and physical assessments, such as hand grip strength (HGS), were performed using an in-shoe IMU sensor. Participants' results were compared with those of the control group, and their recovery was assessed for 6 months after the fracture.

Results: In the fracture group, at 4 weeks after DRF, lower foot height in the swing phase (P=.049) and higher variability of stride length (P=.03) were observed, which improved gradually. However, the dorsiflexion angle in the fracture group tended to be lower consistently during 6 months (at 4 weeks: P=.06; during 6 months: P=.07). As for the physical assessments, the fracture group showed lower HGS at all time points (at 4 weeks: P<.001; during 6 months: P=.04), despite significant improvement at 6 months (P<.001).

Conclusions: With an in-shoe IMU sensor, we discovered the recovery of spatiotemporal gait characteristics 6 months after DRF surgery without the participants' awareness. The consistently unchanged dorsiflexion angle in the swing phase and lower HGS could be associated with fracture risk, implying the high clinical importance of appropriate interventions for patients with

DRF to prevent future fractures. These results could be applied to a screening tool for evaluating the risk of falls and fractures, which may contribute to constructing a new health care system using wearable devices in the near future.

Introduction

Gait analysis is useful for predicting future fall risk and reflecting various underlying physiological processes [1]. Quantitative gait characteristics, such as slower gait speed and shorter stride length, are associated with falls, resulting in fragility fractures [2-4]. Recently, inertial measurement units (IMUs) have been widely used to assess gait under free-living conditions owing to their convenience, low cost, small size, and high accuracy [5-7]. The shank and foot are the preferred placements [8,9], and foot kinematics is an important factor related to falls and physical ability [4].

Among fragility fractures resulting from falls, distal radius fractures (DRFs) are one of the most frequent initial fractures in older adults [10]. Many DRFs occur in women in their postmenopausal period, aged <75 years, who are healthy, active, and functionally independent. More than half of these women do not meet the criteria for osteoporosis [11-13]. However, the initial DRF is associated with a greater risk of functional decline [14] and subsequent fractures [15] in all age groups. These changes are more than 5 times higher, even in those aged 50-59 years [16]. This could reflect early changes in frailty [17].

In patients with DRF, lower gait ability was observed in the laboratory, which slightly improved 6 months after the surgery [13,18]. However, these gait assessments were mainly performed for approximately 10 seconds, which may not accurately depict daily-life gait [19]. Further, most studies have only highlighted the consequences of wrist function and pain when investigating the long-term outcomes of DRF, and little is known about the effect of DRF on physical abilities, such as activities of daily living. Therefore, the long-term alterations of daily-life gait characteristics in patients with fractures remain unknown, and this study attempts to bridge this gap.

We previously found out that in-shoe IMU sensors were effective in the assessment of daily-life gait in patients with an initial DRF [7]. We hypothesized that, in the long term, it could enable us to identify future risk factors for secondary fractures by spatiotemporally following daily-life gait parameters using IMU sensors. We aimed to reveal the characteristics of spatiotemporal gait changes during 6 months following DRF.

Methods

Ethical Considerations

This study was approved by the Institutional Review Board of Tokyo Medical and Dental University (M2020-365) and followed the tenets of the Declaration of Helsinki. Written informed consent was provided by all participants. Participation in the study was voluntary, and no compensation was awarded for participation.

Recruitment

In the fracture group, we recruited 16 female patients with DRF who had undergone surgery for their first fragility fracture from 5 general hospitals. We compared their results to those of 28 healthy female volunteers. Women without a history of fragility fractures were recruited as the control group through local media advertisements. The inclusion criteria involved having the ability to walk without any support, no history of lower-extremity injury, and no known neuromuscular disorders or neurophysiological problems that may affect gait. Fragility fractures were defined as those that followed a fall from standing height or less. We excluded patients with DRF due to traffic or industrial accidents or multiorgan injuries. In the fracture group, 6 patients with DRF fell in the house without shoes, and the other 10 patients fell while wearing shoes. Owing to the lack of previous literature on the long-term data of gait in patients with DRF, the sample size estimations were based on the effect size of 0.78 (from the result of hand grip strength [HGS]) [13], with an assumed power of 0.8 and a type I error of 0.05. A sample of 16 participants with fractures was analyzed using G*Power (version 3.1; Heinrich Heine University Duesseldorf) [20].

Daily-Life Gait Assessments

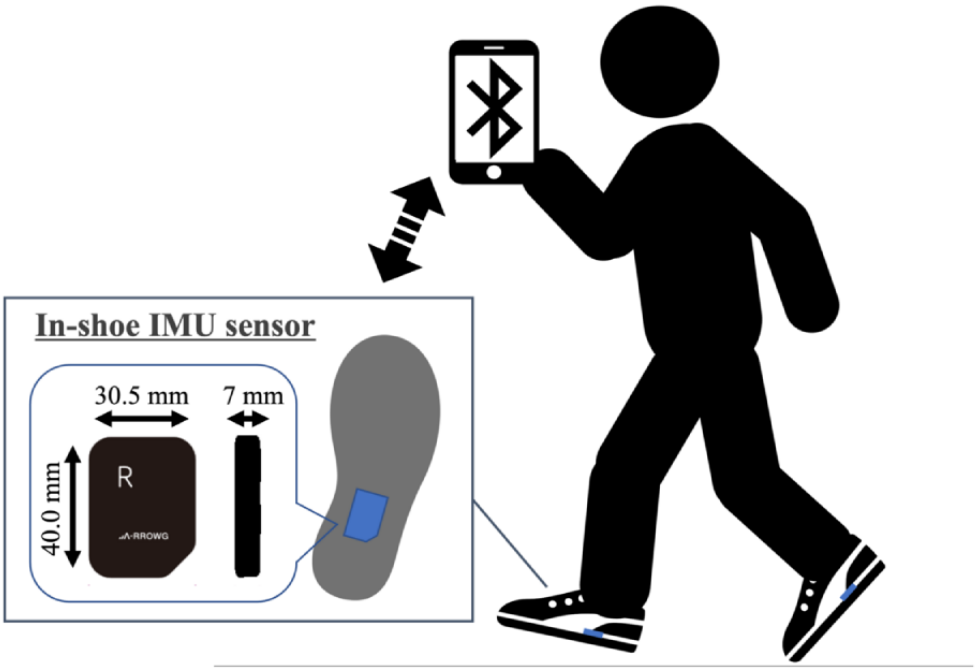
We measured daily-life gait using in-shoe IMU sensors (A-RROWG, NEC Corporation; Figure 1). These sensors are small (40.0 mm × 30.5 mm × 7 mm) and lightweight (11 g), including a 3-axis accelerometer and gyroscope. The IMU sensor in the dedicated insole was placed at the foot arch, and the x-, y-, and z-axes of the IMUs were set along the mediolateral, anteroposterior, and vertical directions, respectively. When a person wearing these sensors walks in a stable straight line over 3 gait cycles between 5 AM and 10 PM, the in-shoe IMU sensor detects that the person is walking based on acceleration in the anteroposterior direction and saves the IMU signals of the next 3 gait cycles as 1 gait measurement [21]. The IMU signals were sampled at a rate of 100 Hz, transferred to a smartphone via Bluetooth, and stored in a specialized app if participants had one with them. If a person did not have a smartphone, the data were uploaded automatically via Bluetooth at 11 PM by keeping the smartphone near the IMU sensors.

From the saved IMU signals, the mean of 7 gait parameters from 3 gait cycles was calculated and stored on a smartphone, as previously described by Fukushi et al [21]. The following 7 parameters were calculated:

1. Gait speed: calculated as stride length (m) divided by stride time (s).
2. Stride length: the distance between the start and end points of the foot trajectory for 1 stride.
3. Dorsiflexion angle: the peak foot angle in the dorsal direction from the ground during the swing phase.
4. Plantarflexion angle: the peak foot angle in the plantar direction from the ground during the swing phase.
5. Foot height: the maximum height of the foot trajectory.
6. Toe-in or toe-out angle: the mean angle of foot adduction or abduction in the direction of the velocity vector during the swing phase.
7. Circumduction: the displacement in the medial-lateral direction during the swing phase.

In addition to these 7 gait parameters, the coefficient of variation (CV), calculated as SD divided by mean multiplied by 100, was used to evaluate the variability.

Figure 1. The in-shoe inertial measurement unit (IMU) sensor. The sensors with accelerometer and gyroscope were set into the dedicated insoles, measured the daily-life gait without the participants' awareness, and saved the obtained data to their smartphone via Bluetooth.



Measurement Protocol

All participants completed a paper-based questionnaire on their general health status, which included fall history in the past year, frequency of stumbling, and fear of falling. Falls at the time of fracture in patients with DRFs were excluded based on the number of falls in the past year.

In the daily gait assessments, we inserted IMU sensors with dedicated insoles into the preferred shoes of both participants' feet. Each participant was provided a smartphone with only the original app for storing gait data. We verified whether participants could walk using the sensors and whether the sensors worked with a smartphone. Participants were instructed to wear shoes with sensors for 2 to 6 weeks. We requested that participants spend their daily lives as usual; therefore, we did not establish a minimum time for wearing or walking with them. The measurements were recorded without the participants' awareness, and they could view their most recent gait data by checking their smartphone. In the fracture group, daily gait assessments in the early postoperative period started 2 weeks after DRF surgery to enable the effects of casting or surgery.

To assess baseline functional ability and frailty, HGS [22] and the Timed Up and Go (TUG) test [23] were performed. HGS was measured in kilograms with a Jamer dynamometer (Sammons Preston). We assessed HGS on the nonfractured side of the fracture group and both sides of the control group. The mean values of 3 measurements were recorded. The time to complete the TUG test was recorded twice: once at the preferred speed and once at the fastest speed. These baseline physical tests were performed 4 weeks after DRF surgery in the fracture group and at the beginning of daily gait measurements in the control group.

To check for long-term functional ability, we asked the fracture group patients to perform the same physical and daily gait assessments again at an outpatient visit 6 months after the surgery.

Data Analysis

The median and CV of each participant were calculated using the obtained gait data. However, the automatically collected data included hills, turns, and straddling, and we used Smirnov-Grubbs analysis for every gait parameter to exclude any outliers from the data. After exclusion, approximately 20-1000 gait measurements were recorded for each participant during the measurement period, reflecting differences in their lifestyles. Even after the exclusion, gait data included various gait types, such as walking exercise and hurried walking; therefore, we excluded participants with less than 50 gait measurements in either foot, based on a previous report [24]. Since we computed the data obtained from both feet together,

we selected participants with 100 or more gait assessments for this study.

Statistical Analysis

Between-group differences were assessed using Student *t* test (2-tailed) for continuous variables in the patient demographics, and the chi-square test for categorical variables. Since the participants' gait data were not normally distributed, they were assessed using nonparametric (ie, Kruskal-Wallis and Steel) tests. The results of the fracture group in the early postoperative and long-term periods were compared using a paired *t* test. Statistical significance was set at $P<.05$.

These analyses were performed using EZR (version 1.55; Division of Haematology, Saitama Medical Center, Jichi Medical University) [25].

Results

Participants' Demographics

There were no significant differences in age, body characteristics, or lifestyle variables between the 2 groups. In the section on questions about falls, patients with fractures demonstrated a significantly higher incidence of falls (Table 1). None of the fracture group members experienced falls or subsequent fractures after the initial DRF.

Table 1. Participants' demographics. *P* values <.05 are considered significant.

Spatiotemporal Data in Daily-Life Gait

The results of the spatiotemporal daily-life gait are presented in Table 2. There were no between-group differences in the number of measurements. Compared with the control group, the dorsiflexion angle measured at any time postoperatively in the fracture group tended to be lower and demonstrated no improvement in the postoperative course. Participants in the fracture group demonstrated significant recovery in gait speed, stride length, and plantarflexion angle between 4 weeks and 6

months postoperatively. Among the CV of each gait parameter, only the CV of stride length between the control group and the 4 weeks–postfracture group demonstrated a significant difference.

Table 2. Daily-life spatiotemporal data. *P* values <.05 are considered significant.

Characteristics	Control group (n=28)	Fracture group (n=16)		*P* value			
		4 weeks after surgery	6 months after surgery	Kruskal-Wallis test	Control (at 4 weeks)	Control (at 6 months)	Control (4 weeks to 6 months)

[b]Steel test was used to compare each group.

[c]Paired sample *t* test was used for analysis between the groups.

[d]CV: coefficient of variation.

HGS and Body Balancing Ability

The HGS in the fracture group demonstrated significant recovery between 4 weeks and 6 months after surgery; however, it was significantly lower in the fracture group compared to the control group. In the TUG test, there were no significant differences between the control and fracture groups or at 4 weeks and 6 months postoperatively in the fracture group (Table 3).

Table 3. Physical tests in the control and fracture groups. *P* values <.05 are considered significant.

Characteristics	Control group (n=28)	Fracture group (n=16)		*P* value			
		4 weeks after surgery	6 months after surgery	Kruskal-Wallis test	Control (at 4 weeks)	Control (at 6 months)	Control (4 weeks to 6 months)
Hand grip strength (kg), mean (SD)	23.3 (3.4)	19.1 (2.6)	20.6 (3.1)	<.001[a]	<.001[b]	.04[b]	<.001[c]
TUG[d] test (s), mean (SD)							
Normal speed	8.07 (1.33)	7.53 (0.85)	8.2 (1.28)	.28[a]	.29[b]	.96[b]	.13[c]

[b]Steel test was used to compare each group.

[c]Paired sample *t* test was used for analysis between the groups.

[d]TUG: Timed Up and Go.

Discussion

Principal Results

We performed daily-life gait assessments with in-shoe IMU sensors and some physical tests, including HGS, to evaluate the differences in spatiotemporal gait and physical ability between patients with DRF and healthy controls. Moreover, we assessed whether these parameters improved during 6 months following DRF. In daily-life gait assessments, patients with DRF demonstrated a lower foot height and higher CV stride length compared to the control group; however, these differences were no longer present 6 months after DRF surgery, reflecting the improvement in some parameters in the fracture group after 6 months of DRF treatment. On the other hand, the dorsiflexion angle in the fracture group tended to be lower consistently during 6 months. In the physical assessments, patients with DRF at 4 weeks and 6 months after the surgery had significantly lower HGS than those without DRF, even though HGS in patients with DRF improved during 6 months.

Some gait parameters, such as gait speed and stride length, improved in the fracture group during 6 months of daily life. Further, the CV of stride length, which is associated with fall risk [26], was higher in the fracture group at 4 weeks after DRF and did not significantly change after 6 months. With the development of wearable sensors, spatiotemporal gait characteristics and their variability in daily life have been increasingly identified. However, few studies have explored the long-term changes in gait characteristics related to falls and fractures. As daily-life gait is influenced by various factors, such as environmental and psychiatric factors [27], changes in patients with DRF could reflect changes in their lifestyle. Conversely, the risk of subsequent fractures is the highest immediately after the initial fracture [28]. Although no subsequent fractures occurred in this study, further research is warranted to determine the relationship between gait changes and subsequent fractures. The in-shoe IMU sensor must play an important role in further evaluating this relationship.

The dorsiflexion angle in the fracture group remained lower, whereas other parameters in the fracture group improved during 6 months. As for vertebral fractures, which are typical fragility fractures as well as DRF, patients with symptomatic vertebral fractures walked with shorter and wider strides at the time of injury. Although those with vertebral fractures show improvement in stride time and stride length over time, even reaching healthy levels again, their gait pattern and stability persist for 6 months, implying a greater risk of incident disability among these patients [29]. Since gait speed is reported to affect other gait parameters, the persistent lower dorsiflexion angle in the fracture group, despite the improvement in gait speed, might be a characteristic of patients with DRF, indicating that patients cannot fully return to healthy states. The dorsiflexion angle in this study, which means the angle between the ground and the sole of the foot, may depend on the movement of all lower extremities. Kyphosis and flexed hip or knee joints, which are common in older people, are related to foot movement or strength [30]. Although further research is needed to determine the cause of this decrease in dorsiflexion angle, the angle could result in stumbling and falls. Older adults with DRF can be assessed as having a high risk of functional decline, particularly those who have access to a health care facility at an early stage. They should receive appropriate intervention to prevent future falls or fractures along with treatment for the initial fracture. Considering that several previous reports have assessed fall risk using machine learning based on gait data from fallers [31,32], our results could be effective in creating a more precise machine learning model for evaluating the risk of falls. Further research is warranted to explore not only the cost of developing sensors and apps but also intervention methods and the extent of fall reduction achievable. Nonetheless, our findings using in-shoe IMU sensors outside the hospital could be valuable for future screening tools to evaluate the risk of falls and fractures.

As for physical assessments, the HGS in the fracture group significantly improved during 6 months after DRF, which is consistent with a previous report [13]. The increased use of the nonaffected hand with DRF in daily life may improve HGS; however, most studies on DRF have focused on the HGS of the affected side, and little is known about that of the nonaffected side. Generally, HGS is associated with health status, including death, falls, and muscle strength [33]. The improvement in HGS could reflect the improvement in health status, and the lower HGS after 6 months of DRF could be associated with a lower

degree of health status in the fracture group. Contrastingly, there were no differences in the TUG test results, contrary to our previous reports [13,18]. The average TUG test time in both the fracture and control groups in this study was faster compared to previous studies, which may mean that the TUG test, which involves a few steps and seconds in the laboratory, may not reflect the true physical characteristics. Therefore, daily-life gait analysis for a certain period is needed to identify the slight difference between fracture group patients and healthy controls. By using this in-shoe sensor for a certain period, the lower dorsiflexion angle in patients with DRF was revealed, which remained 6 months after the fracture. We would like to further investigate long-term changes in the gait of these patients.

Limitations

This study had some limitations. First, the number of participants was small, which could have affected the power of this study. However, individual changes over 6 months appeared to confirm the statistical outcomes and might not have affected the overall conclusions of our study. Second, we observed progress up to 6 months after the fractures. The HGS on the affected side continued to improve beyond 1 year. Long-term changes in more patients with DRF should be further explored. Third, the participants were all Japanese, who had the habit of taking off their shoes indoors. Considering that 6 patients with DRF fell inside their houses without shoes, the results may not accurately reflect the daily free-living assessments of barefoot individuals.

Conclusions

In summary, we performed a case-control study to investigate the long-term changes in HGS and daily-life gait after DRF. Using an in-shoe IMU sensor, we revealed the recovery of spatiotemporal gait characteristics 6 months after DRF surgery without the participants' awareness. The dorsiflexion angle in the swing phase and HGS were still lower in the fracture group after 6 months, which could be associated with fracture risk. This in-shoe IMU sensor could be useful for evaluating the future fall and fracture risk outside the hospital and for constructing a new health care system related to preventive medicine using wearable devices outside the hospital.

Acknowledgments

This study was supported by the Japan Society for the Promotion of Science (JSPS) KAKENHI (grant 21K17469) and joint research funding from NEC Corporation. We would like to thank Masahiro Fujimoto, Kanako Nakajima, Shoma Kudo, and Gaku Kutsuzawa for collecting data; Hiroshi Kajitani for collecting data and software development; Akimoto Nimura, Hidetoshi Kaburagi, and Takafumi Koyama for critical analysis and proofreading; and Editage for English language editing.

Conflicts of Interest

KF has received joint research funding from NEC Corporation. FN and KN are employees of NEC Corporation.

Abstract

Background: Postpartum depression (PPD) poses a significant maternal health challenge. The current approach to detecting PPD relies on in-person postpartum visits, which contributes to underdiagnosis. Furthermore, recognizing PPD symptoms can be challenging. Therefore, we explored the potential of using digital biomarkers from consumer wearables for PPD recognition.

Objective: The main goal of this study was to showcase the viability of using machine learning (ML) and digital biomarkers related to heart rate, physical activity, and energy expenditure derived from consumer-grade wearables for the recognition of PPD.

Methods: Using the *All of Us* Research Program Registered Tier v6 data set, we performed computational phenotyping of women with and without PPD following childbirth. Intraindividual ML models were developed using digital biomarkers from Fitbit to discern between prepregnancy, pregnancy, postpartum without depression, and postpartum with depression (ie, PPD diagnosis) periods. Models were built using generalized linear models, random forest, support vector machine, and k-nearest neighbor algorithms and evaluated using the κ statistic and multiclass area under the receiver operating characteristic curve (mAUC) to determine the algorithm with the best performance. The specificity of our individualized ML approach was confirmed in a cohort of women who gave birth and did not experience PPD. Moreover, we assessed the impact of a previous history of depression on model performance. We determined the variable importance for predicting the PPD period using Shapley additive explanations and confirmed the results using a permutation approach. Finally, we compared our individualized ML methodology against a traditional cohort-based ML model for PPD recognition and compared model performance using sensitivity, specificity, precision, recall, and F_1-score.

Results: Patient cohorts of women with valid Fitbit data who gave birth included <20 with PPD and 39 without PPD. Our results demonstrated that intraindividual models using digital biomarkers discerned among prepregnancy, pregnancy, postpartum without depression, and postpartum with depression (ie, PPD diagnosis) periods, with random forest (mAUC=0.85; κ=0.80) models outperforming generalized linear models (mAUC=0.82; κ=0.74), support vector machine (mAUC=0.75; κ=0.72), and k-nearest neighbor (mAUC=0.74; κ=0.62). Model performance decreased in women without PPD, illustrating the method's specificity. Previous depression history did not impact the efficacy of the model for PPD recognition. Moreover, we found that the most predictive biomarker of PPD was calories burned during the basal metabolic rate. Finally, individualized models surpassed the performance of a conventional cohort-based model for PPD detection.

Conclusions: This research establishes consumer wearables as a promising tool for PPD identification and highlights personalized ML approaches, which could transform early disease detection strategies.

Introduction

Background

Postpartum depression (PPD) is the most common complication of childbirth, occurring in approximately 1 in 7 women [1]. PPD can have several implications for women, manifesting in ways such as irritability, mood swings, fatigue, sleep and appetite disturbance, and thoughts of suicide [2]. Undetected PPD has also been shown to have financial implications for affected individuals as it can lead to challenges in maintaining employment or reduced work performance [3]. Furthermore, PPD has been linked to an elevated risk of mood disorders in the child as well as paternal depression [4,5].

Unfortunately, PPD remains significantly underdiagnosed and undertreated, as indicated by the strikingly low treatment rate of only 15% [6]. The current method of diagnosing PPD relies on screening instruments such as the Edinburgh Postnatal Depression Scale (EPDS), Center for Epidemiologic Studies Depression Scale, Patient Health Questionnaire, and Postpartum Depression Screening Scale, where the EPDS is the most commonly used instrument [7]. Often, women also need to undergo blood tests to assess thyroid function as the symptoms of PPD frequently overlap with hyperthyroidism [7]. Due to the challenges in diagnosing PPD, traditional approaches using these screening tools contribute to inadequate screening of women and subsequent underdiagnosis [8,9]. Therefore, the advent of new technologies is greatly needed to enable adequate and, hopefully, earlier detection of PPD.

Digital health tools have been gaining traction in recent years due to the near-ubiquitous ownership of smartphones [10]. Leveraging data passively collected by wearables (ie, digital biomarkers such as the average heart rate [HR], total steps, and calories burned per day) coupled with machine learning (ML) algorithms provides an opportunity to model the relationship between digital biomarkers and a particular disease for early recognition.

Prior Work

Previous studies have demonstrated that ML algorithms using digital biomarkers from smartwatches can predict cardiovascular diseases, infection, diabetes, and mental health conditions [11-14]. For example, one study demonstrated that a wearable device could estimate the changes in the severity of patients with major depressive disorder, where their findings indicated that ML models exclusively using digital biomarkers from wearables achieved moderate performance with correlation coefficients of 0.56 (95% CI 0.39-0.73) and 0.54 (95% CI 0.49-0.59) in the time-split and user-split scenarios, respectively, between model predictions and actual Hamilton Depression Rating Scale scores [15]. Another study recruited individuals with moderate depression for 4 weeks to develop individualized ML models based on digital biomarkers to predict mood. Their findings displayed a correlation between digital biomarkers and depression, as evidenced by high-performing models with a mean absolute error of 0.77 (SD 0.27) points on the 7-point Likert scale, which corresponds to a mean absolute percent error of 27.9% (SD 10.3%) [16]. A study by Wang et al [17] found that students with higher depressive symptoms measured using the 8-item Patient Health Questionnaire were more likely to (1) use their phone at study locations (correlation coefficient [r]=0.39; P<.001) compared to all-day phone use (r=0.28; P=.01), (2) have irregular sleep time (r=0.30; P=.02) and wake time (r=0.27; P=.04) schedules, (3) be stationary for more time (r=0.37; P=.01), and (4) visit fewer places during the day (r=−0.27; P=.02). In addition, students with higher depressive symptoms measured using the 4-item Patient Health Questionnaire scores (1) were around a fewer number of conversations (P=.002), (2) slept for shorter durations (P=.02), (3) fell asleep later (P=.001), (4) woke up later (P=.03), and (5) visited fewer places (P=.003) over the previous 2-week period [17]. Other studies examining the association between digital biomarkers from wearables and depression include those by (1) Moshe et al [18], who demonstrated a negative association between the variability of locations visited and depressive symptoms (β=−.21; P=.04) and a positive association between total sleep time and time in bed and depressive symptoms (β=.24; P=.02); and (2) Rykov et al [19], who showed that a larger variation in nighttime HR between 2 AM and 4 AM (r=0.26; P=.001) and between 4 AM and 6 AM (r=0.18; P=.04) and lower regularity of weekday circadian activity based on steps (r=−0.17; P=.049) were associated with higher severity of depressive symptoms.

Additional research has been conducted related to understanding the relationship between wearable-derived digital biomarkers and PPD. For instance, one study showed that the features most predictive of maternal loneliness, which is commonly associated with PPD, were activity intensity, activity distribution during the day, resting HR, and HR variability [20]. It was also shown that women with milder depression symptoms typically had a larger daily radius of travel compared to those with more severe symptoms (2.7 vs 1.9 miles; P=.04) [21]. Finally, women with depression have been shown to have a lower HR variability (measured using the SD of 24-hour NN intervals, F=6.4; P=.01, and the SD of the averages of NN intervals in 5-minute segments, F=6.04; P=.02) and elevated HR while sleeping (F=5.05; P=.03) compared to women without depression [22].

While these studies highlight a relationship between digital biomarkers and depression or PPD, they suffer from the following limitations: (1) some studies use data in the model that need active patient engagement with partnered mobile apps,

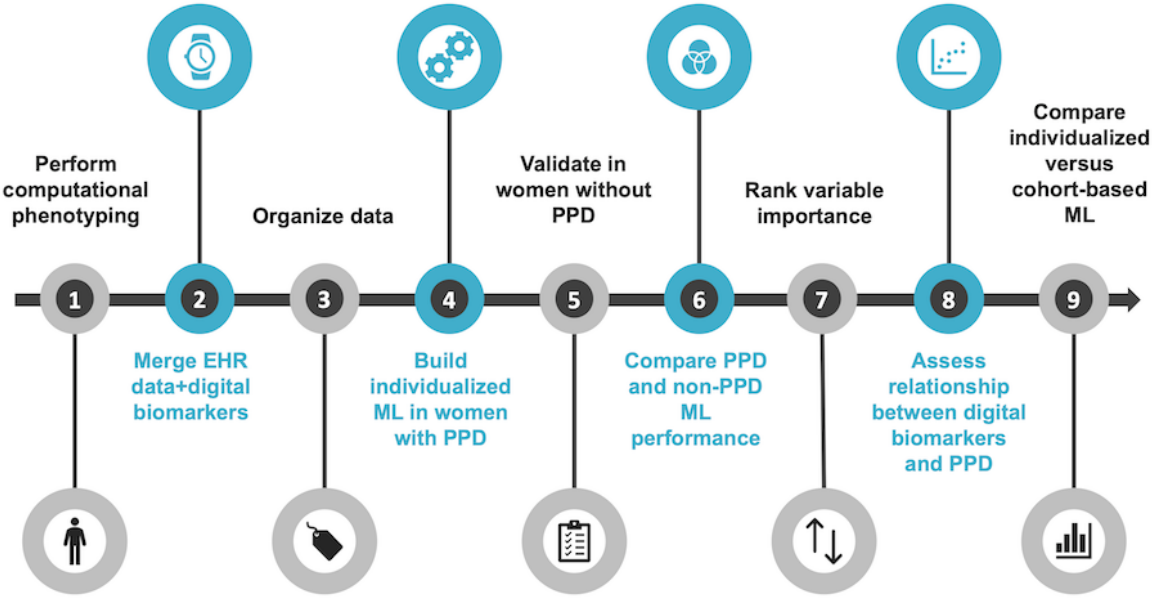
where user retention is known to decrease over time with health-related apps; (2) most studies do not use a predictive framework but rather examine the association between digital biomarkers and depressive symptoms; (3) only one study has developed individualized ML models; (4) most studies analyzing women with PPD have limited time frames and do not capture continuous longitudinal data across different phases of pregnancy; and (5) no studies have developed individualized ML models for women in the postpartum period combining data from wearables and the electronic health record (EHR) [23]. Therefore, a method that provides continuous and personalized monitoring without the need for clinical encounters to enable early detection of mental health disorders, including PPD, is needed.

Goal of This Study

The *All of Us* Research Program (AoURP) is a comprehensive data set that collects several types of health-related data, including surveys, EHRs, physical measurements, and wearable data from Fitbit devices, with an emphasis on patient populations that have been previously underrepresented in biomedical research [24]. Currently, the longitudinal Fitbit data from >15,000 AoURP participants are made available to registered researchers on the *All of Us* Researcher Workbench, providing an opportunity to explore digital biomarkers in a diverse cohort of participants.

It is unknown whether digital biomarkers from consumer wearables can be used to detect PPD. In this study, we combined several orthogonal approaches demonstrating that digital biomarkers can be used for individualized classification of PPD with data collected from Fitbit using the AoURP (Figure 1). This work demonstrated that (1) the integration of data sources, including EHR and wearable data, proves valuable for PPD recognition; (2) using longitudinal and continuous wearable data across various pregnancy phases supports ML model development; and (3) combining these integrated data sources facilitates the creation of individualized ML models, which may outperform cohort-based models. As such, our findings uncovered a novel method for recognizing PPD and serve as a framework that can be leveraged to facilitate early PPD detection. Moreover, the significance of this research underscores the promise of individualized ML models for detecting PPD, which can be applied to other mental health disorders.

Figure 1. An overview of the analysis workflow to evaluate the potential for digital biomarkers in postpartum depression (PPD) recognition. (1) Develop and perform computational phenotyping of PPD and non-PPD cohorts; (2) merge with available digital biomarker data for each woman (heart rate, steps, physical activity, and calories burned); (3) classify each day as 1 of 4 periods (prepregnancy period, pregnancy, postpartum period without depression, or PPD); (4) build and assess individualized ML models testing random forest, generalized linear models, support vector machine, and k-nearest neighbor algorithms; (5) validate the machine learning (ML) approach in women without PPD; (6) compare individualized model performance in women with and without PPD; (7) determine variable importance for PPD recognition; (8) generate Shapley additive explanations dependence plots to assess the relationship between digital biomarkers and PPD; and (9) compare individualized ML models versus a cohort-based model for PPD detection. EHR: electronic health record.



Methods

Data Source and Platform

This study used the AoURP Registered Tier v6 data set. Study analysis was conducted using the AoURP Researcher Workbench cloud platform. All computational phenotyping, data processing, data analysis, and ML algorithms were conducted using R (R Foundation for Statistical Computing). Fitbit data collected in the AoURP adhere to a bring-your-own-device model, wherein participants who contribute their data are already in possession of a Fitbit device. The daily average HR, HR SD, minimum HR, quartile 1 HR, median HR, quartile 3 HR, and maximum HR were calculated using the Fitbit HR level table. The sum of steps was calculated using the Fitbit intraday steps table. Activity calories, calories burned during the basal metabolic rate (calories BMR), calories out, fairly active minutes, lightly active minutes, marginal

calories, sedentary minutes, and very active minutes were taken from the Fitbit activity summary table. Day-level data were calculated for each of the 4 periods: prepregnancy period, pregnancy, postpartum period, and PPD (or PPD equivalent). All digital biomarkers included in this analysis are passively tracked by Fitbit; however, calories BMR is a calculated digital biomarker based on self-reported height, weight, age, and gender [25].

Ethical Considerations

The protocol for the human participant research conducted was reviewed by the institutional review board of the AoURP (protocol 2021-02-TN-001). The institutional review board follows the regulations and guidance of the National Institutes of Health Office for Human Research Protections for all studies, ensuring that the rights and welfare of research participants are overseen and protected uniformly. Participants who contribute data to the AoURP have gone through an informed consent process with the option to withdraw at any time. Privacy is maintained by 1) storing data on protected computers, 2) researchers can't see information to directly identify participants, such as name or social security number, 3) researchers sign a contract they won't try to identify participants. Furthermore, the Researcher Workbench is only accessible to researchers through an institution with a signed Data Use Agreement and to researchers who complete the necessary training. If participants are asked (and decide) to go to an All of Us partner center for physical measurements to give blood, saliva, or urine samples, they are offered a one-time compensation of $25 in the form of cash, a gift card, or an electronic voucher.

In compliance with the Data and Statistics Dissemination Policy of the AoURP, counts of <20 cannot be presented to mitigate the risk of patient reidentification [26]. As the cohort of patients with PPD presented in this analysis comprised <20 patients, percentages were presented as percentage ranges (eg, instead of presenting the data as 53%, they were presented as 50%-55%). Publication of results in this manner has been approved by the AoURP Resource Access Board. Furthermore, race and ethnicity were not reported due to the limited sample size as requested by the AoURP Resource Access Board.

Computational Phenotyping

Identifying Women With PPD

Women with PPD were identified using the following three-fold approach: (1) selecting women with a diagnosis of PPD using the condition data and identifying women with a record of (2) pregnancy or (3) delivery who had been diagnosed with depression or had antidepressant drug exposure during the postpartum period.

The first branch of the 3-fold approach to creating a cohort of women with PPD was conducted using Observational Medical Outcomes Partnership concept IDs in the condition table based on the Observational Health Data Sciences and Informatics initiative in Multimedia Appendix 1 [27,28]. For both the second and third branches of the method, we first identified women with a record of delivery (using condition data) or pregnancy (using the condition and survey tables) based on concept IDs from previously published work in Multimedia Appendix 1. Next, the data were filtered on the earliest record of delivery or pregnancy to capture and analyze digital biomarker data during the prepregnancy period. To estimate the date of pregnancy or delivery (depending on which was available for that individual), the date observed in the EHR from the AoURP was adjusted by adding or subtracting 9 months, which is a typical pregnancy duration [29]. Our next step was to estimate the window of the postpartum period, which was defined as starting from the date of delivery and spanning 24 months after that date, to monitor depressive symptoms [30,31]. Consistent with other EHR computational phenotyping studies of PPD, individuals were also classified as being PPD positive if they had a diagnosis of depression in the condition table or antidepressant drug exposure within the postpartum window [32] (Multimedia Appendix 1). Specific concepts containing the terms *episode*, *remission*, *reactive*, *atypical*, *premenstrual*, *schizoaffective*, and *seasonal* were excluded when identifying individuals with a depression diagnosis as they would not appropriately capture women with a persistent depression during the postpartum period. If a woman in the PPD cohort showed records of depression diagnosis and antidepressant drug exposure, we selected the earliest record to be considered the index date. For women with pregnancy and delivery data available, the index date and data used were based on the delivery record as this provided an elevated level of confidence in defining the postpartum period and, subsequently, whether the depression diagnosis or antidepressant drug exposure occurred during the postpartum period. Finally, the final PPD cohort was generated by selecting unique women from each of the 3 branches of our approach.

Identifying Women Without PPD

Women without PPD were selected as a control group to validate our approach because they experienced the same periods as women in the PPD cohort with the exception of having diagnosed or inferred PPD (see the previous section). Therefore, our modeling approach could be tested in an identical fashion (see more details about ML models in the section titled *Individualized ML Models for Women Without PPD*). To establish a cohort of women without PPD, we applied an identical rationale to that of the second and third branches of our PPD phenotyping, as described previously. Subsequently, women with records indicating PPD or depression diagnosis during the postpartum period from the condition table or any instances of antidepressant drug use from the drug exposure table were excluded.

Data Preparation for Analysis and Individualized ML Models

To prepare the data for analysis and individualized ML models using wearable data, we first merged day-level data from Fitbit (HR, steps, physical activity, and calories burned; see Table S1 in Multimedia Appendix 2 [33-35] for more information on digital biomarkers) for each individual ranging from 2 years before to 30 days after the index date to capture their behavior before, during, and after pregnancy. Previous studies have demonstrated that HR, steps, and activity measurements from Fitbit are fairly accurate and can be used for research purposes [36,37]. The decision to choose measures related to HR instead of resting HR was based on the availability of data and the

consideration of having enough measurements for each individual to train ML models. Digital biomarker data were filtered on days of *compliant* data, which were characterized by (1) at least 10 hours of Fitbit wear time within a day and (2) between 100 and 45,000 steps, as seen in previous studies [38]. Individuals from the PPD cohort were excluded from individualized ML models if they had <50 days of total data.

Statistical Analysis

Assessing Variation in Digital Biomarkers Among Women

The *lme4* and *lmerTest* packages in R were used to construct hierarchical linear regression models aiming to assess the presence of noteworthy differences among women and examine the relationship between each period and digital biomarkers [39,40]. To assess whether there was a significant level of variation in digital biomarkers among individuals, we processed data to calculate the average value of each digital biomarker during each period (eg, average HR during the prepregnancy period, average HR during pregnancy, average HR during the postpartum period, and average HR during PPD) and conducted linear mixed-effects models with person ID as the random effect. One model was built for each digital biomarker, where the digital biomarker served as the outcome variable, the period was considered the independent variable, and person ID was incorporated as a random effect. The presence of significant variability among individuals was evaluated using the performance package at a significance level of .05 [41].

Interrupted Time-Series Analysis, Tukey Honest Significant Differences Test, and Digital Biomarker Directionality Assessment Between Periods

The interrupted time-series analysis (ITSA) was conducted using the *its.analysis* package in R with a significance level of .05 [42]. To compare whether there was a difference in digital biomarkers during different periods before, during, and after pregnancy, in addition to when patients experienced PPD, 4 periods were defined for each individual identified with PPD (prepregnancy period, pregnancy, postpartum period without depression [hereafter referred to as postpartum period], and postpartum period with depression [PPD]). The median duration of each period was 206 (IQR 154.50-313.50) days for the prepregnancy period, 258 (IQR 226-264) days for pregnancy, 42 (IQR 27.5-90) days for the postpartum period, and 42.5 (IQR 40.25-44.75) days for PPD. For each woman, a model was constructed for each digital biomarker, with 250 replications used for bootstrapping, which is a parameter of the *itsa.model()* function. Bootstrapping runs replications of the main model with randomly drawn samples and a trimmed median (10% removed); the *F* value is reported, and a bootstrapped *P* value is derived from it [42]. The dependent variable was the digital biomarker value, the *time* parameter was the date, and the interrupting variable was the period (prepregnancy period, pregnancy, postpartum period, and PPD). The mean and SD were calculated for each digital biomarker during each of the 4 periods for each woman. Furthermore, a Tukey honest significant difference (HSD) test was conducted to assess the statistical significance of the differences in each digital biomarker between each permutation of periods (PPD–prepregnancy period, PPD-pregnancy, PPD–postpartum period, postpartum period–prepregnancy period, postpartum period–pregnancy, and pregnancy–prepregnancy period) within each individual at a significance level of .05 [43]. Next, the percentage of women exhibiting a significant relationship was calculated for each digital biomarker in each group comparison (eg, PPD–prepregnancy period). To determine the overall trend in digital biomarker change between pairs of periods (eg, PPD and prepregnancy period, PPD and pregnancy, and PPD and postpartum period), the average difference across all individuals was computed for each digital biomarker. This average also included nonsignificant differences as they still contributed insights into the directionality of digital biomarkers during those periods even if the differences were not statistically significant. Finally, a 2-sided unpaired *t* test (2-tailed) at a significance level of .05 was conducted to assess the statistical significance of the net difference compared to 0, with positive change defined as an average value of >0 and negative change defined as an average value of <0. The outcomes were visualized in a heat map using the *ggplot2* package in R. Percentages were represented as percentage ranges to preserve patient confidentiality, with the upper value of each range depicted in the heat maps (eg, 62% would fall within the 60%-65% range, and 65% would be displayed in the heat map).

Evaluating Health Care–Seeking Behavior

Health care–seeking behavior was assessed by looking at the number of visits recorded for each woman during the postpartum period (ie, ranging from the date of delivery to 30 days after the index date for each woman). The number of visits was determined by counting the number of rows in the visit occurrence table in the AoURP. We subsequently conducted an unpaired 2-sided Wilcoxon test with a significance level of .05 to determine whether the medians exhibited a significant difference between the PPD and non-PPD cohorts.

We also examined the proportion of women who adhered to the recommendation set by the American College of Obstetricians and Gynecologists, which advised women to attend at least one visit within the initial 6 weeks of the postpartum period. Of note, this guideline was updated in 2018 and now recommends a postpartum visit within the first 3 weeks following delivery [33]. However, we used the pre-2018 guideline in our analysis because the AoURP cohort includes individuals enrolled before 2018. The percentages of women who attended postpartum visits within the first 6 weeks in the PPD and non-PPD cohorts were compared using a 2-proportion *z* test at a significance level of .05. The exact percentage of women in the PPD cohort, in addition to the exact counts used to calculate the percentages, was obfuscated to maintain patient privacy.

Comparing Self-Reported and Gold-Standard Weight Measurements

Weight measurements were queried in AoURP using the measurements table (Observational Medical Outcomes Partnership concept ID 3025315). Self-reported and gold-standard weight measurements were distinguished by referencing the *src_id* column, indicating a physical measurement (self-reported) as opposed to measurements

obtained from an EHR site (gold standard). Subsequently, we identified the self-reported and gold-standard weight measurements with the shortest time interval for each woman. Only measurements taken within a period of <30 days were considered to ensure that the measurements were closely aligned and not too distant. The median and IQR of self-reported and gold-standard measurements were calculated and compared using a paired 2-sided Wilcoxon test at a significance level of .05. This process was repeated in the PPD and non-PPD cohorts.

Comparing Weight Across Periods of Pregnancy

Weights across different periods of pregnancy (prepregnancy period, pregnancy, postpartum period, and PPD [or PPD equivalent for those without PPD]) were computed in the PPD and non-PPD cohorts using linear mixed-effects models in the *lme4* package in R, with weight serving as the outcome variable, period as the independent variable, and person ID as the random effect. The results were evaluated at a significance level of .05. For women in the PPD cohort, the PPD period was used as the reference as it was the period of interest for understanding weight change. Similarly, the PPD-equivalent period was used as the reference for women in the non-PPD cohort. We further calculated the estimated means of weight across periods using the *emmeans* package in R for both the PPD and non-PPD cohorts.

Comparing Weight Retention in the PPD and Non-PPD Cohorts

To assess weight retention among women who experienced PPD compared to those without PPD, we first calculated the median weight of each woman during the prepregnancy period. Second, we identified the weight measurement during the postpartum period that was closest in value to the median prepregnancy weight on an individual basis. Third, the time difference in days was computed between the date of the weight measurement and the onset of pregnancy for each individual. Finally, we determined the median and IQR for the time difference in days mentioned in step 3 (ie, difference in days between the date of the weight measurement during the postpartum time period that was closest in value to the median prepregnancy weight for each individual) and subsequently conducted an unpaired 2-sided Wilcoxon test to assess the difference in medians at a significance level of .05 between women in the PPD and non-PPD cohorts.

Building ML Models

Individualized ML Models for Women in the PPD Cohort

Individualized ML models were developed with the objective of determining the potential of digital biomarkers to differentiate among 4 distinct pregnancy phases: prepregnancy period, pregnancy, postpartum period without depression (ie, postpartum period), and postpartum period with depression (ie, PPD). Specifically, we sought to assess whether we could develop ML models for each woman to make a prediction to classify a day of Fitbit data as falling during the prepregnancy, pregnancy, postpartum, or PPD period based on behavioral and biometric data captured by digital biomarkers on Fitbit. In other words, the models tested whether there was a unique digital signature associated with each period of pregnancy in an individualized manner. Therefore, multinomial models were developed with period as the outcome with all 16 digital biomarkers as the features in the model (see Table S1 in Multimedia Appendix 2 for a list of the digital biomarkers included). Initially, our intention was to examine the model's capacity to discriminate between periods with and without PPD, thereby constructing binomial classification models. However, we recognized the hierarchical nature of the data with repeated measurements (multiple days of data) during the prepregnancy, pregnancy, and postpartum time frames. Consequently, due to the repetitive nature of our data, we opted for constructing multinomial ML models to effectively discern among the 4 identified periods, where the PPD period was treated as both a period and a diagnosis. We were then able to focus on the PPD period by (1) constructing a confusion matrix to assess model performance for the PPD period at an individual level and (2) performing variable importance (see the following *Variable Importance* sections) for the PPD period.

To build intraindividual models, the data were filtered on each woman, where they were considered PPD negative ranging from 2 years before to 15 days before the index date and PPD positive from 14 days before to 30 days after the index date. We selected 14 days preceding the index date as the first day of being positive for PPD because the criteria for diagnosis state that patients must display 5 depressive symptoms lasting 2 weeks [44]. The time frame of 30 days following the index date was chosen because some individuals in the PPD cohort received antidepressant medication on the day of their diagnosis, which can begin to take effect after approximately 4 weeks of use [45]. For each individual, the data were centered and scaled before building models using 3 repeats of 10-fold cross-validation and a tune length of 5 with random forest (RF), generalized linear models (GLMs), support vector machine (SVM), and k-nearest neighbor (KNN) as these algorithms have been used in previous studies assessing depression using wearables [15,46]. Of note, no bootstrapping was performed as part of the individualized ML workflow. Models were built using the *Caret* package in R and evaluated using a combination of the κ statistic and multiclass area under the receiver operating characteristic curve (mAUC), which are standard metrics for classification ML models [47-50]. Model performance for each period was further assessed using a confusion matrix, which calculated sensitivity, specificity, precision, recall, and F_1-score [50].

Comparing Individualized ML Model Performance Between Women With a History of Depression Before or During Pregnancy

To initially ascertain the presence of depression history before or during pregnancy within the PPD cohort, we determined the date of delivery (using condition data) or the date of pregnancy (using condition and survey data) based on the concept IDs detailed in Multimedia Appendix 1. Depending on the available data for each woman, the date of pregnancy was calculated by subtracting 9 months from the date of delivery, whereas the date of delivery was calculated by adding 9 months to the date of pregnancy, representing a standard pregnancy duration [29]. In cases in which both delivery and pregnancy records existed,

priority was given to the date of delivery due to its heightened reliability.

For the evaluation of individualized ML model performance within the PPD cohort concerning women with a history of depression, the cohort was categorized into four subgroups encompassing (1) no previous depression history, (2) depression before pregnancy, (3) depression during pregnancy, and (4) depression both before and during pregnancy. To examine potential disparities in individualized ML model performance, a 2-sided unpaired *t* test was conducted with a significance threshold of .05. This analysis was executed to compare the no-depression-history group with the groups of women exhibiting depression before, during, or both before and during pregnancy. Sensitivity, specificity, precision, recall, and F_1-score metrics were subjected to this statistical comparison process.

Individualized ML Models for Women Without PPD

To construct individualized ML models for women in the non-PPD cohort, we implemented an analogous approach to the one used for women in the PPD cohort, where an ML model was built for each woman with *period* as the multinomial outcome. It is worth noting that women without PPD would not have a fourth period (ie, postpartum period with depression in women with PPD) as they did not experience PPD. To ensure comparability and effectively gauge model performance between women with and without PPD, we created a PPD-equivalent period for the non-PPD cohort mirroring the PPD period. Considering that the median time to diagnose PPD was found to be 83 days following delivery, we ensured uniformity by setting the index date of the PPD-equivalent period at 83 days after delivery. As we established an index date aligned with that of the PPD cohort, the interval of 14 days before the index date was not considered as the PPD-equivalent period for these women because they did not actually experience PPD. The goal was to validate any observed alterations in the PPD cohort by investigating whether there were any changes in the digital signature between the postpartum and PPD-equivalent periods, which should not exist given that these women did not experience PPD. Subsequently, individualized ML models were constructed in a manner akin to those in the PPD cohort using the RF algorithm (as this algorithm yielded optimal results in the PPD cohort) using 3 repetitions of 10-fold cross-validation and a tuning length of 5. Similar to the approach developed for women in the PPD cohort, model performance was evaluated using sensitivity, specificity, precision, recall, and F_1-score [49,50]. Models were not assessed using mAUC or κ as model performance only decreased in the PPD-equivalent period and not in the prepregnancy, pregnancy, or postpartum periods compared to those in the PPD cohort.

Comparing Individualized ML Model Performance for Women in the PPD and Non-PPD Cohorts

For comparing the performance of individualized ML models in the PPD cohort to those in the non-PPD cohort, we performed a 2-sided unpaired *t* test with a significance level of .05.

Variable Importance

Shapley Additive Explanations Approach

We used the RF ML models to generate a ranking of digital biomarkers for each individual as these models had the best performance. Following that, Shapley values were computed for each measurement within each individualized model for the PPD class using the *iml* package in R [51]. To determine the feature ranking within individual models, we computed the average absolute Shapley values across all measurements for each digital biomarker and sorted the rankings from largest to smallest. We then tallied the number of models in which each biomarker ranked among the top 5 most predictive for the PPD class to produce an overall ranking of digital biomarkers. Furthermore, we determined the most predictive feature of PPD by totaling the number of models in which each digital biomarker ranked as the top predictor for the PPD class.

Permutation Approach

To enhance the robustness of our approach, variable importance was also computed using a permutation-based method in the *Caret* package in R [50]. Subsequently, the features were sorted based on the magnitude of values assigned for the variable importance regarding the PPD class. Using a similar methodology as with Shapley additive explanations (SHAP), we tabulated the number of models in which each digital biomarker ranked among the top 5 most predictive for the PPD class, yielding a comprehensive ranking of digital biomarkers. The frequency with which each feature ranked as the foremost predictive digital biomarker was also recorded for the PPD class.

SHAP Dependence Plots

SHAP dependence plots were generated using the *gpplot2* package in R [52]. For each individual, plots were generated by graphing the Shapley value against the corresponding actual value for the digital biomarker. Given that the outcome of the models was multinomial (prepregnancy period, pregnancy, postpartum period, or PPD), 3 separate SHAP dependence plots were generated for each individual using calories BMR data during PPD with one other period (ie, one plot for the prepregnancy and PPD periods [referred to as prepregnancy vs PPD], one plot for pregnancy and PPD [referred to as pregnancy vs PPD], and one plot for the postpartum and PPD periods [referred to as postpartum vs PPD]) to more easily analyze the relationship between calories BMR in a binomial context between PPD and one other period. This process was repeated for women in the non-PPD cohort in a similar fashion to those in the PPD cohort, specifically, PPD-equivalent versus prepregnancy period (prepregnancy vs PPD-equivalent), PPD-equivalent versus pregnancy (pregnancy vs PPD-equivalent), and PPD-equivalent versus postpartum (postpartum vs PPD-equivalent). The Pearson correlation coefficient and its corresponding *P* value were computed at a significance level of .05, followed by calculating the percentages of women with and without a significant correlation. If a significant correlation was observed, we further determined its direction (positive or negative) and calculated the percentages of women with a positive or negative correlation. The overall consensus regarding the relationship was determined by

comparing the percentage of positive and negative correlations for each digital biomarker across all individuals, thereby identifying which direction had a greater rate. In cases in which the proportion of women with a significant correlation was <40%, the direction was not assessed due to the small sample size, which may not be representative of the population.

Building an ML Model for PPD Using a Cohort-Based Approach

For the construction of an ML model that assessed whether a woman had PPD, our focus was on using the PPD and PPD-equivalent periods sourced from both the PPD and non-PPD cohorts. We proceeded to develop a binomial RF classification model in which 75% of individuals from each cohort were designated for the training set and the remaining 25% were assigned to the test set using the *Caret* package in R [50]. To ensure the reliability of model performance assessment, we diligently executed train and test set divisions based on individual person IDs, thereby preventing any overlap of women between the 2 sets that could potentially distort the results [53]. The model's target outcome pertained to a binary classification of whether an individual exhibited PPD relying on all 16 digital biomarkers as input (refer to Table S1 in Multimedia Appendix 2 for a comprehensive description of the digital biomarkers used). The data were normalized through centering and scaling procedures. Notably, repeated cross-validation was omitted due to the presence of repeated measurements stemming from various person IDs. The model's construction integrated a tune length of 5. The models were evaluated using the same κ and area under the receiver operating characteristic curve metrics (not multiclass in this instance as the outcome was binary). Subsequently, a confusion matrix was generated to calculate sensitivity, specificity, precision, recall, and F_1-score [47-50].

Results

Descriptive Statistics

Through computational phenotyping in the AoURP, a patient cohort of women who gave birth with PPD (n<20) and without PPD (n=39) provided valid Fitbit data (Figure 2). The median age in the PPD cohort was 35.60 (IQR 32.83-37.36) years compared to that in the non-PPD cohort, which was 33.60 (IQR 30.72-35.56) years. The median and IQR were calculated for each digital biomarker across all women in the PPD and non-PPD cohorts (Table 1). In both the PPD and non-PPD cohorts, we computed the median number of days with digital biomarker data during the prepregnancy, pregnancy, postpartum, and PPD (or PPD-equivalent) periods and the corresponding IQRs (additional details about the PPD-equivalent period, a similar fourth period for those without PPD, can be found in the *Methods* section; Table 1). Briefly, the digital biomarkers included in this analysis were daily average HR, HR SD, minimum HR, quartile 1 HR, median HR, quartile 3 HR, maximum HR, sum of steps, activity calories, calories BMR, calories out, fairly active minutes, lightly active minutes, marginal calories, sedentary minutes, and very active minutes (see the descriptions in Table S1 in Multimedia Appendix 2).

Figure 2. A schematic of postpartum depression (PPD) computational phenotyping.

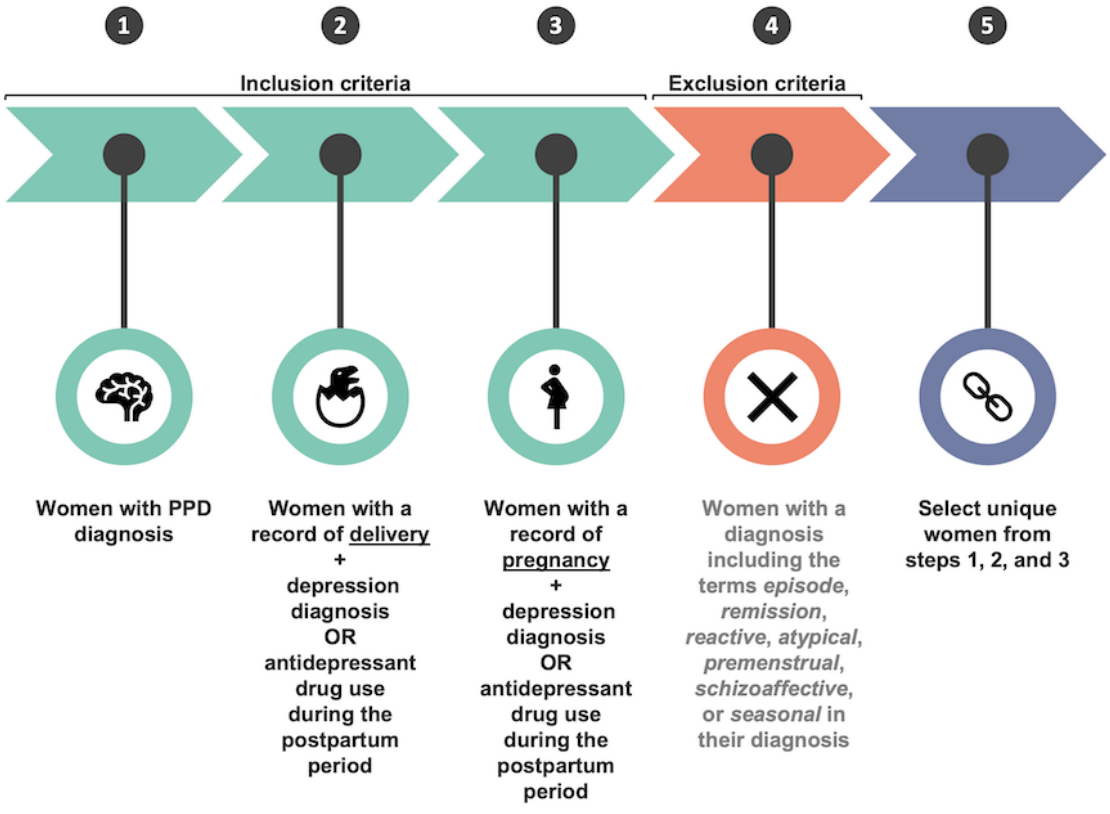


Table 1. Descriptive statistics of the postpartum depression (PPD) and non-PPD patient cohorts in the All of Us Research Program.

Descriptive statistics	PPD (n<20), median (IQR)	Non-PPD (n=39), median (IQR)
Age (y)	35.60 (32.83-37.36)	33.60 (30.72-35.56)
Digital biomarker		
Average HR[a] (bpm)	74.23 (68.36-80.66)	78.31 (72.32-83.97)
HR SD (bpm)	12.18 (10.58-14.05)	12.70 (10.72-15.12)
Minimum HR (bpm)	54.00 (49.00-60.00)	57.00 (52.00-61.00)
Quartile 1 HR (bpm)	64.00 (59.00-71.00)	68.00 (62.00-74.00)
Median HR (bpm)	72.00 (66.00-78.00)	76.00 (70.00-82.00)
Quartile 3 HR (bpm)	81.00 (74.00-88.00)	85.00 (78.00-92.00)
Maximum HR (bpm)	124.00 (117.00-135.00)	127.00 (119.00-141.00)
Sum steps	7567.50 (4884.00-10536.25)	7352.00 (4838.00-10834.00)
Activity calories	989.00 (742.75-1263.00)	964.00 (684.00-1275.00)
Calories burned during BMR[b]	1466.00 (1379.00-1539.00)	1390.00 (1340.00-1496.00)
Calories out	2236.00 (2012.00-2483.25)	2180.00 (1925.00-2465.50)
Fairly active minutes	9.00 (0.00-24.00)	8.00 (0.00-23.00)
Lightly active minutes	245.00 (189.00-315.00)	245.00 (187.50-310.00)
Marginal calories	501.00 (349.00-665.00)	489.00 (322.00-680.00)
Sedentary minutes	646.00 (563.00-741.00)	710.00 (607.00-880.50)
Very active minutes	2.00 (0.00-18.00)	4.00 (0.00-21.00)
Number of days in each period		
Prepregnancy period	206.00 (154.50-313.50)	227.00 (109.50-340.75)
Pregnancy	258.00 (226.00-264.00)	221.00 (129.00-269.50)
Postpartum period	42.00 (27.50-90.00)	72.00 (46.00-82.00)
PPD	42.50 (40.25-44.75)	29.00 (14.50-31.00)

[a]HR: heart rate.

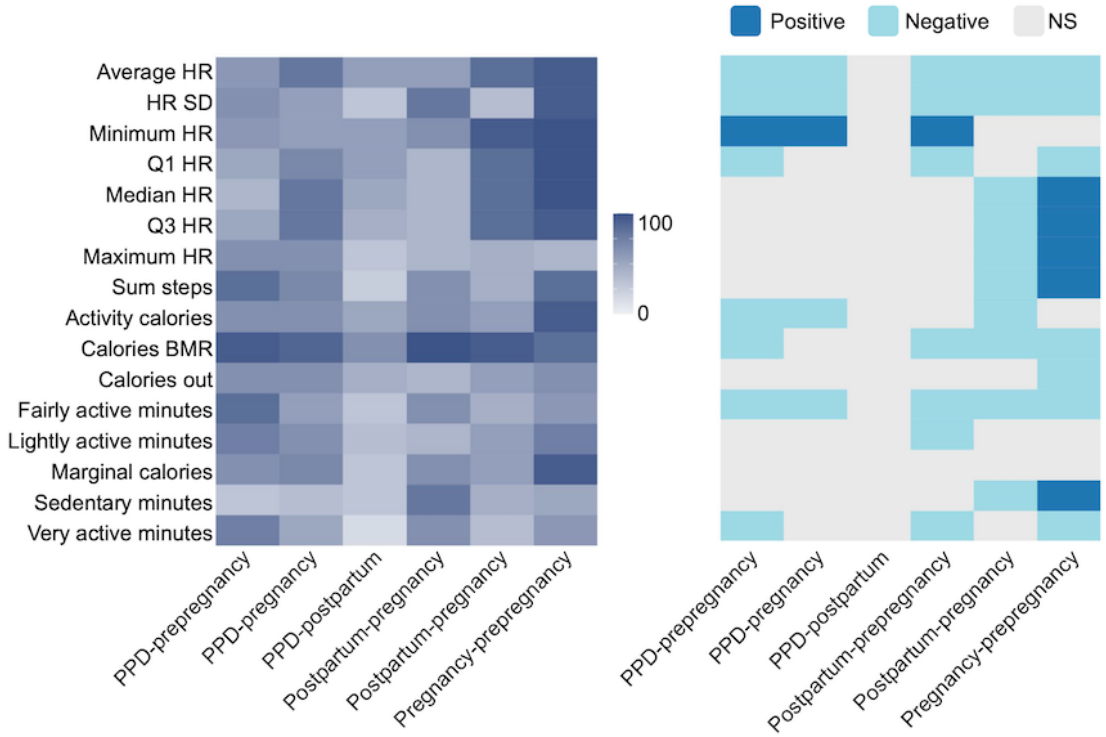
[b]BMR: basal metabolic rate.

Digital Biomarker Comparison Across Periods of Pregnancy Revealed Altered Profiles and Heterogeneity Among Women

Because of the known heterogeneity in depressive symptoms, we hypothesized that variability in digital biomarkers may exist across individuals in the PPD cohort [54]. To test this hypothesis, we conducted linear mixed-effects models for each digital biomarker in women with PPD, where we found that the random effect of person ID was significant (P<.001) for all digital biomarkers, suggesting meaningful variability across individuals (Table S2 in Multimedia Appendix 2). These results, coupled with a smaller cohort sample size, prompted us to perform subsequent analyses using an intraindividual approach.

In women with PPD, we next sought to compare whether there was a difference in digital biomarkers across different periods of pregnancy: prepregnancy period, pregnancy, postpartum period, and PPD (where PPD represents both a period and a diagnosis). Therefore, an intraindividual ITSA and Tukey HSD test were conducted for each digital biomarker. Because of the physiological changes associated with pregnancy, such as increases in blood and stroke volume, in addition to the behavioral fluctuations that occur during PPD, such as a loss of energy and psychomotor retardation, we hypothesized that all digital biomarkers (those related to HR, steps, physical activity, and calories burned) would be altered across the prepregnancy, pregnancy, postpartum, and PPD periods [44,55-57]. ITSA results supported our hypothesis and demonstrated a significant difference in all digital biomarkers across periods in most women with PPD (Table S3 in Multimedia Appendix 2). Consistent with ITSA findings, Tukey HSD results showed that several digital biomarkers were significantly altered between PPD and other periods (prepregnancy, pregnancy, and postpartum periods; Figure 3). We further observed various trends in digital biomarkers between pairs of periods (ie, PPD and prepregnancy period, PPD and pregnancy, and PPD and postpartum period; Figure 3 and Table S4 in Multimedia Appendix 2).

Figure 3. Digital biomarkers vary across different periods of pregnancy among women with postpartum depression (PPD). The percentage of women in the PPD cohort exhibiting a significant difference in digital biomarker values between each pair of periods (left [represented by 0-100]) and the direction of their relationship (right). The x-axis illustrates a comparison of Tukey honest significant differences (HSD) between 2 periods of interest, representing the subtraction of digital biomarker values between the first and second periods. Tukey HSD tests were individually conducted for each woman's data, and the percentage showing a significant relationship was calculated and presented on the heat map. The heat map on the right illustrates the overall relationship between the digital biomarker during the 2 periods of interest among the women who exhibited a significant relationship (as indicated by the percentage shown on the left heat map), with the period listed second serving as the reference. In summary, the findings indicated that digital biomarkers undergo significant alterations across different periods of pregnancy on an individual basis. Calories BMR: calories burned during the basal metabolic rate; HR: heart rate; NS: not significant; Q1: quartile 1; Q3: quartile 3.



Individualized ML Models Effectively Differentiated PPD From Alternative Periods of Pregnancy

Having seen that digital biomarkers were significantly altered across multiple periods of pregnancy in women with PPD, we surmised that individualized multinomial ML models could accurately distinguish between our 4 periods of pregnancy (prepregnancy period, pregnancy, postpartum period, or PPD; Figure 3 and Tables S3 and S4 in Multimedia Appendix 2). Therefore, we sought to assess whether ML models for each woman could accurately classify an unknown day of Fitbit data as falling during the prepregnancy, pregnancy, postpartum, or PPD period based on behavioral and biometric data captured by digital biomarkers on Fitbit. In essence, the models examined whether there existed a distinct digital signature linked to each pregnancy period in an individualized fashion. To probe this hypothesis, intraindividual ML models were generated using RF, GLM, SVM, and KNN to conclude which algorithm would yield the best-performing results. Models were assessed using a combination of the mAUC and κ, which are 2 frequently used metrics [48,58]. After averaging the mAUC for individual models within each algorithm, the results revealed that RF models performed the best, followed by GLM, SVM, and then KNN, with an average mAUC of 0.85, 0.82, 0.75, and 0.74, respectively (Table 2). Assessing models in a similar fashion using another metric, κ, yielded concordant results for RF (0.80), GLM (0.74), SVM (0.72), and KNN (0.62) model performance, suggesting that the RF algorithm had the best performance and should be used going forward (Table 2).

Table 2. Individualized random forest (RF) models exhibited the best performance for multinomial period classification.

Algorithm	mAUC[a], mean (SD)	κ, mean (SD)
Random forest	0.85 (0.09)	0.80 (0.15)
Generalized linear model	0.82 (0.09)	0.74 (0.16)
Support vector machine	0.75 (0.10)	0.72 (0.16)
k-nearest neighbor	0.74 (0.10)	0.62 (0.19)

[a]mAUC: multiclass area under the receiver operating characteristic curve.

As our analysis aimed to assess the potential of digital biomarkers for personalized classification of PPD, we sought to further examine each RF model's performance via a confusion matrix. Thus, the average sensitivity, specificity, precision,

recall, and F_1-score were calculated across all individual models, where the results for the PPD class were 0.79, 0.95, 0.84, 0.79, and 0.81, respectively (Figure S1 in Multimedia Appendix 2). The same metrics for the prepregnancy, pregnancy, and postpartum periods were also calculated (Figure S1 in Multimedia Appendix 2).

To ensure the widespread applicability of these algorithms to a diverse range of women, we did not exclude individuals with a history of depression either before or during pregnancy. Therefore, we sought to determine whether having depression before or during pregnancy impacted individual model performance, specifically for recognizing the PPD class. To answer this question, we computed the average sensitivity, specificity, precision, recall, and F_1-score within the group of women experiencing PPD categorized based on their depression history: (1) no previous history of depression, (2) history before pregnancy, (3) history during pregnancy, or (4) history both before and during pregnancy. Notably, the findings revealed no statistically significant variations in any of these metrics between women with a history of depression during the prepregnancy or pregnancy periods and those without such a history (Figure S2 in Multimedia Appendix 2). Promisingly, this suggests the potential for a forthcoming technology focused on detecting PPD through digital biomarkers to be relevant for women with or without a previous history of depression before or during pregnancy.

Individualized ML Models for PPD Recognition Were Specific

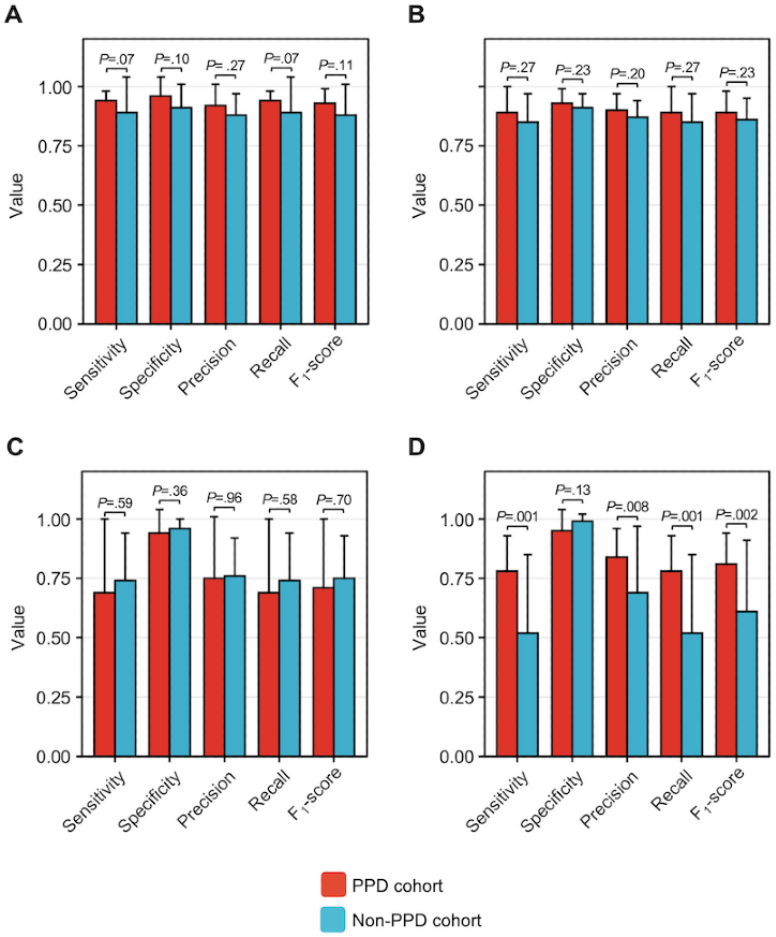
To validate our approach of using digital biomarkers in individualized ML models for PPD detection, we aimed to test our strategy in a cohort of women who had given birth but did not experience PPD. We chose women without PPD as a control group for validation because they experienced the same 3 phases of pregnancy (prepregnancy period, pregnancy, and postpartum period) as women in the PPD cohort with the exception of PPD. Given that women without PPD did not have a distinct PPD-specific period as observed in the PPD cohort, we introduced a fourth time segment in the non-PPD cohort (the PPD-equivalent period). Following the same ML pipeline as for the PPD cohort, individualized RF models were built for women in the non-PPD cohort. If our conjecture held, we anticipated observing elevated model metrics during the prepregnancy and pregnancy periods followed by diminished performance in the postpartum and PPD-equivalent time segments. This expectation arose from the idea that digital biomarkers remain unaltered during the postpartum and PPD-equivalent periods, resulting in the model's inability to differentiate between them.

In line with our hypothesis, the sensitivity, specificity, precision, recall, and F_1-scores substantiated that ML models effectively identified the prepregnancy (0.89, 0.91, 0.88, 0.89, and 0.88, respectively) and pregnancy (0.85, 0.91, 0.87, 0.85, and 0.86, respectively) time intervals through digital biomarkers (Table 3). When compared to model performance in the prepregnancy and pregnancy periods, there was no significant reduction in model performance during the postpartum period (0.74, 0.96, 0.76, 0.74, and 0.75, respectively); however, a noticeable decline in performance was observed during the PPD-equivalent period (0.52, 0.99, 0.69, 0.52, and 0.61, respectively; Table 3). To further assess potential variations in the classification performance between the PPD and PPD-equivalent periods, we carried out a *t* test comparing the average sensitivity, specificity, precision, recall, and F_1-score between the PPD and non-PPD cohorts for these periods. The findings indicated a statistically significant decrease in sensitivity, precision, recall, and F_1-score when predicting the PPD-equivalent period in the non-PPD cohort as opposed to predicting the PPD period in the PPD cohort (Figure 4). On the other hand, specificity remained largely unchanged (Figure 4). The decrease in performance among individualized ML models in the PPD-equivalent period implies that the models were unable to accurately classify the PPD-equivalent period, which was expected as there was no actual distinction between the postpartum and PPD-equivalent periods for these women. Collectively, these outcomes helped demonstrate the specificity of our approach in identifying PPD, reinforcing the agreement that personalized models using digital biomarkers can indeed effectively recognize PPD.

Table 3. Machine learning (ML) models did not accurately detect the postpartum depression (PPD)–equivalent period in women without PPD.

Time period and metric	Value, mean (SD)
Prepregnancy period	
Sensitivity	0.89 (0.15)
Specificity	0.91 (0.10)
Precision	0.88 (0.09)
Recall	0.89 (0.15)
F_1-score	0.88 (0.13)
Pregnancy period	
Sensitivity	0.85 (0.12)
Specificity	0.91 (0.06)
Precision	0.87 (0.07)
Recall	0.85 (0.12)
F_1-score	0.86 (0.09)
Postpartum period	
Sensitivity	0.74 (0.20)
Specificity	0.96 (0.04)
Precision	0.76 (0.16)
Recall	0.74 (0.20)
F_1-score	0.75 (0.18)
PPD-equivalent period	
Sensitivity	0.52 (0.33)
Specificity	0.99 (0.03)
Precision	0.69 (0.28)
Recall	0.52 (0.33)
F_1-score	0.61 (0.30)

Figure 4. Individualized machine learning models for postpartum depression (PPD) recognition outperformed those in women without PPD detecting the PPD-equivalent period. The sensitivity, specificity, precision, recall, and F1-score were calculated across individual random forest models for women in the PPD and non-PPD cohorts for the prepregnancy (A), pregnancy (B), postpartum (C), and PPD or PPD-equivalent periods (D). Individualized model performance was not significantly different regarding sensitivity, specificity, precision, recall, and F1-score for predicting the prepregnancy, pregnancy, or postpartum periods between women in the PPD and non-PPD cohorts. Individualized model performance was reduced for sensitivity, precision, recall, and F1-score, whereas specificity did not differ between the PPD and non-PPD cohorts. Data are expressed as mean and SD.



Calories BMR Was the Most Predictive Digital Biomarker of PPD

To elucidate which digital biomarkers were most predictive of the PPD class, we performed SHAP to explain individual predictions for each digital biomarker across all RF intraindividual models [59]. Features were sorted based on their predictive value for the PPD class within each individual model, and subsequently, the occurrences of each digital biomarker ranking in the top 5 across all intraindividual models were tallied, where an example beeswarm plot for one woman is shown in Figure S3 in Multimedia Appendix 2. This process aimed to identify whether any digital biomarkers consistently played a crucial role in predicting the PPD class. The results showed that the 5 features most frequently ranked in the top 5 were calories BMR, average HR, quartile 1 HR, lightly active minutes, and minimum HR (Table 4). Interestingly, calories BMR ranked in the top 5 features predictive of the PPD class in 95% to 100% of the models and was the number 1 rated digital biomarker in 80% to 85% of the individualized models (Table 4).

To add a layer of robustness to our approach assessing which features were most predictive of the PPD class, the variable importance of each digital biomarker was also calculated using a permutation approach [60]. Consistent with our findings obtained using SHAP, the top 5 digital biomarkers for the PPD class were calories BMR, average HR, quartile 1 HR, minimum HR, and lightly active minutes (Table 4). Calories BMR again ranked in the top 5 digital biomarkers predictive of the PPD class 95% to 100% of the time and ranked number one 95% to 100% of the time (Table 4).

Because of the intriguing observation that calories BMR was highly predictive of PPD across all models, we sought to better understand its relationship with the PPD class in our models using SHAP dependence plots to visualize and calculate the Pearson correlation coefficient between the PPD period and the prepregnancy, pregnancy, or postpartum periods (see Figure S4A-C in Multimedia Appendix 2 for example plots from individual women). Across all individual SHAP dependence plots of calories BMR filtered in the prepregnancy versus PPD periods, our initial observation revealed that 95% to 100% of women exhibited a significant Pearson correlation coefficient (Figure 5A). Of these women, 60% to 65% showed a positive relationship, indicating an elevated level of calories BMR during the PPD period relative to the prepregnancy period (Figure 5A). Compared to the prepregnancy versus PPD period, it was

observed that 75% to 80% and 85% to 90% of individualized SHAP dependence plots of calories BMR during the pregnancy versus PPD and postpartum versus PPD periods exhibited a significant Pearson correlation coefficient, respectively (Figure 5A). Of those, 60% to 65% and 85% to 90% of women during the pregnancy versus PPD and postpartum versus PPD periods demonstrated a negative relationship, respectively, suggesting that a decrease in calories BMR relative to the pregnancy and postpartum periods was predictive of PPD (Figure 5A). SHAP dependence plots were also generated for individualized models of the other top 4 digital biomarkers predictive of PPD (average HR, quartile 1 HR, minimum HR, and lightly active minutes) in the prepregnancy versus PPD, pregnancy versus PPD, and postpartum versus PPD periods (Figure 5A). Notably, during the prepregnancy versus PPD periods, half of the women exhibited a positive relationship in plots of lightly active minutes, indicating an increase in lightly active minutes associated with PPD in those models (Figure 5A). To examine the rise in lightly active minutes relative to other digital biomarkers of physical activity (sedentary minutes, fairly active minutes, and very active minutes), we calculated the ratio of the number of lightly active minutes to each of the 3 other digital biomarkers of physical activity across all individuals. In this case, we observed that the average ratios of lightly active minutes to sedentary minutes, fairly active minutes, and very active minutes were 0.35 (SD 0.49), 17.7 (SD 4.92), and 21.72 (SD 5.11), respectively (Figure S5 in Multimedia Appendix 2).

Table 4. The variable importance rankings demonstrated that calories burned during the basal metabolic rate (calories BMR) were the most predictive digital biomarker of the postpartum depression (PPD) class.

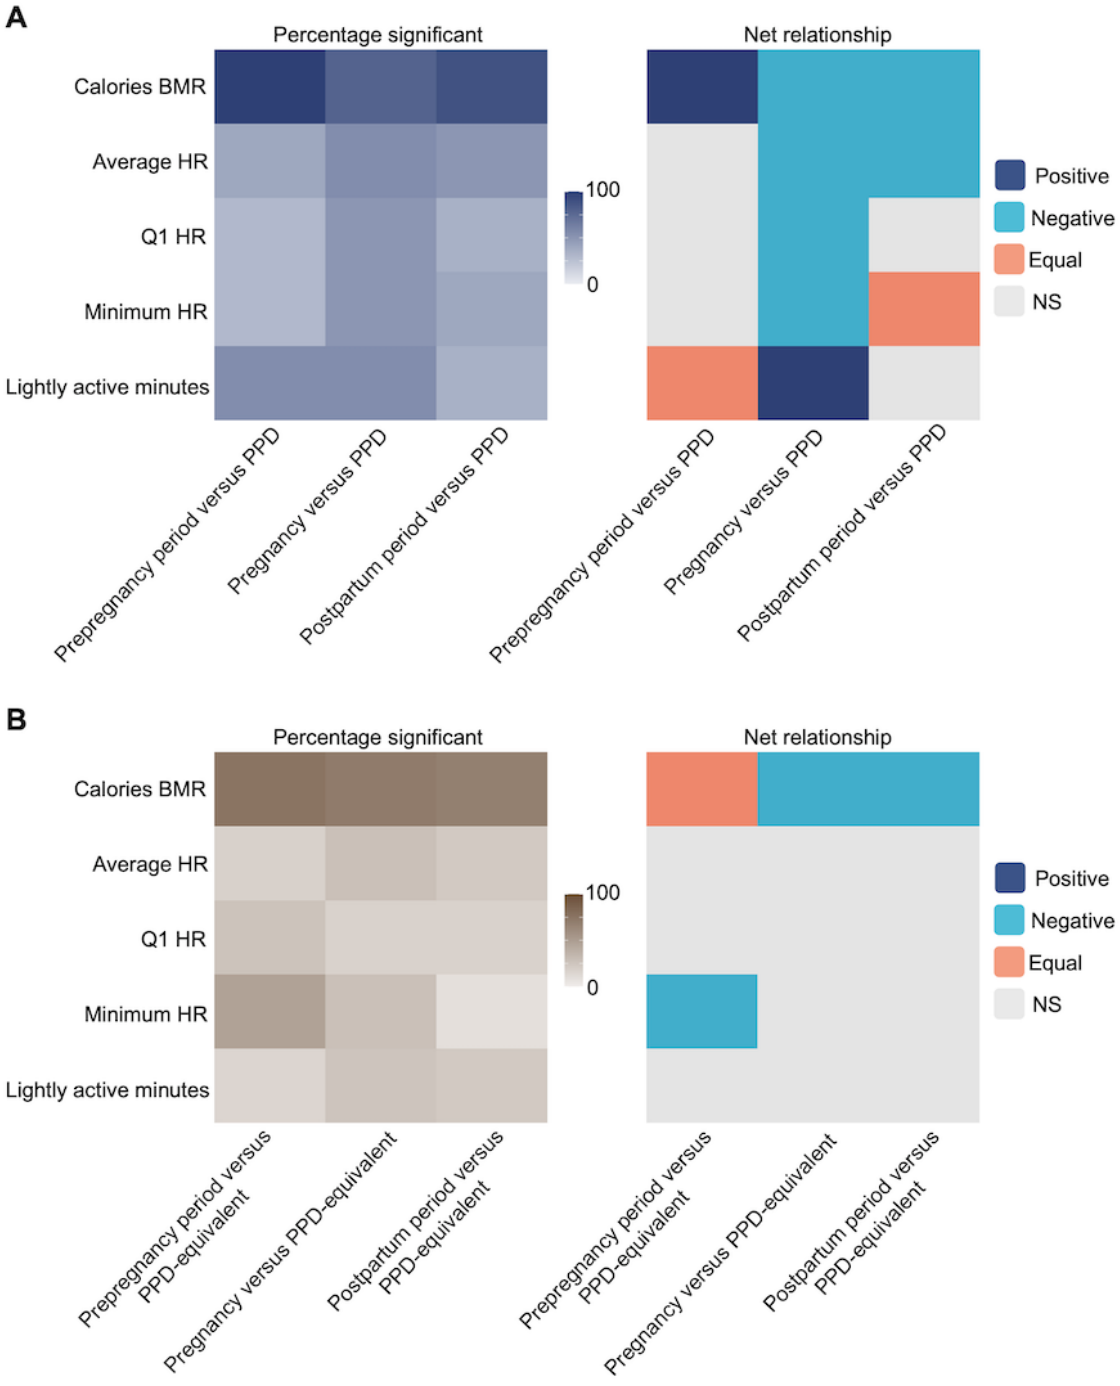
Method and digital biomarker	Percentage ranked top 5	Percentage ranked number 1
SHAP[a]		
Calories BMR	100	85
Average HR[b]	40	0
Quartile 1 HR	40	0
Lightly active minutes	35	10
Minimum HR	35	0
Sedentary minutes	0	10
Sum of steps	0	10
Permutation		
Calories BMR	100	100
Average HR	65	0
Quartile 1 HR	60	0
Minimum HR	50	0
Lightly active minutes	40	0

[a]SHAP: Shapley additive explanations.

[b]HR: heart rate.

For a more comprehensive evaluation of the connection between calories BMR and PPD, we also crafted SHAP dependence plots from individualized ML models for women without PPD. When first assessing the number of women with a significant correlation in SHAP dependence plots of the prepregnancy versus PPD-equivalent, pregnancy versus PPD-equivalent, and postpartum versus PPD-equivalent periods, the results showed that 75% to 80%, 70% to 75%, and 65% to 70% of women had a significant relationship, respectively (Figure 5B). Of those, there was an equal number of women with a positive and negative relationship in the prepregnancy versus PPD-equivalent periods compared to the PPD cohort, where most women (60%-65%) exhibited a positive relationship (Figure 5B). This implies that, among women in the PPD cohort, an escalation in calories BMR corresponds to a higher likelihood of PPD when compared to the prepregnancy period (Figures 5A and 5B). On the other hand, in the non-PPD cohort, there was no uniform pattern of association between calories BMR during the prepregnancy and the PPD-equivalent periods across all women, highlighting the distinctive nature of our observation. During the pregnancy versus PPD-equivalent and postpartum versus PPD-equivalent time frames, 80% to 85% and 75% to 80% of women, respectively, exhibited a significant correlation in SHAP dependence plots between calories BMR and Shapley values (Figure 5B). As anticipated, this follows a similar pattern to women in the PPD cohort (Figure 5A). These findings implied that a reduction in calories BMR compared to the pregnancy or postpartum periods is linked to the PPD (or PPD-equivalent) periods (Figures 5A and 5B).

Figure 5. The direction of digital biomarkers in machine learning models for postpartum depression (PPD) classification was heterogeneous. (A) The percentage of women in the PPD cohort with a significant Pearson correlation (left) and the net relationship (right) for the top 5 overall ranked digital biomarkers for PPD classification. (B) The percentage of women in the non-PPD cohort with a significant Pearson correlation (left) and the net relationship (right) for the top 5 overall ranked digital biomarkers for PPD-equivalent classification. The proportion of women showing a significant Pearson correlation coefficient between Shapley additive explanations (SHAP) values and digital biomarkers varied in both the PPD and non-PPD cohorts. The x-axis illustrates the comparison of 2 periods, with the first period as the reference, whereas the shading indicates the percentage (0%-100%) of women showing a significant relationship (A) or the net relationship among those with a significant relationship (B). SHAP dependence plots were generated for each woman on an individual basis. For instance, the upper left tile in A presenting prepregnancy versus PPD and Calories BMR indicates the percentage of women who showed a significant correlation on SHAP dependence plots of calories burned during the basal metabolic rate (calories BMR) between the prepregnancy and PPD periods. In B, the upper left tile of the heat map for prepregnancy versus PPD and Calories BMR illustrates that most women in the PPD cohort showed a positive relationship (elevated SHAP values with increases in calories BMR, meaning that a higher level of calories BMR was more predictive of PPD than in the prepregnancy period) among women with a significant correlation, as shown in A. Among those showing a significant relationship in SHAP dependence plots during the prepregnancy versus PPD (and prepregnancy versus PPD-equivalent) periods, the correlation pattern for SHAP values and calories BMR differed—most women exhibited a positive correlation in the PPD cohort, whereas there was no uniform pattern among women in the non-PPD cohort. Among women in the pregnancy versus PPD and postpartum versus PPD (and PPD-equivalent) periods, most demonstrated a negative relationship between SHAP values and calories BMR in both the PPD and non-PPD cohorts. HR: heart rate; NS: not significant; Q1: quartile 1.



We further investigated (1) health care–seeking behavior among women in the PPD and non-PPD cohorts; (2) the reliability of self-reported weight (as calories BMR are calculated based on age, sex, height, and weight); (3) the weight difference across each of the 4 periods (prepregnancy period, pregnancy, postpartum period, and PPD [or PPD equivalent]) between women in the PPD and non-PPD cohorts; (4) the relationship among weight, calories BMR, and PPD; and (5) weight retention between women in the PPD and non-PPD cohorts (see more details in Tables S5-S11 in Multimedia Appendix 2).

To showcase the effectiveness of our approach using individualized ML models for PPD detection, we constructed an ML model using conventional techniques. In this endeavor, we harnessed the PPD and PPD-equivalent periods of the PPD and non-PPD cohorts, respectively, enabling an assessment of our individualized approach compared to conventional methods using a binomial model for the classification of individuals with or without PPD. By evaluating model outcomes through metrics such as sensitivity, specificity, precision, recall, and F_1-score, we found that the average performance of the individualized model surpassed that of the cohort-based strategy (Table 5). Specifically, in the individualized approach, we observed sensitivity, specificity, precision, recall, and F_1-score values of 0.78, 0.95, 0.84, 0.78, and 0.81, respectively, in contrast to 0.54, 0.55, 0.49, 0.54, and 0.52, respectively, for the cohort-based approach (Table 5).

Table 5. Individualized machine learning (ML) models outperformed a cohort-based model for postpartum depression (PPD) recognition.

Method and digital biomarker	Value
Sensitivity	
Cohort-based model[a]	0.54
Individualized models, mean (SD)	0.78 (0.15)
Specificity	
Cohort-based model	0.55
Individualized models, mean (SD)	0.95 (0.09)
Precision	
Cohort-based model	0.49
Individualized models, mean (SD)	0.84 (0.12)
Recall	
Cohort-based model	0.54
Individualized models, mean (SD)	0.78 (0.15)
F_1-score	
Cohort-based model	0.52
Individualized models, mean (SD)	0.81 (0.13)

[a]Since the cohort-based ML approach is only to generate 1 model, there is no mean or SD.

Discussion

Principal Findings

In this study, our multifaceted analysis demonstrated that (1) digital biomarkers differed among the prepregnancy, pregnancy, and postpregnancy periods (up to 2 years before pregnancy, pregnancy, postpartum period, and PPD; Figure 3 and Tables S3 and S4 in Multimedia Appendix 2); (2) personalized N-of-1 ML models using digital biomarkers from consumer-grade wearables were able to classify PPD and other periods of pregnancy (Table 2 and Figure S1 in Multimedia Appendix 2); (3) a history of depression before or during pregnancy did not impact individualized ML model performance for PPD recognition (Figure S2 in Multimedia Appendix 2); (4) calories BMR, average HR, quartile 1 HR, lightly active minutes, and minimum HR were the most influential digital biomarkers in predicting the PPD period across all individualized models (Table 4); and (5) individualized ML models for PPD recognition outperformed the traditional cohort-based model approach (Table 5). The results presented in this paper provide a new opportunity for the potential to leverage passively collected digital biomarkers from consumer-grade wearables to facilitate early detection of PPD.

To the best of our knowledge, this is the first study proposing that individualized ML models using passively collected digital biomarkers from consumer-grade wearables can recognize PPD. Moreover, this study is also unique due to (1) integrating EHR and wearable data sources, (2) using longitudinal and continuous wearable data across multiple periods of pregnancy for ML methods, and (3) using individualized ML models for PPD recognition. PPD is most commonly diagnosed using the EPDS, which suffers from the following limitations: (1) postpartum women must attend follow-up visits assessed by care providers for PPD screening, where the rate of postpartum visits is highly variable; (2) using the EPDS only captures the mental health of a woman at a single point in time; and (3) the EPDS uses self-reported symptoms, which may not be representative of a patient's actual mental health status [61-63]. For these reasons,

our approach using passively monitored digital biomarkers from consumer wearable technology may serve as an effective tool for facilitating the detection of PPD in an individualized fashion, especially in nonclinical settings.

Because of the variation in digital biomarkers detected among women across different periods, our limited sample size, and the availability of continuous intraindividual data, our study was geared toward an individualized analytic approach (Table S2 in Multimedia Appendix 2). The observed variability across individuals is consistent with previous studies that have emphasized the heterogeneous nature of depression prompting individualized methodologies [16,54,64-66]. Moreover, ITSA and Tukey HSD results revealed that digital biomarkers were significantly altered among periods within each woman (Figure 3 and Tables S3 and S4 in Multimedia Appendix 2). Overall, there were numerous individual-level alterations, which can be explained by the considerable heterogeneity in depressive symptoms [54]. Collectively, these data suggest that digital biomarkers were significantly different across periods within each person, leading us to believe that individualized ML models would be able to accurately discriminate between PPD and other periods of pregnancy.

Our study also highlights the strength of using individualized N-of-1 ML models using digital biomarkers for identifying PPD. Our findings underscored the models' ability to differentiate between distinct pregnancy phases—namely, prepregnancy, pregnancy, postpartum, and PPD periods (Table 2 and Figure S1 in Multimedia Appendix 2). Notably, our approach's validity was confirmed by the noticeable decrease in model performance during the PPD-equivalent period for the non-PPD cohort compared to the PPD period for the PPD cohort (Table 3 and Figure 4). This demonstrated the distinct behavioral shifts that are observed during the onset of PPD, effectively captured by digital biomarkers [2]. Furthermore, our results did not indicate a significant variation in individualized model performance across the 4 pregnancy periods among women with a history of depression before or during pregnancy (Figure S2 in Multimedia Appendix 2). This accentuated the robust capability of individualized models to differentiate among periods based on the distinct behavioral characteristics and metabolic shifts linked to PPD after pregnancy as opposed to the behavior changes exhibited by each woman before or during pregnancy. This suggests that forthcoming technology centered on detecting PPD through digital biomarkers could have relevance for both individuals with and without a preexisting history of depression before or during pregnancy. Future studies should be conducted in a prospective framework to validate our individualized methodology. We also want to emphasize in future studies the importance of ML algorithms minimizing false positives for PPD detection to prevent unnecessary interventions [67].

Another crucial finding of our study was that the vital digital biomarkers for PPD classification were calories BMR, average HR, quartile 1 HR, minimum HR, and lightly active minutes, where calories BMR was the most predictive feature (Table 4). Therefore, we constructed SHAP dependence plots to enhance our understanding of the relationship between calories BMR and PPD. Plots for the prepregnancy versus PPD periods suggested that an elevated level of calories BMR is predictive of PPD, which is indicative of weight gain in these women (Figure 5A) [2,68]. In plots for the pregnancy versus PPD and postpartum versus PPD periods, the relationship between Shapley and actual values of calories BMR flipped, signifying that an increased number of calories BMR was inversely associated with PPD (Figure 5A). The negative relationship in the context of pregnancy versus PPD can likely be explained by the metabolic changes during pregnancy, resulting in an increased basal metabolic rate [69]. In the context of the postpartum versus PPD periods, we speculate that the negative relationship is because the median duration between the delivery date and PPD diagnosis is 83 days, when patients may not have fully returned to their prepregnancy physiological or behavioral patterns, which can take up to 6 months [70]. As a result, the relationship between Shapley values and actual values of calories BMR may reflect this transitional period and the ongoing postpartum changes experienced by women.

On the other hand, for the prepregnancy versus PPD-equivalent periods for women in the non-PPD cohort, SHAP dependence plots failed to unveil a uniform connection between calories BMR and the PPD-equivalent period, likely due to physiological distinctions, lifestyle changes during pregnancy, and random dissimilarities among women [57,71-73]. However, the comparison of SHAP dependence plots across the pregnancy versus PPD-equivalent and postpartum versus PPD-equivalent periods for women in the non-PPD cohort exhibited a consistent negative correlation, similar to what was observed in the PPD cohort (Figures 5A and 5B). This trend is likely a result of the common occurrence of an increased basal metabolic rate during pregnancy [69]. In the context of the postpartum versus PPD-equivalent periods, our use of an index date set at 83 days after delivery—the median number of days after delivery for PPD diagnosis in the PPD cohort—implies that women likely have not fully returned to their prepregnancy physiological baseline [70]. This aligns with the parallel observation seen during the pregnancy versus PPD-equivalent periods, reaffirming the persisting metabolic effect postpartum.

Calories BMR are calculated using a combination of age, gender, height, and weight. Hence, considering the relative stability of age, gender, and height throughout the 4 phases of pregnancy (prepregnancy period, pregnancy, postpartum period, and PPD), alterations in calories BMR are likely indicative of weight changes [74]. Calories BMR likely rely on self-reported height and weight measurements as most individuals do not have routine access to gold-standard measurements. Previous research has indicated that self-reported weight is generally reliable and accurate, where BMI was correctly determined for 91% of pregnancies using self-reported weight; however, accuracy varied between 70% in women who are underweight and 98% in women who are overweight [75]. In our study, we found no significant difference in self-reported and gold-standard weight measurements (Table S6 in Multimedia Appendix 2). Hence, it is important to acknowledge that an ideal approach would involve a combination of gold-standard weight measurements for accuracy and self-reported weight measurements for feasibility and accessibility to longitudinal data in analyses related to PPD.

Given the known positive relationship between calories BMR and weight, our analyses sought to further examine this relationship in the context of women with PPD. To do so, we leveraged the results from SHAP dependence plots, where we found that the 60% to 65% of women with a positive relationship between calories BMR and PPD relative to the prepregnancy period (ie, a higher value of calories BMR during PPD compared to the prepregnancy period) experienced weight gain (Table S9 in Multimedia Appendix 2). Similarly, the 85% to 90% of women who showed a negative relationship between calories BMR and PPD relative to the postpartum period (ie, a lower value of calories BMR during PPD compared to the postpartum period) showed weight loss (Table S10 in Multimedia Appendix 2). It is worth noting that previous research has suggested that some women experience weight gain during PPD, whereas others experience weight loss. For instance, it has been shown that women with PPD may experience weight gain attributed to emotional overeating [76,77]. Conversely, other studies propose that women grappling with PPD might experience weight loss resulting from skipped meals and overwhelming anxiety [78]. Consistent with the individualized framework presented in our study, we posit that it may be crucial to monitor changes in weight (or calories BMR). For example, although most women in our study exhibited an increase in calories BMR during the PPD period compared to the prepregnancy period, a percentage of women experienced a significant decrease in calories BMR during PPD relative to the prepregnancy period. When assessing the relationship between weight in the prepregnancy and PPD periods in these women, we found that these women did experience weight loss during the PPD period relative to the prepregnancy period. Therefore, we suggest that changes in body weight (or calories BMR), whether positive or negative, could potentially serve as more informative indicators of PPD. Considering the diverse manifestations of depression—some individuals may gain weight, whereas others may lose weight—we advocate for future studies to investigate these changes on an individual level.

Considering previous research indicating that women with PPD encounter challenges in reverting to prepregnancy weight compared to those without PPD, we aimed to assess this phenomenon in our cohorts. Strikingly, our findings did not detect a significant difference in the time taken for women to reach their prepregnancy weight between the PPD and non-PPD cohorts (Table S11 in Multimedia Appendix 2). Due to the association between calories BMR and weight, we aimed to validate this observation using calories BMR data. Interestingly, we observed a consistent pattern of no significant difference in the time taken to return to prepregnancy calories BMR between the PPD and non-PPD cohorts (Table S11 in Multimedia Appendix 2). It is posited that the lack of difference may be because women in the PPD cohort started at a higher average weight during the prepregnancy period compared to those without PPD (Table S8 in Multimedia Appendix 2). We also suspect that the discrepancy in the results between the number of days to return to prepregnancy weight detected via weight measurements and calories BMR was a product of the limited availability of weight data.

In the PPD cohort, the SHAP dependence plots for average HR, quartile 1 HR, and minimum HR during the pregnancy versus PPD periods also demonstrated a negative relationship, indicating that higher values of these digital biomarkers are inversely associated with PPD (Figure 5A). This relationship may be ascribed to the elevated HR commonly observed during pregnancy, which is a physiological response resulting from vascular remodeling for promoting augmented blood flow to the uterus [79-81]. In addition, there was a positive correlation between the increase in lightly active minutes and the occurrence of PPD in the pregnancy versus PPD periods, which may be explained by an inverse relationship between lightly active minutes and fairly active minutes or very active minutes (Figure S5 in Multimedia Appendix 2). Specifically, a higher number of lightly active minutes is concomitant with a decrease in the amount of time spent in fairly active and very active physical activities, aligning with the well-established understanding that reductions in overall physical activity can contribute to an increase in depressive symptoms [82]. In contrast, among women without PPD, a notable correlation was found solely in the prepregnancy versus PPD-equivalent periods concerning minimum HR, where an elevation in minimum HR was linked to the PPD-equivalent period (Figure 5B). Although a subset of women demonstrated a significant correlation in SHAP dependence plots concerning digital biomarkers of average HR, quartile 1 HR, or lightly active minutes across the prepregnancy versus PPD-equivalent, pregnancy versus PPD-equivalent, or postpartum versus PPD-equivalent periods, the overall proportion of women exhibiting such patterns was insufficient to draw definitive conclusions regarding the relationship between digital biomarkers during the prepregnancy, pregnancy, or postpartum periods and the PPD-equivalent period (Figure 5B). We postulate that the contrasting patterns of digital biomarkers between women in the PPD and non-PPD cohorts imply potential differences in these biomarkers for women who eventually experience PPD. Therefore, future studies of great interest may seek to develop ML models during the prepregnancy or pregnancy periods to predict a woman's risk of future PPD onset. These models would allow for the prediction of PPD risk in advance.

Comparison With Prior Work

In general, previous investigations have adhered to conventional ML strategies revolving around the development of a solitary model. In this paradigm, a model is constructed using an extensive patient data set encompassing individuals exhibiting either continuous outcomes (for regression-based models) or categorical outcomes. Subsequently, when a new patient is introduced, the model generates predictions for the patient based on their data and the pre-established model [83]. While this approach carries advantages, it is beset by two primary limitations: (1) reliance on an ample sample size and (2) neglect to accommodate the diverse and heterogeneous spectrum of depressive symptoms [16]. Hence, a captivating domain of exploration has honed in on crafting intraindividual ML models. This advancement tackles the constraints of conventional approaches in 2 ways: first, it sidesteps the need for an extensive sample size given that the model is tailored to a single patient's data, and second, it conscientiously acknowledges the

heterogeneous spectrum of depressive symptoms through a focused evaluation of the unique behaviors exhibited by that specific patient.

The use of individualized models may serve as a superior preference compared to those formulated using cohort-based methodologies. For instance, a cross-sectional study using traditional ML models from Fitbit data from healthy adults to predict depression severity only showed a moderate area under the receiver operating characteristic curve range of 0.51 to 0.66. Moreover, while the results demonstrated commendable specificity (0.98-1), sensitivity exhibited marked inadequacy (0.03-0.13) [19]. Another study aimed to investigate the potential of ML models using digital biomarkers in distinguishing between patients with unipolar and bipolar depression against healthy controls. However, the most successful model exhibited an accuracy rate of 0.73 (73%) and a κ value of 0.44, which does not indicate a notably high-performing model [84,85]. Additional investigations have also been conducted within a cohort-based framework; nevertheless, these studies grapple with a noteworthy drawback—they incorporated patient mood as a predictive feature in their models. Considering that these studies aimed to predict the severity of depression, it is unsurprising that these models exhibited heightened performance levels [13,86].

To effectively underscore the viability of personalized ML models over cohort-based methods, our study directly juxtaposed the performance of both approaches (individualized vs cohort-based ML models) side by side. Notably, our findings vividly showcased the superior performance achieved through the personalized methodology for the PPD class in comparison to conventional techniques with a cohort-based model leveraging digital biomarkers from Fitbit for PPD detection (Table 5). This outcome accentuated that individualized models present an encouraging avenue for crafting ML models aimed at identifying mood disorders.

Limitations

Although this study provides a strong foundation for using digital biomarkers to classify PPD, it is not without limitations. First, this study faced constraints due to the restricted number of patients available, which hindered the implementation of conventional ML techniques. However, due to the limited sample size, we opted for an individualized approach, which not only addressed the small sample size but also provided a means to accommodate the inherent variability among individuals [54]. Second, the process of phenotyping patients with PPD relied on a PPD diagnosis or medication use, which could potentially lack specificity in diagnostic codes and miss undiagnosed cases. Third, our approach assumed a standard pregnancy length of 9 months, which may not always align with individual variations. Fourth, there are several layers of confounding that occur during the different phases of pregnancy that may indirectly influence digital biomarkers and ML models, especially as it relates to PPD classification, such as (1) significant hormonal changes that impact physical and mental states; (2) metabolic changes that occur as a result of pregnancy; (3) increased levels of stress during pregnancy and the postpartum period; (4) modifications to one's lifestyle, such as food consumption during pregnancy and the postpartum period; and (5) alterations in physical activity during the postpartum period as a result of birthing complications [87-91]. This could create a risk of model overfitting on general postpartum features compared to those that are specific to the PPD period. In general, to avoid overfitting of the training data, our method used 3 repetitions of 10-fold cross-validation, a strategy known to reduce overfitting compared to a conventional train-test split [92]. Fifth, this study excluded patients with chronic conditions to mitigate the potential influence of those conditions on digital biomarkers. Sixth, sleep data were absent in the AoURP data set at the time of this analysis using Registered Tier v6 although they might also hold predictive value for PPD. Seventh, there is a possibility of false negatives in the non-PPD cohort given the 1 in 7 prevalence of PPD. We attempted to identify women in the non-PPD cohort with undiagnosed PPD by re-evaluating individual model performance for the PPD-equivalent class, where we counted approximately 10 women in the non-PPD cohort who exhibited results with elevated model performance (sensitivity≥0.78 [the average performance of the PPD class for women in the PPD cohort]). However, estimating the prevalence of undiagnosed PPD is difficult in itself; estimating undiagnosed PPD in EHR data is additionally challenging. We suggest that these exploratory findings require future model development, including true negatives (ie, women who are definitely not experiencing PPD) and false negatives for validation. Eighth, there may be delays in PPD diagnosis due to health care–seeking behavior. However, we observed no significant difference in health care use during the postpartum period between the PPD and non-PPD cohorts along with similar adherence to American College of Obstetricians and Gynecologists postpartum visit guidelines in the PPD and non-PPD cohorts. We posit that delays in diagnosis due to health care–seeking behavior might be minimal (Table S5 in Multimedia Appendix 2). These data suggest that women in the PPD cohort exhibited a fairly normal rate of health care use, which should minimize delay in diagnosing PPD. Furthermore, it may be beneficial for subsequent analyses to account for features such as seasonal variation that may also indirectly influence behavior (which is not possible using the Registered Tier of AoURP) in addition to testing other ML algorithms, such as Extreme Gradient Boosting [93,94].

Conclusions

Overall, the findings of this study suggest that it is feasible to characterize PPD in addition to other periods of pregnancy using passively collected digital biomarkers from consumer-grade wearables. The development of individualized models allows for a personalized approach to capture behavioral differences in the form of digital biomarkers. This research lays a robust foundation for forthcoming applications aimed at enhancing the early detection of PPD, a condition that is often underdiagnosed and undertreated. Moreover, on a broader scale, it indicates the exciting potential for intraindividual ML models to be extended to various health conditions.

Abstract

Background: Personal sensing, leveraging data passively and near-continuously collected with wearables from patients in their ecological environment, is a promising paradigm to monitor mood disorders (MDs), a major determinant of the worldwide disease burden. However, collecting and annotating wearable data is resource intensive. Studies of this kind can thus typically afford to recruit only a few dozen patients. This constitutes one of the major obstacles to applying modern supervised machine learning techniques to MD detection.

Objective: In this paper, we overcame this data bottleneck and advanced the detection of acute MD episodes from wearables' data on the back of recent advances in self-supervised learning (SSL). This approach leverages unlabeled data to learn representations during pretraining, subsequently exploited for a supervised task.

Methods: We collected open access data sets recording with the Empatica E4 wristband spanning different, unrelated to MD monitoring, personal sensing tasks—from emotion recognition in Super Mario players to stress detection in undergraduates—and devised a preprocessing pipeline performing on-/off-body detection, sleep/wake detection, segmentation, and (optionally) feature extraction. With 161 E4-recorded subjects, we introduced E4SelfLearning, the largest-to-date open access collection, and its preprocessing pipeline. We developed a novel E4-tailored transformer (E4mer) architecture, serving as the blueprint for both SSL and fully supervised learning; we assessed whether and under which conditions self-supervised pretraining led to an

improvement over fully supervised baselines (ie, the fully supervised E4mer and pre–deep learning algorithms) in detecting acute MD episodes from recording segments taken in 64 (n=32, 50%, acute, n=32, 50%, stable) patients.

Results: SSL significantly outperformed fully supervised pipelines using either our novel E4mer or extreme gradient boosting (XGBoost): n=3353 (81.23%) against n=3110 (75.35%; E4mer) and n=2973 (72.02%; XGBoost) correctly classified recording segments from a total of 4128 segments. SSL performance was strongly associated with the specific surrogate task used for pretraining, as well as with unlabeled data availability.

Conclusions: We showed that SSL, a paradigm where a model is pretrained on unlabeled data with no need for human annotations before deployment on the supervised target task of interest, helps overcome the annotation bottleneck; the choice of the pretraining surrogate task and the size of unlabeled data for pretraining are key determinants of SSL success. We introduced E4mer, which can be used for SSL, and shared the E4SelfLearning collection, along with its preprocessing pipeline, which can foster and expedite future research into SSL for personal sensing.

Introduction

Mood disorders (MDs) are a group of mental health conditions in the *Diagnostic and Statistical Manual, Fifth Edition* (DSM-5) classification system [1]. They are chronic, recurrent disorders featuring disturbances in emotions, energy, and thought, standing out as a leading cause of worldwide disability [2,3] and suicidality [4]. Timely recognition of MD episodes is critical toward better outcomes [5]. However, this is challenging due to generally limited patient insight [6], compounded with the low availability of specialized care for MDs, with rising demand straining current capacity [7,8].

Personal sensing, involving the use of machine learning (ML) to harness data passively and near-continuously collected with wearable devices from patients in their ecological environment, has been attracting interest as a promising paradigm to address this gap [9]. Indeed, some of the core MD clinical features (eg, disturbance in mood and energy levels) translate into changes in physiological parameters measurable with wearable devices [10-12]. A major barrier to the development of clinical decision support systems featuring personal sensing has been the scarcity of labeled data, that is, data with annotations by clinicians about the MD state (eg, diagnosis, disease phase, symptom severity). Collecting and annotating data for personal sensing in MDs is, indeed, an expensive and time-consuming enterprise; thus, studies typically use samples running into only a few dozen patients [13-20].

In this work, we took a different perspective and leveraged *unlabeled* data collected with the Empatica E4 (hereafter E4) wristband [21], a popular research-grade device for personal sensing studies [22], as well as recent advancements in self-supervised learning (SSL) techniques that can learn meaningful representations from such unlabeled data. Specifically, we took advantage of open access data sets that record physiological data with the E4 across different settings but do not address MDs and therefore do not provide information about the mood state of the subjects involved. Although each such data set has only a limited number of subjects, our aggregated and preprocessed data set E4SelfLearning can break the labeled data bottleneck for personal sensing in MDs (Figure 1) [23-33].

Fully supervised systems require vast amounts of data to train, thus limiting their application in different fields, such as health care, where amassing large, high-quality data sets is demanding in terms of time and human resources [34]. Although previous studies on personal sensing for MDs have investigated different tasks, including acute MD episode detection [13-16], regression of a psychometric scale total score [17-19], and, more recently, multitask inference of all items in 2 commonly used psychometric scales [35], they all developed their models in a fully supervised fashion (ie, they were trained on samples for which ground-truth labels were available). As a result, considering that obtaining clinical annotations from patients, especially when on an acute MD episode, is a challenging and expensive enterprise, the sample size is generally modest (eg, N=52 in Côté-Allard et al [15], N=45 in Tazawa et al [13], and N=31 in Pedrelli et al [18]).

SSL, in contrast, is a framework where the model creates proxy supervisory signals within the data themselves, therefore alleviating the annotation bottleneck and allowing us to repurpose existing unlabeled data sets [36]. Specifically, SSL derives supervisory signals from the data themselves, thanks to pretext tasks, which are new supervised challenges, for example, imputing occluded parts of the input data. Through such preparatory pretext tasks, not requiring expert annotation, the model learns useful representations, partial solutions to the downstream target task of interest, for which only a comparatively small amount of annotated data are available [37]. On the back of the great success of SSL in computer vision (CV) [37] and natural language processing (NLP) [38], and with encouraging findings in other health care applications [39], we extended pioneering SSL works on multivariate time series [40-42] to personal sensing in MDs.

In this work, we made the following contributions:

- We gathered 11 open access data sets recording physiological data with an E4 wristband and developed a pipeline for preprocessing such data that performed on-/off-body detection, sleep/wake detection, segmentation, and (optionally) feature extraction. We made the

preprocessing pipeline and the preprocessed data publicly available. This collection (E4SelfLearning), with 161 subjects, is the biggest open access data set to date. We believe that this effort can stimulate future research into SSL with multivariate time-series sensory data by removing 2 barriers, preprocessing and data availability.

- We proposed a novel E4-tailored transformer (E4mer) architecture (Figure 2) [43] and showed that SSL is a viable paradigm, outperforming both fully supervised E4mer and classical machine learning (CML) models using handcrafted features in distinguishing acute MD episodes from clinical stability (euthymia in psychiatric parlance), that is, a time-series (binary) classification task.
- We investigated what makes SSL successful. Specifically, we compared 2 main pretext task designs (ie, masked prediction [MP] and transformation prediction [TP]) [44], and for the best-performing routine, we studied its sensitivity to the unlabeled data availability in ablation analyses. We inspected learned embeddings and showed that they capture meaningful semantics about the underlying context (ie, sleep/wake status) and symptom severity.

Figure 1. A total of ~6254 hours (261 days) of unlabeled recordings from 252 subjects while awake were used for self-supervised pretraining. Unlabeled data comprised a collection of 11 open access data sets, whose aggregation we make publicly available (E4SelfLearning), along with part of the TIMEBASE/INTREPIBD study that was not relevant for the target task under investigation (ie, acute episode vs euthymia classification). Unlabeled data were passed through a model consisting of an encoder and a transform head for self-supervised pretraining; the pretrained encoder block was then retained for the target task, while the transform head was replaced with a new, randomly initialized classification head. *The target task (labeled) training set from the TIMEBASE/INTREPIBD study was also used during self-supervised pretraining. Further details on the data sets used in this study are available in Table S1 in Multimedia Appendix 1. ADARP: Alcohol and Drug Abuse Research Program; PGG-DaLia: PPG Dataset for Motion Compensation and Heart Rate Estimation in Daily Life Activities; TIMEBASE/INTREPIBD: Identifying Digital Biomarkers of Illness Activity in Bipolar Disorder/Identifying Digital Biomarkers of Illness Activity and Treatment Response in Bipolar Disorder; UE4W: Unlabeled Empatica E4 Wristband; WEEE: Wearable Human Energy Expenditure Estimation; WESAD: Wearable Stress and Affect Detection; WESD: Wearable Exam Stress Dataset.

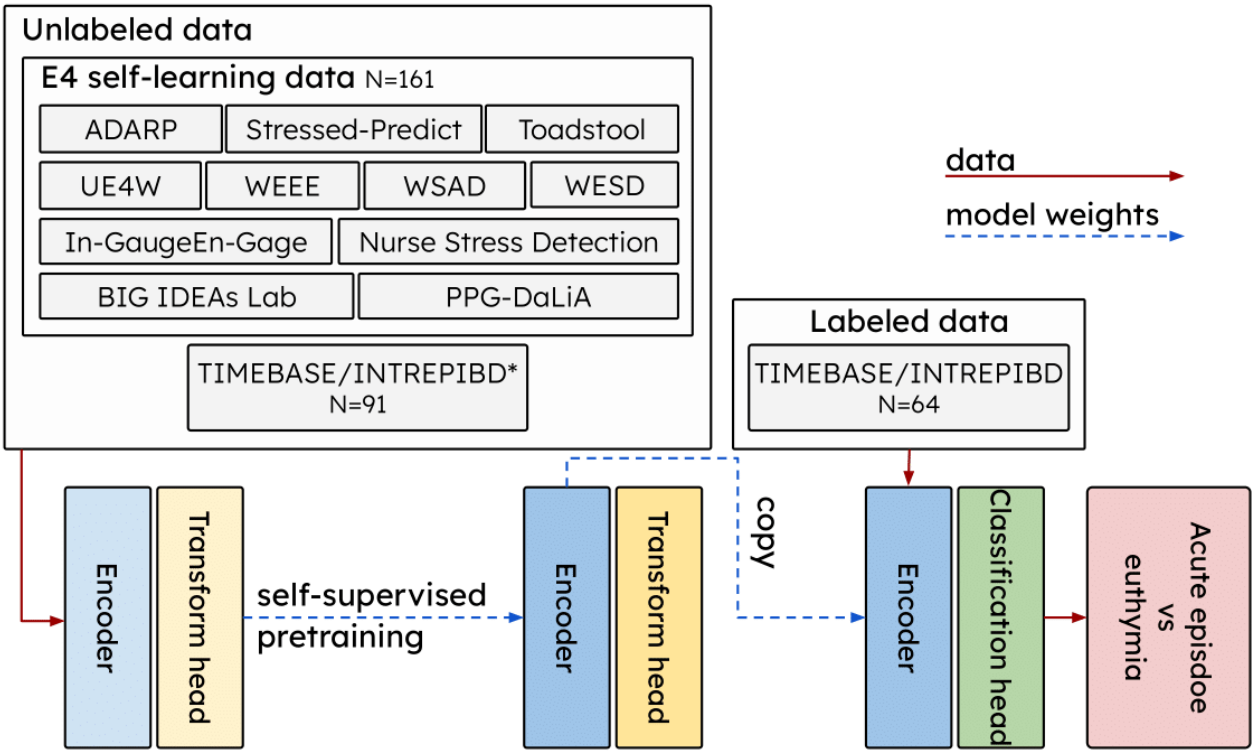

Figure 2. E4mer is a transformer model tailored to the Empatica E4 input data. E4mer consists of 3 sequential modules: (1) channel embeddings set in parallel, 1 for each Empatica E4 raw input channel (ie, acceleration$_x$, acceleration$_y$, acceleration$_z$, BVP, EDA, TEMP), extracting features and mapping channels to tensors of dimensionality (B=batch size, N=time steps, F=number of filters) so that they can be conveniently concatenated along dimension F; (2) RM learning contextual representations of the input time steps within the input segment, thanks to the multihead self-attention mechanism; (3) classification head outputting probabilities for the 2 target classes (ie, acute MD episode and euthymia). SSL models used in our experiments featured the same E4mer architecture described before, where, however, the classification head was replaced with a transform head projecting onto a label space compatible with the pretext task at hand. BVP: blood volume pressure; E4mer: E4-tailored transformer; EDA: electrodermal activity; MD: mood disorder; MLP: multilayer perceptron; RM: representation module; SSL: self-supervised learning; TEMP: temperature.

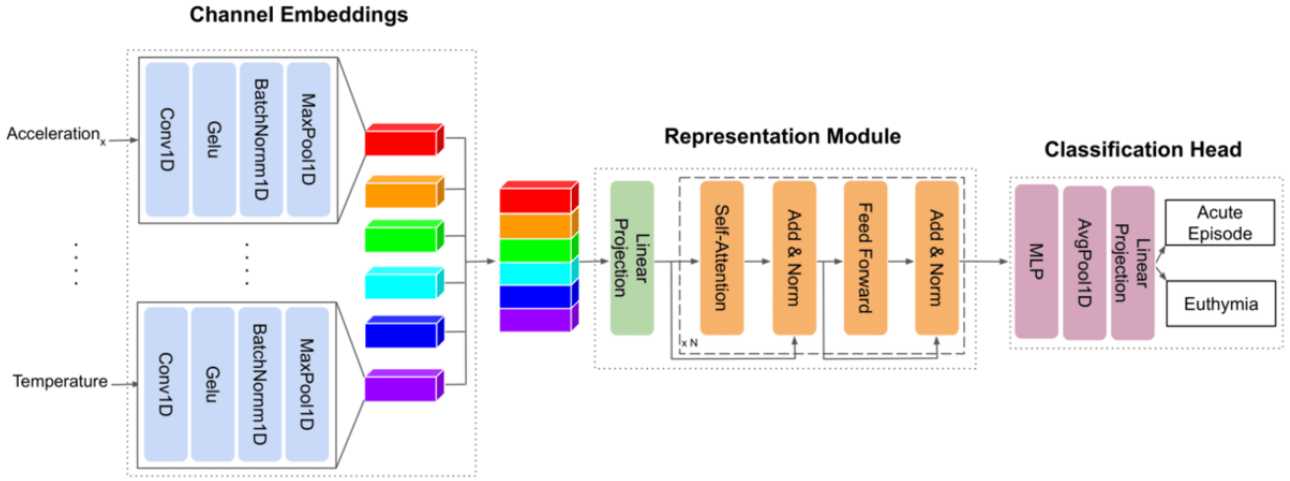

Methods

Study Sample

The TIMEBASE/INTREPIBD Cohort

Our target task was to distinguish acute MD episodes from euthymia using wearable data. We started from a data set for which we had labeled samples, the TIMEBASE/INTREPIBD (Identifying Digital Biomarkers of Illness Activity in Bipolar Disorder/Identifying Digital Biomarkers of Illness Activity and Treatment Response in Bipolar Disorder) cohort [45]. A detailed description of the data collection campaign was given by Anmella et al [45]. In brief, this was a prospective, exploratory, observational study conducted at the Hospital Clìnic, Barcelona, Spain. Patients with a DSM-5 diagnosis of either major depressive disorder (MDD) or bipolar disorder (BD) were enrolled either in the acute affective episode group (defined according to the "Structured Clinical Interview" for DSM-5 disorder criteria) or in the euthymia group (score≤7 on the Hamilton Depression Rating Scale-17 [46] and the Young Mania Rating Scale [47] for at least 8 weeks [48], as confirmed with weekly ambulatory assessments). The former group had post–acute-phase follow-ups, which were, however, excluded from all analyses presented here. At the time of conducting this study, a total of 64 patients were available for the target task, half in the acute affective episode group and half in the euthymia group. Additionally, an extra 91 subjects (including healthy controls, subjects with schizophrenia, and subjects with a substance abuse disorder), whose status was not relevant to the target task, were available from the TIMEBASE/INTREPIBD cohort for self-supervised pretraining.

Patients were interviewed by a psychiatrist collecting clinical demographics (Table 1 and Table S2 in Multimedia Appendix 1) and were required to wear on their nondominant wrist an E4 wristband until the battery ran out (~48 hours). The E4 records 3D acceleration (sampling rate 32 Hz), blood volume pressure (BVP, sampling rate 64 Hz), electrodermal activity (EDA, sampling rate 4 Hz), heart rate (HR, sampling rate 1 Hz), interbeat interval (IBI, ie, the time between 2 consecutive heart ventricular contractions), and skin temperature (TEMP, sampling rate 1 Hz).

As shown in Table 1, MD episodes clinically lie on a spectrum, with depression on one end and mania on the other; mixed episodes, featuring symptoms from both polarities, are a bridge between the 2 spectrum extremes. In this study, we considered acute MD episodes of any polarity, and similarly, we considered euthymia as a unique class, whether in the context of a BD or an MDD diagnosis. Medication classes administered to the cohort are shown in Table S2 in Multimedia Appendix 1; Bonferroni-corrected chi-square tests found no significant association between treatment status (being on a given drug class or not) and target class (acute affective episode vs euthymia).

Table 1. Clinical-demographic features of the target task (acute affective episode vs euthymia classification) population (N=64).

Features	Acute affective episode group (n=32)	Euthymia group (n=32)
Age (years), means (SD)	50.56 (13.05)	47.22 (16.06)
Females, n (%)	15 (46.9%)	14 (43.8%)

E4SelfLearning

For self-supervised pretraining, we gathered 11 open access data sets recording with an E4 [23-33]. Although they all used the same hardware, software, and firmware, such data sets could differ substantially for population, recording setting, and task: from students taking exams [29] or attending classes [31] to nurses carrying out their duty [30] and subjects performing different physical activities [28] or playing Super Mario [27]. Subjects that were not part of the target classes from the TIMEBASE/INTREPIBD study were also included in the unlabeled data for SSL.

Data Preprocessing

Our preprocessing encompassed the following sequential stages: on-/off-body detection, sleep/wake detection, segmentation, and (when preparing data for CML models) feature extraction.

During free-living wear, subjects might remove their device or contact with the wrist might be suboptimal. As a result, off-body periods can be erroneously mistaken for periods of sleep or sedentary behavior, due to the shared feature of an absence of movement. Signal discontinuity in biopotentials, such as EDA, due to a lack of skin contact can be reliably leveraged to detect nonwear periods. As shown by Vieluf et al [49] and Nasseri et al [50], we considered measurements less than 0.05 µS as indicative of off-body status. Furthermore, as we noticed occurrences of values greater than the EDA sensor range (ie, 100 µS [51]), as well as instances of TEMP values outside the physiological range (30°C-40°C), we set both to off-body.

As physiological data vary wildly across sleep and wake statuses, we used sleep/wake detection as a form of data cleaning to reduce the variance in the signal and considered only the wake time in our analyses, especially as most publicly available data sets are recorded in wake conditions. We opted for the algorithm developed by Van Hees et al (*Van Hees*) [52], which was reported as the best-performing algorithm in a recent benchmark study on sleep/wake detection (average F_1-score=79.1) [53]. Like most nonproprietary algorithms, Van Hees uses triaxial acceleration and, specifically, relies on a simple heuristic defining sleep with the absence of a change in the arm angle >5° for 5 minutes or more. To accommodate this rule, wherever on-body sampling cycles did not constitute unbroken sequences of at least a 5-minute duration, all the measurements in that period were considered as off-body and discarded from further analysis.

The wake time from each recording was then segmented with a sliding window, whose segment length (ω) and step size (Δω) were set to 512 and 128 seconds, respectively. This approach, also referred to as window slicing [54], is a common form of data augmentation in time-series classification as multiple segments are produced from a single recording, each one marked with the same label, and is common in personal sensing for MDs. Previous relevant works [15,18,55] have defined ω (Δω) based on clinical intuition and convenience concerning the available data. Another work [35] investigating the regression of HDRS and the YMRS items found the optimal ω through tuning, a computationally expensive approach in our setting; however, it showed that ω was not among the most important hyperparameters for the task at hand. Here, we opted for 512 seconds (~8.5 minutes, conveniently a power of 2 for computational efficiency in binary computers), similar to the 5-minute intervals used by Panagiotou et al [55] for training neural autoencoder architectures on anomaly detection by reconstruction error estimation. Our choice was a trade-off between clinical insight and technical constraints. Clinical intuition suggests that too small a value of ω may be ill suited to capture enough information toward acute affective episode versus euthymia discrimination. However, unlabeled data sets used for self-supervised pretraining recorded relatively short sessions (eg 1 hour [26]). As both CML and deep learning models are trained on individual segments and too long a segment length equates to fewer training data points, a 512-second-long segment allowed us to have enough data for developing ML models [55].

Recording segments constituted our basic unit of analysis, and for the target task, segments from the same recording all shared the same ground-truth label (ie, either acute affective episode or euthymia). When fed to deep learning models, segments were channel-wise standardized by subtracting the mean and dividing by the SD. Such statistics were learned from the target task training set or, in the case of SSL, its aggregation with unlabeled data. Acceleration, the BVP, EDA, and TEMP were considered in deep learning models, while the HR and the IBI, as features derived from the BVP through a proprietary algorithm, were excluded from the deep learning experiments shown here (see Multimedia Appendix 1). However, when using CML, handcrafted features were extracted from segments using *FLIRT* [56], a popular open access feature extraction toolkit for the E4. Note that a single row of features per segment was extracted; in other words, the window size parameter in FLIRT was set equal to ω. We used all features available through this package, derived with the *flirt.acc.get_acc_features* (eg, acceleration entropy), *flirt.eda.get_eda_features* (eg, tonic and phasic EDA components), and *flirt.hrv.get_hrv_features* (eg, HR and HR variability measures) functions. As FLIRT does provide built-in functions for TEMP, we also extracted the segment mean (SD) for this channel. Any missing value was handled with mean imputation. The percentage rate of missing values had a range of 0-37.31, with a mean of 10.44 (SD 16.78).

Data Splits and Metrics

In SSL experiments, we split unlabeled data in a ratio of 85:15 into train and validation sets, partitioning recordings across the 2 sets. For the target task, we investigated a time-split scenario, therefore splitting each recording into train, validation, and test sets again in a ratio of 70:15:15 along the recording time, thus testing generalization across future time points. We made sure that segments with overlapping motifs at the border between target task splits (resulting from using a sliding window with $\Delta\omega<\omega$) were confined to 1 split only, thus ultimately producing 18896, 3904, and 4128 segments for the train, validation, and test sets. The target task validation set doubled as a test set for estimating generalization performance on the SSL pretext task. The time-split scenario is common in personal sensing for MDs (eg, [18,35]), and indeed, despite efforts toward learning subject-invariant representations [57,58], cross-subject generalization remains an unsolved challenge, so personal sensing systems typically require access to each subject's physiological data distribution at training time [59].

The target task was a time-series binary classification. As expected in free-living wear, the total wear time and the off-body and wake times varies across subjects (and, as a result, so did the number of segments). Two-tailed *t* tests were performed to verify significant mean differences in off-body and wake times across individuals from the 2 target classes (acute affective episode and euthymia) but yielded a Bonferroni-corrected P value of >.05 (P=.56 for off-body time and P=.82 for wake time). An equal number of segments from each class was extracted for the target task. To that end, we found the pairing of euthymia and acute affective episode recordings that minimized the pairwise difference between the number of segments available per participant; next, within each pair, the first n segments were retained, where n is the number of

segments of the shortest recording in the pair. We optimized models on the target task for segment-level accuracy ($ACC_{segment}$). Second, to provide a subject-level perspective, we reported the subject ACC:

where y_s is the ground-truth mood state of the s-th subject, which is constant across all the s-th subject's recording segments, and  is a majority vote on the s-th subject, corresponding to the majority predicted class across the s-th subject's recording segments.

Machine Learning Models

We developed 2 types of baselines for the target task: (1) an E4-tailored deep learning pipeline inputting raw recording segments (E4mer) and (2) CML models using handcrafted features extracted with FLIRT from recording segments. We then assessed what boost in performance, if any, a self-supervised pretraining phase might deliver, where the SSL models shared the same building blocks as E4mer.

Baseline Models

E4-Tailored Transformer

E4mer is an artificial neural network discriminative classifier modeling the probability of an acute MD episode, given a recording segment. As shown in Figure 2, E4mer has 3 sequential blocks: (1) channel embeddings (CEs) set in parallel, consisting of the same 1D convolutions with a kernel size equal to the channel sampling frequency, followed by Gaussian error linear unit (Gelu) activation, 1D BatchNorm, and 1D MaxPooling using the channel sampling frequency as both kernel size and step size, so each CE output has the same dimensionality and can be conveniently concatenated with the others before being passed onto (2) a transformer [43] representation module (RM), and (3) a multilayer perceptron (MLP) classification head (H_{sl}). The CEs extract features from the input E4 channels and are designed to handle channels sampled at different frequencies; the RM, powered by multihead self-attention, learns contextual representations of the input tokens (timestamps in our case) within a recording segment; lastly, the H_{sl} maps such representations onto a label space appropriate for a binary classification. E4mer was trained to minimize the binary cross-entropy (BCE) loss between acute affective episode/euthymia predictions and the corresponding ground truth.

Classical Machine Learning

We experimented with the following algorithms, given their popularity and state-of-the-art performance in biomedical applications [60], including personal sensing [13,14]: elastic net logistic regression (ENET), K-nearest neighbor (KNN), support vector machine (SVM), and extreme gradient boosting (XGBoost).

Self-Supervised Learning Schemes

SSL schemes rely on devising a pretext task, for which a (relatively) large amount of unlabeled data is available, conducive to learning, during a pretraining phase, representations useful to solve the downstream target task [44]. What defines an SSL paradigm is thus its pretext task, consisting of a process, P, to generate pseudo labels and an objective to guide the pretraining. An SSL model typically consists of (1) an encoder EN(x;θ): X->V, learning a mapping from input views  to a representation vector  , and (2) a transform head $H_{ssl}(\upsilon;\xi)$: V-> Z, projecting the feature embedding into a label space  compatible with the pretext task at hand. When solving the target task, the pretrained encoder EN is retained as a partial solution to the target problem, whereas the pretrained transform head H_{ssl} is discarded and replaced with a new one, H_{sl}. Next, EN's parameter θ may be kept fixed and only H_{sl}'s parameters may be learned on the target task. This approach, often referred to as *linear readout* (LR), amounts to treating EN as a frozen feature extractor. Alternatively, instead of just training a new head, the entire network may be retrained on the target task, initializing EN's parameter θ to the values learned during self-supervised pretraining, a paradigm known as *fine-tuning* (FT). Our SSL models used the same architecture as E4mer, that is, an encoder EN, consisting of convolutional CEs, followed by a transformer RM, and an MLP for the transform head H_{ssl}. The success of SSL methods largely comes from designing appropriate pretext tasks that produce representations useful for the downstream target task. This usually involves domain knowledge of the target task. We investigated how different pretext tasks affected downstream performance, experimenting with 2 popular SSL routines that have shown success in other applications: MP and TP.

Masked Prediction

This family of SSL methods is characterized by training the model to impute data that have been removed or corrupted by P. It relies on the assumption that context can be used to infer some types of missing information in the data if the domain is well modeled. This strategy was popularized by the huge success of bidirectional encoder representations from transformers (BERT) [38] in NLP applications, and 1 of the first adaptations to multivariate time-series classification was proposed by Zerveas et al [41]. Similar to their implementation, for each segment channel, we sampled a Boolean mask where the sequences of 0s and 1s were sampled from geometric distributions with means of l_0 and l_1, respectively, with:

where r is the masking ratio. As shown by Zerveas et al [41], the average length of the 0 sequences (l_m) and the proportion of masked values (r) were set to 3 seconds and 0.15, respectively. Each segment channel was then multiplied by its corresponding mask, effectively setting to 0 some of the channel-recorded measurements, and inputted to a model that was tasked to recover the original channel values. This was done by minimizing the root mean square error (RMSE) between the masked original value x(t, c) and its reconstruction outputted by the network  :

where c and t, respectively, index the channels, and the timestamps of the 0 values in the masks M and |M| are the total number of 0s sampled (ie, the masks' cardinality).

Transformation Prediction

We followed the implementation shown by Wu et al [42], which used SSL for a target task of emotion recognition with E4 recordings. In brief, for each channel, 1 of 6 transformations (ie, identity, Gaussian noise addition, magnitude warping, permutation, time warping, and cropping) was sampled uniformly at random and then applied. The transformed segment was then inputted into a model, which was tasked to guess, for each channel, which of the 6 transformations was applied. This amounted to a multitask, multiclass classification, where the model was trained to minimize channel average categorical cross-entropy (CCE):

where c indexes the channels and j the transformations, $1_{i,j}$ is an indicator taking value 1 when j is the correct transformation for channel c and 0 otherwise, and $p_{c,j}$ denotes the predicted probability that transformation j was applied to channel c. By solving this task, Wu et al [42] argued that the model learns representations robust to disturbances in the magnitude and time domains.

Tuning

A hyperparameter search for all models was carried out with hyperband Bayesian optimization [61]. For the target task, we selected the setting yielding the highest $ACC_{segment}$ in the validation set, whereas in self-supervised pretraining, we selected hyperparameters associated with the lowest relevant loss in the validation pretraining set. Multimedia Appendix 1 shows the hyperparameter search space and the best configuration across all models. Deep learning models were trained with the AdamW optimizer for a maximum of 300 epochs, with a batch size of 256. Moreover, to speed up the training and search procedure, we used an early stopping learning rate scheduler: we reduced the learning rate α_{LR} by a factor of 0.3 if the model did not improve in its validation performance after 10 consecutive epochs, and we terminated the training procedure if the model did not improve after 2 learning rate reductions. Dropout [62] and weight decay were added to prevent overfitting.

Post hoc Analyses

Toward elucidating key contributors to the viability of SSL, in addition to comparing different pretext task designs, we studied how (1) progressively downsampling unlabeled data sets or (2) removing each data set in turn from the unlabeled collection might impact the performance of our best SSL model. Thus, using the most performative self-supervised scheme, we retrained the SSL model from scratch under configurations (1) and (2) and then tested it on the target task. Note that in both settings, the entire target task training set was kept for pretraining; this is because pretraining on the training set can be always performed at no extra cost in terms of data acquisition. Lastly, we conducted statistical tests to better appreciate how the self-supervised E4mer compared against its fully supervised counterpart and the best-performing CML algorithm and how it was affected by different ablations. Based on whether we considered either (1) recording segments or (2) subjects as our basic analysis units, we had 2 different hypotheses. In (1), we used a linear mixed effects (LME) model to analyze the difference in correct class probabilities between the SSL model and each comparator, considering subjects as a random effect. This accounted for the nested structure of the data, where segments were sampled from individual subjects. A fixed effects intercept was included to test a 0 mean difference between the classifiers at the population level. Additionally, as the ML models we implemented, like most state-of-the-art algorithms [63], effectively treat segments as independent and identically distributed, we used a 2-tailed paired *t* test to assess whether a 0 mean difference in the probability assigned to the correct class was 0. In (2), we checked with a 2-tailed paired *t* test whether the between-classifiers mean difference in the $ACC_{segment}$ by subject was different from 0. To account for multiple testing, within both (1) and (2), a Bonferroni correction was applied. The number of tests was 19, that is, 17 different ablation settings plus 2 tests comparing the best baselines (fully supervised E4mer and the best CML) to SSL.

Code Used

Python 3.10 programming language was used where deep learning and CML models were implemented in PyTorch [64] and Scikit-learn [65]/XGBoost [66] respectively, while hyperparameter tuning was performed in both cases with weights and biases [67]. The best hyperparameter setting found during tuning for each model is reported in Multimedia Appendix 1. All deep learning models were trained on a single Nvidia A100 graphical processing unit (GPU).

Ethical Considerations

The TIMEBASE/INTREPIBD study was conducted in accordance with the ethical principles of the Declaration of Helsinki and Good Clinical Practice and the Hospital Clinic Ethics and Research Board (HCB/2021/104). All participants provided written informed consent prior to their inclusion in the study. All data were collected anonymously and stored encrypted in servers complying with the General Data Protection Regulation (GDPR) and the Health Insurance Portability and Accountability Act (HIPAA). Regarding other studies included in this work, we referred to relevant publications.

Results

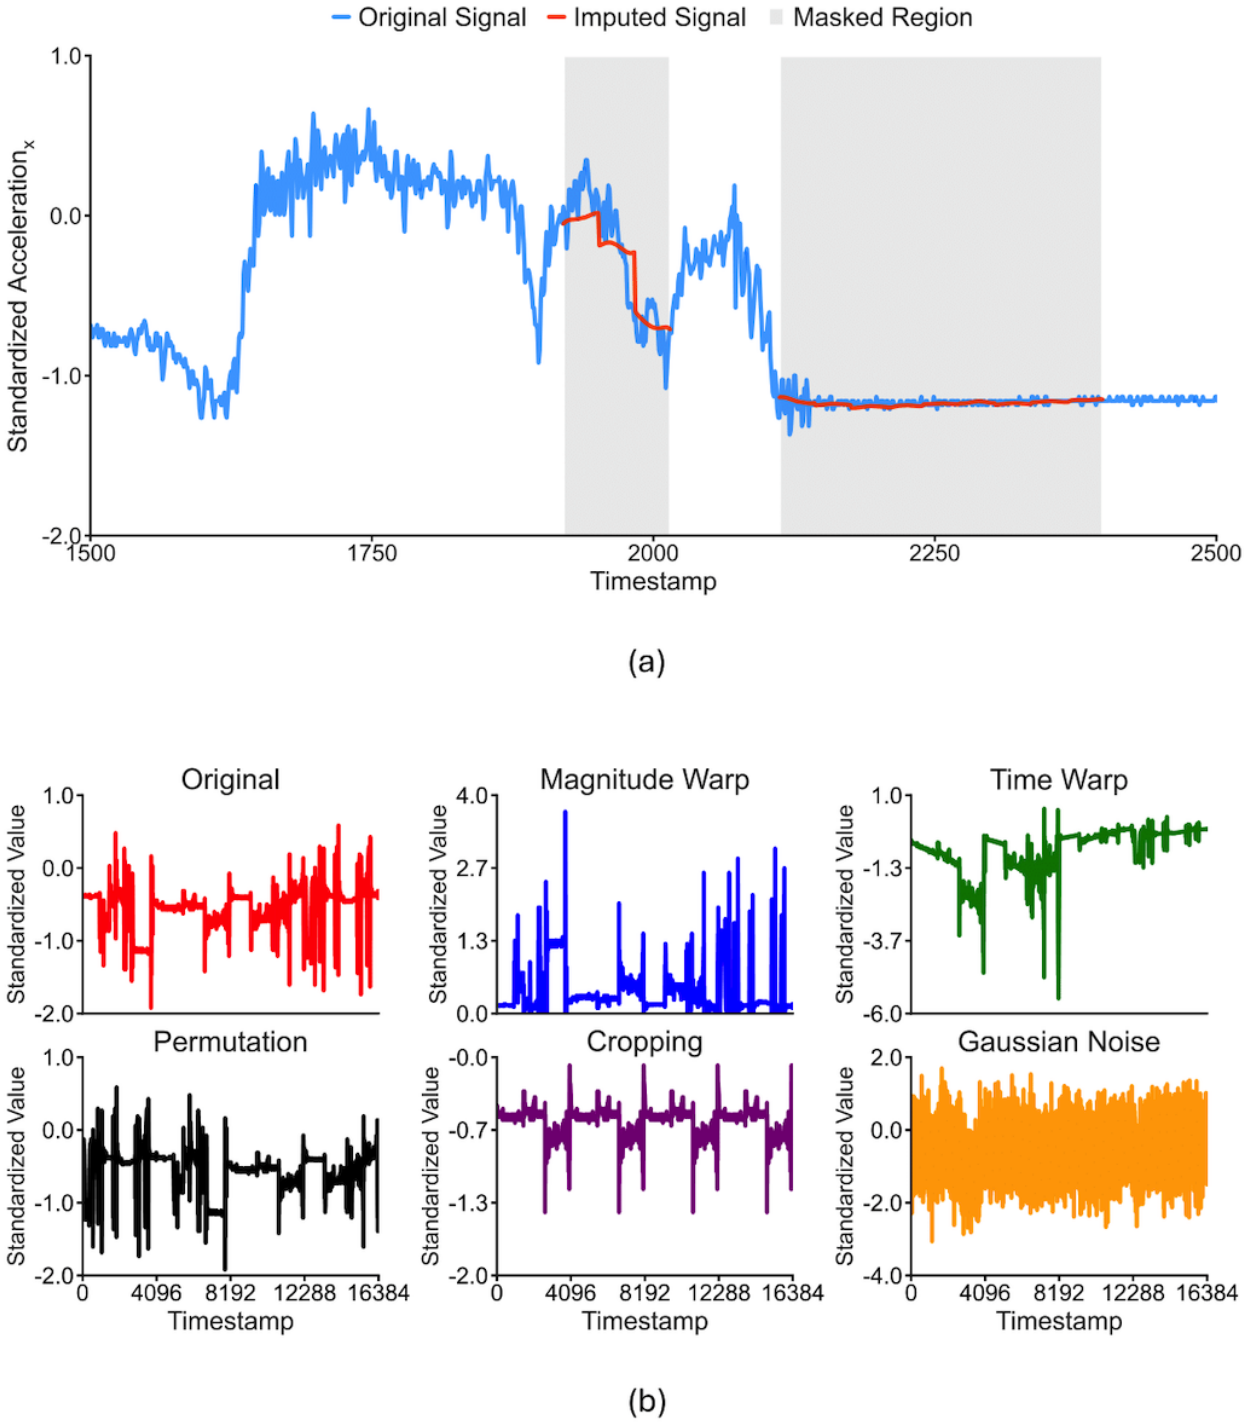
Surrogate Tasks Used in Self-Supervised Pretraining

The same model, using the E4mer architecture (Figure 2), was used across different pretext tasks. Figure 3 illustrates the surrogate tasks we experimented with. In MP (Figure 3a), parts of the input segments were zeroed out by multiplication with a Boolean mask sampled, as shown by Zerveas et al [41], and the model was trained to recover the original input segments. Although the model output entire segments, only the masked values were considered toward the loss computation, that is, the RMSE. The assumption was that the model acquires good representations of the underlying structure of the data when

learning to solve this task. Our best model had an error of 0.1347 on the test set (notice that input segments were channel-wise standardized).

In TP (Figure 3b), 1 transformation was sampled from a set and applied to each channel independently, and the model learned which transformation each channel underwent, minimizing the channel average CCE. We used the same transformations as Wu et al [42], who experimented with an E4 for a downstream task of emotion recognition. The rationale was to encourage robustness against signal disturbances introduced with the transformations. The test loss of the selected model was 0.5000.

Figure 3.



Target Task Performance Comparison

Table 2 illustrates the performance under each model we developed. Although they were all optimized for segment ACC, we also reported subject ACC since in a clinical scenario, a decision needs to be made at the subject level. Note that although ACC was a suitable metric in our use case as data were perfectly balanced, we also provided complementary metrics (precision, recall, F_1-score, and area under the receiver operating characteristic curve [AUROC]), both at the segment and at the patient level. At the subject level, the predicted class was the

result of a majority vote over that subject's segments, while the predicted probabilities under each class were derived by summing segments' predicted probabilities for that subject and normalizing by the corresponding segment number. MP self-supervised pretraining comfortably outperformed end-to-end SSL, while also surpassing other self-supervised approaches.

Table 2. Performance in differentiating an acute MD[a] episode from euthymia across different models.

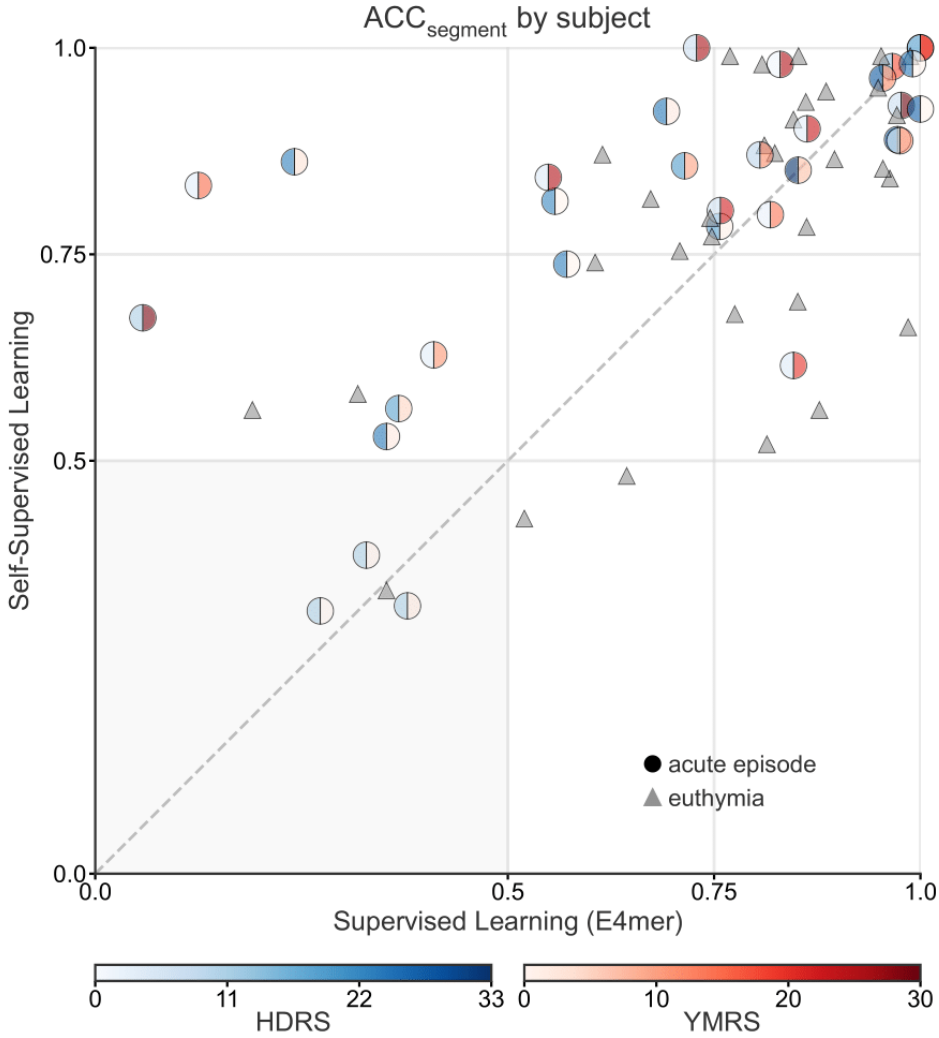
[k]MP: masked prediction.
[l]LR: linear readout.
[m]FT: fine-tuning.
[n]The best results.
[o]TP: transformation prediction.

The E4mer and CML baselines performed to a similar level: although E4mer was superior to XGBoost in terms of $ACC_{segment}$ (75.35 vs 72.02), it was trumped by CML on $ACC_{subject}$ (82.81 vs 81.25). Other CML baselines fared worse than XGBoost. MP pretraining led to a target task performance, substantially higher than the baselines, under both metrics. Although both LR and FT dominated over supervised learning (SL), the latter scored the highest performance with $ACC_{segment}$ and $ACC_{subject}$ of 0.8123 and 0.9063, respectively. However, TP led to only modest improvement over E4mer. Statistical tests comparing the best SSL scheme (ie, MP with FT) against the fully supervised E4mer and XGBoost were significant at both the segment and the subject level. In particular, comparison with E4mer yielded $P_{Bonferroni}$ values of .03 for the LME model and <.001 and .02 for the *t* test at the segment and the subject level, respectively. For XGBoost, $P_{Bonferroni}$ values were .04 for the LME model and <.01 and .01 for the *t* test at the segment and the subject level, respectively.

Comparison of the best SSL with its SL counterpart in terms of $ACC_{segment}$ by subject (Figure 4) suggested that only 2 (3.1%) patients with euthymia were misclassified by SSL but correctly classified by the supervised E4mer. However, SL mispredicted 8 (12.5%) individuals that SSL got right. Patients on an acute MD episode are shown as dots with a color gradient proportional to their total score on the HDRS [46] (left half) and the YMRS [47] (right half), 2 clinician-administered questionnaires tracking depression and mania severity, respectively. Subjects on an acute MD episode misclassified by SL included patients with severe depressive (or manic) symptomatology. Notably, both SSL and SL failed in the case of 4 (6.3%) subjects, including 3 (75%) patients on an acute MD episode with relatively moderate severity.

Figure 4. SSL beats SL by 4 (9.4%) more correctly classified subjects. ACCsegment under SSL and SL (E4mer) within each subject's test segments: subjects in the euthymia group are represented as triangles, while subjects on an acute affective episode are shown as circles with the left half colored in blue and the right half in red, with a gradient proportional to the total sum on the HDRS and the YMRS, respectively. Subjects' position on the x and y axes corresponds to their proportion of recording segments correctly classified by SL and SSL, respectively. Note that a subject's majority vote over their segments is in agreement with the subject's true mood state when the proportion of correctly classified segments from that subject is greater than 0.5. The HDRS and the YMRS range shown on the color bar refer to values scored in the TIMEBASE/INTREPIBD sample, while the total score, in general, range is 0-52 and 0-60, respectively. ACCsegment: segment accuracy; E4mer: E4-tailored transformer; HDRS: Hamilton Depression Rating Scale-17; SL: supervised learning; SSL: self-supervised learning; TIMEBASE/INTREPIBD: Identifying Digital Biomarkers of Illness Activity in Bipolar Disorder/Identifying Digital Biomarkers of Illness Activity and Treatment Response in Bipolar Disorder.



Ablation Analyses and Learned Representations

Tables 3 and 4 show the difference in the target task $ACC_{segment}$ and $ACC_{subject}$ resulting from pretraining the best SSL on parts of the unlabeled data collection and then FT it onto the target task. Ablation analyses showed a positive trend between unlabeled data availability and target task performance, but data set–specific unobserved factors likely played a role. The difference in $ACC_{segment}$ and $ACC_{subject}$ from pretraining on just parts of the entire unlabeled data collection is shown in the tables. An LME model and a 2-tailed paired *t* test assessed whether the mean difference in predicted probabilities for the segment's correct class differed from 0, with the former correcting for subjects as a random effect. A 2-tailed paired *t* test assessed whether the mean difference in the number of correctly classified segments by subject differed from 0. In each test, the comparator was the best-performing self-supervised model. P values are corrected with Bonferroni's method. Note that a majority vote over a subject's segments was used to issue subject-level predictions, and $ACC_{subject}$ was simply the fraction of correct majority votes in the test set. $ACC_{subject}$, therefore, did not consider the proportion of votes over a subject's segments in favor of the subject's correct class but just whether a majority, no matter how small or large, was reached in agreement with the correct class. However, the *t* test (subject) assessed a 0 mean difference in the proportion of votes, within subjects, for the correct class. As shown in Table 3, self-supervised pretraining, preceding FT on the target task, therefore used only a fraction of the total unlabeled collection. A resampling ratio of 0% meant that self-supervised pretraining was performed on the target training set only.

The Pearson correlation coefficient (PCC) between unlabeled data downsampling ratios and the difference in $ACC_{segment}$ and $ACC_{subject}$ was 0.9401 and 0.9449, respectively, indicating a strong dependence between performance and unlabeled data

availability. Similarly, excluding individual data sets from pretraining impacted $ACC_{segment}$ and $ACC_{subject}$ proportionally to their relative size (PCC=–0.8185 and –0.4083, respectively). Notably, however, TIMEBASE/INTREPIBD, despite being collected at the same site as the target task data and making up the largest share of the unlabeled data collection, did not leave the largest dent in performance when excluded from training. Furthermore, excluding some data sets resulted in performance improvement. Differences in $ACC_{segment}$ and $ACC_{subject}$ did not always have the same sign because of the way they were defined. Indeed, it is, for example, possible that the absolute number of correctly classified segments decreased but enough previously misclassified segments within a subject were now correctly classified so that the majority vote for that subject flipped. Statistical analyses showed that the ablation of a single data set was associated with nonsignificantly different performance in terms of correctly classified segments within subjects. At the level of the probability assigned to the correct class for each segment, LME results were significant only for a data set, whereas results were mixed for *t* tests. Stratified resampling gave positive results, but the significance for LME was reached only at lower downsampling ratios.

Lastly, we visualized the representations learned by the encoder, EN, part of our best-performing models to gain further insights. As EN's output had dimensionality (B=number of segments, N=number of timestamps, D=transformer's model dimension), for visualization purposes, we averaged out the D axis and then used Uniform Manifold Approximation and Projection (UMAP) [68], a powerful nonlinear dimensionality reduction technique, to embed the resulting N-dimensional data points into 3 dimensions. The top-left plot of Figure 5 shows the representations learned during self-supervised pretraining with MP. The segments shown are the target task test segments, along with an equal number of segments belonging to the same sessions but taken from the sleep state, which the SSL model was never exposed to during training. Wake and sleep segments have different embeddings, suggesting that the model captured this structure in the physiological data: a Gaussian mixture model, indeed, recovered 2 clusters, one with predominantly sleep segments (n=4081, 82.66%) and the other with the majority of wake segments (n=3272, 95.58%). It should be noted that sleep and wake naturally have quite different semantics with respect to physiological data, and the algorithm we used for sleep/wake differentiation (Van Hees [52]) uses a simple heuristic defining sleep as a sustained lack of significant changes in the acceleration angle. The top-right and bottom plots of Figure 5 illustrate the representations from the SSL model upon FT on the target task. The top-right scatter plot displays the target task test segments, as well as pretraining validation set segments (except for the pretraining segments from the TIMEBASE/INTREPIBD collection). The latter group of segments we assumed as being taken from subjects without an acute MD episode and, arguably, most even without any historical MD diagnosis, since the open access data sets we found did not select for patients with an MD. The plot shows 3 clusters whose composition, as recovered with a Gaussian mixture model, was as follows: (1) n=1464 (79.26%) acute MD episode and n=383 (20.7%) euthymia; (2) n=1120 (74.16%) euthymia and n=390 (25.84%) acute MD episode; and (3) n=7801 (91.01%) unlabeled segments, n=683 (7.96%) euthymia, and n=88 (1.02%) acute MD episode. The bottom plots in Figure 5 show target task segments test segments only (no unlabeled segment), colored with a gradient proportional to symptoms' severity, as assessed with the HDRS [46] and the YMRS [47]. Embeddings would seem to suggest a progression in symptoms' severity across the 2 clusters of segments on the right of the scatter plot.

Table 3. Ablation analyses results: the unlabeled collection was downsampled, stratifying by data sets.

Resampling ratio	80%	60%	40%	20%	0%

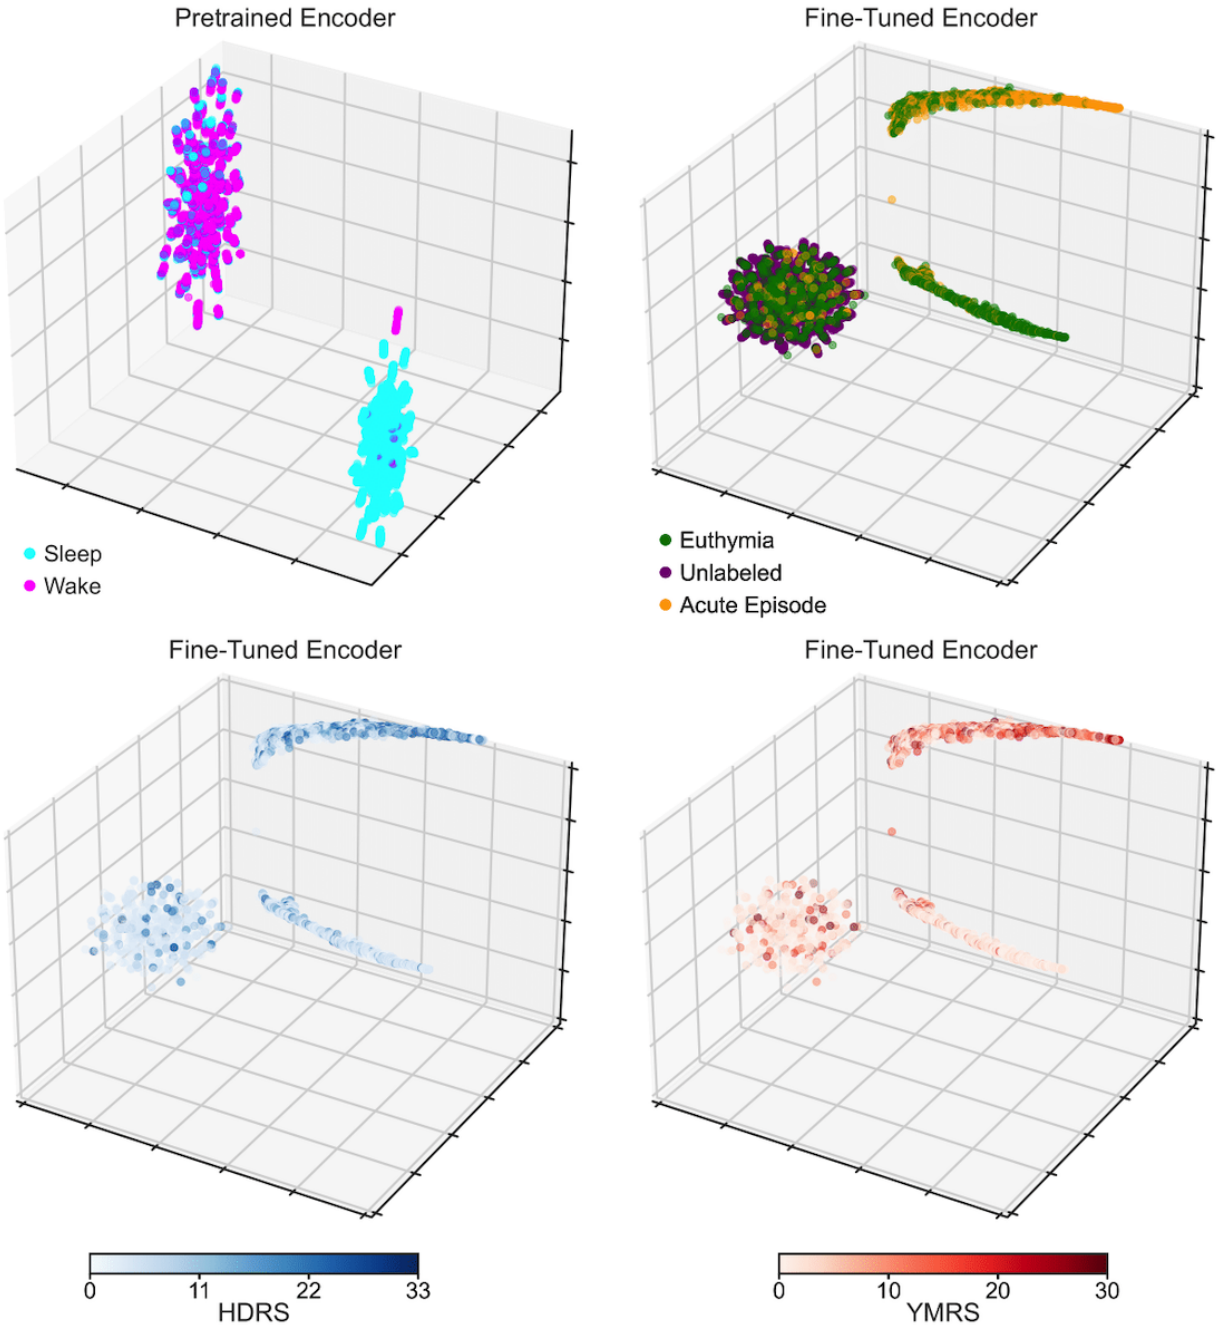
[d]Improvement in performance upon retraining on the ablated unlabeled data collection.

[e]TIMEBASE/INTREPIBD: Identifying Digital Biomarkers of Illness Activity in Bipolar Disorder/Identifying Digital Biomarkers of Illness Activity and Treatment Response in Bipolar Disorder.

Figure 5. Reassuringly, the learned embeddings seem to have captured meaningful semantics about the underlying context. (Top left) Embeddings from the encoder pretrained on MP map sleep and wake segments to different parts of the latent space. (Top right) Embeddings from the encoder FT on the target task show that segments from the unlabeled open access data sets, which presumably do not contain subjects on an acute MD episode, tend to cluster with part of the segments from patients in euthymia. Embeddings from the fine-tuned encoder show a gradient in symptoms' severity across target task segments, as revealed by (bottom left) the HDRS and (bottom right) the YMRS total score. Note that unlabeled segments are not shown in the bottom left or right plot and that the HDRS and YMRS ranges shown on the color bar refer to values scored in the TIMEBASE/INTREPIBD sample, while the total score range, in general, can be 0-52 and 0-60, respectively. FT: fine-tuning; HDRS: Hamilton Depression Rating Scale-17; MD: mood disorder; MP: masked prediction; TIMEBASE/INTREPIBD: Identifying Digital Biomarkers of Illness Activity in Bipolar Disorder/Identifying Digital Biomarkers of Illness Activity and Treatment Response in Bipolar Disorder; YMRS: Young Mania Rating Scale.



Discussion

Principal Findings

Personal sensing is likely to play a key role in health care supply, creating unprecedented opportunities for patient monitoring and just-in-time adaptive interventions [69]. Toward delivering on this promise, expert annotation is a major obstacle; this is especially the case with MDs, wherein data annotation is particularly challenging and time-consuming, considering the nature of the disorders.

To the best of our knowledge, we are the first to show that SSL is a viable paradigm in personal sensing for MDs, mitigating the annotation bottleneck, thanks to the repurposing of existing unlabeled data collected in settings as different as subjects playing Super Mario [27], taking university exams [29], or performing physical exercise [28].

We took on a straightforward yet fundamental task, that is, to distinguish acute MD episodes from euthymia. Timely recognition of an impending MD episode in someone with a historical MD diagnosis regardless of the episode polarity (depressive, manic, or mixed) may, indeed, enable preemptive interventions and better outcomes [5]. Our results suggest that with a sample size on the order of magnitude that is typical of studies into personal sensing for MDs, a modern deep learning fully supervised pipeline (E4mer) may offer no substantial improvements over simpler CML algorithms (eg, XGBoost), despite higher development and computational costs. However, the accumulation and repurposing of existing unlabeled data sets for an SSL pretraining phase leads to a confident margin of improvement: $ACC_{segment}$ and $ACC_{subject}$ improve by 7.8% and 11.54%, respectively, relative to the fully supervised E4mer, with 6 (9.4%) of 64 more subjects correctly classified.

Our findings further show that careful choice of the pretext task, as well documented in the literature on SSL [40], is key toward learning useful representations for the downstream target task. Unlike MP, improvement, if any at all, from TP was only modest. This is not to say that such a pretext task may in general fail to deliver on acute MD episode versus euthymia differentiation. Indeed, the specific transformations we implemented, borrowed from Wu et al [42], may have been suboptimal for our downstream task, pointing to the importance of domain knowledge (including clinical expertise) in pretext task design. Lastly, although SSL relaxes dependence on large, annotated data sets, our results indicate that its success relies on the size of unlabeled data. Ablation analyses, indeed, showed a positive correlation between target task performance and the size of the corpus available for pretraining. Data set–idiosyncratic factors accounting for the nonperfect correlation between the relative size and impact on target task performance may be present. Speculatively, these may include noise in the data, (dis)similarity of recording conditions, or (ir)relevance for the target task of the representations learned modeling the domain of the unlabeled data set.

Statistical analyses showed that excluding from pretraining any of the individual unlabeled data sets, while keeping all others, is not associated with a significant change in performance on the proportion of correctly classified segments within subjects. The lack of a significant effect in either direction (improvement or deterioration), along with a significantly superior performance of SSL over fully supervised schemes, indicate that pretraining on big data collections leads to higher performance than taking on the target task from scratch. Of importance, adding data sets for pretraining from domains not immediately related to the target task did not undermine the model. Pretraining under progressively lower downsampling ratios lent further support to the importance of data size. This is consistent with the deep learning recipe where the bigger the pretraining corpus, the better the results [70]. Results from tests at the level of segment-predicted probabilities are consistent with this view. Of the data sets comprising less than 1% of the entire unlabeled collection, only 1 reached statistical significance. LME has more flexibility to explain the data since rather than pooling all segments together in a unique (bigger) population, it treats them as embedded within subjects. This explains the lack of statistical significance relative to the *t* tests under various data ablation regimes.

Limitations

We acknowledge the following limitations of this study. We deliberately chose the simplest task that has clinical relevance in personal sensing for MDs since our focus was on SSL; however, we appreciate that a more fine-grained MD description, beyond a simple acute MD episode versus euthymia binary classification, may add further clinical value [35]. As the literature on SSL is expanding at a fast pace, a thorough search of different approaches was beyond the scope of this work. We acknowledge that other pretext tasks can be deployed, and although the architectural choice may have an impact on SSL, we settled for just 1 reasonable, modern model design with a transformer [43] as a workhorse for representation learning. Lastly, given the naturalist design of the study, reflective of the intended use of personal sensing in a clinical setting, we could not exclude the effect of confounders, including medications, on the physiological variables. However, we reported medication classes administered in the cohort and verified a lack of any significant association between target classes (euthymia vs acute MD episode) and being on a given medication class.

Future Directions

As our findings indicate that the choice of the pretext task has a significant impact on target task performance, further efforts should be put into pretext task design. Indeed, although MP is a general-purpose strategy inspired by the great success of BERT [38] in NLP, the literature on SSL [40] suggests that domain knowledge may help tailor the pretext task to the specific use case. A promising approach we did not explore is contrastive learning [71], which, indeed, relies on domain knowledge of how augmented views of the input are created, especially since most experience today is in computer vision and NLP, while physiological multivariate time series are relatively unexplored.

Conclusion

This work shows that SSL is a promising paradigm for mitigating the annotation bottleneck, 1 of the major barriers to the development of artificial intelligence–powered clinical decision support systems using personal sensing to help monitor MDs, thus enabling early intervention. The collection and preprocessing of open access unlabeled data sets that we curated (E4SelfLearning) can foster future research into SSL, therefore advancing the translation of personal sensing into clinical practice.

Acknowledgments

We acknowledge the contribution of all the participants of the study.

Data Availability

The E4SelfLearning collection is available at Reference [72], and the codebase is available at Reference [73]. Data in deidentified form from the Identifying Digital Biomarkers of Illness Activity in Bipolar Disorder/Identifying Digital Biomarkers of Illness Activity and Treatment Response in Bipolar Disorder study may be made available from the corresponding author upon reasonable request.

Authors' Contributions

FC conceived of the study, proposed the methodology, developed the software codebase for the analyses, prepared the manuscript, and curated data collection. BML contributed to codebase development and manuscript writing. GA, CVP, AM, IP, MV, IGF, AB, and MG collected the data for the TIMEBASE/INTREPIBD (Identifying Digital Biomarkers of Illness Activity in Bipolar Disorder/Identifying Digital Biomarkers of Illness Activity and Treatment Response in Bipolar Disorder) study. EV, AHY, SL, and HW critically reviewed the manuscript and provided feedback on the clinical side. DHM is the coordinator of the TIMEBASE/INTREPIBD study and critically reviewed the manuscript. AV supervised this study and contributed to the study design, methodology development, and manuscript writing.

Conflicts of Interest

GA has received continuing medical education–related honoraria, or consulting fees from the Janssen-Cilag, Lundbeck, Lundbeck/Otsuka, and Angelini, with no financial or other relationship relevant to the subject of this paper. IG has received grants and served as a consultant, advisor, or CME speaker for the following identities: ADAMED, Angelini, Casen Recordati, Esteve, Ferrer, Gedeon Richter, Janssen-Cilag, Lundbeck, Lundbeck-Otsuka, Luye, SEI Healthcare, and Viatris outside the submitted work. She also receives royalties from Oxford University Press, Elsevier, and the Editorial Médica Panamericana. All authors report no financial or other relationship relevant to the subject of this paper.

Abstract

Background: Technology has become an integral part of our everyday life, and its use to manage and study health is no exception. Romantic partners play a critical role in managing chronic health conditions as they tend to be a primary source of support.

Objective: This study tests the feasibility of using commercial wearables to monitor couples' unique way of communicating and supporting each other and documents the physiological correlates of interpersonal dynamics (ie, heart rate linkage).

Methods: We analyzed 617 audio recordings of 5-minute duration (384 with concurrent heart rate data) and 527 brief self-reports collected from 11 couples in which 1 partner had type II diabetes during the course of their typical daily lives. Audio data were coded by trained raters for social support. The extent to which heart rate fluctuations were linked among couples was quantified using cross-correlations. Random-intercept multilevel models explored whether cross-correlations might differ by social contexts and exchanges.

Results: Sixty percent of audio recordings captured speech between partners and partners reported personal contact with each other in 75% of self-reports. Based on the coding, social support was found in 6% of recordings, whereas at least 1 partner self-reported social support about half the time (53%). Couples, on average, showed small to moderate interconnections in their heart rate fluctuations (r=0.04-0.22). Couples also varied in the extent to which there was lagged linkage, that is, meaning that changes in one partner's heart rate tended to precede changes in the other partner's heart rate. Exploratory analyses showed that heart rate linkage was stronger (1) in rater-coded partner conversations (vs moments of no rater-coded partner conversations: r_{diff}=0.13; P=.03), (2) when partners self-reported interpersonal contact (vs moments of no self-reported interpersonal contact: r_{diff}=0.20; P<.001), and (3) when partners self-reported social support exchanges (vs moments of no self-reported social support exchange: r_{diff}=0.15; P=.004).

Conclusions: Our study provides initial evidence for the utility of using wearables to collect biopsychosocial data in couples managing a chronic health condition in daily life. Specifically, heart rate linkage might play a role in fostering chronic disease management as a couple. Insights from collecting such data could inform future technology interventions to promote healthy lifestyle engagement and adaptive chronic disease management.

Introduction

Coping with a chronic health condition refers to the various psychological, emotional, and behavioral strategies individuals use to manage the challenges, stressors, and lifestyle adjustments associated with living with a long-term health condition [1]. Challenges associated with the maintenance of health-promoting behaviors such as being physically active, following a medication regime, and monitoring one's current health status on top of direct effects of the chronic health condition on cognitive and physical resources (eg, fatigue) can lead to lapses in treatment adherence, which are common [2]. Poor treatment adherence, in turn, results in higher morbidity and mortality rates, as well as increased expenses related to outpatient care and hospitalization for managing diabetes-related complications [3]. Models of chronic disease management acknowledge the important role that close others generally, and romantic partners specifically, play in coping [1,4-6]. Social support refers to how social relationships provide resources and assistance to manage stressors and challenges [7]. These forms of assistance manifest in instrumental ways (ie, practical assistance with a problem or task) and emotional ways (ie, comfort, encouragement, reassurance, and listening empathetically [8]). Social support can facilitate coping by promoting healthy lifestyle choices and helping manage disease-related demands in daily life and has been associated with better disease adjustment and higher quality of life among patients [9,10]. Moreover, in a dyadic context, providing social support has also been conceptualized as a specific form of coping [11]. In laboratory stress paradigms, social support (eg, in the form of physical touch) buffers physiological stress reactivity and speeds up recovery, for example, as assessed by heart rate and salivary cortisol levels [12,13]. This effect is particularly pronounced when the social support comes from a close person, such as a romantic partner [12].

The couple as a unit of study is particularly interesting for researchers studying chronic health conditions because romantic partners tend to be a major source of support and partners' health is closely linked [11,14,15]. For example, individuals are more than 2 times more likely to have diabetes themselves when they are in a relationship with someone who has diabetes [16,17]. This is not surprising as lifestyle risk factors for diabetes such as eating patterns, physical activity, and other health behaviors are often shared in couples [18]. Newer conceptual models of chronic health conditions and coping, including the dyadic regulation connectivity model [5], see couples as a dynamic system, in which dyadic regulation of chronic health conditions occurs in a flexible, dynamic, and complex way adjusting to changing internal contexts (eg, emotional states) as well as external contexts (eg, work demands). Specifically, dyadic regulation involves different network hubs (illness representations hub, coping behaviors hub, and outcomes hub), interconnected through feedback loops and constantly interacting at the person and dyad level. This dynamic process is described as "a 'living' mechanism which is continuously constructed and reconstructed in the mind and the behaviors of the individuals and the couples" [5]. Consequently, the field has called for more advanced methods to be able to study time- and context-sensitive processes shaping health behavior and disease management [19].

New technology including smartphones and smartwatches allows to collect observational and physiological data to observe dynamic phenomena as they unfold in daily life [20]. For example, researchers have equipped couples with audio recorders to capture sound snippets as they go about their usual routines, finding that use of certain speech (eg, positive word use, deep conversation) was associated with better disease adjustment to breast cancer in women [21,22]. Furthermore, health behaviors such as physical activity and medication adherence can be objectively tracked and this information can be used to develop targeted interventions in real time [23]. Researchers have also used sensor data to measure individuals' physiological functioning, for instance, electrodermal activity (EDA), skin temperature, respiratory rate, blood pressure, and heart rate [24,25]. Measures of the autonomic nervous system such as heart rate hold particular significance because they tend to change rapidly in response to shifting contexts (eg, emotions or behavior [26]). This responsiveness, in combination with the relative ease of data collection through wearable devices, makes it an excellent indicator of physiological linkage in couples.

Studies analyzing physiological time series data in couples have found that romantic partners are interconnected in daily fluctuations of heart rate, a phenomenon that has been called "physiological synchrony" or "physiological linkage" [27-29]. Physiological linkage has been associated with central interpersonal outcomes such as trust, empathy, and effective cooperation [28,30-32], and could thus be important for social processes such as supportive interactions in managing a chronic health condition. For example, synchrony in skin conductance levels predicted higher cooperative success in 76 dyads (college students) playing a Prisoner's Dilemma game [30]. In addition, heart rate linkage was increased in 110 college student dyads

when randomized to playing a trust-related game versus a control condition [32]. A recent meta-analysis of 60 published and unpublished experiments also demonstrated that synchrony exhibits a medium-sized effect on prosocial attitudes and behaviors [33]. Thus, physiological linkage might be relevant for coregulation between partners and enable adaptive couple functioning [34]. Yet, no prior research has examined heart rate linkage in the context of everyday social contexts and social support exchanges in individuals with chronic health conditions.

Previous studies on interpersonal dynamics and heart rate linkage in couples have mostly used electrocardiogram data from medical-grade devices such as the BIOPAC collected in laboratory settings [34,35]. However, commercial devices such as smartwatches could be a cost-effective way to collect biopsychosocial data on couples managing chronic health conditions in daily life. Therefore, the objective of this study is to outline the methods we used to gather two types of data: (1) information concerning psychosocial processes, encompassing social contexts and interactions, using observational techniques (audio recordings), and self-report measures; and (2) data on biological processes, specifically heart rate. In doing so, we summarize the feasibility of collecting such data and present descriptive and exploratory findings. Specifically, we examine whether heart rate linkage in couples is higher in moments of personal contact and support.

Methods

Participants and Procedure

We used data of 11 couples who took part in the DYadic MANagement of Diabetes (DYMAND) study (study protocol [36]; description of monitoring system [37]). This study was funded by the Swiss National Science Foundation (CR12I1_166348). Couples were recruited through newspaper advertisement, flyer distribution to diabetes specialists and pharmacies, diabetes forums, and in diabetes departments of hospitals in the German-speaking part of Switzerland from 2019 to 2021. The original recruitment target was 180 couples. However, due to the COVID-19 pandemic and associated restrictions regarding in-person research with vulnerable populations recruitment had to be paused for a considerable duration. This resulted in the current sample size. Eligibility criteria comprised one partner having a medical diagnosis of type II diabetes with prescribed oral drugs and the other partner (without such diagnosis) being willing to participate as well. Participants were excluded if they required insulin injections, inpatient treatment, were working in shiftwork, or had insufficient command of the German language. We collected data from 13 couples, who were living in metropolitan and rural regions in the German-speaking part of Switzerland. Two couples dropped out during the monitoring phase because of time constraints, resulting in a final sample of 11 couples (see Table 1 for descriptives). Participants with type II diabetes were aged 52-80 years (mean 68.9, SD 7.7 years), mostly male (10 males, 1 female), and a majority did not have a higher secondary school degree (8 with lower secondary education, 3 with higher secondary degree). Less than half of the participants with type II diabetes measured their blood sugar levels daily (4/11, 36%) and the average long-term blood sugar concentration was 6.8% (hemoglobin A_{1c} [HbA_{1c}], SD 0.5%; normal HbA_{1c} <5.7% [38]). Most participants reported a positive influence of their partnership on their diabetes management (10/11, 91%). Partners were aged 47-80 (mean 66.7, SD 9.2) years, mostly female (1 male, 10 females), and 1 participant had a higher secondary school degree. Less than half of the participants with type II diabetes (3/11, 27%) and partners (4/11, 36%) were employed, whereas the majority was retired. Couples' average relationship duration was 31.5 (SD 14.6) years. Most couples had a monthly household income above the poverty line for a household of 2 people in Switzerland (>4000 Swiss Francs; 80% [39]).

Table 1. Sample descriptives (N=11 couples).

Variable	Person with type II diabetes	Partner
Age (years), mean (SD)	68.91 (7.71)	66.68 (9.19)
Sex	91% male, 9% female	9% male, 91% female
Education	73% with lower secondary degree	91% with lower secondary degree
Employment status	27% employed	36% employed
Relationship duration (years), mean (SD)	31.58 (14.95)	31.45 (15.01)
Household income (Swiss Francs[a])	2001-4000 (n=1); 4001-6000 (n=2); 6001-8000 (n=4); 8001-10,000 (n=1); and >10,000 (n=3)	4001-6000 (n=3); 6001-8000 (n=2); 8001-10,000 (n=1); >10,000 (n=3); and missing (n=2)
Children, n	No children (n=2), 1 child (n=3), 2 children (n=3), 3 children (n=1), and 4 children (n=2)	No children (n=3), 1 child (n=1), 2 children (n=5), and 3 children (n=2)

[a]1 Swiss Franc=US $1.13.

After a baseline session in which the participants were trained to use the equipment and completed a questionnaire battery, the participants entered a 7-day monitoring phase. An assessment was triggered every hour during a specified time defined by the couples in the morning (eg, 6 AM to 9 AM) and evening (eg, 5 PM to 9 PM) during the week and all day (waking hours, eg, 8 AM to 9 PM) on the weekend. This decision was made to alleviate participant burden by abstaining from data collection during periods when partners are typically at work, thus ensuring that we capture meaningful partner interactions effectively.

Assessments were elicited when partners were close to each other (when the smartwatch Bluetooth system detected a signal strength of the partner's watch greater than –80 dB corresponding to approximately 5 m), and speech was detected. When the 2 conditions of physical closeness and speech were not detected, an assessment was triggered at the end of the hour to ensure sufficient data coverage. The assessment included a 5-minute audio and heart rate recording, followed by a brief self-report questionnaire on the smartphone which asked about partner interactions and health behaviors. Each evening, partners answered a longer survey about their own and their partner's behaviors (data not used in this study). Participants reported that the study app was easy to use (persons with type II diabetes: mean 5.9, SD 0.7; partners: mean 6.0, SD 0.7; 1=completely disagree to 7=fully agree). See the study by Boateng et al [37] for a detailed description of the development and deployment of the smartwatch- and smartphone-monitoring system. After the 7-day monitoring phase, partners returned to the laboratory for an exit session during which feedback on the study was collected, and partners were videotaped while having a 10-minute conversation about their diabetes management. In this exit session, the participants were also allowed to review their audio recordings and delete files before the research team accessed them. None of the couples chose to remove any of the audio recordings. Couples received 100 Swiss Francs as reimbursement for taking part in the study.

Ethical Considerations

Ethics approval was granted by the cantonal ethics committee of the Canton of Zurich, Switzerland (Req-2017_00430), and informed consent was obtained from all participants.

Measures

Audio Recordings

A smartwatch (Polar M600) recorded daily life audio snippets for 5 minutes each. Four trained research assistants used the Social Environment Coding of Sound Inventory [40] to code couples' location, activity, conversation partner, and conversation type. Conversation types included (1) practical: pragmatic conversations focusing on practical daily matters such as making plans and discussing meals; (2) small talk: an interaction without instrumental purpose, involving superficial exchanges of information that have no significant impact or consequence on participants' lives; (3) deep or substantive: conversations with the purpose to exchange thoughts, information, values, and ideas on nonemotional topics such as current events; (4) disclosure: conversations that involve sharing personal feelings or emotions, which may include discussing topics such as the relationship, hopes and dreams, or other deeply meaningful experiences, surpassing the threshold of triviality. Furthermore, we coded for instrumental and emotional social support, following procedures outlined in the study by Wang and Repetti [41]. Instrumental support entailed help with practical problems and tasks, such as assistance with chores or the provision of information to help handle a task-oriented problem (eg, figuring out the fastest driving route to the doctor's office). Emotional support included provisions of comfort, encouragement, advice, or guidance of an emotional nature, for example, listening empathetically to a spouse's frustrations about work. Fifteen percent of recordings were coded by all 4 research assistants to calculate interrater reliability (intraclass correlation [ICC] of 2.1, calculated using SPSS; IBM Corp), which was satisfactory (>0.60 [42]; location: ICC=0.77, activity: ICC=0.67, conversation partners: ICC=0.60-0.74, and support: ICC=0.63), except for conversation types (ICC=0.39 for practical, 0.50 for small talk, 0.24 for deep or substantive, and 0.28 for disclosure).

Heart Rate

The smartwatch also collected heart rate information during the 5-minute audio recordings. The watch did not collect equally spaced recordings (mean spacing=2.7, SD 2.8 seconds). Thus, to match partner heart rate data, we calculated the mean of all heart rate values captured in 5 seconds frames (average n=2.1, SD 1.2, range 1-6 values; if aggregated to 10-second frames, pattern of findings remains the same). This resulted in a total of 55,175 heart rate values. We then aligned the heart rate data of couples by time stamp and kept only segments in which data from both partners were available (n=37,834, 69% heart rate pairings). Missing values in paired data are due to devices eliciting recordings with a small lag in partners or additional recordings that were triggered in just 1 partner. Furthermore, 5-minute units with less than 10 paired heart rate values of partners were deleted (n=6, <1%).

Self-Reported Social Contexts and Exchanges

Subsequently to the audio and heart rate recording, participants reported whether they had any personal contact with their partner in the last 5 minutes. Furthermore, participants with type II diabetes indicated whether they received emotional or practical support from their partner in the last 5 minutes with yes or no: "My partner has supported me emotionally in the last five minutes"/"My partner has supported me practically in the last five minutes." Partners reported emotional and practical support provision with yes or no: "I have been emotionally supportive of my partner in the last five minutes"/"I have been practically supporting my partner in the last five minutes." A social support exchange was coded when provided or received support was indicated by at least 1 partner.

Statistical Analysis

Descriptives were calculated using frequencies, means, and SDs. Heart rate linkage in couples was quantified using cross-correlations [43], calculated with the ccf function in R (Stats Package; R Core Team [44]). The linkage between partners can be in-phase (positive correlation), meaning that fluctuations in partners' heart rates are in the same direction, or antiphase (negative correlation), meaning that couples show opposite patterns of heart rate fluctuations over time. The cross-correlation models the relationship between both partners' heart rate time series data for a given recording. An advantage of the cross-correlation method over traditional correlation techniques is that it calculates the correlation between dyadic time series of heart rate data at a given maximum lag. Specifically, it quantifies the dependence of the heart rate time series data of the person with type II diabetes on its past observations, the partner's concurrent heart rate, and the past or future observations of the partner's heart rate. In this way,

the ccf identifies the maximum cross-correlation for each recording, which could occur at a positive, no, or negative lag. We considered only a lag of ±1 time fragment because we had averaged heart rate recordings across 5-second windows, and cross-correlations can be biased if longer lags are used (see suggestions outlined in the study by Behrens et al [45]). In the presented results, a lag of –1 indicates that changes in the heart rate of the person with type II diabetes tended to be a precursor to changes in the partner's heart rate. A lag of 0 indicates that changes in heart rate tended to co-occur. A lag of +1 indicates that changes in the partner's heart rate tended to be a precursor to changes in the heart rate of the person with type II diabetes. Finally, we explored whether cross-correlations might differ by social contexts and exchanges using simple random-intercept multilevel models (observations nested within individuals nested within couples, controlling for person-level averages; R package lme4 [46]). For these models, cross-correlations were Fisher-Z transformed to normalize the distribution.

Results

Descriptives

We collected 992 audio files from 11 couples, of which 375 captured the same content (ie, they co-occurred in partners; 37.8%). After removing the audio file of 1 partner in these cases, we had a total of 617 audio recordings for analysis (mean 56.1, SD 14.5 per couple; range: 35-83 files). Three-quarters of the audio files contained speech (74%), and participants were mostly at home (80%; 8% in public, 5% in transit, 4% outdoors, and 3% other or unknown). Participants were most frequently watching TV or listening to radio (195/590, 33%), socializing (189/590, 32%), or doing housework (69/590, 12%), and, to a lesser extent, were eating or drinking (32/590, 5%) or physically active (12/590, 2%). In 16% (85/590) of recordings, activities were unknown. Recorded conversations (423/617) mainly included partners talking (372/423, 88%), whereas conversations with friends (77/423, 18%), strangers (17/423, 4%), children (10/423, 2%), and other family members (9/423, 2%) or self-talk (24/423, 6%) occurred less frequently. Concerning conversation types, most conversations were substantive (194/423, 46%), with fewer conversations of practical content (139/423, 33%) or small talk (76/423, 18%; 3% other). Social support was coded in 6% of recorded conversations (27/423), with the most frequent support providers being the partner (16/27, 60%) or a friend (9/27, 33%). The nature of the supportive interaction was 63% (17/27) instrumental and 37% (10/27) emotional (single choice only).

We collected 606 brief self-report questionnaires from partners, of which 79 captured the same situation (completed simultaneously by the partners). Thus, we analyzed 527 self-report questionnaires. In three-quarters of the questionnaires, partners reported having had personal contact with each other (394/527, 75%). Support was self-reported in more than half of the instances (277/527, 53%), with emotional support occurring 84% (233/277) of the time and practical support occurring 82% (227/277) of the time (multiple-choice possible).

Heart Rate Linkage

Dyadic heart rate data were available for 384 of the 617 audio recordings (ie, the 5-minute segments contained heart rate data from both partners). Concerning heart rate linkage, on average, all couples showed small to moderate cross-correlations in their heart rate (range: r=0.04-0.22; see Table 2). However, there was considerable variation in the observed cross-correlation between recordings (SDs 0.26-0.38). This means that couples showed a large variety of cross-correlations between recordings: Each couple sometimes showed a positive cross-correlation (ie, heart rate increases in one partner were linked with heart rate increases in the other partner; see Figure 1 panels A and B for examples), sometimes a cross-correlation close to 0 (ie, changes in heart rate throughout the recording were not systematically linked), and sometimes a negative cross-correlation (eg, heart rate increases in one partner were linked with heart rate decreases in the other partner; see Figure 1 panel C for an example). Histograms of couples' cross-correlations can be found in Figure 2, panel A.

Table 2 also denotes the average of the lags corresponding to each cross-correlation separately by couple. As outlined in the Methods section, the maximum cross-correlation could occur at a lag of +1, 0, or –1 for each recording. As seen in Figure 2 panel B, couples showed large heterogeneity in the occurrence of lags. In some couples, the extent to which heart rate changes in either the person with type II diabetes or the partner tended to precede heart rate changes in the other dyad member was balanced (couples 2, 4, 8, 10, and 11). However, in couples 1 and 7, a large share of recordings featured a negative lag (43%), suggesting that heart rate linkage in the dyad tended to be driven by the partner's heart rate. There was also variation in the extent to which recordings occurred that featured a lag of 0 (indicating same-time linkage with no partner driving the changes)—from every fifth (17%) recording in couple 2 to almost half of recordings in couple 3 (46%).

Table 2. Overview of cross-correlations and their lags by couple.

Couple ID	Number of observations	Cross-correlation, mean (SD)	Lag[a], mean (SD)	Percent negative lag	Percent no lag	Percent positive lag
1	14	0.184 (0.27)	–0.214 (0.80)	43	36	21
2	18	0.086 (0.38)	0.056 (0.94)	39	17	44
3	50	0.133 (0.30)	–0.220 (0.71)	38	46	16
4	44	0.084 (0.29)	0.000 (0.86)	36	27	36
5	22	0.172 (0.32)	0.136 (0.83)	27	32	41
6	53	0.045 (0.35)	0.321 (0.73)	15	38	47
7	47	0.036 (0.37)	–0.106 (0.87)	43	26	32
8	31	0.215 (0.37)	0.000 (0.82)	32	35	32
9	27	0.146 (0.26)	0.185 (0.83)	26	30	44
10	45	0.198 (0.34)	0.067 (0.75)	24	44	31
11	34	0.102 (0.34)	0.059 (0.89)	35	24	41

[a]A negative lag indicates that changes in the heart rate of the person with type II diabetes tend to be a precursor to changes in the partner's heart rate. A lag of 0 indicates that changes in heart rate tended to co-occur. A positive lag indicates that changes in the partner's heart rate tend to be a precursor to changes in the heart rate of the person with type II diabetes.

Figure 1. Three examples of collected dyadic heart rate data across a 5-minute recording. Panel A shows a high positive cross-correlation at a lag of 0 (r=0.91), indicating that partners show linked concurrent increases and decreases in heart rate in the same direction. Panel B shows a high positive cross-correlation at a lag of 1 (r=0.79), indicating that partners show linked increases and decreases in heart rate with heart rate changes in the partner preceding heart rate changes in the individual with type II diabetes by 5 seconds. Panel C shows a high negative cross-correlation at a lag of 0 (r=–0.79), indicating that partners show concurrent increases and decreases in heart rate in opposite directions (eg, one partner shows an increasing heart rate while the other shows decreasing heart rate). T2D: type II diabetes.

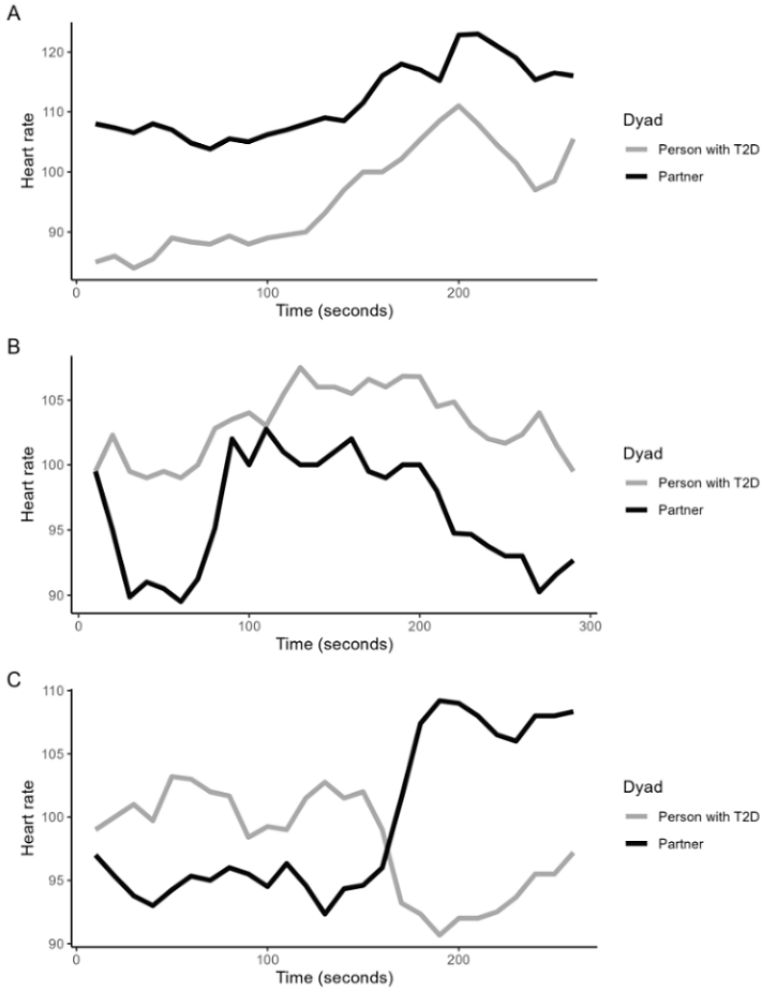

Figure 2. Distributions of cross-correlations (A) and the respective lags of cross-correlations (B) per couple. A lag of –1 indicates that changes in the heart rate of the person with type II diabetes tend to be a precursor to changes in the partner's heart rate. A lag of 0 indicates that changes in heart rate tended to co-occur. A lag of 1 indicates that changes in the partner's heart rate tend to be a precursor to changes in the heart rate of the person with type II diabetes.

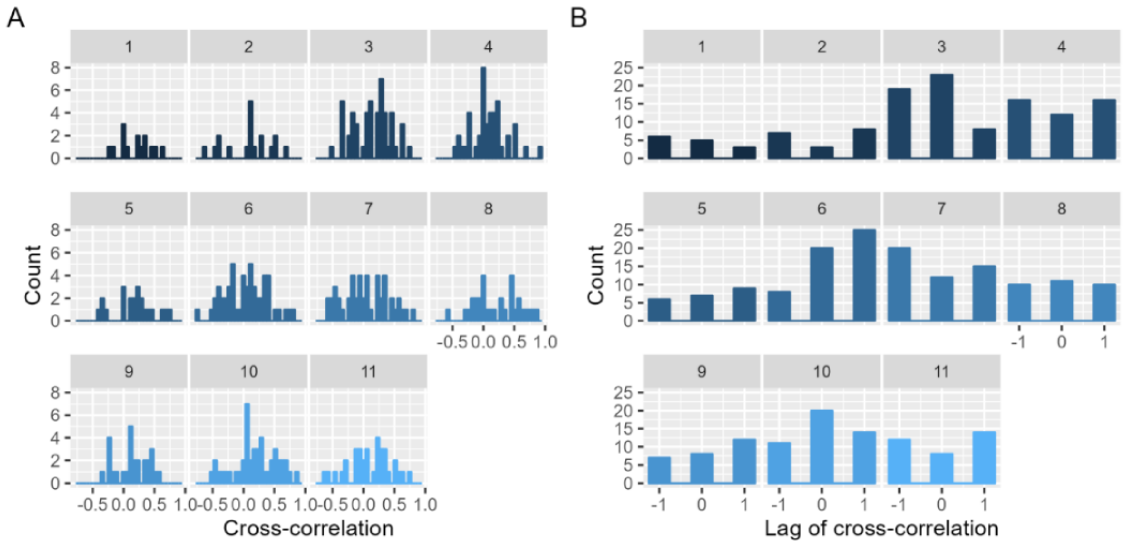

Heart Rate Linkage and Social Contexts and Exchanges

Finally, we explored whether heart rate linkage between partners might differ by social contexts and exchanges. Using the rater codings, we found that heart rate linkage was higher in moments when partners were talking with each other (mean r=0.17) than in moments when they were not engaged in conversation (mean r=0.04; b=0.15, SE=0.07; P=.03). Self-report data replicated these findings, showing that heart rate linkage was higher in moments when participants reported having had personal contact with each other (mean r=0.20) than in moments when they reported no such interpersonal contact (mean r<0.01; b=0.22, SE=0.06; P<.001). Furthermore, heart rate linkage was higher when participants self-reported giving or receiving support (mean r=0.22) than in moments of no support (mean r=0.07; b=0.18, SE=0.06; P=.004). We did not examine associations between rater-coded social support and heart rate linkage due to its very low frequency. The findings are displayed in Multimedia Appendix 1.

Discussion

Principal Findings

Most chronic health conditions require major modification of one's lifestyle, including adhering to sometimes complex medication regimes and engaging in health-promoting behaviors. Using new technology to monitor everyday biopsychosocial dynamics in couples coping with chronic health conditions could provide important insights for future intervention development. This study focused on testing a monitoring system that collected audio recordings, brief self-reports, and physiological data (heart rate) to log naturally occurring social interactions and to quantify the extent of physiological linkage in 11 persons with type II diabetes and their partners. Specifically, we used smartwatches to assess the feasibility of using commercially available devices. The smartwatches elicited 5-minute audio and heart rate recordings once an hour (mornings and evenings on weekdays, all day on weekends) when the Bluetooth signal indicated that partners were physically close, and speech was detected or when these 2 conditions were not detected, an assessment was triggered at the end of the hour to ensure sufficient data coverage. Self-reports were triggered consequently on linked smartphones to these recordings. Whereas raters coded social support as relatively infrequent (6% of audio recordings), participants self-reported that social support exchanges took place 53% of the time. On average, couples showed heart rate linkage of small to moderate degree. Notably, there was considerable variation in the extent of heart rate linkage and the occurrence of lags (indicating that one partner tended to drive heart rate changes in the other partner) across recordings within each couple. According to exploratory analyses, heart rate linkage was stronger when raters coded partner conversations and when interpersonal contact or social support exchanges were self-reported by partners. The following outlines important implications and considerations when collecting such data.

Rater-Coded and Self-Reported Social Contexts and Exchanges

Raters coded conversations between partners in 6 out of 10 audio recordings, and couples self-reported personal contact with each other 75% of the time, speaking to a good performance of the triggering system [37]. Concerning social exchanges, raters coded social support in 6% of audio recordings, whereas partners self-reported social support in 53% of self-reports. The low frequency of rater-coded social support dovetails with a previous study showing that support occurred only in about 4% of video data captured during 4 days of healthy couples' daily lives [41].

Self-report measures of social support may be influenced by social desirability bias and gender stereotypes [47]. For example, while self-report data support the gender support-gap hypothesis with men receiving more support from women within couples, naturalistic observational studies show that men provided the same or more everyday support to their partners than women

did [41,48], although the quality of the support might differ [49]. Women might also more frequently seek support from their partners, demonstrating the importance of collecting data on support solicitation in daily life [41]. On the other hand, observational measures are less vulnerable to demand characteristics and can capture supportive interactions that are not explicitly recognized or acknowledged by the individual receiving it [40,41].

However, self-report data capture types of interactions the individual perceives as supportive, whereas such interactions may not be immediately apparent to outside observers unfamiliar with the couple's unique dynamics. Indeed, the same action might be perceived as supportive by one person and as controlling or intrusive by another. The discrepancy between self-reported and rater-coded social support in this study emphasizes the need for a comprehensive approach to assessing social support in future research. For example, in future investigations, researchers could use text message content analysis [50] to capture conversations, expressions of empathy, encouragement, and tangible assistance between the couple. Participants could also be asked to press a button on a smartwatch whenever they are about to provide support, thereby eliciting an audio recording of the real-time support exchange. Furthermore, approaches could be developed using machine learning to automatically detect and capture moments when social support is occurring in daily life. Supplementary subjective measures could then be used to assess individuals' satisfaction with and the quality of support they receive within these objectively captured interactions.

Using Commercial Smartwatches to Monitor Heart Rate Linkage

Over the last decade, researchers have used different physiological parameters to demonstrate physiological linkage in couples, such as breathing rate, EDA, and cortisol [43,51,52] or voice stress [53]. With this project, we build on and extend this work by taking the research out of the laboratory and into daily life, using commercially available devices for heart rate monitoring. We found that everyday heart rate fluctuations in persons with type II diabetes and their partners showed intercorrelations of small to moderate degrees. Using an optical sensor (photoplethysmography) instead of electrical signals (electrocardiogram [ECG]) to estimate heart rate with commercially available devices has the benefit of being relatively unobtrusive, user-friendly, and affordable [54]. Contrasting consumer-grade wearables with the gold standard ECG, initial research overall shows promising findings regarding the accuracy of wrist-worn photoplethysmography devices, although they tend to underestimate heart rate slightly [55]. Specifically, wearables might be less accurate than ECG-based devices when participants are physically active versus resting (about 30% higher absolute error [56]). In our participants, audio recordings were coded for physical activity, which happened relatively rarely (in 2% of cases). However, future research should consider collecting objective movement data via accelerometry as an essential confounder and other covariates (for guidelines, see the study by Nelson et al [55]). Furthermore, future studies could consider integrating multiple physiological markers, such as blood pressure, cortisol, and heart rate variability, and leverage advanced sensor capabilities of wearables (eg, apple sensor kit [57]). This has the benefit of collecting data on markers sensitive to different features of everyday social contexts, for example, cortisol for socioevaluative situations and heart rate variability for prosocial behavior or compassion [58,59]. However, when doing so, it is vital to keep the inherent temporal dynamics of each system in mind. The appropriate sampling rate will differ between fast-acting systems, such as sympathetic activation as indexed by heart rate (seconds) versus hypothalamic-pituitary-adrenal activation as indexed by salivary cortisol (15-20 minutes) and needs to align with the psychosocial context under study [26].

Heart Rate Linkage and Social Contexts and Exchanges

Our exploratory analysis found that heart rate linkage was stronger when raters coded partner conversations and couples self-reported interpersonal contact, compared with moments when raters did not code that partners were engaged in conversations or when couples did not self-report having had personal contact with each other. Findings dovetail with theoretical notions of the dyadic regulation connectivity model, which suggests that any changes in the dyadic system such as interpersonal environments trigger immediate and synchronized changes throughout the network of dynamically linked processes between partners, including their physiology [5]. Other studies have also shown increased physiological linkage when partners are in each other's presence [52,60]. For example, research using a wristwatch to measure EDA in 40 young couples for 1 day showed that EDA linkage was significant only when couples self-reported being together but not apart [61]. When partners are engaged in conversation, they might follow the same narrative stimuli, which has been associated with increased heart rate linkage [62]. Our findings extend past research by focusing on moments when partners were actively interacting with each other instead of just being in physical proximity.

Heart rate linkage was also stronger when social support exchanges were self-reported by partners, as compared with moments when no social support exchanges were reported. Rater-coded social support was relatively infrequent (6%), preventing us from conducting exploratory analyses concerning its association with heart rate linkage. High physiological linkage has been associated with empathy, perspective-taking, positive interpersonal contexts such as feeling understood, appreciated or seeking help, and closeness to the partner [28,52,63]. A recent study investigating partners' cardiovascular markers found significant physiological linkage in heart rate and heart rate variability in 27 young to middle-aged couples while discussing positive and negative aspects of their relationship in the laboratory [34]. In addition, a laboratory study found that synchronicity in younger couples' skin conductance was higher during supportive touch when exposed to a pain stimulus, compared with the partner merely being present [64]. Our findings extend this research by indicating that heart rate fluctuations of couples managing a chronic health condition might link up during supportive, real-life interactions. Coherence between partners, for example, indicated by heart rate linkage, has been theorized to be central to dyadic regulation [5]. Yet, other studies demonstrated high physiological linkage

in couples with marital strain, particularly regarding markers of the stress response system such as cortisol [65]. Potentially, parasympathetic nervous system markers (eg, respiratory sinus arrhythmia) might synchronize more during positive interpersonal contexts. In contrast, markers of the sympathetic nervous system (eg, EDA) might more likely become entrained during negative interpersonal contexts [28,29].

Future studies need to build on and replicate our findings using larger sample sizes, also looking at the underlying mechanisms and moderators of heart rate linkage, such as perspective taking, contagion of emotions, attachment style, relationship quality, and interdependent self-construal [28]. For example, is heart rate linkage stronger when partners try to take each other's perspective and higher in couples with greater relationship satisfaction? Does lagged heart rate linkage accompany emotions (positive and negative) or stress being transferred from one partner to the other? [53] Such a study could use audio recordings to derive indices of vocal quality or pitch indexing emotional arousal such as the fundamental frequency [66]. It is also an open question whether stronger physiological heart rate linkage during social support exchanges is associated with more or less favorable outcomes of supportive interactions [67]. For example, increased skin conductance synchronicity was associated with less self-reported pain intensity during painful thermal stimulation when receiving supportive touch from the partner [64].

Limitations and Future Research

Considering the sample size of 11 couples due to the impact of the COVID-19 pandemic on data collection, findings from this study need to be replicated to test generalizability. Furthermore, our sample comprised couples managing diabetes of mostly older age, long relationship duration, and relatively good diabetic control. Therefore, these couples could represent dyadic systems demonstrating reasonably effective dyadic regulation and thus higher heart rate linkage. It remains to be seen whether biopsychosocial dynamics differ by age and chronic disease type (eg, cancer [21]). In addition, we coded limited information about the nature of everyday social interactions between partners (social support occurrence, type of conversation), and interrater reliabilities were low for some coding categories. The unsatisfactory reliability of rater codings for conversation types prevented us from examining differences in heart rate linkage by type of conversation (eg, deep vs practical). Whether heart rate linkage is tied to the nature and content of partner conversations thus presents an important future direction.

Future studies could also investigate heart rate linkage in the context of support quality and types of support (emotional, instrumental). Given that previous literature has linked conflict to increased physiological linkage, it would also be important to study heart rate synchronization in the context of negative types of social exchanges managing chronic health conditions such as negative social control [68]. Future research should also examine other relevant constructs for couples managing disease, such as dyadic efficacy [69] or shared appraisals of the disease ("we-disease" [70]), and include measures of well-being (eg, happiness, meaning). Eventually, more advanced systems that collect multimodal data from couples managing chronic health conditions could learn when and how to intervene (eg, to nudge partners to provide support) to promote healthy lifestyle engagement and adaptive disease management [61,71]. Increasingly, researchers use machine learning algorithms to design just-in-time adaptive interventions [72,73], although they have seldom been applied in a dyadic context. These interventions can be delivered through digital platforms, making them widely accessible, particularly for individuals living in remote or underserved areas or those with transportation or mobility limitations.

Conclusions

This study explored the feasibility of using commercial wearables to monitor the unique communication and support dynamics between romantic partners, particularly in managing a chronic health condition. First, the rater-coded audio recordings and self-report analysis provided valuable information about the occurrence of social support. Interestingly, while self-reports indicated that partners reported social support approximately half of the time, raters coded social support in only 6% of the recordings. This suggests a potential disparity between partners' self-perception and external observation of supportive behaviors. Second, we demonstrated that couples exhibited small to moderate interconnections in heart rate fluctuations, indicating physiological linkage between partners. Heart rate linkage was stronger when partner conversations were coded, partners self-reported interpersonal contact, and partners self-reported social support exchanges. Findings provide initial evidence on contexts and behaviors that may influence physiological interconnectivity within couples. Overall, the use of wearables for continuous and unobtrusive collection of biopsychosocial data combined with self-report data in real-world settings holds great promise for enabling better and targeted support for individuals managing chronic health conditions and their partners.

Acknowledgments

This study was funded by the Swiss National Science Foundation (CR12I1_166348/1). Theresa Pauly gratefully acknowledges support from the Canada Research Chairs program. We thank Dr Matthias Mehl for his valuable contribution to study design.

Conflicts of Interest

GB, TK, and EF are affiliated with the Centre for Digital Health Interventions (CDHI); a joint initiative of the Institute for Implementation Science in Health Care, University of Zurich; the Department of Management, Technology, and Economics at ETH Zurich; and the Institute of Technology Management and School of Medicine at the University of St. Gallen. CDHI is funded in part by the Swiss health insurer CSS, the Austrian health care provider (and corporate start-up of UNIQA) Mavie Next, and

the Swiss investor MTIP. EF and TK are also cofounders of Pathmate Technologies, a university spin-off company that creates and delivers digital clinical pathways. However, neither CSS, Mavie Next (UNIQA), and MTIP nor Pathmate Technologies were involved in this study. All other authors declare no conflict of interest.

Multimedia Appendix 1
Magnitude of cross-correlation by rater-coded and self-reported social context and exchange. The figure shows that cross-correlations tended to be higher in situations when raters coded that partners were engaged in conversations (A), when participants self-reported a partner interaction (B), and when participants self-reported a social support exchange (C).

Abstract

Background: The COVID-19 pandemic prompted various containment strategies, such as work-from-home policies and reduced social contact, which significantly altered people's sleep routines. While previous studies have highlighted the negative impacts of these restrictions on sleep, they often lack a comprehensive perspective that considers other factors, such as seasonal variations and physical activity (PA), which can also influence sleep.

Objective: This study aims to longitudinally examine the detailed changes in sleep patterns among working adults during the COVID-19 pandemic using a combination of repeated questionnaires and high-resolution passive measurements from wearable sensors. We investigate the association between sleep and 5 sets of variables: (1) demographics; (2) sleep-related habits; (3) PA behaviors; and external factors, including (4) pandemic-specific constraints and (5) seasonal variations during the study period.

Methods: We recruited working adults in Finland for a 1-year study (June 2021-June 2022) conducted during the late stage of the COVID-19 pandemic. We collected multisensor data from fitness trackers worn by participants, as well as work and sleep-related measures through monthly questionnaires. Additionally, we used the Stringency Index for Finland at various points in time to estimate the degree of pandemic-related lockdown restrictions during the study period. We applied linear mixed models to examine changes in sleep patterns during this late stage of the pandemic and their association with the 5 sets of variables.

Results: The sleep patterns of 27,350 nights from 112 working adults were analyzed. Stricter pandemic measures were associated with an increase in total sleep time (TST) (β=.003, 95% CI 0.001-0.005; *P*<.001) and a delay in midsleep (MS) (β=.02, 95% CI 0.02-0.03; *P*<.001). Individuals who tend to snooze exhibited greater variability in both TST (β=.15, 95% CI 0.05-0.27; *P*=.006) and MS (β=.17, 95% CI 0.03-0.31; *P*=.01). Occupational differences in sleep pattern were observed, with service staff experiencing longer TST (β=.37, 95% CI 0.14-0.61; *P*=.004) and lower variability in TST (β=–.15, 95% CI –0.27 to –0.05; *P*<.001). Engaging in PA later in the day was associated with longer TST (β=.03, 95% CI 0.02-0.04; *P*<.001) and less variability in TST (β=–.01, 95% CI –0.02 to 0.00; *P*=.02). Higher intradaily variability in rest activity rhythm was associated with shorter TST (β=–.26, 95% CI –0.29 to –0.23; *P*<.001), earlier MS (β=–.29, 95% CI –0.33 to –0.26; *P*<.001), and reduced variability in TST (β=–.16, 95% CI –0.23 to –0.09; *P*<.001).

Conclusions: Our study provided a comprehensive view of the factors affecting sleep patterns during the late stage of the pandemic. As we navigate the future of work after the pandemic, understanding how work arrangements, lifestyle choices, and sleep quality interact will be crucial for optimizing well-being and performance in the workforce.

Introduction

Background

Sleep is a crucial component of daily life, closely interconnected with all aspects of our routines and overall well-being, including mental health [1,2], physical health [3], and work performance [4,5]. The COVID-19 pandemic profoundly impacted various aspects of daily life, with sleep patterns being a particularly significant area of concern. However, the effects on sleep were often indirect, resulting from changes in daily routines and lifestyle adjustments rather than being a direct consequence of the virus.

In response to the pandemic, outdoor restrictions limited our exposure to natural daylight, a crucial element for regulating circadian rhythms and sleep patterns [6]. Similarly, mobility restrictions altered daily physical activity (PA) patterns. Additionally, workplace restrictions led to work-from-home policies, which resulted in reduced mobility and flexible working hours. While these changes led to more relaxed work schedules, they also blurred the boundaries between professional and personal life. Notably, factors such as daylight exposure, PA, and work routines—each significantly affected by the pandemic—are well-established influences on sleep health [7,8].

Traditional sleep measurements often rely on self-reported methods, such as the Karolinska [9] or Pittsburgh sleep diary [10]. While these methods are effective for tracking day-to-day sleep over short periods, conducting diary studies over longer intervals is generally not feasible due to the cognitive burden on participants. Nonintrusive measurements using smartphones and fitness trackers have recently emerged as a more viable alternative for capturing sleep data over extended periods. While consumer-grade devices may not precisely detect sleep stages, they have shown promising results for measuring sleep onset, duration, and wake-up time. Assessing sleep with these devices has the advantage of capturing data in people's natural living environments, unlike sleep laboratories. Additionally, this method is not subject to memory biases that can occur with survey responses and sleep diaries.

The evolution of mobile health (mHealth) technologies has significantly enhanced traditional sleep monitoring methods, particularly through the use of wearable devices. These devices offer a more accessible and less invasive way to monitor sleep patterns, while also deepening our understanding of sleep-related phenomena. For instance, wearable devices have been used to determine individuals' chronotypes and track their sleep and activity rhythms over extended periods [11,12]. They have also been used to measure sleep alignment between coworkers [13], examine the relationship between sleep and burnout [14], and assess sleep patterns in various populations, including patients with mental disorders [15]. Several studies have confirmed the validity and reliability of wearable devices, demonstrating notable sensitivity compared with the gold-standard polysomnography (PSG). For example, a review of 7 consumer sleep-tracking devices [16] highlighted their high effectiveness in detecting sleep relative to PSG. Similarly, a study [17] evaluated 6 consumer wearable devices and validated their accuracy in assessing sleep timing and duration compared with PSG.

Prior research comparing sleep patterns before and during the pandemic has revealed notable differences. Studies found that following the pandemic's onset, individuals tended to go to bed later [18], slept for longer durations [19], exhibited reduced variability between weekday and weekend sleep [20,21], and experienced increased sleep disturbances or diminished sleep quality [22]. Various factors have been identified as contributing to these disruptions in sleep routines, including decreased PA [23], social isolation [24], increased use of electronic devices [4], and the shift to working from home [13].

While previous studies have focused on the immediate consequences of lockdowns and restriction policies, less attention has been paid to the long-term effects, particularly during the late stages of the pandemic when restrictions began to relax. This phase is crucial for understanding the residual effects of the pandemic on sleep patterns and how quickly individuals revert to their prepandemic sleep habits. The transition to working from home as the default mode has resulted in a less constrained work-life routine, leading to more flexible sleep-wake schedules. Certain demographics may benefit more from these transitions, such as individuals with more flexible routines (eg, research personnel) or those who tend to snooze their alarms after waking, referred to as "snoozers." Additionally, occupation is a known factor influencing sleep patterns, with a classic example being the contrast between shift workers and nonshift workers [25,26]. However, less is understood about the differences between various roles within academia, such as researchers with deadline-driven roles and administrative personnel typically following a 9-to-5 schedule. Therefore, a comprehensive, longitudinal analysis of sleep patterns that includes these variables and extends into the late stages of the pandemic is important.

Objectives

Our study aims to provide a holistic view of how the pandemic has influenced sleep patterns. We evaluate the long-term relationships between sleep patterns, including average and variability in total sleep duration and sleep timing, alongside individuals' characteristics (demographics, occupation, and PA) and external factors (stringency of restriction policies and seasonal variations). Our research utilizes longitudinal data from fitness trackers and questionnaire responses collected from working adults at a Finnish university. This extensive data set enables us to examine shifts in sleep behavior during the later stages of the COVID-19 pandemic, from June 2021 to June 2022. The study's timeframe covers a full annual seasonal cycle, which is crucial for analyzing sleep patterns in Finland, where significant seasonal changes and daylight variations occur due to its northern latitude.

Methods

Study Data

This work used data from the cor:ona (comparison of rhythms: old vs. new) study [27] as part of a 1-year multimodal data set of working adults.

Ethics Approval

The study was approved by the Aalto University Research Ethics Committee (approval number D/536/03.04/2021_COR_ONA).

Participants and Procedures

The cor:ona study recruited 128 full-time employees from a university in Finland for a 1-year investigation into how their daily activities changed during different stages of the COVID-19 pandemic. Throughout the study, participants wore a Polar Ignite fitness tracker (Polar Electro Oy), enabling us to unobtrusively collect various measures related to sleep and PA. In addition, participants completed an initial baseline questionnaire, an exit questionnaire, and a shorter version of the baseline questionnaire each month. The monthly questionnaires asked for information about their daily routines, work, and sleep quality over the past month. The detailed recruitment procedure and participants' demographics were described in a previous study [27].

Fitness Tracker Data

Sleep Measures

The fitness trackers measured bedtime (defined as the recorded time when a person fell asleep), waketime (defined as the recorded time when a person woke up), and interruption duration (defined as the total time in seconds spent awake between sleep start and end times) for each day. A sleep period was defined as the longest sleep episode for each day. Sleep patterns were measured using 4 metrics: (1) total sleep time (TST), which measured the time a person spent asleep, calculated as the duration from bedtime minus the interruption duration; (2) midsleep (MS), the midpoint between bedtime and waketime, which was used to measure sleep timing and computed as (bedtime + TST)/2. Additionally, we proposed 2 other metrics to measure sleep regularity: (3) TST variability, computed as the SD of TST during weekdays (Sunday night to Thursday night); and (4) MS variability, computed as the SD of MS during weekdays. We focused exclusively on weekdays due to the expected differences between weekday and weekend sleep patterns. The Niimpy behavioral data analysis toolbox [28] was used for extracting sleep measurements.

Physical Activity Measures

The fitness tracker recorded the number of steps taken each hour, which were then summed to provide a daily step count. To comprehensively account for daily PA patterns, including their timing and distribution, we introduced 2 additional metrics: midstep and intradaily variability (IV) [29]. These metrics are designed to capture the timing and dispersion of PAs throughout the day. Specifically, midstep represents the hour of the day when half of the total number of steps is achieved, analogous to MS in the context of PA. By contrast, IV quantifies the fragmentation of the activity-rest rhythm and is measured as follows:

where N=24 is the total number of samples within each day; X_i is the i measurement sampled at P=60-minute interval; and  is the average value of all samples in a day. Low IV indicates less fragmented activity-rest rhythm, whereas high IV could imply daytime naps or nighttime awakenings.

External Data

Seasonal data were collected from the World Weather Online developer application programming interface [30]. Given the significant variation in day length in Finland during the study (up to 13 hours), day length was used as a proxy for seasonal variables. The choice of day length as a proxy was motivated by Friborg et al [31]. The study compared 2 geographically distinct locations with substantial differences in day length variability: Ghana and Norway. Although no noticeable seasonal effects of day length were observed in Ghanaians, Norwegians showed a delay in both bedtime and waketime during summer weekdays, though sleep duration remained relatively unaffected.

We also utilized the Stringency Index (SI) [32], a composite measure ranging from 0 to 100, to assess daily COVID-19 restriction policies. Higher values on this index indicate more stringent COVID-19 restrictions, including measures such as school and workplace closures, the cancellation of public events, and the enforcement of stay-at-home orders. This index allows for standardized comparisons of policy responses across different countries or regions, as well as changes within the same region over time.

Questionnaire Data

Upon entering the study, participants completed a baseline questionnaire that collected basic background information, including age, gender, chronotype, occupation, and origin, among others. Chronotype was assessed using the reduced Morningness-Eveningness Questionnaire (MEQ) [33], with higher scores indicating a morning type and lower scores indicating an evening type. For the origin-related question, participants chose from 3 options: Finland, Europe (excluding Finland), or outside of Europe. Participants indicating they were from Finland were classified as Finnish, while those selecting other options were described as having a "migrant background." Regarding occupation, participants specified whether they were academic or service staff. The term "academic staff" refers to individuals involved in academic and research activities within the organization, while "service staff" includes those in roles such as human resources and other administrative or support functions. Participants were determined as a snoozer if they answered "yes" to the following question: "Snoozing can be considered as choosing to go back to sleep after an alarm has awakened you intending to wake up later; setting the alarm earlier than when you intend to wake up; or setting multiple alarms with the intent to not wake up on the first alarm. Do you currently consider yourself a snoozer using this definition?," as adapted from [34].

For the analysis of snoozer characteristics, we used the 2-item Patient Health Questionnaire (PHQ-2) [35] and the short form of the Pittsburgh Sleep Quality Index (PSQI) [10], averaging the values collected from the monthly questionnaires. Additionally, the short form of the Positive and Negative Affect Schedule (PANAS-SF) [36] was used in the initial baseline questionnaire.

Data Exclusion and Preprocessing

Sleep data were restricted to the period from July 1, 2021, to May 31, 2022. Because of our rolling recruitment process, which started in mid-June 2021 and ended in June 2022, we excluded data from June of both years. This exclusion was necessary because we lacked complete data for these months, and including partial data could have introduced bias. A standard filter, adopted from [37], was applied to remove outliers in TST (TST<3 hours and TST>13 hours). Participants with fewer than 30 recorded nights due to dropout or technical issues were excluded. For gender-related analysis, nonbinary participants (n=1) were excluded to preserve their privacy. To maintain the interpretability of the relationships between sleep patterns and the examined variables, we chose not to normalize the dependent and independent variables.

Statistical Analysis

We used a logistic regression model to examine factors predicting snoozing behavior. Using snoozing behavior as the dependent variable, and to replicate the findings from [34], we included the same set of independent variables: age, gender, step count, TST, BIG-5 personality traits (openness, conscientiousness, extraversion, agreeableness, and neuroticism), PANAS-SF, PHQ-2, PSQI, and MEQ. To further investigate the potential confounding effects of chronotype (measured by MEQ) on the relationship between personality traits and snoozing behavior, we conducted a Baron and Kenny [38] mediation analysis.

Given the nature of our data set, which included repeated sleep measurements for each participant, we used mixed effects linear models [39] to analyze how sleep patterns and their regularity evolve over time. The models included TST, MS, and the variability of TST and MS as dependent variables. For models with variability of TST and MS as dependent variables, the numerical independent variables were averaged across weekdays. We adopted a sequential modeling strategy, building 3 distinct models for each dependent variable. Model 1 included basic characteristics such as chronotype, age, gender, origin, occupation, and parenting cohabitation status (number of children in the household). Model 2 extended model 1 by adjusting for external factors such as the stringency of restrictions and day length. Finally, model 3 built on model 2 by incorporating PA metrics, including step count, midstep, and IV. This approach allows for the exploration of the unique contributions of each new set of variables beyond those accounted for in the previous model. All models included hierarchical random effects for the study participants to account for repeated measurements. The models are formulated as follows:

$$\text{Model 1: } Y_{ij} = \beta_0 + \beta_1 x_{ij1} + \beta_2 xij_2 + \cdots + \beta_2 xij_7 + \beta_8 x_{ij8} + u_j + {}_{ij}$$

$$\text{Model 2: } Y_{ij} = \beta_0 + \beta_1 x_{ij1} + \beta_2 xij_2 + \cdots + \beta_9 xij_9 + \beta_{10} x_{ij10} + u_j + {}_{ij}$$

$$\text{Model 3: } Y_{ij} = \beta_0 + \beta_1 x_{ij1} + \beta_2 xij_2 + \cdots + \beta_{11} xij_{11} + \beta_{12} x_{ij12} + \beta_{13} x_{ij13} + u_j + {}_{ij}$$

where the independent variables are x_{ij1}=age, x_{ij2}=gender, x_{ij3}=number of children, x_{ij4}=origin, x_{ij5}=occupation, x_{ij6}=MEQ, x_{ij7}=snoozer, x_{ij8}=free day, x_{ij9}=Stringency Index, x_{ij10}=day length, x_{ij11}=steps(×1000), x_{ij12}=midstep, and x_{ij13}=step entropy.

95% CIs were reported using bootstrapping. The performance of the model was compared using the likelihood ratio test (LRT) to ensure model parsimony. All statistical analyses were performed using R software (version 3.6.1; R Foundation) [40]. Linear mixed models were tested using the lme4 package [41], and *P* values for these models were calculated using the lmerTest package [42].

Results

Data Summary

In total, 112 users and 27,350 nights were included in the TST and MS analyses. The models for the variability of TST and MS used the weekday SD of both measures, which included 3682 observations. The average age of participants was 39.5 (SD 9.9) years. Of these 112 participants, 49 were academic staff and 63 were service staff. Figure 1 presents the average values of the 4 sleep metrics—TST, MS, and their corresponding SDs—for each participant included in the analysis. Figure 2 illustrates the sleep patterns over time for 2 participants: 1 with low variability and 1 with high variability in their sleep patterns.

Figure 1. TST, MS, and their SDs of participants included in the analysis. Each dot represents the participant's mean value for the corresponding metrics. MS: midsleep; TST: total sleep time.

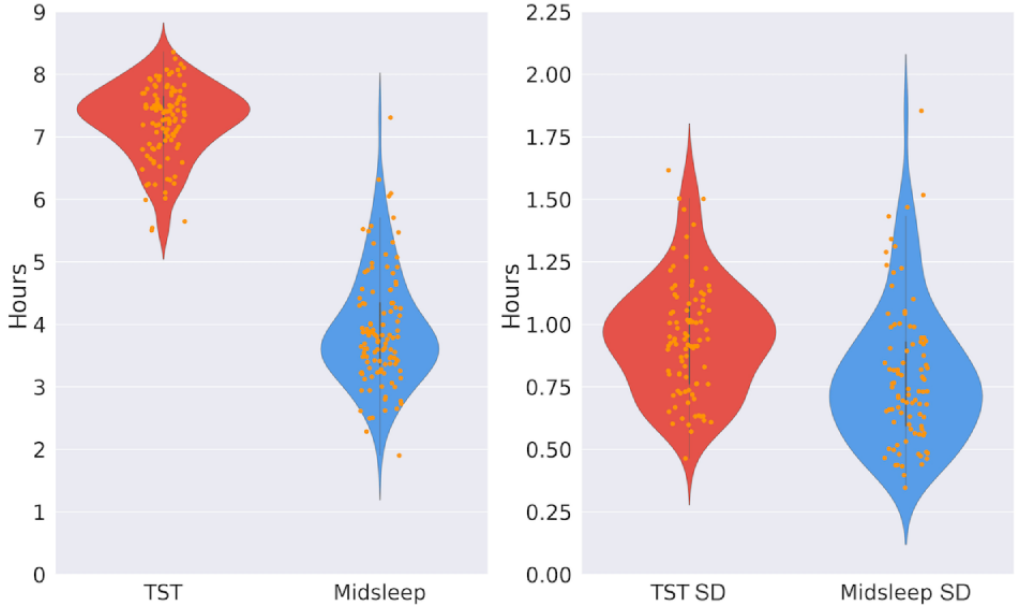

Figure 2. Sleep data over time from two participants. Participant 1 (red line) demonstrates shorter, later, and more variable sleep compared to Participant 2 (blue line).

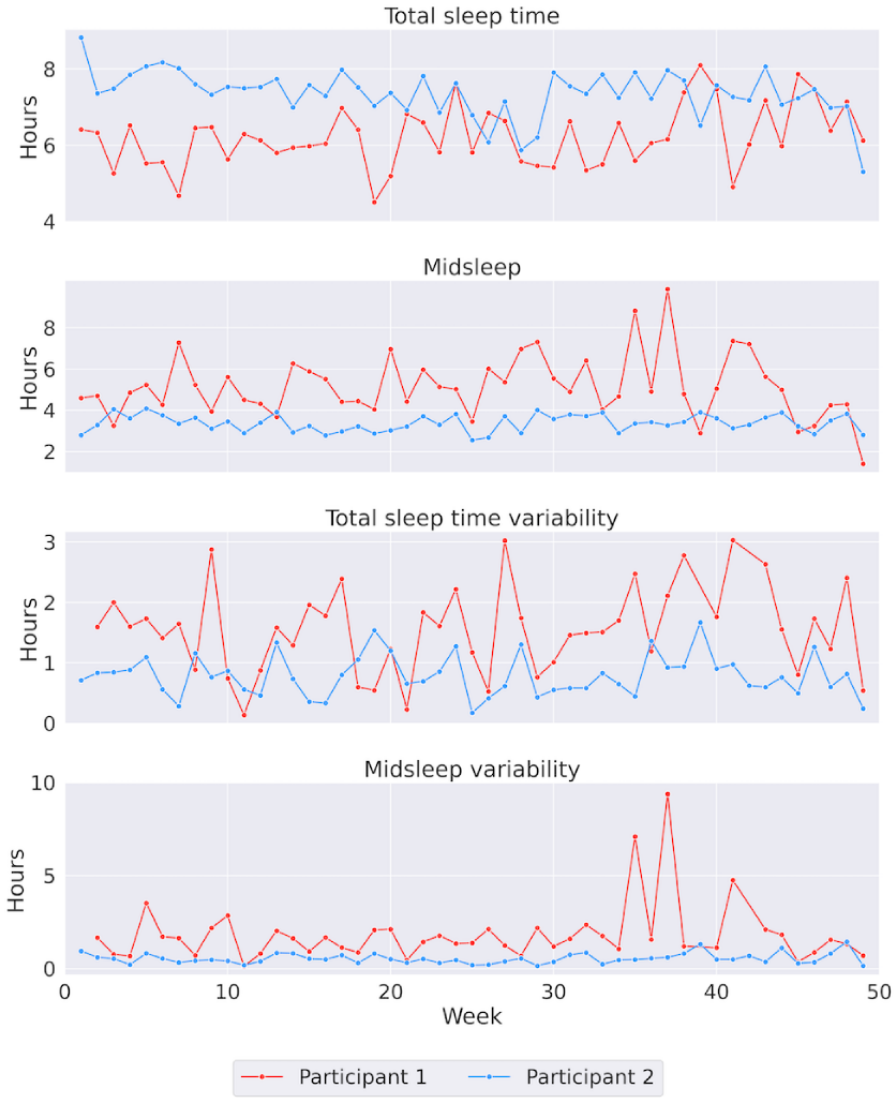

Total Sleep Time

We begin by investigating the factors that influence TST using the 3 linear mixed models described earlier. Table 1 presents the results of these models predicting TST. For improved interpretability, the rate of change in TST is expressed as the estimate of the predictors multiplied by 60 minutes. In the full model (model 3), an increase in age by 1 year was associated with a 1.2-minute decrease in TST (95% CI –1.8 to –0.6; *P*=.008). Regarding gender, males were found to sleep 20.4 minutes less than females (95% CI –33.0 to –7.8; *P*<.001). Comparing occupations, service staff were found to sleep 22.2 minutes more than academic staff (95% CI 8.4-36.6; *P*=.004). A detailed monthly breakdown of the variations in sleep pattern measurements across different occupations is provided in Multimedia Appendix 1. After adjusting for day length and the SI, an additional hour of day length was associated with a 0.60-minute decrease in TST (95% CI –0.72 to –0.36; *P*<.001). Conversely, a 1-point increase in the SI offset this decrease by 0.18 minutes (95% CI 0.06-0.30; *P*<.001). In the full model, which included PA, a 1-unit increase in IV was associated with a 15.6-minute decrease in TST (95% CI –17.5 to –13.8; *P*<.001). Moreover, an additional hour in midstep was associated with a 1.8-minute increase in TST (95% CI 1.2-2.4; *P*<.001).

[a]The σ^2 values for models 1-3 were 1.13, 1.13, and 1.1, respectively. The intraclass correlation coefficient values for models 1-3 were 0.19, 0.19, and 0.19, respectively. The marginal R^2/conditional R^2 values for models 1-3 were 0.055/0.234, 0.057/0.235, and 0.069/0.245, respectively. The Akaike information criterion values for models 1-3 were 81,208.16, 81,154.98, and 80,783.26, respectively.

[b]Includes demographic and occupational variables.

[c]Includes model 1 + restriction and seasonal factors.

[d]Includes model 2 + physical activity influences.

[e]Italicized values denote significance.

[f]*P*<.01.

[g]*P*<.001.

[h]*P*<.05.

[i]Not available.

The marginal R^2 values represent the proportion of variance explained by the fixed effects, while the conditional R^2 values indicate the proportion of variance accounted for by both fixed and random effects. The increase in both R^2 values suggests that more complex models, particularly model 3, explained a greater proportion of the variance in the dependent variable. The LRT between models 1 and 2 indicated that model 2 was a significantly better fit (χ^2_2=57.17; *P*<.001). Additionally, the LRT between models 2 and 3 showed that model 3 provided a significantly improved fit (χ^2_3=377.72; *P*<.001). The performance of the full model (model 3) was further supported by the Akaike information criterion (AIC), which was lowest for model 3 (AIC 80,783.26), indicating that it offered the most optimal fit for the data.

Midsleep

Using the same approach, we developed 3 linear mixed models to assess the associations between the same set of predictors and MS. The results are presented in Table 2. To enhance interpretability, the rate of change in MS is measured as the estimate of the predictors multiplied by 60 minutes. Across all 3 models, chronotype (MEQ) (*P*<.001) and sleep on a free day (*P*<.001) consistently emerged as significant factors. In the full model (model 3), a 1-point increase in the MEQ was associated with an 8.4-minute decrease in MS (95% CI –10.8 to –5.4; *P*<.001). Sleep on a free day occurred 11.4 minutes later (95% CI 9.6-12.6; *P*<.001) compared with a workday. After adjusting for season and restriction policies, MS was delayed by 0.6 minutes (95% CI 0.6-1.2; *P*<.001) for each additional hour of day length. A 1-point increase in the SI was associated with a 1.2-minute increase in MS (95% CI 1.2-1.8; *P*<.001). In the full model, which included PA variables, a 1-unit increase in IV was linked to a 17.4-minute earlier MS (95% CI –19.8 to –15.6; *P*<.001). Similarly, an increase in step count was associated with a 0.6-minute earlier MS (95% CI –1.2 to 0.0; *P*=.04).

The LRT between models 1 and 2 indicated that model 2 was a better fit (χ^2_2=443.70; *P*<.001). Additionally, the LRT between models 2 and 3 showed that model 3 provided a significantly improved fit (χ^2_3=291.63; *P*<.001). The AIC value for model 3 was also the lowest (AIC 86,315.145), indicating that it provided the best fit for the data.

Total Sleep Time Variability

Table 3 presents the factors predicting the variability in TST. Across the 3 models, age (*P*=.01), number of children (*P*=.03), occupation (*P*<.001), and snoozing behavior (*P*=.006) emerged as significant factors. In the final model (model 3), each additional year of age was associated with a 0.01-unit increase in TST variability (95% CI 0.00-0.01; *P*=.01). Notably, participants with snoozing habits exhibited higher TST variability, increasing by 0.15 units (95% CI 0.05-0.27; *P*=.006). Each additional child was associated with a 0.06-unit reduction in TST variability (95% CI –0.11 to –0.00; *P*=.03). Service staff also demonstrated lower TST variability, with a reduction of 0.15 units compared with academic staff (95% CI –0.27 to –0.05; *P*<.001). When accounting for PA, a decrease of 1 hour in midsteps was correlated with a 0.01-unit increase in TST variability (95% CI –0.02 to –0.00; *P*=.03), while a 1-unit increase in IV was associated with a 0.16-unit decrease in TST variability (95% CI –0.23 to –0.09; *P*=.03). The LRT indicated that model 2 did not provide an improvement over the baseline model (χ^2_2=4.78; *P*=.09). However, model 3 demonstrated better performance compared with the baseline model (χ^2_5=31.95; *P*<.001).

Midsleep Variability

Table 4 presents the factors predicting the variability of MS. Across the 3 models, the number of children (*P*=.004), snoozing behavior (*P*=.01), midsteps (*P*=.008), and IV (*P*=.001) emerged as significant factors. For each additional child, MS variability was reduced by 0.10 units (95% CI –0.16 to –0.03; *P*=.004). In all models, being a snoozer correlated with increased MS variability. Specifically, snoozers experienced a 0.17-unit increase in MS variability compared with nonsnoozers (95% CI 0.03-0.31; *P*=.01). To better understand the characteristics of snoozers, we conducted an analysis based on Mattingly et al's study [34]. Interestingly, our results revealed that age (*P*=.02) and chronotype (*P*=.002) were significant factors in predicting snoozing behavior. The full results are detailed in Multimedia Appendix 2.

In the full model, including PA variables, midsteps also became significant. Each hour increase in midsteps was associated with a 0.02-unit decrease in MS variability (95% CI –0.04 to –0.00; *P*=.008). However, the more complex models did not show a significant improvement over the baseline model, as indicated by the LRT (model 2: χ^2_2=1.00; *P*=.60/model 3: χ^2_5=10.17; *P*=.07).

Discussion

Principal Findings

In this study, we used a year-long longitudinal data set from 112 working adults and identified several significant relationships between changes in sleep over time and various factors, including restriction policies, seasonal changes, PA, and sociodemographics. We found that more stringent restrictions were associated with increased TST and delayed MS. Additionally, seasonal factors played a notable role: increased day length was linked to reduced TST and delayed MS. Changes in work arrangements, particularly the shift to remote work, directly impacted individuals based on their occupations and sleep patterns. Academic personnel, with more flexible schedules, slept less and exhibited greater variability in TST compared with service personnel, who had more structured work schedules. Additionally, individuals identified as “snoozers” had more flexible sleep schedules with greater variability in both TST and MS compared with nonsnoozers. Moreover, activity patterns played a significant role: exercising later in the day was associated with longer TST and reduced variability in both TST and MS. To contextualize our findings within the broader scope of sleep during the pandemic, the following section details our results and compares them with previous studies.

Demographic Factors

Previous research has highlighted several epidemiological factors affecting sleep patterns, notably, age, gender, and chronotype. Consistent with previous studies, we found that older individuals tend to sleep less [43,44]. However, our findings reveal a correlation between older age and increased TST variability, which contrasts with prior results [45]. The

variance in the observed correlations may be due to our study using objective sleep measures, while [45] relied on self-reported data. Additionally, we found no significant association between MS variability and age. Regarding gender differences, our study shows that males tend to have shorter and less consistent TST compared with females. While the shorter TST among males is well-documented [46,47], evidence regarding gender disparity in TST variability is inconsistent. For instance, an actigraphy study on a middle-aged cohort found that females exhibited greater TST variability than males [48]. Conversely, a survey-based study on university students [49] reported no gender differences in TST variability. Additionally, our study observes that parental duties significantly impact sleep patterns. Parents typically exhibited earlier sleep times and more consistent TST and MS than nonparents. The underlying reasons for these observations remain uncertain, but one hypothesis is that parents' sleep/wake schedules are more stable due to the need to synchronize their sleep patterns with those of their children. While the specific relationship between parenting and sleep pattern variability has not been extensively studied, research on cohabitation suggests that living with others can influence sleep patterns by reducing variability in sleep timing and duration [50,51]. This context highlights how factors related to shared living arrangements, such as parenting, can contribute to greater sleep pattern regularity.

Snoozing Behavior

We observed higher variability in TST and MS among individuals identified as "snoozers." Interestingly, younger individuals and those with an evening chronotype are more likely to be "snoozers," suggesting an interplay between age, chronotype, and snoozing habits. The natural sleep-wake patterns associated with an individual's chronotype may influence their tendency to snooze alarms. Morning types, who wake up earlier, might not feel the need to snooze as much because their schedules align better with societal norms, in contrast to evening types.

Clinically, snoozing can be linked to prolonged sleep inertia, a state of reduced alertness upon waking [52]. Morning types (with high MEQ scores) may be less prone to snoozing and thus avoid significant sleep inertia, potentially leading to better alertness and performance. Conversely, evening types who snooze might experience greater sleep inertia, which could present additional challenges, such as managing increased work demands.

Occupational Factors

We found that academic staff have shorter and more variable TST compared with service staff, and also exhibit greater variability in MS. The flexible and deadline-driven nature of academic schedules may contribute significantly to these irregular sleep patterns. As academics frequently adjust their schedules to meet project deadlines or prepare lectures, the dynamic nature of their workload can disrupt regular sleep patterns. Additionally, the intellectual and creative demands of academic work often extend beyond the traditional 9-5 workday, further contributing to irregular sleep schedules.

Nonetheless, it is noteworthy that increased variability in sleep patterns might impact overall health and well-being. For instance, studies using actigraphy have found that higher TST variability is associated with an increase in depressive symptoms [53,54]. These implications become even more significant in the context of the COVID-19 pandemic. The shift to remote working and learning may introduce greater flexibility for academic personnel. Although this flexibility allows for more control over schedules, it may also blur the boundaries between work and personal life, potentially leading to longer work hours and more irregular sleep patterns.

Restriction Policies

The influence of lockdown measures during the pandemic on sleep patterns is well documented, with increased TST and later MS observed during lockdown periods [18,21,22]. Our findings further reinforce previous evidence at a more granular scale. In a more detailed analysis using the SI to measure lockdown severity, Ong et al [55] found that a higher SI was correlated with later and more variable MS. Contrary to Ong et al's findings, our study did not find a correlation between the SI and the variability of MS. However, it is important to note the methodological differences between our studies: while Ong et al [55] conducted their correlation measurements on a monthly basis, our analysis was performed at a weekly level. These differences in granularity may account for the contrasting results.

Although not closely examined in this study, we postulate that the side effects of restriction policies might significantly impact sleep. Prolonged periods of staying at home could induce stress, potentially increasing the prevalence of insomnia [56]. Furthermore, loneliness due to self-isolation could further worsen sleep quality [57]. Despite these adverse effects, restriction policies have also had positive aspects. The shift to remote work persists, as postpandemic workplace policies increasingly encourage hybrid and remote work [58]. This change allows for greater flexibility in daily schedules, potentially leading to improved and longer sleep.

Seasonality

Seasonal factors, such as day length, have been shown to influence sleep patterns, including sleep duration and timing [59,60]. Longer daylight hours during summer may encourage longer waking periods, while shorter days in winter can disrupt melatonin production, potentially leading to extended sleep duration. Additionally, these seasonal shifts align with changes in social schedules, such as holidays, which can further affect regular sleep routines. In southern Finland, where day length can vary by up to 13 hours between summer and winter, these influences might be more pronounced. It is possible that reduced exposure to natural daylight, due to limited mobility during the pandemic, could have altered the effect of day length on sleep.

Physical Activity

The connection between PA and sleep has been extensively studied [61-63]. While regular PA is generally recommended for promoting good sleep, it is crucial to recognize that PA is a multifaceted behavior with various elements—such as duration, timing, and intensity—that can each influence sleep differently [61]. Therefore, investigations into the relationship

between sleep and PA should consider these diverse aspects of PA.

When considering the timing of PA and its effect on sleep, our findings indicate that engaging in PA later in the day is associated with longer TST and reduced variability in both TST and MS. This supports previous research, such as a review by Youngstedt et al [63], which suggested that exercising later in the day can be beneficial for sleep. Similarly, a survey study found that engaging in light- to moderate-intensity workouts early in the evening may have beneficial effects on sleep [64]. The impact of PA's intensity on sleep could potentially modify the effects of its timing. Sleep hygiene guidelines suggest that vigorous exercise late at night may increase arousal and subsequently impair sleep quality [65]. However, recent research challenges this convention. For instance, Myllymäki et al [66] conducted a study under controlled laboratory conditions and found that exercise performed 4 hours before bedtime did not disturb sleep. Furthermore, a review by Stutz et al [67] suggested that evening exercise does not necessarily adversely impact sleep, although exercising less than an hour before bedtime could potentially disrupt sleep.

In addition to the volume and timing of PA, we found that the fragmentation of activity rhythms, measured by IV, significantly predicted sleep patterns. Our finding of a negative association between IV and TST reinforces previous research [68], which suggests that greater fragmentation in daily PA is linked to shorter sleep duration. Additionally, the novel associations between IV and MS, as well as the variability of TST, contribute new insights into the study of activity rhythms and sleep patterns.

By leveraging longitudinal data from fitness trackers, our study highlights the potential of mHealth to offer deeper insights into behavioral health patterns, especially regarding how lifestyle changes during the pandemic have impacted sleep. This integration of mHealth approaches in sleep research exemplifies how technological advancements can enhance our understanding and interventions in public health.

Limitations

This work has several unavoidable limitations. First, the absence of baseline data from the prepandemic period limits our study, preventing a comparison of sleep patterns and quality before and during the later stages of the pandemic. Second, the study was conducted among university staff, leading to a nonrepresentative sample that may introduce bias and result in a limited sample size. The relatively small sample size may have contributed to the wide CIs observed, indicating that the precision of our estimates could be improved. Consequently, our findings should be interpreted with caution, especially when generalizing to a broader population. Third, although we attempted to control for all known factors affecting sleep, there may still be unaddressed confounding variables. Fourth, we used consumer-grade wearables for data collection, which, despite their accessibility, may not provide the same accuracy and reliability as professional-grade equipment. Fifth, recall bias in self-reported measures is an inherent challenge. However, we addressed this issue by using validated questionnaires and conducting monthly data collection to minimize recall intervals. Finally, the study's geographical limitation restricts the generalizability of our findings to other cultural or social contexts.

Future Directions

One possible future research direction is to further investigate the relationship between snoozing behavior and specific demographics, such as age, to identify potential causative factors. For example, a case-control study could be conducted to compare individuals who frequently snooze with those who rarely or never do, across various age groups. This approach would enable a detailed examination of how snoozing behavior varies with age, while controlling for potential confounding variables.

Conclusions

Our study, through a holistic approach, provided insights into the changes in sleep patterns and PA levels among working adults during the late stages of the COVID-19 pandemic. The flexible working hours during the pandemic led to corresponding flexibility in sleep patterns in certain occupations and sleep traits, particularly among individuals who self-identified as snoozers. Our findings underscore the significant impact of lifestyle habits on sleep health, particularly during unprecedented times like a global pandemic. Moving forward, it is essential to further investigate changes in sleep patterns across diverse populations. Such research will help inform workplace policies in the postpandemic era, considering the potential benefits and challenges of remote work. One notable advantage to consider is the increased amount of sleep that workers may experience, potentially enhancing overall efficiency and productivity. As we navigate the future of work, understanding the interplay between work arrangements, lifestyle choices, and sleep quality will be essential for promoting optimal well-being and performance in the workforce.

Abstract

Background: The increasing prevalence of obesity necessitates innovative approaches to better understand this health crisis, particularly given its strong connection to chronic diseases such as diabetes, cancer, and cardiovascular conditions. Monitoring dietary behavior is crucial for designing effective interventions that help decrease obesity prevalence and promote healthy lifestyles. However, traditional dietary tracking methods are limited by participant burden and recall bias. Exploring microlevel eating activities, such as meal duration and chewing frequency, in addition to eating episodes, is crucial due to their substantial relation to obesity and disease risk.

Objective: The primary objective of the study was to develop an accurate and noninvasive system for automatically monitoring eating and chewing activities using sensor-equipped smart glasses. The system distinguishes chewing from other facial activities, such as speaking and teeth clenching. The secondary objective was to evaluate the system's performance on unseen test users using a combination of laboratory-controlled and real-life user studies. Unlike state-of-the-art studies that focus on detecting full eating episodes, our approach provides a more granular analysis by specifically detecting chewing segments within each eating episode.

Methods: The study uses OCO optical sensors embedded in smart glasses to monitor facial muscle activations related to eating and chewing activities. The sensors measure relative movements on the skin's surface in 2 dimensions (X and Y). Data from these sensors are analyzed using deep learning (DL) to distinguish chewing from other facial activities. To address the temporal dependence between chewing events in real life, we integrate a hidden Markov model as an additional component that analyzes the output from the DL model.

Results: Statistical tests of mean sensor activations revealed statistically significant differences across all 6 comparison pairs (P<.001) involving 2 sensors (cheeks and temple) and 3 facial activities (eating, clenching, and speaking). These results demonstrate the sensitivity of the sensor data. Furthermore, the convolutional long short-term memory model, which is a combination of convolutional and long short-term memory neural networks, emerged as the best-performing DL model for chewing detection. In controlled laboratory settings, the model achieved an F_1-score of 0.91, demonstrating robust performance. In real-life scenarios, the system demonstrated high precision (0.95) and recall (0.82) for detecting eating segments. The chewing rates and the number of chews evaluated in the real-life study showed consistency with expected real-life eating behaviors.

Conclusions: The study represents a substantial advancement in dietary monitoring and health technology. By providing a reliable and noninvasive method for tracking eating behavior, it has the potential to revolutionize how dietary data are collected

and used. This could lead to more effective health interventions and a better understanding of the factors influencing eating habits and their health implications.

chewing detection; eating detection; smart glasses; automatic dietary monitoring; eating behavior

Introduction

Background

Obesity is a public health issue that leads to chronic diseases [1], including diabetes [2], cancer [3], and cardiovascular diseases [4]. In the United Kingdom, the obesity levels increased from 15% in 1993 to 28% in 2019 [5]. Similarly, in the United States, the obesity levels increased from 14.5% in 1970s to 39.6% [6]. Furthermore, poor diet was estimated to have contributed to 11 million deaths globally in 2017 [7].

Given these alarming statistics, gaining insight into people's dietary habits is crucial for designing effective interventions aimed at promoting a healthy lifestyle. Dietary behavior tracking includes a spectrum of approaches ranging from manual to highly automated methods. At the most manual end, traditional food diaries require users to write down manually or digitally every item they eat or drink. The most commonly used manual tools to assess dietary intake and eating behaviors are 24-hour recalls, food records (food diaries), and food frequency questionnaires [8,9]. Major limitations of these methods include participant burden and recall or memory bias [10], which can lead to under- and overreporting of dietary intake. Digital tools and apps (eg, MyFitnessPal [11]) simplify the manual input process and integrate nutritional data, yet they require active user engagement, and in some cases nutrition knowledge to estimate calorie intake from precooked meals. A visual and less structured alternative is photographing meals, which offers an alternative way to recall and review dietary choices, sometimes shared with a dietitian for professional advice.

Related Works

The existing research indicates a growing interest in developing automated tools for monitoring eating activities. Regarding the tools and studies closest to our study, several studies have explored monitoring eating activities based on sensor-enabled glasses. Most of these studies are focused on detecting eating or drinking episodes [12-16] and are performed in controlled environments [17,18]. Only one study has explored a more complicated scenario than the typical eating or noneating detection [18] by exploring the detection of chewing events using eyeglasses equipped with electromyography sensors in a study involving 10 participants both in controlled and in real-life conditions. Compared to the existing work, we present the first study to use smart glasses with integrated optical surface tracking sensors and deep learning (DL) to accurately identify both eating and chewing events, assessed both in controlled laboratory settings and through real-life trials, thus addressing research gaps and proving its efficacy in natural environments.

Objective

This study aimed to develop and evaluate a novel, noninvasive system for automatically monitoring eating behavior by detecting eating and chewing activities. The system aims to enhance the accuracy and ease of tracking eating behaviors, addressing the limitations of self-reporting by providing precise, objective data.

The study provides a comprehensive evaluation of the proposed method using a combination of laboratory-controlled and real-life user studies, ensuring robust and noninvasive way to distinguish chewing activity from other activities, such as speaking, teeth clenching, grinding, smiling, frowning, brow raise, and winking.

The real-life data collection and analysis addresses a substantial gap in previous research and allows for the evaluation of the system's performance in natural settings, providing insights into its practical application and adaptability.

Methods

Terminology

Throughout this study, several terms related to eating behaviors are used. To ensure clarity and consistency in their use, the following definitions are provided:

- Bite: the act of placing food into the mouth, chewing it, and then swallowing it as part of the eating process.
- Chew: a masticatory cycle involving the grinding or crushing of food with the teeth, preparing it for swallowing.
- Chewing: the overall process of breaking down food with the teeth.
- Chewing rate: the frequency of masticatory cycles (chews) per unit of time, measured in chews per second.
- Eating segment: a continuous period during which the participant consumes food without interruption, encompassing consecutive bites and chewing cycles without pauses between bites. Thus, one eating segment can include one or several bites and chewing events.

Smart Glasses and Data Collection Setup

Overview

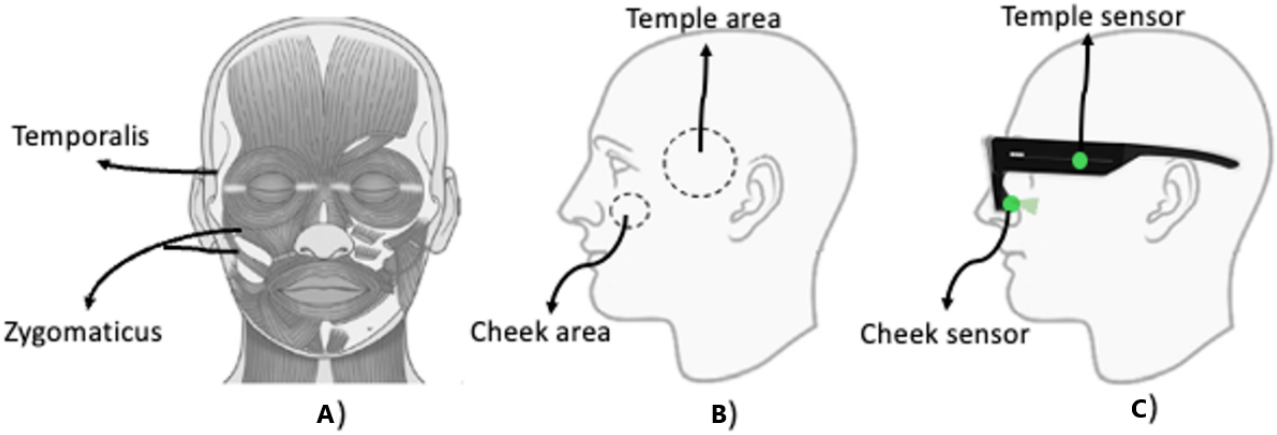
In this section, we describe our data collection setup, providing insights into the configuration and sensors of the used smart glasses. In addition, we describe the methodologies used for data collection in both controlled laboratory settings and real-life scenarios.

In contrast to the methods that require manual input, in this study, we propose an approach to automatic monitoring of eating behavior by monitoring facial muscle activations using optical

sensors incorporated in smart glasses frame. The approach offers real-time feedback that can be integrated with mobile health apps, allowing users to monitor their dietary habits seamlessly. The data collected can be used to personalize dietary recommendations, support weight management programs, and contribute to research in nutritional epidemiology. Ultimately, the goal is to empower individuals with actionable insights to improve their eating habits and promote long-term health and well-being.

The proposed system is depicted in Figure 1: (A) facial muscles associated with chewing that we aim to monitor; (B) the areas of skin that are monitored by the system; and (C) OCO optical sensors embedded in smart glasses. One of the muscles associated with the chewing activity is the temporalis muscle. The temporalis muscle is near the temple and extends downward in a direction toward the mouth. It controls movement of the lower jaw (eg, opening and closing of the mouth). This area is monitored by the OCO *temple* sensor in the glasses. Other muscles that are activated during chewing are the cheek muscles such as zygomaticus major and minor. This area is monitored by the OCO *cheek* sensor in the glasses. Our approach is based on the assumption that chewing activates multiple facial muscles, which causes the facial skin to move in a parallel direction relative to the sensors embedded within a glasses frame. These movements of the facial skin in the X-Y plane are monitored by our novel patented optical tracking sensors—OCO. The optical sensor data are then analyzed using DL to distinguish chewing activity from other activities that cause facial skin movements, such as speaking, teeth clenching, smiling, frowning, winking, and similar.

Figure 1. (A) The 2 types of facial muscles related to chewing (temporalis and zygomaticus); (B) monitored skin areas by the smart glasses; and (C) the placement of OCO sensors within the glasses frame.



OCOsense Smart Glasses and OCO Sensors Data

The OCOsense smart glasses integrate 6 optical tracking—OCO sensors [19], 3 proximity sensors, a 9-axis inertial measurement unit, an altimeter, and dual speech detection microphones. The OCO sensors use optomyography, an optical noncontact methodology, to measure skin movement in 2 dimensions resulting from underlying myogenic activity. They consist of an optical surface tracking sensor that measure relative movements on the skin's surface in 2 dimensions (*X and Y* dimensions). These sensors operate accurately within a range of 4 to 30 mm without requiring direct skin contact [19]. Positioned within the glasses frame, their focus lies on monitoring skin movement over specific facial muscle groups, including the frontalis and corrugator muscles on both sides of the forehead, the zygomaticus major and minor muscles on the left and right sides of the cheeks, the orbicularis muscles around each eye, and the left and right temples.

The eating activity activates two types of facial muscles that we can monitor with the glasses: (1) the temporalis muscle, which is near the temple, and controls movement of the lower jaw (opening and closing of the mouth), and (2) zygomaticus major and minor, which are located in the cheek area, and are activated during the chewing activity. Therefore, in this paper, we primarily focus on data collected from the cheek and temple OCO sensors (marked with green rectangles in Figure S1 in Multimedia Appendix 1), as these areas are more relevant to eating activity, compared with the rest of the sensors available in the glasses (marked with red rectangles in Figure S1 in Multimedia Appendix 1). A corresponding sensor data are presented in Figures S2 and S3 in Multimedia Appendix 1.

Data Collection Methodology

For development and evaluation of our method we collected 2 data sets. The first data set was collected in laboratory environment, while the second data set was collected in-the-wild. The laboratory data enabled us to establish a foundational understanding of eating behaviors under controlled conditions. However, evaluating the method on real-life data allows for assessing its generalization capability and adaptability to diverse and unpredictable environments.

To be more precise, we used the laboratory data sets to:

- Perform a statistical analysis comparing measurements obtained during 3 activities (eating or chewing, speaking, and teeth clenching) from both temple and cheek sensors, assessing skin movement along both the X and Y axes. This analysis is based on data from 28 participants for whom we have both eating and noneating labeled data.
- Develop and evaluate DL models for chewing detection. We compared the performance of four DL architectures. For the best-performing DL method, we conducted a more detailed analysis, including the impact of individual sensors

on the performance of DL models (eg, temple, cheek, temple + cheek, left temple + left cheek, and right temple + right cheek), and the impact of segmentation window size on the performance the DL models, varying the window size between 2 and 15 seconds.

We used the real-life data set to evaluate chewing detection and eating segments detection methods using data collected in-the-wild. Summary of the collected data sets is presented in Table 1.

Participant recruitment involved booking a time for data collection through social media announcements and completing a Google form to confirm eligibility. Eligible participants were required to be in good health; with no history of eating disorders; and without dietary restrictions, allergies, or intolerances. In addition, participants with conditions affecting facial muscle activation, such as stroke or facial palsy, or any other conditions impacting normal and symmetrical chewing and swallowing were excluded. An important inclusion criterion was that participants have proper glasses fit to ensure accurate detection of skin movements by the sensors.

Table 1. Summary of collected data sets.

Data set	Participants, n	Median duration	Total duration
Eating (laboratory)	28	9 min 49 s	369 min 15 s
Noneating (laboratory)	126 (same 28+98 new)	11 min 50 s	1601 min 47 s
Real life	8	907 min	7163 min

Study Procedures

Laboratory-Based Data Collection (Controlled Environment)

In the laboratory-based experiments, we collected two data sets:

1. Eating data set: the participants engaged in a full meal, providing them with the freedom to choose from a diverse range of food options, including:
   - Crispy or hard foods: apples, carrots, nuts, crisps, and crackers
   - Creamy or soft foods: porridge, banana, yogurt, fruit salad, and green salad
   - Chewy foods: breakfast bars; pop-tart; toast, bagel, or croissant; and biscuits

In addition, they were allowed to eat with or without utensils, based on their preference. There were no time constraints for completing the meal. Participants ate their meals in a laboratory setting designed to simulate a natural dining environment. They consumed their meals alongside the researchers, which helped create a more relaxed and realistic atmosphere. Despite the laboratory setting, participants were encouraged to consume their meals in a natural manner, simulating real-life conditions. This allowed for varied behaviors, for example, some participants used their phones during meals and others engaged in conversations. During the data collection, the participants were continuously video recorded, providing synchronized data between the video recording and sensor data. This enabled us to label each chewing segment later manually. For the eating activity, we annotated all segments where the participants had food in their mouth. Two researchers independently coded the bites, ensuring reliability and validity through cross-verification. The availability of video data allowed for accurate annotation, as each segment was reviewed by at least 2 researchers to confirm the presence of food in the participants' mouths.

2. Noneating data set: the data collection was performed in a controlled laboratory setting, where participants were instructed on the activities they should perform. First, participants performed a subset of activities associated with facial muscle engagement. This category includes brushing teeth, engaging in conversation, reading aloud, and diverse expressions of bruxism, encompassing teeth clenching, grinding, and tapping. In addition, we incorporated various facial expressions and gestures, such as smiling, frowning, winking, and similar, to capture a diverse range of facial movements. Moreover, we included a variety of activities that do not specifically rely on facial muscle engagement. These include hygiene-related activities such as handwashing and dishwashing, routine activities such as walking and sitting in a chair, and physical activities such as jogging and stair climbing.

Real-Life Data Collection (Uncontrolled Environment)

In the real-life setting, the participants were instructed to wear the OCOsense smart glasses continuously for a minimum of 8 hours a day over a span of 2 days. The participants were allowed to follow their daily routines without any imposed limitations during this period. This enabled the capture of eating behaviors in various settings such as home, workplace, and other public spaces. In addition, there were no restrictions placed on participants regarding their food choices or other diet-related decision. For the data collection procedure, we developed an application that collects data from the glasses and enables the participants to annotate when engaged in eating activities. More specifically, they were asked to press a button when they start eating and press it again when they finish eating. A researcher monitored the number of labeled eating events per day per participant. In instances where participants forgot to press the start or end buttons, they were asked to note the approximate times of their eating sessions. These cases were then manually analyzed by a researcher using the sensor data from the glasses to provide precise labels for the eating start and end times. These labeled segments served as the ground truth for subsequent experiments. The annotations collected with this approach result in whole data segments labeled as eating, yet these segments may also include a range of activities beyond eating itself, such as engaging in conversation or pausing briefly between bites, which typically occur during regular real-life meals.

Statistical Analysis

Data Preprocessing

To perform statistical comparison, the following data preprocessing steps were applied to the sensor data:

1. Calculation of the vector magnitude for each sensor: as the OCO sensors measure skin movement in 2 dimensions (*X* and *Y*), the vector magnitude was calculated for each sensor ( ).
2. Combination of processed sensor signals values from the left and right sensors: the vector magnitude value from the left cheek sensor was added to the vector magnitude value from the right cheek sensor, and the same was done for the temple sensors. This resulted in the creation of 2 signals, one representing the total cheek movement (left+right), and one representing the total temple movement (left+right).
3. Smoothing of the resulting signals: the resulting cheek and temple signals were smoothed using a rolling median filter with a window size of 15 samples (0.3 s) to reduce the effects of noise on the signals.

Hypothesis Testing

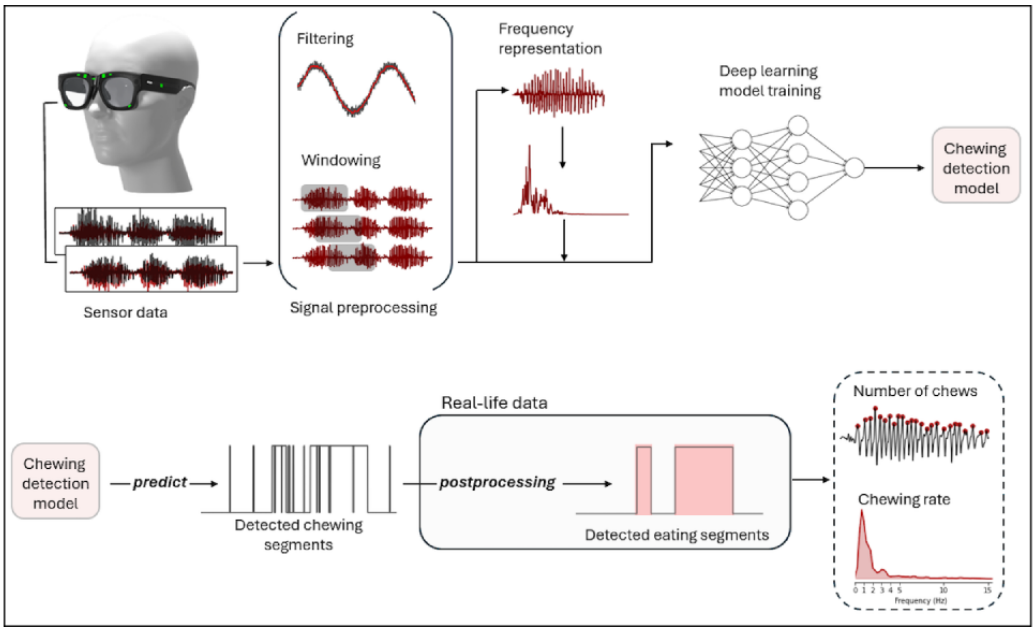
Hypothesis testing was conducted using the Wilcoxon signed-rank test, a nonparametric alternative to the paired 2-tailed *t* test. This test evaluates the distribution of differences between related paired samples to ascertain whether they originate from the same distribution. The null hypothesis is that the samples derive from the same distribution. To account for multiple comparisons, *P* values were adjusted using the Bonferroni correction method (α=.05).

Chewing Detection Methodology

Overview

This section describes the method used in this study for automatic chewing and eating segment detection. Initially, the sensor data undergoes preprocessing, including filtering and segmentation into windows. Then, both the filtered signals and their frequency representations are used as input to DL models, which classify the windows into chewing or nonchewing. To enhance the accuracy in real-life scenarios, we introduce a supplementary model—hidden Markov model (HMM). This integration enables the grouping of chewing predictions and the construction of coherent eating segments. Finally, we calculate the number of chews and the chewing rate for the detected eating segments. The block diagram of the pipeline is shown in Figure 2.

Figure 2. Overview of the developed method for detection of chewing and eating segments estimation.



Signal Preprocessing

The method uses data from the 4 OCO sensors—left and right temple and left and right cheek. Let O_{RC}, O_{LC}, O_{RT}, *and* O_{LT} denote these sensors in the specified sequence. The set of sensors can be represented as S = {O_{RC}, O_{LC}, O_{RT}, O_{LT}}, where each sensor S^i reads data . in the time interval of *T* from timestamps t_1 to t_n. The main objective is defined as:

1. Partitioning *T* into partially overlapping windows of equal size $W = \{W_1,W_2,...,W_n\}$ and assuming a target activity set $Y = \{Y_1,Y_2,...,Y_n\}$
2. Assigning each window W_i a target label Y_j from the target label set $Y = \{Y_1,Y_2,...,Y_n\}$ and training a classifier accordingly

First, to remove the noise from the data, a fifth order median filter was applied to each sensor channel within the sensor set *S*. This filter was proven to effectively remove noise while preserving essential signal features in our previous studies on expression recognition using the same type of sensor [20]. Following the medial filter, the next step in the process involved determining the appropriate window size for data segmentation. We experimented with various window sizes ranging between 1 and 15 seconds. Once the sensor set *S* was segmented into

windows (W), the next step was to enhance the information carried by the input signals further. To achieve this, we used Fourier transformation for each sensor within the segmented windows. This transformation allowed us to convert the time-domain signals into their frequency representations, thereby extracting additional features from the data. The Fourier transformation process provided valuable insights into the frequency components present in the sensor data, which could be crucial for detecting subtle patterns associated with chewing activity.

Chewing Detection With DL Models

In this study, we used 4 distinct DL models based on convolutional neural networks (CNNs) for the purpose of chewing detection. We focused on DL architectures commonly used for wearable sensor data, such as CNN 1D [21,22], CNN 2D [21], attention model [23], and convolutional long short-term memory (ConvLSTM) [24]. By using these common architectures, we aim to demonstrate the baseline accuracy achievable with existing methods. This serves as a foundation upon which further improvements can be made. Specifically, developing DL architectures tailored to the unique specifications of the glasses and the specific use-case of detecting eating activity could potentially enhance accuracy beyond the baseline results established in this study.

An overview of the architectures and their associated hyperparameters is as follows:

1. CNN 2D: Our initial model adopts a standard CNN [21], crafted to extract hierarchical spatial features from input data. The feature extraction module consists of 3 consecutive convolutional layers, each followed by group normalization and max-pooling layers. Extracted features are then passed through 2 fully connected layers, each containing 128 neurons, connecting to the output nodes.
2. ConvLSTM: Expanding on CNN's foundation, the ConvLSTM model [24] introduces a temporal dimension to our analysis. It shares the same convolutional layers with the CNN 2D architecture and integrates 2 LSTM layers, each featuring 128 hidden units. This modification allows the model to effectively capture sequential patterns and dependencies within the data.
3. Attention model: Incorporating insights from attention mechanisms, the attention model [25] comprises 4 convolutional layers with 64 feature maps followed by 2 LSTM layers, each with 128 hidden units [23], and an attention layer. The attention layers allow the model to prioritize relevant information during the learning process.
4. CNN 1D with statistical features: The last model incorporates a 1D CNN architecture [22], enhanced with statistical features. It consists of a single convolutional layer with 256 filters followed by a max-pooling layer. The resulting features are then flattened and fused with statistical features extracted from filtered sensor data, including mean, variance, and absolute sum. The joint vector is then processed through a fully connected layer with 1024 neurons capturing both spatial and statistical characteristics.

The determination of architecture parameters, such the kernel size in the convolutional layers, output size of CNN layers, LSTM units, and fully connected units, was guided by a pragmatic approach focused on achieving a balance between model's ability to capture complex data patterns and model's complexity. These parameters were fine-tuned on the validation set to optimize performance.

Each model was trained for 100 epochs with a batch size set at 256. Prior the beginning of the learning process, we used orthogonal weight initialization for both weights and biases, aiming to enhance the stability and effectiveness of neural network training. Cross-entropy loss was used as the objective function for training. Furthermore, all the models were trained using the Adam optimizer with an initial learning rate of 1e-3. To avoid overfitting as well as to reduce the training time, early stopping, monitoring validation F_1-macro score with patience of 15 epochs was applied. In the end, the optimal weights were selected based on the epoch with the highest validation F_1-macro score.

Detection of Eating Segments

In the initial phase of our eating detection system, we use a DL model to detect chewing moments at a window-level granularity. By incorporating the temporal dependence between the detected chews, we aim to enable our system to identify not only individual chewing instances but also to discern when eating segments occur within real-life data. This allows us to effectively mitigate the occurrence of short false-positive predictions and consolidate densely clustered chewing instances into coherent eating segments. By doing so, we anticipate a more robust and precise analysis of dietary patterns.

To address the temporal dependence between chewing events in real life, we integrate HMM as a supplementary model that analyzes the detected chews from the DL model. The HMM was initialized and trained as described in the study by Stankoski et al [26]. This process is visually illustrated in Figure S4 in Multimedia Appendix 1.

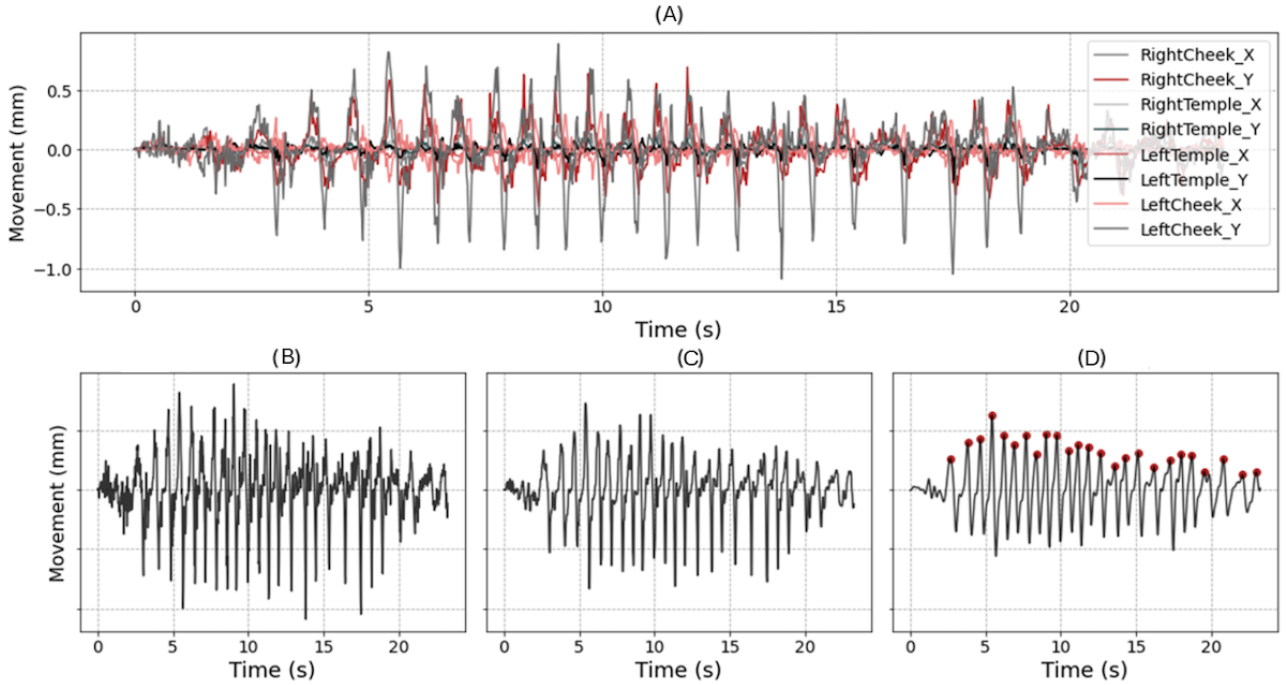
Detection of Number of Chews and Chewing Rate Estimation

After the detection of eating segments, to determine the number of chews in an eating segment, we additionally analyze and process the signals from the sensors. Figure 3 presents a visual representation of the data processing steps used in the detection of chews within a randomly selected eating segment from the data set. The initial step involves identifying the signal with the highest root mean square value. Subsequently, we use a 2-step filtering process to enhance the selected signal. First, a median filter with a kernel size of 5 is applied, followed by a second-order bandpass filter within the frequency range of 0.5 to 3 Hz. For the calculation of the number of chews, we used an existing peak detection algorithm (using SciPy [27]) on the processed signal. This involves configuring the threshold and distance parameters to identify relevant peaks in the signal. Furthermore, peaks with insufficient prominence are excluded from the final set.

Each retained peak after this step is considered as a separate chew in the signal. The parameter values used in the filtering and peak detection processes were determined empirically.

Following the detection of chews within eating segments, we extend the analysis to estimate the chewing rate. To achieve this, we use the same signal with the highest root mean square value. This signal is subjected to further analysis through Fourier transformation to compute its frequency spectrum. By examining the resulting spectrum, we identify the most substantial frequency component, which corresponds to the dominant chewing frequency within the examined eating segment.

Figure 3. Processing steps for detecting the number of chews in an eating segment: (A) cheek and temple signals; (B) selection of signal with highest root mean square (RMS) value; (C) filtering the chosen signal; (D) detection of peaks and chews in the filtered signal.



Evaluation Setup

To evaluate the effectiveness of the models, we used the Leave-One-Group-Out cross-validation technique. This involved dividing the initial data set into N separate groups, where the data from a single participant is present in only one subset. Each model is trained on combined data from *N*-2 subsets, leaving one subset to be used as validation data set and a second subset for testing the final model. Thus, all the models are person-independent, that is, the experimental results demonstrate the model's accuracy on unseen test users.

Regarding evaluation metrics, we used recall, precision, and F_1-score. Recall indicates the proportion of actual chewing segments correctly identified by the model, while precision denotes the proportion of identified chewing segments that are truly chewing segments. The F_1-score is the harmonic mean of the recall and the precision—which is more balanced metric compared with accuracy especially in unbalanced data sets where one of the classes is more frequent. The reported metrics reflect the models' ability to detect chewing at a window level, and they are calculated as follows:

(1)

(2)

(3)

In the equations (1) to (3), *TP* represents true positives, *TN* represents true negatives, *FP* represents false positives, and *FN* represents false negatives. In the context of chewing detection, these metrics can be interpreted as follows:

- *TP* indicates the number of windows from the chewing class correctly classified as chewing.
- *FP* indicates the number of windows from the nonchewing class incorrectly classified as chewing.
- *FN* indicates the number of windows from the chewing class incorrectly classified as nonchewing.

In addition, for the evaluation of eating detection in the real-life scenario, we used custom metric to provide deeper insights into the models' performance within eating segments. The metric was defined to analyze the number of eating segments that are correctly identified based on the frequency of positive chewing predictions within each eating segment:

- Detected eating segments: the number of eating segments where at least 50% of the instances (windows) are correctly identified as eating.

Ethical Considerations

To ensure ethical compliance, ethics approval was obtained from the London—Riverside Research Ethics Committee on July 15, 2022 (ref: 22/LIO/0415). After a detailed explanation of the experimental procedure, all participants provided written

informed consent before participating in the study. The consent forms addressed the use of their data. To protect participant privacy, all data were deidentified. The participants who took part in the laboratory sessions were compensated with US $26.5, while those involved in the real-life study received US $26.5 per day for their participation. The experiment was conducted following institutional ethical provisions and the Declaration of Helsinki.

Results

Overview

In this section, we present the results from the experiments. The *Statistical Analysis of OCO Sensors for Facial Muscle Movements* section presents the outcomes of the statistical analysis, focusing on the ability of OCO sensors in detecting facial muscle movements during various activities, including eating. The *Laboratory-Based Data Set DL Experiments* section assesses the performance of different DL models, sensor combinations, and window sizes for chewing detection in a controlled laboratory data set. Finally, the *Real-Life Data Set Experiments—Chewing and Eating Segments Detection* section presents the results obtained with the real-life data set and evaluate the performance of the method for detection of eating segments.

Statistical Analysis of OCO Sensors for Facial Muscle Movements

To evaluate the ability of the OCO sensors to detect facial muscle movements during different activities, we first conducted a statistical analysis. Our focus was on comparing measurements obtained from both temple and cheek sensors, assessing skin movement along both the *x* and *y* axes. In this context, we focused on comparing facial muscle movements during the activities of eating or chewing, speaking, and teeth clenching. The selection of these activities was based on the potential similarity in facial muscle activation patterns. For example, Figure 4 presents 6 graphs. The top row measures movements from sensors placed over the zygomaticus major muscle (cheek area) and the bottom row from sensors positioned on the temples. Each column of graphs represents 1 of the 3 activities being measured (eating, speaking, and clenching). The horizontal axis of each graph represents time in seconds, and the vertical axis shows the magnitude of skin movement in millimeters. By comparing these graphs, we can assess the differences and similarities in facial muscle activation patterns during the 3 activities.

We calculated mean movements measured from the cheek and temple OCO sensors for each participant during eating or chewing, speaking, and teeth clenching. The mean values were calculated over all data points corresponding to each activity, resulting in n=28 (number of participants present in both the eating and noneating laboratory data set) tuples, with each tuple comprising 3 values representing the mean cheek or temple movement for eating or chewing, speaking, and teeth clenching.

Figure 5 shows the mean cheek (left plot) and temple (right plot) movements during different activities, presented on the x-axis, and the results from the Wilcoxon signed-rank (paired) test with Bonferroni correction (α=.05).

For the cheek OCO sensors, we can observe an increased movement during eating (median value 0.113 mm) compared with relatively lower values observed during speaking (median value 0.036 mm) and the teeth clenching (median value 0.008 mm). The results from the statistical test further indicate significant differences in cheek movements between speaking and eating (P<.001), eating and teeth clenching (P<.001), as well as speaking and teeth clenching (P<.001).

Similarly, for the temple OCO sensors, a notable increase in movement with a median value of 0.027 mm during eating is observed, compared with 0.008 mm during speaking and 0.002 during the teeth clenching. The statistical tests affirm the significance of these differences, demonstrating that mean temple movements differ significantly between speaking and eating (P<.001), eating and the teeth clenching (P<.001), as well as speaking and the teeth clenching (P<.001).

These findings highlight the potential sensitivity of the cheek and temple OCO sensors in capturing distinct patterns and subtle variations in facial muscle activation across different activities.

Figure 4. Sensor signals from the sensors on the right cheek and temple recorded during eating, speaking, and teeth clenching activity performed by one participant.

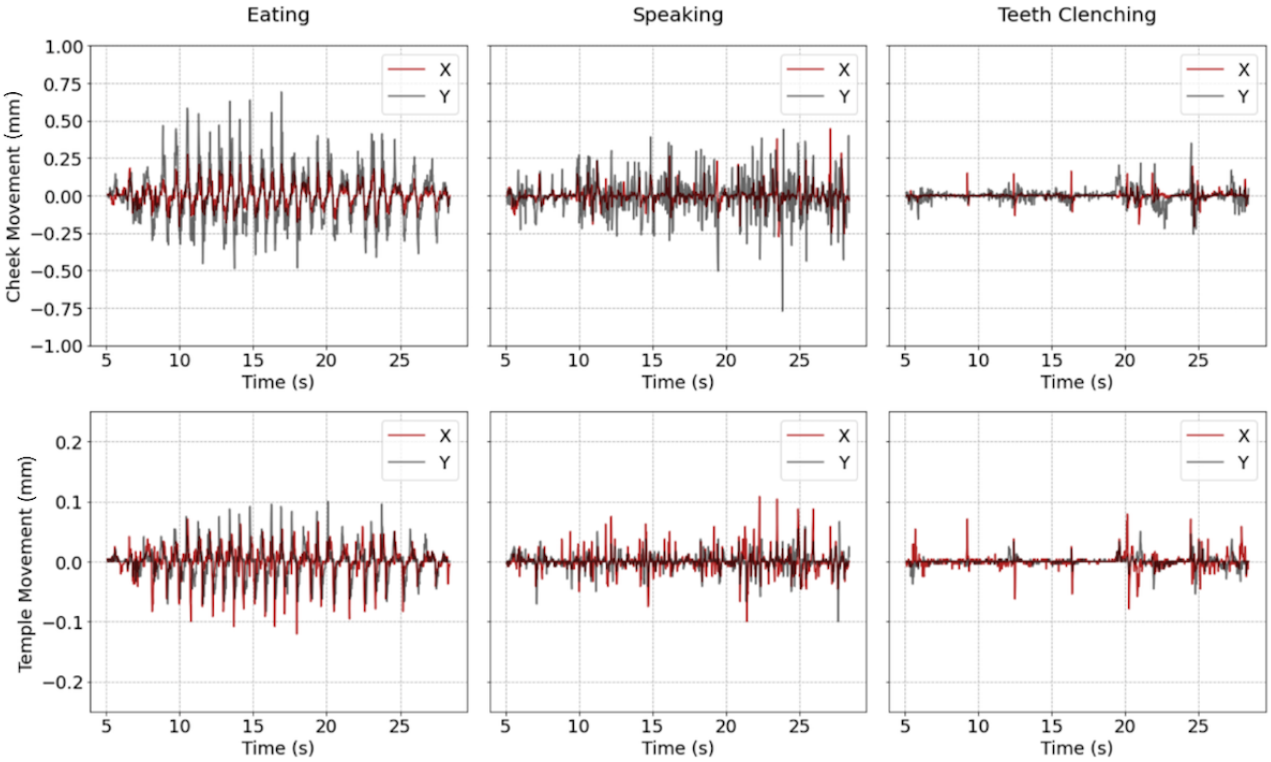


Figure 5. Wilcoxon signed-rank (paired) test with Bonferroni correction for comparing mean cheek and temple movements during activity pairs (n=28): clenching versus eating, clenching versus speaking, and eating versus speaking. Statistical significance annotations: *If P ∈ {.05, .01); **if P ∈ {.01, .001); ***if P ∈ {.001, .0001); and ****if P≤.001.

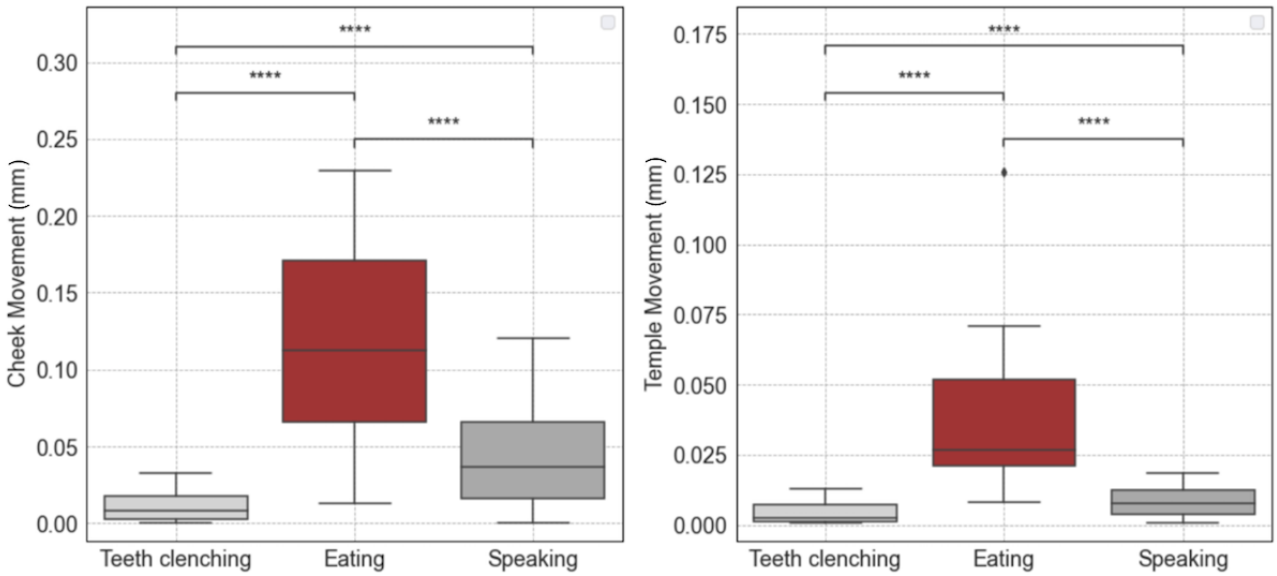

Laboratory-Based Data Set DL Experiments

In this section, we present the sample characteristics of the data set, the results of the experiments for chewing detection, conducted on the laboratory-based data set, offering insights into the results achieved across various DL architectures, sensor combinations, and window sizes.

Sample Characteristics

The laboratory-based data set consists of 2 subsets, one for eating activities and another for noneating-related activities. In the controlled eating data set, we gathered data from a cohort of 28 participants, comprising 13 (46%) males and 15 (54%) females, with an average age of 25.6 (SD 9.1) years. The data set comprises a total of 6.1 hours of recorded data. The noneating data set includes data from the same 28 participants, along with an additional 98 participants (n=48, 49% males and n=50, 51% females) with an average age of 23.3 (SD 6.4) years. Each participant contributed data for various activities, totaling 26.7 hours of recorded data. In summary, the data set comprises 126 participants and spans a combined total of 32.8 hours of recorded data.

DL Models for Chewing Detection

In this section, we present a comparison of various DL architectures used for the task of chewing detection. Table 2 provides a summary of the performance metrics, including F_1-score, recall, and precision for the chewing class, for each architecture.

The results show that all architectures demonstrated strong results, indicating that the sensor data provided from the glasses is informative for the chewing detection task. ConvLSTM demonstrated the highest F_1-score of 0.91, precision of 0.92, and recall of 0.89. CNN 2D also performed well with balanced metrics, achieving a slightly lower precision of 0.90, recall of 0.90, and F_1-score of 0.90. In contrast, the attention model displayed moderate performance with precision, recall, and F_1-score of 0.89, 0.90, and 0.89, respectively. The CNN 1D architecture, despite exhibiting a high precision of 0.90, fell short in recall at 0.86, resulting in a lower overall F_1-score of 0.88.

The confusion matrices for the evaluated models are presented in Figure 6. They provide additional insights into the models' behavior. Notably, the ConvLSTM model also demonstrated a lower number of false positives (FPs), totaling 1749 instances. This number is approximately 20% lower than that of the second-best model, CNN 2D, which recorded 2089 FP instances.

Figure S5 in Multimedia Appendix 1 shows the FP rates for various noneating activities detected by the ConvLSTM model. Socializing has the highest rate (0.72%), followed by reading (0.28%). Both involve speaking, leading to confusion with eating due to similar facial movements. The overall FP rate is 2%, also shown in Figure 6 (0.02 in confusion matrix D).

Table 3 provides a comparison of complexity and resource metrics for the evaluated architectures focusing on network parameters, computational complexity expressed as the number of floating-point operations per second (FLOPS) during a forward pass and the size of the model. CNN 1D with 2.4 gigaFLOPS and the 270-kB model size is the smallest model making it suitable for embedded applications in the future. CNN 2D, although larger, offers a balanced trade-off between performance and model size. The attention model, despite having fewer parameters than CNN 2D, has the highest computational complexity of 80.25 gigaFLOPS. ConvLSTM demonstrates a balance between accuracy and resource requirements.

Considering the results, ConvLSTM emerged as the preferred choice for the chewing detection tasks based on the model accuracy and computational complexity and resources needed, thus this architecture was used in the subsequent experiments.

Table 2. Performance metrics of different deep learning architectures for chewing detection. Precision, recall, and F1-score are calculated for the eating class.

DL architecture	Precision	Recall	F_1-score
CNN[a] 1D	0.9	0.86	0.88
CNN 2D	0.9	0.9	0.9
Attention model	0.89	0.9	0.89
ConvLSTM [b]	*0.92* [c]	*0.89*	*0.91*

[a]CNN: convolutional neural network.

[b]ConvLSTM: convolutional long short-term memory.

[c]Best performing algorithm.

Table 3. Complexity and resource metrics for the evaluated deep learning (DL) architectures.

DL architecture	Total parameters	Computational complexity (GFLOPS[a])	Model size (MB)
CNN[b] 1D	43,366	2.41	0.27
CNN 2D	1,208,578	20.92	4.88
Attention model	407,620	80.25	2.68
ConvLSTM[c]	997,890	31.42	4.03

[a]GFLOPS: giga floating-point operations per second.

[b]CNN: convolutional neural network.

[c]ConvLSTM: convolutional long short-term memory.

Impact of Individual Sensors on the Performance of Chewing Detection Models

In this section, we present the results from the analysis of the impact of individual sensors on the performance of the chewing detection models. Having identified the ConvLSTM architecture as the best-performing architecture among the models that we evaluated in the previous experiments, we proceeded with this architecture for a series of experiments encompassing various sensor combinations. The tested sensor combinations included temple, cheek, temple and cheek, as well as the left versus right side. The results from these experiments are presented in Table 4.

From Table 4 it can be observed that the cheek sensor outperforms the temple sensor. Specifically, in detecting chewing segments, the cheek sensor achieves recall of 0.88, which is 4 percentage points higher than the recall achieved by the model trained with temple sensor data (0.84).

The performance of the model trained with data from the cheek sensors can be attributed to the role of the cheek region in eating activities, predominantly chewing. The sensors are adept at capturing the specific circular movements of the cheek area during such activities, which produce distinct signal pattern associated with eating. The ability to capture these specific patterns results in the model's high precision in distinguishing eating episodes, thus enhancing recall rates.

Although the temple muscle is uniquely activated during chewing activity, the results show that the activation measured by the sensor is not very high across all people. However, if we combine the temple and the cheek sensors, we can see that the recall is improved by 1 percentage point. This shows that the temple sensor data provides additional information to the model.

In addition, we explored the performance of the models by using only one side of the temple and cheek sensors. On the basis of the results, we can see that the combination with the sensors measuring the right temple and cheek achieves recall of 0.89, which is 3 percentage points higher than the recall achieved by the model trained with left temple and cheek sensor data. This might be expected because most people prefer to chew the food on one side of their mouth [27,28] and the activation of the muscles is higher, which results in higher values in the sensor data.

Table 4. Performance metrics of convolutional long short-term memory for chewing detection with multiple combinations of sensor data. Precision, recall, and F1-score are calculated for the eating class.

Sensor combination	Precision	Recall	F_1-score
Temple	0.83	0.84	0.83
Cheek	0.92	0.88	0.90
Temple+cheek	*0.92* [a]	*0.89*	*0.91*
Left temple+left cheek	0.9	0.86	0.88
Right temple+right cheek	0.89	0.89	0.89

[a]The selected combination shows the best results based on the F_1-score.

Window Size Impact on the Performance of Chewing Detection Models

This section presents the results of the analysis of how window size influences the performance of the chewing detection models. For this purpose, a series of experiments were conducted, exploring various window sizes that extend beyond the default 4-second window size used in the previous experiments. For this analysis, we used a consistent 1-second window slide, with the aim to prevent delays in prediction changes and to ensure that the model will be able to promptly detect eating-related movements. The results from the experiments are presented in Table 5.

The performance of the ConvLSTM architecture demonstrated a noticeable enhancement with the increase in window size in terms of precision, recall, and F_1-score. More specifically, as the window size extends from 2 to 10 seconds, we consistently observe improvements in results. However, upon reaching a 15-second window, we observe saturation in performance metrics, where the obtained results remain consistent with those achieved at the 10-second window. This is probably because

longer windows might include nonchewing data, leading the model to misclassify entire instances as noneating.

Although, among the window sizes of 6- and 10-second improvement can be observed, we decided to proceed with the 4-second window. This decision was based on its advantage in processing fewer data compared with the 6- and 10-second modes, leading to a reduced computational demand and potentially lower energy use.

Table 5. Performance metrics of convolutional long short-term memory for chewing detection with various window sizes. Precision, recall, and F1-score are calculated for the eating class.

Window size	Precision	Recall	F_1-score
2 seconds	0.90	0.86	0.88
4 seconds	0.92	0.89	0.91
6 seconds	0.93	0.92	0.92
10 seconds	*0.93* [a]	*0.94*	*0.93*
15 seconds	0.92	0.94	0.93

[a]Best performing result.

Real-Life Data Set Experiments: Chewing and Eating Segments Detection

Overview

To assess the effectiveness of our chewing detection and eating segments detection methods using data collected in-the-wild, we conducted a series of experiments. In the first subsection, we present the sample size of the data set. Then, in the second subsection, we present the results of the chewing detection method using real-life data. Next, in the third subsection, evaluation of the eating segment detection is presented. In the last subsection, we show the estimation of the chewing characteristics.

Sample Characteristics

The real-life setting data collection involved 8 participants (5 males and 3 females; average age 30.8, SD 12.4 years). Each participant wore the glasses for a minimum of 8 hours per day over 2 days, resulting in 16 hours of recorded data per participant and a total of 128 hours of recorded data.

Chewing Detection Evaluation Using Real-Life Data

This evaluation allows us to explore whether a model trained with seminaturalistic behavior data collected in a laboratory setting can perform well on a real-life data from unseen participants. Figure 7 presents the results obtained on the real-life data set at a window level using the model for chewing detection. The classification report is shown in Table 6. It shows that the model achieved precision of 0.95, recall of 0.82, and an F_1-score of 0.88 for the eating class. The accuracy of this model was 98%.

We derived the probability density function of the model's probability outputs. The resulting graph, depicted in Figure 8, reveals a bimodal distribution, exhibiting one smaller peak near a probability of 0.2 and a larger, more substantial peak beginning at approximately 0.8 probability. The prominence of the second peak starting from a higher probability threshold signifies the model's strong confidence in identifying chewing activity, within the labeled eating segments. In addition, the predictions around the first peak can be interpreted as instances where the model is relatively certain that chewing is not occurring within the eating-labeled segments.

These results are in line with our expectations and understanding of the real-life data set. As previously described, the ground truth of the real-life data set contains only the information when eating segments took place. When evaluating the chewing detection method on data set where eating segments are labeled, the presence of false negatives can be attributed to the nature of the data set. Eating segments may encompass various activities beyond just chewing, such as talking, short breaks between bites, holding food, and similar. Therefore, segments labeled as "eating" may indeed involve nonchewing activities.

Figure 7. Confusion matrix for the chewing detection model evaluated on the real-life data set on window level.

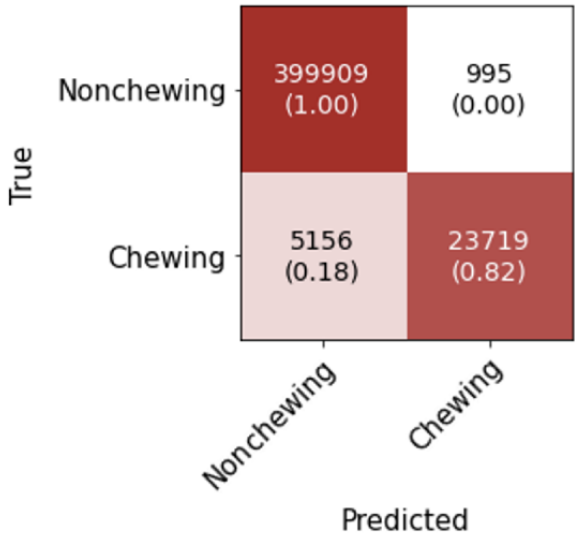

Table 6. Classification report for the chewing detection model evaluated on the real-life data set on window level.

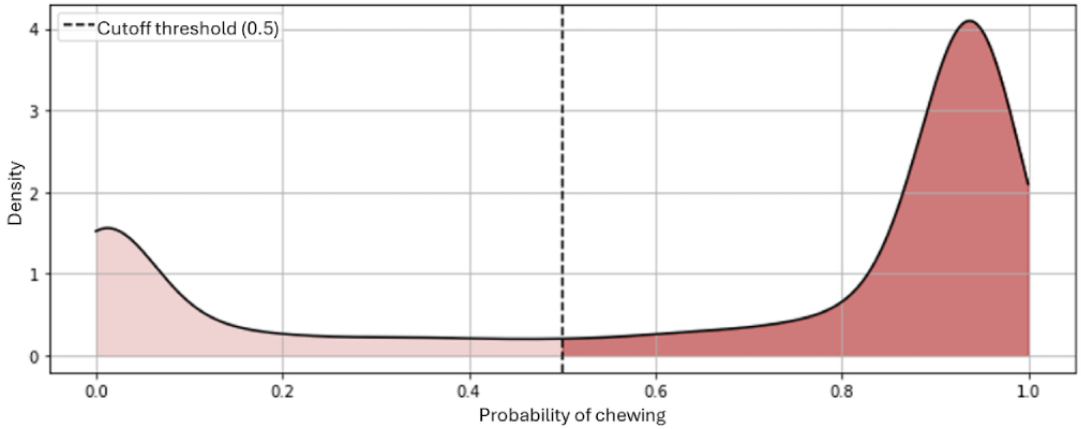
Class	Precision	Recall	F_1-score
Noneating	0.99	1.00	0.99
Eating	0.95	0.82	0.88
Macroaverage	0.97	0.91	0.94

Figure 8. Probability density function of the model's output probabilities for the chewing-labeled instances.



Evaluation of the Method for Eating Segment Detection

As previously described, the ground truth for the real-life data set contains information when the eating segments took place. This means that the annotated eating segments may contain short breaks between bites, conversations, food preparation, and similar. Because of this, we evaluated the eating segments detection based on the temporal information of the chewing detection algorithm as described in the *Detection of Eating Segments* section.

The results obtained on a segment level are shown in Table 7. This table contains the total number of eating segments, number of detected eating segments, and falsely detected eating segments for each participant. An eating segment is considered as detected if >50% of the instances in the labeled segment are predicted as chewing. The result of this evaluation shows that from total of 74 eating segments labeled by the participants, we can accurately detect 71 eating segments. The number of the falsely detected eating segments is relatively low for all participants, having total of 7 false detections.

Furthermore, we extended our analysis of the real-life data set to explore the suitability of the sensor data obtained from the smart glasses in-the-wild for capturing more detailed eating-related metrics, beyond only detecting instances of eating. In particular, we aimed to quantify the number of chews and the chewing rate within eating segments, although this method was not subjected to formal evaluation, mainly because of the lack of ground truth in the real-life data set.

Table 7. Evaluation of eating segment (ES) detection on the real-life data set, including total number of ES, number of true detected ES, number of false detected ES, and mean duration of falsely detected ES per participant.

Participant ID	Total ES	True detected ES	False detected ES	Mean duration of falsely detected ES, SD (min)
1	5	4	0	—[a]
2	12	12	1	1.77 (0)
3	20	20	0	—
4	7	6	2	0.72 (0.5)
5	5	4	3	0.54 (0.2)
6	15	15	0	—
7	4	4	1	0.46 (0)
8	5	5	0	—
Total	74	71	7	—

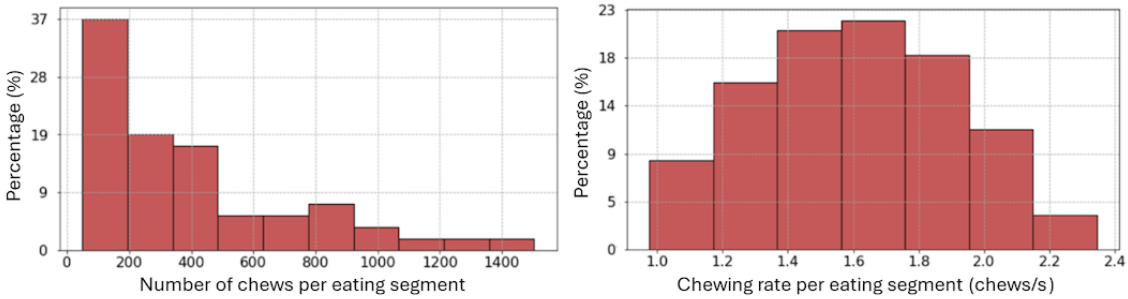
Estimation of Chewing Rate and Number of Chews Using Real-Life Data

After using the previously described methodology for calculating the number of chews on a window level for the eating segments, the resulting values ranged from 48 to 1505. The distribution of these values, as depicted in Figure 9A, indicates that participants have recorded both short snacks and long-duration meals, reflecting the diversity of eating behaviors captured in the data set.

Similarly, upon applying the approach for chewing rate estimation on a window-level for the eating segments, the derived values ranged between 0.8 and 2.3 chews/s. Notably, these values align with expectations observed in real-life eating scenarios [28]. Figure 9B depicts the distribution of the chewing rate values. Figure S6 in Multimedia Appendix 1 presents the mean chewing rate and the total number of chews for all eating segments across all participants in the data set.

Figure 9. Distribution of estimated number of chews and chewing rates per eating segment in the real-life data set.



Discussion

Principal Findings

While most people know that modifying eating behavior is key to sustained weight management, improving what is not measured is difficult. Traditional methods of eating assessment typically summarize dietary measures at the hour, day, week, or even year level [10]. Although these can clarify high-level relationships between eating behavior and disease risk, important short-term patterns are not measured and cannot be explored with the traditional methods. The ability to explore microlevel eating activities—such as meal microstructure (eg, meal duration and chewing frequency) [29] and food choices [30]—is important because they play an important role on food selection, dietary intake, and ultimately, obesity and disease risk [31-33].

In this study, we explored the potential of optical tracking sensors integrated into smart glasses for detection of eating, focusing on chewing activity as a critical component of dietary monitoring. Table 8 compares our study with existing glasses-based eating and chewing monitoring systems, highlighting differences in study goals, sensor types, number of participants, study setups, and performance metrics. It is important to note that the performance metrics may not be directly comparable due to differences in sensors, devices, population, and evaluation setup. Unlike most studies, which primarily monitor eating and drinking behaviors, our approach provides a more granular analysis by specifically detecting chewing activities. Only 2 other studies, including Zhang and Amft [18], have focused on chewing as an activity, and among these, only Zhang and Amft [18] and our study have conducted evaluations in real-world settings. Our results are slightly better, likely because electromyography sensors used by Zhang and Amft [18] require skin contact, whereas our optical sensor-based tracking does not, making our estimates more robust and less intrusive.

Accurate estimates of chewing can further be used for calculating eating rate. Such granularity offers better insights

for nutritional management. For example, eating rate has gained interest over recent years, as studies suggest a link between eating quickly and being overweight [31]. Other studies suggest that faster eating rate is associated with higher BMI and higher energy intake [32]. Studies also suggest that eating rate is independently associated with insulin resistance [33], which might be explained by the rapid entrance of glucose into the circulation at the beginning of the meal [34].

Our investigation spanned controlled laboratory settings to the real-life environment, providing a robust assessment of the technology's effectiveness and practicality. The system leverages contactless optical tracking technology—OCO, to monitor facial muscle activation related. These activations are further processed by a DL model for detection of eating and chewing segments. On the basis of the results of the experiments where we evaluated various DL architectures, ConvLSTM model was selected as the best-performing model for identifying chewing events in our eating detection experiments. Regarding the real-life experiments, our method for chewing detection and eating segments detection, validated on data collected in-the-wild with 8 participants, demonstrates promising results. The model achieved high precision (0.95) and recall (0.82) for the eating class, with an F_1-score of 0.88 at a window level. However, false negatives in chewing detection can be attributed to the diverse activities encompassed within eating segments beyond just chewing, such as talking or short breaks between bites. Evaluating eating segments detection based on temporal information from the chewing detection algorithm revealed accurate detection of 71 out of 74 labeled eating segments, with only 7 false detections across participants.

Regarding the sensor positioning, based on the results in Table 4 and the data from 128 participants, we observed that the cheek sensor outperforms the temple sensor, achieving a recall of 0.88 compared with 0.84 for detecting chewing segments. The addition of temple sensor data shows a modest 1 percentage point improvement in recall, indicating its supplementary role in enhancing overall performance.

Regarding the segmentation window size, as we increased the window size from 2 to 10 seconds, the ConvLSTM model's precision, recall, and F_1-score improved. However, at a 10-second window, performance plateaued, likely due to the inclusion of irrelevant nonchewing data. Despite better results at 6 and 10 seconds, we chose a 4-second window for its lower computational load and energy consumption. This aspect is crucial for deployment on mobile or wearable devices, where processing power and battery life are limited. Moreover, the use of a 4-second window has proven to offer stable performance that ensures the model is sufficiently fast to adapt to changes in eating behavior without substantial delays, due to the 1-second sliding segment.

Table 8. Comparison with glasses-based eating and chewing monitoring systems.

Study	Goal	Sensors	Participants, n	Setup	Performance
Bedri et al [13], 2020	Eating and drinking	IMU[a], proximity, and camera	18 (laboratory) and 5 (real-world)	Laboratory and real world	F_1-score: 0.89

Limitations and Future Work

Regarding limitations, while our study included data from >100 participants, most of the data were collected in controlled setup. In contrast, our real-world data came from 8 participants observed for 2 days. To strengthen these findings, a broader and more prolonged study is needed.

Regarding the technical aspects of the system, the technology should be assessed across various demographics and age groups to ensure its generalizability. Factors such as the shape of a participant's head or nose might alter sensor position and data quality, and participants' adherence to wearing the device properly must be considered. Developing personalized models that adapt to individual eating patterns and preferences could improve the system's accuracy and user acceptance. Machine learning algorithms that learn and adapt to each user's unique behaviors over time could provide personalized and more accurate monitoring.

In terms of system application domains, combining the eating detection system with nutritional analysis tools could provide a comprehensive solution for monitoring not only eating behaviors but also dietary intake and nutritional quality, offering more actionable insights for health interventions. Furthermore, investigating the long-term impact of using such monitoring systems on health outcomes, including weight management, metabolic health, and behavior change, could provide valuable evidence for the efficacy of these technologies in promoting healthy eating habits and preventing chronic diseases.

Conclusions

Our study demonstrates the efficacy and feasibility of using optical tracking sensors integrated into smart glasses, particularly with the OCO technology, for noninvasive monitoring of eating behaviors, with a focus on chewing detection and eating segment detection. Through rigorous experimentation on data from 128 in-laboratory participants and 8 real-world participants, we determined that the proposed approach can accurately detect chewing activity in both laboratory and real-life scenario, highlighting the promising potential of this system for dietary monitoring applications.

Abstract

Background: Consumer-based wearables are becoming more popular and provide opportunities to track individual's clinical parameters remotely. However, literature about their criterion and known-groups validity is scarce.

Objective: This study aimed to assess the validity of the Fitbit Charge 4, a wrist-worn consumer-based wearable, to measure clinical parameters (ie, daily step count, resting heart rate [RHR], heart rate variability [HRV], respiratory rate [RR], and oxygen saturation) in patients with chronic obstructive pulmonary disease (COPD) and healthy controls in free-living conditions in Belgium by comparing it with medical-grade devices.

Methods: Participants wore the Fitbit Charge 4 along with three medical-grade devices: (1) Dynaport MoveMonitor for 7 days, retrieving daily step count; (2) Polar H10 for 5 days, retrieving RHR, HRV, and RR; and (3) Nonin WristOX$_2$ 3150 for 4 nights, retrieving oxygen saturation. Criterion validity was assessed by investigating the agreement between day-by-day measures of the Fitbit Charge 4 and the corresponding reference devices. Known-groups validity was assessed by comparing patients with COPD and healthy controls.

Results: Data of 30 patients with COPD and 25 age- and gender-matched healthy controls resulted in good agreement between the Fitbit Charge 4 and the corresponding reference device for measuring daily step count (intraclass correlation coefficient [ICC$_{2,1}$]=0.79 and ICC$_{2,1}$=0.85, respectively), RHR (ICC$_{2,1}$=0.80 and ICC$_{2,1}$=0.79, respectively), and RR (ICC$_{2,1}$=0.84 and ICC$_{2,1}$=0.77, respectively). The agreement for HRV was moderate (healthy controls: ICC$_{2,1}$=0.69) to strong (COPD: ICC$_{2,1}$=0.87). The agreement in measuring oxygen saturation in patients with COPD was poor (ICC$_{2,1}$=0.32). The Fitbit device overestimated the daily step count and underestimated HRV in both groups. While RHR and RR were overestimated in healthy controls, no difference was observed in patients with COPD. Oxygen saturation was overestimated in patients with COPD. The Fitbit Charge 4 detected significant differences in daily step count, RHR, and RR between patients with COPD and healthy controls, similar to those identified by the reference devices, supporting known-groups validity.

Conclusions: Although the Fitbit Charge 4 shows mainly moderate to good agreement, measures of clinical parameters deviated from the reference devices, indicating that monitoring patients remotely and interpreting parameters requires caution. Differences in clinical parameters between patients with COPD and healthy controls that were measured by the reference devices were all detected by the Fitbit Charge 4.

Introduction

In recent years, consumer-based wearables have become increasingly popular due to their relatively low cost, ease of use, and ability to provide real-time feedback on several clinical parameters such as heart rate and step count. In Europe, 26% of 45 - to 74-year-olds used a wearable device in 2022 [1]. Alongside their rising popularity, wearable technologies also advanced significantly. Contemporary generation wrist-worn wearables use photoplethysmography technology, which measures the volumetric variations of blood circulation via an infrared light [2]. This technology enables to measure multiple parameters of autonomic function (ie, resting heart rate [RHR], heart rate variability [HRV], and respiratory rate [RR]) and oxygen saturation (SpO_2) [3].

Chronic obstructive pulmonary disease (COPD) is the third leading cause of death worldwide [4]. Although COPD is a disease characterized by respiratory symptoms and exercise intolerance related to abnormalities of the airways, the alveoli, or both, COPD seems also to alter the autonomic nervous system [5]. The autonomic nervous system adjusts heart rate, blood pressure, and RR in response to internal and external stimuli [6]. Patients with COPD show an elevated RHR, a reduced HRV and an increased RR compared to healthy controls [5,7]. Besides the autonomic function, SpO_2 is a clinical parameter that differs between patients with COPD and healthy controls, with patients with COPD having a lower SpO_2 due to alterations in gas exchange and experiencing a sudden drop in SpO_2 during exercise and when experiencing an acute exacerbation [4,8]. Both parameters of autonomic function and SpO_2 are prognostic markers of mortality and thus important to monitor [5,8,9].

Wearables potentially enable continuous monitoring of clinical parameters remotely and unobtrusively over a long period of time [10]. Whereas manufacturers specify that consumer-based wearables are not intended for medical purposes as they do not qualify as medical devices, continuously monitoring these parameters would provide information on the management of the patients' health at home, and investigate the effectiveness of interventions based on measures outside clinical visits in an easy way [11]. Moreover, given that these clinical parameters are linked to the worsening of health in various chronic diseases, it is tempting to actively monitor these parameters remotely, as this may lead to earlier detection of patients' deterioration or provide an explanation for reduced engagement in physical activity [12-16].

Previous literature showed that Fitbit wearables are valid devices for monitoring daily step counts in healthy individuals and can be used to monitor patterns of physical activity in patients with COPD [17-19]. However, literature in the healthy population on the validity of Fitbit measuring other clinical parameters is scarce, and no data are available for patients with COPD [18,20-22]. These studies used various devices, including medical-grade devices (such as the ActiGraph GT3X+ and Dynaport MoveMonitor for daily step count, and the Polar H7 for heart rate), as well as gold-standard measurements (such as ECG Holter monitoring for heart rate), to assess the validity of Fitbit wearables.

The aim of this observational study was to investigate the criterion validity and the known-groups validity of a consumer-based wearable for monitoring physical activity (ie, daily step count) and parameters of autonomic function (ie, RHR, HRV, and RR) in patients with COPD and a reference population consisting of healthy age-matched controls. Furthermore, the criterion validity and known-groups validity of this consumer-based wearable for monitoring SpO_2 was examined in patients with COPD.

Methods

Population and Design

This observational study was nested in a randomized controlled trial investigating the long-term effects of a telecoaching intervention in patients with COPD (NCT04139200). All patients with COPD included via Ghent University Hospital (Ghent, Belgium) and examined between April 2022 and June 2023 were enrolled in this substudy, ensuring representation of the entire patient cohort at this site. Patients aged 40 years and older with a smoking history of at least 10 pack years and with a clinical diagnosis of COPD (confirmed by spirometry [Tiffeneau-index<70%]) but no history of exacerbations in the past month were eligible to participate. Patients were excluded if they had orthopedic or other problems preventing them from improving physical activity, had undergone lung transplantation, were involved in a multidisciplinary rehabilitation program, or were unable to learn to work with electronic devices.

In addition, healthy controls were recruited between November 2022 and August 2023. These participants were 50 - 80 years old, had never smoked or had stopped smoking more than 20 years before inclusion, had a Tiffeneau-index ≥70%, had no chronic health problems or orthopedic problems preventing them from being physically active, and did not participate in a rehabilitation program.

Ethical Considerations

This study consisted of a single clinical visit and a follow-up period of 7 days. Both studies were approved by the ethical committee of Ghent University Hospital (BC-10267 [COPD] and ONZ-2022 - 0387 [healthy controls]). All participants signed the informed consent prior to data collection and were assigned a study ID number. No compensation was provided for participation in this study.

Clinical Assessments

At the clinical visit, the following assessments were performed in both groups: (1) sociodemographic and clinical data (age, sex, height, weight, smoking history, and medication intake); (2) postbronchodilator spirometry according to European Respiratory Society (ERS) – American Thoracic Society (ATS) guidelines [23]; (3) functional exercise capacity based on the best of two 6-minute walk tests following ERS-ATS guidelines [24]; and (4) Composite Autonomic Symptom Score (COMPASS) 31 questionnaire questioning autonomic nervous system symptoms [25]. In patients with COPD, the modified Medical Research Council scale (mMRC) questioning dyspnea and COPD Assessment Test (CAT) questioning health status were collected additionally [26,27].

During the 7-day wearing period following the clinical visit, participants were asked to wear a wrist-worn wearable, the Fitbit Charge 4, along with 3 approved medical-grade devices. During this wearing period, participants completed a daily diary including the time of waking up and going to bed, intake of medication, and consumption of beverages influencing the heart rate (eg, coffee, tea, alcohol, and energy drinks).

Wearable

The Fitbit Charge 4 (Fitbit Inc) is a triaxial consumer-based wearable worn on the nondominant wrist of the participant. This device records daily step count (accelerometry), as well as RHR, HRV, RR, and SpO_2 (photoplethysmography). These variables were extracted as day-by-day outcomes from the Fitbit platform, as calculated by the proprietary algorithms. Fitbit defines RHR as the heart rate while in a relaxed state during both sleep and being awake. HRV and RR are defined as the variation of duration between heartbeats, expressed as the root mean square of successive differences (RMSSD) in milliseconds (ms), and the number of breaths per minute during the night, respectively, when more than 3 hours of continuous sleep are recorded. Transcutaneous SpO_2 was defined as the average hemoglobin SpO_2 during the night (>3 hours of continuous sleep). Participants were instructed to wear the device for 7 consecutive days (24 hours per day). The device had a battery life of up to 7 days, but participants were advised to charge the battery when the battery level dropped below 10% and when they were not performing any activity.

Reference Devices

Physical Activity—Dynaport MoveMonitor

The Dynaport MoveMonitor (DAM; McRoberts) is a triaxial accelerometer validated to objectively measure physical activity in patients with COPD and healthy controls [28,29]. Participants were instructed to wear the monitor at the lower back during waking hours for 7 consecutive days, except for bathing and water activities, according to current recommendations [30]. Days with a wearing time lower than 8 hours were excluded for further analyses [30]. Wearing time and daily step count were extracted from the monitor for further analysis.

Cardiac Autonomic Function—Polar H10

The Polar H10 sensor chest strap (Polar Electro Oy) is a validated device to capture heart rate and HRV in healthy subjects [31]. This sensor was moistened before being applied below the chest muscles of the participants, as described by the manufacturer. To collect heart rate data for 100 hours, participants wore a corresponding Polar Ignite 2 watch (at the preferred wrist), which was used as a Polar H10 data logger. They were instructed to wear these devices for 5 consecutive days (24 hours per day), except for bathing and water activities, based on recommendations and the maximum recording capacity of 100 hours. Data were recorded using a 1-second time interval. Heart rate and beat-to-beat RR intervals (time between 2 successive R-waves of the QRS signal on the electrocardiogram) were extracted from the device using the Polar Flow web service.

To obtain the RHR, the average heart rate during the night (actual sleep time, ie, starting 1 hour later than the reported time of going to bed and ending 1 hour earlier than the reported time of waking up) was calculated to best match Fitbit's definition. Nights with 3 hours of sleep or less were excluded for further analyses.

The beat-to-beat RR intervals (time between 2 successive R-waves of the QRS signal on the electrocardiogram) were transferred to Kubios HRV Software (version 4.0.1, Kuopio) to analyze HRV (expressed as RMSSD in ms) and RR [32]. The actual sleep time as reported in the diary was entered into the software. Nights with 3 hours of sleep or less were excluded for further analyses to best fit with Fitbit's definition.

SpO_2 (COPD Only)—Nonin WristOX$_2$ 3150

The wearable finger pulse oximeter Nonin $WristOX_2$ 3150 (Nonin Medical Inc) was used as a reference device for measuring SpO_2, as it has become a commonly used device for home monitoring of patients with COPD and has a high accuracy (±2%) according to the manufacturer [33]. Patients with COPD were instructed to wear the device on the index finger of their dominant hand for 4 consecutive nights (limited battery life of 48 hours using continuous measurements, allowing up to 12 hours of monitoring per night). Data were recorded using a 4-second time interval. Data were stored on the internal memory of the device and downloaded after the 7-day follow-up period using the nVISION software (version 6.5.1.2, Nonin Medical Inc). The average SpO_2 during the night measured by Nonin was calculated after removing impossible values. Nights with 3 hours of sleep (as judged by the Fitbit device) or less were excluded for further analyses to best fit with Fitbit's definition.

Statistical Analyses

The sample size of this substudy was chosen to align with prior research within this field [18]. All statistical analyses were performed using the SAS statistical package (version 9.4, SAS Institute). Data are presented as mean (SD) or median (IQR), as appropriate after testing for normality using the Shapiro-Wilk test. Statistical significance was set at $P<.05$ for all analyses.

Criterion validity was investigated by comparing day-by-day data obtained by the Fitbit Charge 4 with the reference devices by use of a 2-tailed paired *t* test, Bland-Altman plots, and intraclass correlation coefficients ($ICC_{2,1}$). The cutoffs that were used to interpret the findings were ICC<0.50 as "poor," ICC=0.50 - 0.75 as "moderate," ICC=0.75 - 0.90 as "good," and ICC>0.90 as "excellent" [34]. These analyses were performed for patients with COPD and healthy controls separately. To evaluate whether the Fitbit Charge 4 is able to pick up day-by-day fluctuations, the delta (day minus day-1) of each measured clinical parameter was calculated on consecutive days. The agreement between the Fitbit Charge 4 and the corresponding reference device with regard to day-by-day fluctuations was determined via Pearson correlation. The correlation was interpreted using the cutoffs $r<0.30$ classed as "no correlation," $r=0.30$ - 0.50 as "weak correlation," $r=0.50$ - 0.70 as "moderate correlation," $r=0.70$ - 0.90 as "strong correlation," and $r>0.90$ as "very strong correlation" [35]. Next, known-groups validity was assessed by investigating

whether the differences between patients with COPD and healthy controls were picked up by the reference device and the Fitbit Charge 4 in the same way. For this, the outcomes were compared between patients with COPD and healthy controls for both devices using an unpaired *t* test. The differences between both groups were examined by an interaction effect based on a mixed model analysis. As a sensitivity analysis, all analyses were performed with the exclusion of patients taking beta-blockers.

Results

Patient Characteristics

In total, 32 patients with COPD and 26 age- and gender-matched healthy controls were included in this study. Overall, valid data of 30 patients with COPD (1 patient dropped out and 1 patient was not willing to wear the additional devices) and 25 healthy controls (1 participant was excluded because spirometry displayed an obstructive syndrome) were obtained, but across the clinical parameters, there is a variation in participants included in the analyses. This variation can be attributed to various reasons, such as technical problems (the Fitbit not capturing clinical parameters at night, sudden interruptions in the measurement by the reference device, battery issues), as well as participants forgetting to wear the (reference) device. Baseline characteristics are shown in Table 1.

Table . Characteristics of all participants included in the analyses.

	Patients with COPD[a] (n=30)	Healthy controls (n=25)	*P* value
Age (years), mean (SD)	70 (7)	68 (7)	.28
Sex (male), n (%)	23 (77)	20 (80)	.77
BMI (kg/m^2), mean (SD)	27 (6)	28 (4)	.86
Forced expiratory volume in the first second (% predicted), mean (SD)	54 (15)	109 (15)	<.001
Severity of COPD, n (%)			
I-II	2 (7)-15 (50)	N/A[b]	N/A
III-IV	12 (40)-1 (3)	N/A	N/A
Use of β-blockers, n (%)	8 (27)	4 (16)	.34
Current smokers, n (%)	1 (3)	0 (0)	.36
6MWD[c] (m), mean (SD)	482 (95)	618 (81)	<.001
6MWD (% predicted), mean (SD)	78 (14)	97 (10)	<.001
COMPASS 31[d] (score), median (IQR)	11 (4 - 21)	5 (2-12)	.005
mMRC[e] (score), median (IQR)	2 (1-2)	N/A	N/A
CAT[f] (score), mean (SD)	15 (6)	N/A	N/A

[a]COPD: chronic obstructive pulmonary disease.

[b]N/A: not applicable.

[c]6MWD: 6-minute walking distance.

[d]COMPASS 31: Composite Autonomic Symptom Score 31 questionnaire (0 - 100); a higher score indicated more symptoms of autonomic dysfunction.

[e]mMRC: modified Medical Research Council dyspnea scale (0 - 4); a higher score indicated more dyspnea.

[f]CAT: COPD Assessment Test (0 - 40); a higher score indicated a worse health status.

Criterion Validity

Physical Activity

Daily step count was analyzed based on 199 (min-max 4 to 7 days per patient, n=30) and 157 (4 to 7 days per participant, n=24) overlapping data points for patients with COPD and healthy controls, respectively. As expected, patients with COPD were less active compared to healthy controls (Table 2).

Table . Average step count, resting heart rate, heart rate variability, and respiratory rate in patients with COPD[a] and healthy controls.

	Patients with COPD (n=30), mean (SD)	Healthy controls (n=25), mean (SD)	Difference, mean (SD)	*P* value[b]
Daily steps (steps/day)				
Dynaport MoveMonitor	5625 (3618)	7933 (4263)	−2308 (3915)	<.001
Fitbit Charge 4	7423 (4325)	9055 (4956)	−1632 (4613)	.001
Resting heart rate (beats/min)				
Polar H10	70 (8)	60 (10)	10 (9)	<.001
Fitbit Charge 4	70 (8)	64 (10)	6 (9)	<.001
Heart rate variability (ms)				
Polar H10	27 (19)	33 (21)	−6 (20)	.16
Fitbit Charge 4	24 (14)	26 (13)	−2 (14)	.53
Respiratory rate (breaths/min)				
Polar H10	16 (2)	14 (2)	2 (2)	<.001
Fitbit Charge 4	16 (3)	15 (2)	1 (2)	.01

[a]COPD: chronic obstructive pulmonary disease.

[b]*P* values based on unpaired *t* test.

In both groups, the mean step count measured by the Fitbit Charge 4 was significantly higher compared to DAM (mean, SD; COPD: Δ+1798, SD 2070 steps/day; *P*<.001 and healthy controls: Δ+1122, SD 2297 steps/day; *P*<.001). However, in both groups, a good agreement between the devices was found (COPD: $ICC_{2,1}$=0.79; 95% CI 0.36 - 0.90 and healthy controls: $ICC_{2,1}$=0.85; 95% CI 0.74 - 0.91). These findings are supported by the Bland-Altman plots depicted in Figure 1A and 1B. Concurrent validity with associated scatterplots can be found in Multimedia Appendix 1.

Figure 1. Bland-Altman plots with mean and 95% CI for Fitbit Charge 4 compared to the reference devices. (**A, B**) Daily steps (steps/day) measured by Fitbit Charge 4 and DAM (COPD: n=30 and healthy controls: n=24). (**C, D**) Resting heart rate (beats/min) measured by Fitbit Charge 4 and Polar H10 (COPD: n=25 and healthy controls: n=20). (**E, F**) Heart rate variability (RMSSD in ms) measured by Fitbit Charge 4 and Polar H10 (COPD: n=22 and healthy controls: n=16). (**G, H**) Respiratory rate (breaths/min) measured by Fitbit Charge 4 and Polar H10 (COPD: n=21 and healthy controls: n=17). (**I**) Oxygen saturation (%) measured by Fitbit Charge 4 and Nonin WristOX$_2$ 3150 (COPD: n=19). Large open dots represent the mean individual outcome per patient. Small dots represent daily data. Mean and 95% CI are calculated based on average data. COPD: chronic obstructive pulmonary disease; DAM: Dynaport MoveMonitor; RMSSD: root mean square of successive differences.

Figure 2A shows the scatterplot of the day-by-day fluctuations in daily step count measured with the Fitbit Charge 4 and the DAM. A strong to very strong association was observed between both devices in patients with COPD (r=0.71) and healthy controls (r=0.91), respectively.

Figure 2. Scatterplots of the day-by-day fluctuations in daily step count, parameters of autonomic function, and SpO_2 in patients with COPD and healthy controls. (**A**) Day-by-day fluctuations in daily step count (COPD: 169 data points and healthy controls: 133 data points). (**B**) Day-by-day fluctuations in resting heart rate (COPD: 42 data points and healthy controls: 39 data points). (**C**) Day-by-day fluctuations in heart rate variability (COPD: 27 data points and healthy controls: 28 data points). (**D**) Day-by-day fluctuations in respiratory rate (COPD: 24 data points and healthy controls: 30 data points). (**E**) Day-by-day fluctuations in oxygen saturation (COPD: 42 data points). Patients with COPD are depicted in the closed dots and healthy controls are depicted in the open dots. An identity line is displayed on the scatterplots. COPD: chronic obstructive pulmonary disease; DAM: Dynaport MoveMonitor; HRV: heart rate variability; RHR: resting heart rate; RR: respiratory rate; SpO_2: oxygen saturation.

Resting Heart Rate

RHR was analyzed based on 66 (min-max 1 to 4 days per patient, n=25) and 59 (1 to 4 days per healthy control, n=20) overlapping data points. RHR was higher in patients with COPD compared to healthy controls (Table 2).

In the COPD group, RHR measured by the Fitbit showed no difference compared to Polar H10 (Δ−0.3, SD 5 beats/min; *P*=.67), whereas Fitbit significantly overestimated RHR in the healthy control group (Δ+4, SD 6 beats/min; *P*<.001). In both groups, Fitbit Charge 4 and Polar H10 showed a good agreement for assessing RHR (COPD: $ICC_{2,1}$=0.80; 95% CI 0.70 - 0.87 and healthy controls: $ICC_{2,1}$=0.79; 95% CI 0.50 - 0.90). The findings are depicted in Bland-Altman plots (Figure 1C and 1D). A strong association between the devices was observed in both groups (Multimedia Appendix 1).

A weak negative association was observed in patients with COPD for picking up day-by-day fluctuations in RHR (*r*=−0.35; Figure 2B).

Heart Rate Variability

HRV analyses are based on 49 (min-max 1 to 3 days per patient, n=22) and 44 (1 to 4 days per participant, n=16) overlapping data points for patients with COPD and healthy controls, respectively. No difference in HRV was observed between patients with COPD and healthy controls (Table 2).

The Fitbit Charge 4 significantly underestimated HRV in both groups (respectively in COPD and healthy controls: Δ−3, SD 8 ms; *P*=.03 and Δ−7, SD 13 ms; *P*=.001). In patients with COPD, a good agreement was observed between both devices ($ICC_{2,1}$=0.87; 95% CI 0.77 - 0.93). Whereas in the healthy control group, a moderate agreement was found for measuring HRV ($ICC_{2,1}$=0.69; 95% CI 0.43 - 0.83). Bland-Altman plots (Figure 1E and 1F) represent these results. Scatterplots showing the concurrent validity can be found in Multimedia Appendix 1.

In patients with COPD, a strong association was found for picking up day-by-day fluctuations in HRV (*r*=0.83), whereas healthy controls exhibited a moderate association (*r*=0.64; Figure 2C).

Respiratory Rate

RR was analyzed based on 45 (min-max 1 to 5 days per patient, n=21) and 47 (1 to 4 days per healthy control, n=17) overlapping data points. RR was higher in patients with COPD compared to healthy controls (Table 2).

In patients with COPD, no difference was detected in RR measured by Fitbit Charge 4 compared to Polar H10 (Δ+0.3, SD 1 breaths/min; *P*=.25). However, in the healthy control group, the Fitbit Charge 4 significantly overestimated the RR (Δ+1, SD 1 breaths/min; *P*<.001). A good agreement was observed in patients with COPD, as well as healthy controls (COPD: $ICC_{2,1}$=0.84; 95% CI 0.72 - 0.91 and healthy controls: $ICC_{2,1}$=0.77; 95% CI 0.44 - 0.89). These findings are supported by the Bland-Altman plots depicted in Figure 1G and 1H. In both groups, a strong association was found (Multimedia Appendix 1).

A weak association was observed in both groups for picking up day-by-day fluctuations in RR (COPD: *r*=0.47 and healthy controls: *r*=0.50; Figure 2D).

Oxygen Saturation

SpO_2 was analyzed based on 61 (min-max 1 to 5 days per patient, n=19) overlapping data points in patients with COPD. Fitbit Charge 4 significantly overestimated SpO_2 (Δ+2, SD 2%; *P*<.001). A poor agreement between both devices was found ($ICC_{2,1}$=0.32; 95% CI −0.10 - 0.65). The Bland-Altman analysis is shown in Figure 1I.

Figure 2E displays the scatterplot of the day-by-day fluctuations measured with the Fitbit Charge 4 and the Nonin $WristOX_2$ 3150, showing a weak association for SpO_2 in patients with COPD (*r*=0.40).

Known-Groups Validity

The significant differences between patients with COPD and healthy controls in daily steps, RHR, and RR identified by the reference devices were picked up in a similar way by the Fitbit Charge 4 (see Table 2). The difference between both groups is significantly smaller when assessing RHR or RR using the Fitbit Charge 4 compared to the reference device (*P*<.05).

Sensitivity Analysis

Excluding participants on stable doses of beta-blockers had minimal impact on the results. The agreement between the Fitbit Charge 4 and its corresponding reference devices remained unchanged. The exclusion of participants taking beta-blockers had no effect on the known-groups validity (Multimedia Appendix 2).

Discussion

Principal Findings

This study, which aimed to investigate the validity of a consumer-based wearable, the Fitbit Charge 4, in patients with COPD and healthy controls found mixed results for criterion validity. First, the Fitbit Charge 4 significantly overestimated daily step count and significantly underestimated HRV in patients with COPD and healthy controls. In patients with COPD, RHR and RR are not different between the Fitbit Charge 4 and the Polar H10, but both parameters were overestimated in the healthy control group. The Fitbit Charge 4 significantly overestimated SpO_2 in patients with COPD. Second, the agreement between the Fitbit Charge 4 and the corresponding reference devices is moderate to good for monitoring most clinical parameters (ie, daily steps, RHR, HRV, and RR) but poor for tracking SpO_2. The Fitbit is able to pick up day-by-day fluctuations in daily step count and HRV but lacks accuracy to pick up the small day-by-day fluctuations in RHR, RR, and SpO_2. The known-groups validity of the Fitbit Charge 4 is good. All expected differences between patients with COPD and age- and gender-matched healthy controls are picked up by the wearable.

Our results are consistent with previous research in older adults in free-living conditions showing that the daily step count

measured by the Fitbit Charge, a wrist-worn wearable, is highly correlated with the daily step count measured by a validated accelerometer, but the Fitbit Charge significantly overestimates the daily step count [21,36,37]. Previous studies conducted in other patient cohorts within our department showed that the wrist-worn Fitbit device significantly overestimated the daily step count in healthy individuals and cancer survivors, whereas it did not in people with Parkinson disease [38,39]. Blondeel et al [19] concluded that the Fitbit Alta, also a wrist-worn wearable, did not significantly overestimate step count in patients with COPD, but did in healthy controls. This corresponds well with our findings, although in our sample, the wearable also overestimated daily step count in patients with COPD. This could potentially be explained by the inclusion of patients with a better functional exercise tolerance (6-minute walking distance of 482 m vs 454 m) in this study.

A few studies examined the validity of Fitbit measuring the heart rate during sleep among healthy adults in different situations (ie, home environment and laboratory-based setting). One study in healthy adolescents showed that Fitbit significantly underestimated the heart rate by 0.9 beats/min on average as compared to ECG, while another study in healthy adults found no difference between Fitbit and the reference device [40,41]. These findings are consistent with our results in the COPD group but are inconsistent with our results showing that Fitbit significantly overestimates RHR by 4 beats/min in the healthy control group. The discrepancy in results can possibly be attributed to the difference in how the definition is applied, with Fitbit defining RHR as the heart rate while in a relaxed state during both sleep and being awake, whereas we calculated RHR from Polar for sleep time values only because we do not have exact information on how RHR is calculated by Fitbit.

To the best of our knowledge, the validity of Fitbit measuring HRV, RR, and SpO_2 has not been investigated so far. However, some research has been performed regarding other wearables also using photoplethysmography technology (eg, Apple watch, Garmin, and Polar), showing a large range for measuring HRV (ICC ranging from 0.24 to 0.99) depending on the wearable used in a laboratory setting in healthy adults [42]. These results are consistent with our findings in healthy controls ($ICC_{2,1}$=0.69). Interestingly, we found a higher agreement in patients with COPD ($ICC_{2,1}$=0.87), but no previous research has been conducted on the validity of wearables measuring HRV among this population.

Data on the validity of a wrist-worn wearable estimating RR based on photoplethysmography have not been published so far. Existing studies have only focused on the validity of devices measuring this parameter using different technologies (ie, wearable biosensors and wearable pressure sensors) [43,44]. This difference in technology makes it challenging to compare these results.

Several studies indicate that the Apple Watch Series 6 shows a good agreement for measuring SpO_2 compared to the gold-standard (ie, arterial blood gas analyses) or reference devices (ie, oximeters) in patients with lung diseases (ICCs ranging from 0.90 to 0.94), as well as healthy individuals (mean bias 1.7, SD 2.1%) [45-47]. These results are in contrast with our findings achieving an ICC of 0.32. The results of Garmin concerning the measurements of SpO_2 in healthy individuals vary widely, with ICCs ranging from 0.28 to 0.55, which is more in line with our results [48,49]. In our study, the SpO_2 was measured during sleep, where the contact between the watch and the skin was maybe occasionally suboptimal due to unintentionally lying on the wearable, leading to divergent measurements through photoplethysmography. This is in contrast to the other studies where the measurement of SpO_2 was conducted under controlled settings over a short period of time (maximum 10 minutes) while being awake.

Regarding the known-groups validity, the differences in daily step count (lower in COPD), RHR (higher in COPD), and RR (higher in COPD) were in line with previous research [7,9,19]. We could not confirm a difference in HRV, which was shown to be lower in COPD in previous research (COPD and healthy controls: 27, SD 19 ms and 33, SD 21 ms; *P*=.16 [this study] vs 11, SD 3 ms and 19, SD 7 ms; *P*=.002, respectively) [50]. This study confirms that previously laboratory-based findings are now also observed in free-living situations.

It is remarkable that our findings indicate that Fitbit estimates certain clinical parameters, such as RHR, HRV, and RR, better in patients with COPD as compared to healthy controls. In this regard, we speculate that faster aging of the skin and skin thinning, a typical feature in patients with COPD on inhaled and systemic steroids, improve reflection of lights for measuring clinical parameters through photoplethysmography compared to slightly thicker skins in healthy controls as the distance of the infrared light to measure volumetric changes in the blood is reduced [51-53].

Clinical Implications

While our results suggest that Fitbit can measure certain clinical parameters better in patients with COPD than in healthy controls, it is not the best choice if one aims to measure important parameters of autonomic function (ie, RHR and RR) as well as SpO_2 in patients with COPD, as the wearable fails to pick up day-by-day fluctuations. Nevertheless, Fitbit can be used for commercial purposes and well-being monitoring, including data on daily step counts and HRV. Advanced and accurate (medical) devices are more appropriate for remotely monitoring clinical parameters. However, these results are only based on a 5 - to 7-day assessment in a stable situation. Longer time series of data also including larger fluctuations in the clinical parameters (eg, when patients experience a deterioration in their health) are needed to confirm these findings.

Strengths and Limitations

This study offers valuable insights into the validity of a popular wearable device to estimate various clinical parameters during a free-living situation. Our approach involved studying both patients with COPD, as well as age- and gender-matched healthy controls, aiming to establish evidence in both populations. Even though 4 of the 25 (16%) control participants were using beta-blockers, they can be considered as a representative sample of the general population [54]. Nonetheless, this study has some limitations. First, it should be mentioned that Fitbit operates as

a black box, using proprietary algorithms of which its details are not disclosed. This makes it challenging to establish an agreement with reference devices. Second, technical issues arose, preventing the collection of certain data. In some cases, Fitbit failed to measure parameters of autonomic function or SpO_2, rendering a comparison with reference devices impossible. Third, validated medical-grade devices that show good agreement with gold-standard methods were used in this study to assess the validity of the Fitbit Charge 4 in free-living conditions. Unfortunately, gold-standard devices (ie, video recording or manual step counting [physical activity] and ECG Holter monitoring [HRV]) are restricted to laboratory-based measurements. However, it is important to acknowledge that the reference devices may still involve measurement inaccuracies. Given that the measurements were conducted in daily life, the results have a high level of generalizability. Fourth, a selection bias within our healthy controls is difficult to avoid, as probably the more motivated individuals are more prone to participate in these kinds of studies. However, the clinical parameters in our control group align with those reported in the general population [55,56].

Conclusions

Both in patients with COPD and healthy controls, measures of clinical parameters collected by the commercially Fitbit Charge 4 showed moderate to good agreement with the reference devices. However, these measures deviated significantly. In patients with COPD, the Fitbit Charge 4 is accurate in measuring RHR and RR. The wearable lacks accuracy to pick up day-by-day fluctuations in RHR, RR, and SpO_2; hence, the Fitbit Charge 4 should be used with caution when information on clinical parameters is collected over a short period of time.

Acknowledgments

The authors would like to thank the colleagues from the pulmonary function testing at Ghent University Hospital for their assistance with the clinical assessments. They would also like to thank Dr Nathalie Michels for providing access to the Kubios software and for sharing her expertise on its usage. This research was funded by the Flemish Research Foundation (FWO project G0C0720N). AB is a predoctoral research fellow of the Flemish Research Foundation (FWO-Flanders 1194320N). WJ is a senior clinical research fellow of the Flemish Research Foundation (FWO-Flanders). HD is a postdoctoral research fellow of the Flemish Research Foundation (FWO-Flanders 12H7517N).

Abstract

Background: Many patients with chronic heart failure (HF) experience a reduced health status, leading to readmission after hospitalization despite receiving conventional care. Telemonitoring approaches aim to improve the early detection of HF decompensations and prevent readmissions. However, knowledge about the impact of telemonitoring on preventing readmissions and related costs remains scarce.

Objective: This study assessed the effectiveness of adding a telemonitoring solution to the standard of care (SOC) for the prevention of hospitalization and related costs in patients with HF in Finland.

Methods: We performed a nonrandomized pre-post telemonitoring study to estimate health care costs and resource use during 6 months on SOC followed by 6 months on SOC with a novel telemonitoring solution. The telemonitoring solution consisted of a digital platform for patient-reported symptoms and daily weight and blood pressure measurements, automatically generated alerts triggering phone calls with secondary care nurses, and rapid response to alerts by treating physicians. Telemonitoring solution data were linked to patient register data on primary care, secondary care, and hospitalization. The patient register of the Southern Savonia Social and Health Care Authority (Essote) was used. Eligible patients had at least 1 hospital admission within the last 12 months and self-reported New York Heart Association class II-IV from the central hospital in the Southern Savonia region.

Results: Out of 50 recruited patients with HF, 43 completed the study and were included in the analysis. The hospitalization-related cost decreased (49%; *P*=.03) from €2189 (95% CI €1384-€2994; a currency exchange rate of EUR €1=US $1.10589 is applicable) during SOC to €1114 (95% CI €425-€1803) during telemonitoring. The number of patients with at least 1 hospitalization due to HF was reduced by 70% (*P*=.002) from 20 (47%) out of 43patients during SOC to 6 (14%) out of 43 patients in telemonitoring. The estimated mean total health care cost per patient was €3124 (95% CI €2212-€4036) during SOC and €2104 (95% CI €1313-€2895) during telemonitoring, resulting in a 33% reduction (*P*=.07) in costs with telemonitoring.

Conclusions: The results suggest that the telemonitoring solution can reduce hospital-related costs for patients with HF with a recent hospital admission.

Introduction

The prevalence of heart failure (HF) and related costs is increasing worldwide due to an aging population [1]. The estimated prevalence of HF in the adult population is 1% to 2%, increasing to 10% in older adults aged 70 years or older [2,3]. HF often leads to gradual or acute changes in HF symptoms (decompensation) that require repeated and prolonged hospitalization [4]. Hospital admission is a strong predictor of further hospital admission: 20% to 25% of patients with HF are rehospitalized within 1 month and approximately 50% within 5 months of discharge [5]. Decompensation requiring hospitalization is also linked to increased mortality. A European registry study following patients for 1 year after hospitalization reported mortality rates of 24% for acute HF and 6.4% for chronic HF [6]. Hospitalization accounted for around 80% of HF health care costs [1].

An early return to the hospital following discharge may be a result of incomplete inpatient treatment and poor coordination and planning of follow-up care. Even for patients with regular follow-up care, however, the signs of decompensation may not occur during cardiology visits. Patients often contact clinics when symptoms are at an advanced stage [7]. Self-monitoring of symptoms, such as increased blood pressure, weight gain, or other health status-related symptoms, is particularly important in HF management [4]. Self-monitoring requires patients to be motivated to measure symptoms associated with HF and to have access to clinical advice when symptoms appear [8].

Remote monitoring aims to improve monitoring of patients' health status and is defined as a part of telehealth [9]. A basic level of remote monitoring involves regular and structured telephone support provided by health care professionals (HCPs) to discuss symptoms, self-monitoring measurements, lifestyle, and drug therapy. Structured telephone support can reduce HF-related hospitalization but does not seem to have an impact on the all-cause hospitalization of patients with HF [10]. Remote monitoring solutions are noninvasive stand-alone systems in which patient data on biometric measurements (such as body weight, blood pressure, and heart rate) and reported symptoms are frequently transmitted to HCPs through a secure digital system. HCPs manually review the data on digital platforms, which may also include integrated automated alerts, and necessary action is taken to optimize treatment.

The effect of noninvasive telemonitoring has been compared to the standard of care (SOC) in several studies, primarily through randomized trials. Some studies found telemonitoring had a beneficial impact on reducing hospitalization [11], while others did not find any effect [12,13]. However, a recent meta-analysis, encompassing 91 randomized trials and observational studies, revealed that noninvasive telemonitoring reduced all-cause mortality by 16%, first hospitalization by 19%, and total HF hospitalizations by 15%. When comparing telemonitoring studies and developing optimal telemonitoring approaches, it is crucial to consider various determinants, including the telemonitoring intervention models, health care systems, and the characteristics of the population with HF in the studies [14].

There are only a few international studies that have explored the cost-effectiveness of telemonitoring compared to the SOC [15-18].

The objective of this nonrandomized pre-post intervention study in patients with HF with a recent (<12 month) hospitalization was to assess the effectiveness of adding a telemonitoring solution to SOC on hospitalizations and related costs in the Finnish health care system. The study compared hospitalization occurrence and related costs with SOC and following the introduction of a telemonitoring solution. Secondary outcomes included hospital admissions and total health care costs.

Methods

Study Design

The nonrandomized pre-post intervention study was performed in Southern Savonia, Finland. During the 12-month study period, patients were treated with SOC for the first 6 months and then with a telemonitoring solution in addition to SOC for the next 6 months. The primary outcome was hospitalization-related costs during 6 months with SOC versus telemonitoring. Secondary outcomes included the number of patients with at least 1 hospital admission due to HF or a cardiovascular cause other than HF emergency care visits and primary care or cardiology (secondary care) calls and visits. Health care costs for secondary outcomes included the total health care costs of primary care, secondary care (for cardiology), emergency visits, and phone calls. The study was designed to demonstrate the effectiveness of remote monitoring within the Finnish health care system. The costs of the telemonitoring service itself were not analyzed.

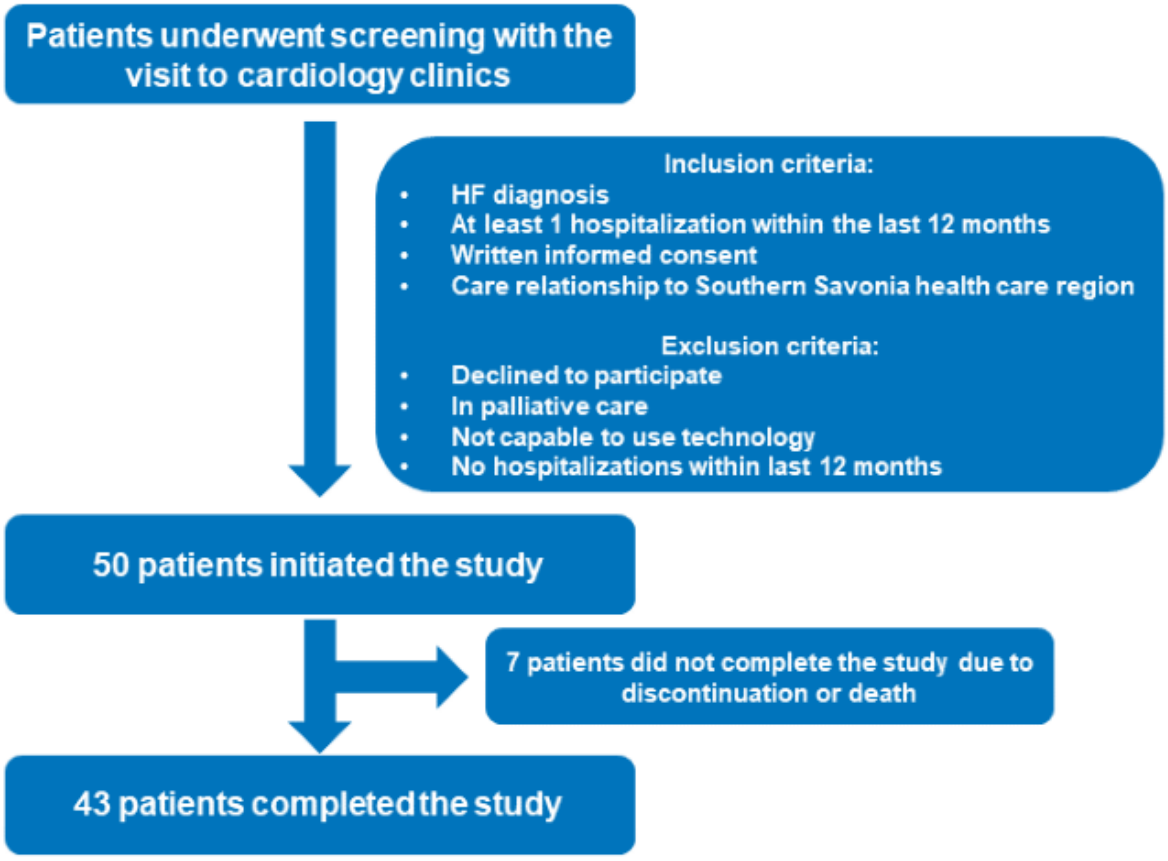
Health care resource use was collected for each patient during SOC and telemonitoring from the patient register of the Southern Savonia Social and Health Care Authority (Essote). The data was pseudonymized by the register holder. The Health Care Authority is responsible for all social and health care services for the population of approximately 100,000 inhabitants in Southern Savonia, Finland.

Study Patients

Patients were recruited from Mikkeli Central Hospital in Finland's Southern Savonia region. Patients with an HF

diagnosis confirmed by a cardiologist, at least 1 hospital admission in the 12 months preceding study initiation, and self-reported New York Heart Association (NYHA) class II-IV were eligible for the study (Figure 1).

Figure 1. Flowchart for patient selection for the study.



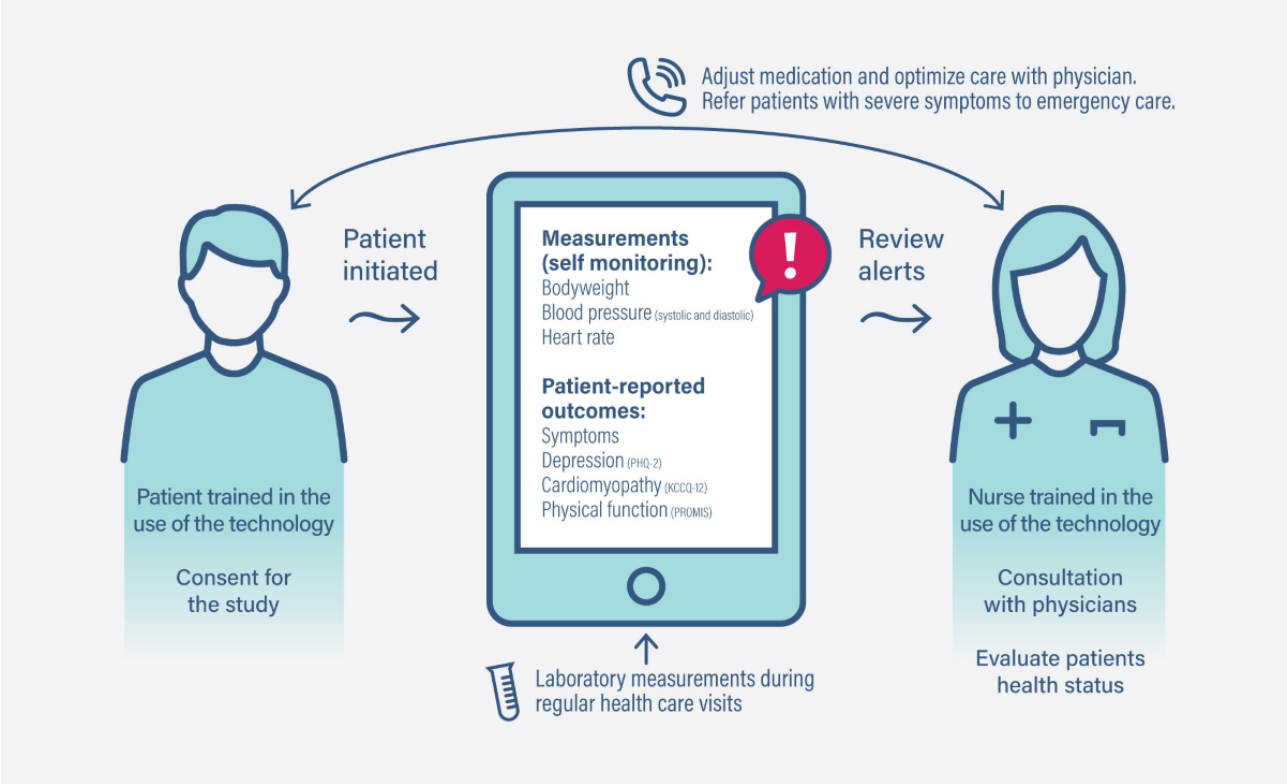
The inclusion criteria also stated that patients must be able to manage the telemonitoring devices and digital platform used in the study. Palliative care was an exclusion criterion.

Study Procedures

The SOC, during the first 6 months, included regular cardiology appointments and laboratory tests planned by a cardiologist for each patient with HF according to local care guidelines for HF treatment. Nurses followed up with patients through phone calls, depending on the state of HF. After inpatient stays, the cardiologist or internist at the hospital made an individual plan for the follow-up of patients posthospitalization. During the follow-up period, patients measured their weight and blood pressure at home, and nurses followed up with patients through phone calls to discuss their health status and measurement results.

Telemonitoring was added on top of SOC during the next 6 months and consisted of a digital platform, home measurement devices, and nurses monitoring patients through the digital platform. The digital platform used Veta Health's remote patient monitoring platform (Veta Health Inc), customized for the study. Patients used their smartphones, handheld devices, or personal computers to access the digital platform. Patients measured their weight daily with a digital scale (Omron Corporation) and their blood pressure with a digital blood pressure measuring device (Omron M7000 Intelli IT) and transferred the measurements into the digital platform (Figure 2). The digital platform also included symptom-related questions.

Figure 2. A schematic presentation of the remote patient management model. KCCQ-12: Kansas City Cardiomyopathy Questionnaire-12; PHQ2: Patient Health Questionnaire-2; PROMIS: Patient Reported Outcomes Measurement Information System.



The digital platform automatically compared patients' body weight and HF symptom answers against preset thresholds and generated semiurgent or urgent alerts predicting HF worsening (Table S1 in Multimedia Appendix 1). Depending on the alert type, the digital platform either advised the patient to contact a nurse or a nurse to contact the patient to validate the health status. Nurses had access to alerts on working days. If needed, nurses referred a patient to a cardiologist to optimize HF care or medication. The treating cardiologist reacted to the nurses' referrals within 24 hours. For urgent alerts, the digital platform advised patients to go to emergency care. Nurses also provided technical support for patients as required. The digital platform collected blood pressure data and laboratory results from regular health care visits, not for the alert algorithm but to allow nurses to evaluate the patient's health status.

Health Care Resource Use and Costs

Patients' health care costs and resource use were estimated from the Essote patient register and consisted of public primary care, secondary care (cardiology unit), emergency visits, hospitalizations (cardiology and internal medicine; primary care), and phone calls for primary and secondary care (cardiology). A unique personal identification number for each resident in Finland connected the digital platform data and patient register data. The *International Classification of Diseases, Tenth Revision* (ICD-10) diagnosis code registered for each health care event was used to separate hospitalizations for HF (ICD-10 code I50) from hospitalizations for a cardiovascular cause other than HF (ICD-10 codes I10, I25, I42, I46, I48, I49, and I70). All-cause hospitalizations included hospitalizations with any diagnosis. The costs of health care use were calculated using Essote diagnosis-related group prices.

Statistical Analysis

The study analysis included only patients who completed the study. Patients who died during the study or discontinued the study were excluded.

Patient demographics and NYHA class were summarized as n (%) of patients per category or median (IQR). During the SOC and telemonitoring periods, n (%) of patients with at least 1 hospitalization and the mean number of inpatient days per patient (95% CI) were reported. The mean number (95% CI) of visits per patient (primary, secondary, and emergency) and the mean number of calls (primary and secondary care) per patient were also reported for each period. Mean health care costs per patient were reported for each period. The normal distribution of each variable was assessed through visual inspection and the Shapiro-Wilk test. For data found to be nonnormally distributed, differences between SOC and telemonitoring periods were tested using the Wilcoxon signed rank test, and a value of $P<.05$ was considered statistically significant. The Pearson chi-square test with Yates correction was used for testing the difference between SOC and telemonitoring periods (a binary variable) in the number of patients with at least 1 hospitalization.

Ethical Considerations

The ethics committee of the Northern Savonia Hospital District approved the study protocol (1401/2020). The study followed good clinical practice following the Declaration of Helsinki and the laws and regulations applicable in Finland. Patients gave written consent upon recruitment to the study. Participation in the study was voluntary and no financial compensation was awarded for participation.

Results

Study Population and Patient Characteristics

Between December 15, 2020, and March 24, 2021, a total of 50 patients with HF were recruited from the Mikkeli Central Hospital. A total of 7 patients did not complete the study due to their deaths or withdrawals from it. All 43 (86%) patients who completed the 12-month study period were included in the analysis. During the telemonitoring period, 20% (9/43) of the daily weight and blood pressure measurements were missing.

The median age of patients was 73 (IQR 66-80) years, 74% (37/50) were male, and 60% (30/50) of patients had NYHA classes III-IV (Table 1).

Table 1. Patient demographics and disease characteristics (n=50).

Characteristic	Value
Age (years), median (IQR)	73 (66-80)
Sex, n (%)	
Male	37 (74)

Health Care Resource Use

Significantly fewer patients (6 patients in telemonitoring vs 20 patients in SOC; *P*=.002) had an HF hospitalization during the telemonitoring versus SOC period. The number of inpatient days per patient due to HF decreased by 48% during the telemonitoring period (mean 1.2, 95% CI 0.1-2.3 days vs 2.3, 95% CI 1-3.6 days with SOC; *P*=.17). The number of emergency care visits decreased significantly during the telemonitoring period by 44% (mean 0.7, 95% CI 0.4-1 vs mean 1.3, 95% CI 0.9-1.7 with SOC; *P*=.006). Patients with HF made significantly more phone calls to secondary care during the telemonitoring period (mean 8.3, 95% CI 6.6-10 vs mean 2, 95% CI 1.3-2.7 with SOC; 318% increase; *P*.001) and had significantly more primary care visits (mean 4, 95% CI 2.2-5.8 vs mean 2.8, 95% CI 1.7-3.9; 44% increase; *P*=.02; Table 2).

Table 2. Use of health care per patient in standard of care (SOC) or telemonitoring solution for a 6-month period. Statistics were calculated with the Wilcoxon signed rank test or the Pearson chi-square test with Yates correction for the binary variables.

Variable	SOC (n=43)	Telemonitoring (n=43)	Absolute change (relative change; %)	*P* value for difference
All-cause hospitalizations				
Patients with ≥1 event, n (%)	23 (53)	14 (33)	–9 (–39)	.08
Inpatient days, mean (95% CI)	2.9 (1.6)	1.7 (1.2)	–1.2 (–41)	.20
Hospitalizations for cardiovascular cause other than HF[a]				
Patients with ≥1 event, n (%)	6 (14)	<5 (~10)	<5 (~–30)	.70
Inpatient days, mean (95% CI)	0.2 (0.3)	0.02 (0.05)	–0.16 (–88)	.40

[a]HF: heart failure.

Health Care Costs

Mean hospitalization costs per patient decreased significantly by 49% during the telemonitoring period (mean €1114 vs €2189 with SOC; *P*=.03; a currency exchange rate of EUR €1=US $1.10589 is applicable), while total health care costs decreased by 33% (mean €2104 vs €3124 with SOC; *P*=.07; Table 3).

The cost of emergency care visits was also significantly lower in the telemonitoring period (mean €209 vs €347 with SOC; 40% decrease; *P*=.009), and mean costs per patient for phone calls to secondary care increased significantly (mean €268 vs €114 with SOC; 134% increase; *P*.001) in the telemonitoring period (Table 3).

Table 3. Estimated mean direct health care cost per patient in standard of care (SOC) and in telemonitoring solution, respectively, during a 6-month period (2021). A currency exchange rate of EUR €1=US $1.10589 is applicable. Statistics were calculated with the Wilcoxon signed rank test.

Cost category	SOC (n=43), mean cost (€; 95% CI)	Telemonitoring (n=43), mean cost (€; 95% CI)	Absolute change (€; relative change in mean cost; %)	*P* value for difference
Hospitalizations[a]	2189 (805)	1114 (689)	–1075 (–49)	.03
Primary care visits	75 (37)	101 (74)	27 (+36)	.30
Secondary care visits (cardiology)	288 (77)	337 (87)	50 (+17)	.20
Emergency care visits	347 (122)	209 (99)	–137 (–40)	.009

Phone calls to secondary care	114 (42)	268 (68)	153 (+134)	<.001
Total cost	3124 (912)	2104 (791)	–1020 (–33)	.07

[a]Hospitalization from cardiology and internal medicine ward and from primary care.

Discussion

Principal Findings

In this pre-post study of a novel telemonitoring solution for patients with HF in Finland, hospitalization costs were significantly lower during the 6-month telemonitoring period versus the SOC period (from €2189 per patient during SOC to €1114 during telemonitoring). The number of hospitalized patients was significantly lower during telemonitoring (from 20 during SOC to 6 patients), and the mean length of stay decreased from 2.3 days to 1.2 days (not statistically significant). The number of emergency visits and associated costs were also significantly lower during telemonitoring. By contrast, patients with HF had significantly more primary care visits and phone calls to secondary care nurses during telemonitoring versus SOC; however, total health care costs were 33% lower than during SOC (not statistically significant).

The reduction in inpatient days due to HF during telemonitoring was not statistically significant, most probably due to the low number of patients with HF in the study. While secondary care phone calls increased significantly, a substantial part of these were for technical help in using the digital platform at the start of the telemonitoring period. The number of primary care phone calls, on the other hand, decreased during the telemonitoring period, which may be because secondary care nurses were monitoring patients.

Comparison With Previous Work

A comprehensive meta-analysis of recently published studies on telemonitoring has provided evidence that telemonitoring is beneficial in reducing mortality and hospitalizations in patients with HF. However, individual studies show both beneficial and neutral effects of telemonitoring when compared to SOC [11,13,19-21]. The main objective of the studies was to investigate whether remote monitoring can improve the detection of early signs of decompensation and decrease hospitalization and mortality. The variability of the results may be due to differences in the health care system, telemonitoring model, population with HF, and follow-up durations [9,14].

This study found that 47% (20/43) of patients were hospitalized due to HF during the SOC period, versus 14% (6/43) during the telemonitoring period in the Southern Savonia region of Finland. Vuorinen et al [21] conducted a telemonitoring study in Finland from 2010 to 2012. They showed that only 28% of patients were hospitalized in the SOC group and 17% in the remote monitoring group during a 6-month follow-up period. The inclusion criteria for the population with HF included NYHA II-IV but did not require a recent hospitalization, which could explain the lower HF hospitalization risk compared with this study. Our data align with previous studies showing that nearly half of patients with HF are rehospitalized within 6 months after discharge [21,22]. However, further studies using a similar population with HF are needed to confirm these findings.

Similar to this study, Vuorinen et al [21] also found a nonstatistically significant decrease in inpatient days with telemonitoring (mean 0.7 vs 1.4 days with SOC). The significant reduction in hospitalization-related costs and the number of patients hospitalized due to HF in this study support the idea that telemonitoring reduces hospitalizations.

A Spanish telemonitoring trial (n=117) had similar findings to this study. In this trial, 50% of the patients were hospitalized in the SOC group versus 28% in the telemonitoring group over a 6-month follow-up period. The patients were enrolled in the study upon hospitalization [19]. Thus, the results from this study support our findings on the benefits of telemonitoring in reducing hospitalizations. However, a large Better Effectiveness After Transition–Heart Failure (BEAT-HF) trial (n=1437) conducted in California could not see a reduction in readmissions in patients with HF in a telemonitoring group compared to SOC during a 6-month follow-up period [20]. The BEAT-HF trial's limitations were that patients were recruited from academic medical centers, which may restrict the generalizability of the results, as most patients with HF do not receive care in academic medical centers. Upon receiving alerts, nurses advised patients to contact the physicians, or nurses called the physicians, but physicians were not directly involved with the interventions. Thus, the monitoring may not have affected care in practice. In this study and the Spanish study, nurses and treating physicians collaborated upon receiving alerts, which may have increased the benefits of telemonitoring. For example, in this study, physicians reacted to patient alerts within 24 hours.

There are several studies on the effect of telemonitoring on hospitalization and mortality, but only a few studies on costs.

This study estimated the health care cost related to resource use using real-word data and showed that health care costs were 33% (€2104/€3124) lower during telemonitoring versus SOC. As expected, most of the cost reductions originated from reduced hospitalizations. A cost-effectiveness study in a Danish telemonitoring trial (n=274) reported similar results by showing that telemonitoring reduced total health care costs by 35% versus SOC with a 1-year follow-up [16]. In a Spanish telemonitoring trial, Comin-Colet et al [15] found a total cost reduction of 45% with telemonitoring versus SOC, with 178 patients and a 6-month follow-up. A Belgian Telemonitoring in the Management of Heart Failure (TEMA-HF) study (n=160) found a 27% cost reduction (not statistically significant) with telemonitoring versus SOC during a 6-month follow-up [23]. The German Heart Failure II trial (TIM-HF2) showed an 18% reduction in annual costs per patient in the telemonitoring group compared to the SOC group during a 1-year follow-up [18]. These studies support our conclusion that telemonitoring may result in substantial cost savings in HF care. To justify reimbursement for telemonitoring, studies are needed on the cost-effectiveness of large-scale telemonitoring for decision makers. Furthermore, a cost-effective telemonitoring model applicable to different health care systems and settings needs to be developed.

Strengths and Limitations

A strength of this study was the cost analysis, which included both HF-related health care costs as well as other costs accrued during the follow-up period. The study had some limitations. The study was conducted in a single region, the Southern Savonia region, which may limit the generalizability of the results. However, the study population is representative of the region, as all patients are directed to the same central hospital where recruitment was done. A randomized controlled trial design was not feasible due to the limited number of suitable patients with HF for remote monitoring. No patients with HF were included from other health care districts, as divergent monitoring practices could potentially bias the analysis results. Patients were not randomized, and patients needed to be able to use the digital platform, which may have resulted in a possible selection bias. As the pre-post design uses a historical control group (ie, patients on SOC in the period before starting telemonitoring), the underlying assumption in the analysis, given the deteriorating nature of HF, is that health care use in the absence of telemonitoring would remain at least at the same level as during SOC. Follow-up with telemonitoring was limited to 6 months, and it is unclear how use of health care services would develop beyond this period. Finally, due to the small patient numbers, the absence of a control group, and the 6-month follow-up period, it was not feasible to conduct mortality analyses.

The following must be considered when generalizing our results and applying our telemonitoring solution to other health care systems: our telemonitoring solution was applied to a patient population with a high risk of readmission due to a recent hospital admission and NYHA class II-IV. Other patient characteristics considered were the mean age (73 years), male proportion (37/50, 74%), proportion of patients in NYHA class II-IV (30/50, 60%), and proportion of patients with at least 1 admission within 6 months (20/50, 47%). These patient characteristics were comparable to those of other reported telemonitoring study populations [11,13,18,19].

Conclusions

In conclusion, our results suggest that the novel telemonitoring solution can help reduce hospital admissions and hospitalization costs as well as total health care costs in a population with HF with a recent hospital admission in the past 12 months.

Abstract

Background: Depressive disorder and type 2 diabetes mellitus (T2DM) are prevalent in primary care (PC). Pharmacological treatment, despite controversy, is commonly chosen due to resource limitations and difficulties in accessing face-to-face interventions. Depression significantly impacts various aspects of a person's life, affecting adherence to medical prescriptions and glycemic control and leading to future complications and increased health care costs. To address these challenges, information and communication technologies (eg, eHealth) have been introduced, showing promise in improving treatment continuity and accessibility. However, while eHealth programs have demonstrated effectiveness in alleviating depressive symptoms, evidence regarding glycemic control remains inconclusive. This randomized controlled trial aimed to test the efficacy of a low-intensity psychological intervention via a web app for mild-moderate depressive symptoms in individuals with T2DM compared with treatment as usual (TAU) in PC.

Objective: This study aimed to analyze the cost-effectiveness and cost-utility of a web-based psychological intervention to treat depressive symptomatology in people with T2DM compared with TAU in a PC setting.

Methods: A multicenter randomized controlled trial was conducted with 49 patients with T2DM, depressive symptoms of moderate severity, and glycosylated hemoglobin (HbA_{1c}) of 7.47% in PC settings. Patients were randomized to TAU (n=27) or a web-based psychological treatment group (n=22). This web-based treatment consisted of cognitive behavioral therapy,

improvement of diabetes self-care behaviors, and mindfulness. Cost-effectiveness analysis for the improvement of depressive symptomatology was conducted based on reductions in 3, 5, or 50 points on the Patient Health Questionnaire–9 (PHQ-9). The efficacy of diabetes control was estimated based on a 0.5% reduction in HbA_{1c} levels. Follow-up was performed at 3 and 6 months. The cost-utility analysis was performed based on quality-adjusted life years.

Results: Efficacy analysis showed that the web-based treatment program was more effective in improving depressive symptoms than TAU but showed only a slight improvement in HbA_{1c}. Incremental cost-effectiveness ratios of 186.76 for a 3-point reduction in PHQ-9 and 206.31 for reductions of 5 and 50 percentage points were obtained. In contrast, the incremental cost-effectiveness ratio for improving HbA_{1c} levels amounted to €1510.90 (€1=US $1.18 in 2018) per participant. The incremental cost-utility ratio resulted in €4119.33 per quality-adjusted life year gained.

Conclusions: The intervention, using web-based modules incorporating cognitive behavioral therapy tools, diabetes self-care promotion, and mindfulness, effectively reduced depressive symptoms and enhanced glycemic control in patients with T2DM. Notably, it demonstrated clinical efficacy and economic efficiency. This supports the idea that eHealth interventions not only benefit patients clinically but also offer cost-effectiveness for health care systems. The study emphasizes the importance of including specific modules to enhance diabetes self-care behaviors in future web-based psychological interventions, emphasizing personalization and adaptation for this population.

Introduction

Depressive disorder and type 2 diabetes mellitus (T2DM) are highly prevalent pathologies, mainly treated in primary care (PC) [1-5]. Their comorbidity has been reported in the previous literature in numerous studies [6-12]. However, the diagnosis of depression in PC is very low and only half of the diagnosed patients receive adequate care [1,2]. Pharmacological treatment remains the alternative of choice despite controversial results [13] and the existence of more effective psychological interventions preferred by patients [14,15]. This situation is due to the lack of available resources [16], the difficulty in accessing face-to-face interventions, and the shortage of professionals [17]. The identification and treatment of depression are essential components in the comprehensive treatment of diabetes since the presence of depressive symptoms in these patients not only affects mood but also has repercussions on all aspects of the person's life and influences adherence to medical prescriptions [18-20], glycemic control, and the number of future complications [21,22]. All these have an impact on increased health care costs [18,23], so it is necessary to offer comprehensive treatment aimed at improving both psychological and medical outcomes [24].

Information and communication technologies have recently been incorporated into the health care setting (eHealth) as an alternative to improve the continuity and accessibility of treatment, offering economic advantages. In a recent systematic review [25], the authors identified the main randomized controlled trials published to date on eHealth psychological interventions for depression in adults with diabetes. These programs contributed to improving depressive symptomatology [26-32], but there is still no evidence in improvement in glycemic control. This study aimed to evaluate the efficacy of a low-intensity psychological intervention for the treatment of mild-moderate depressive symptomatology specifically in people with T2DM using a web application compared with treatment as usual (TAU) implemented in PC.

Methods

Design

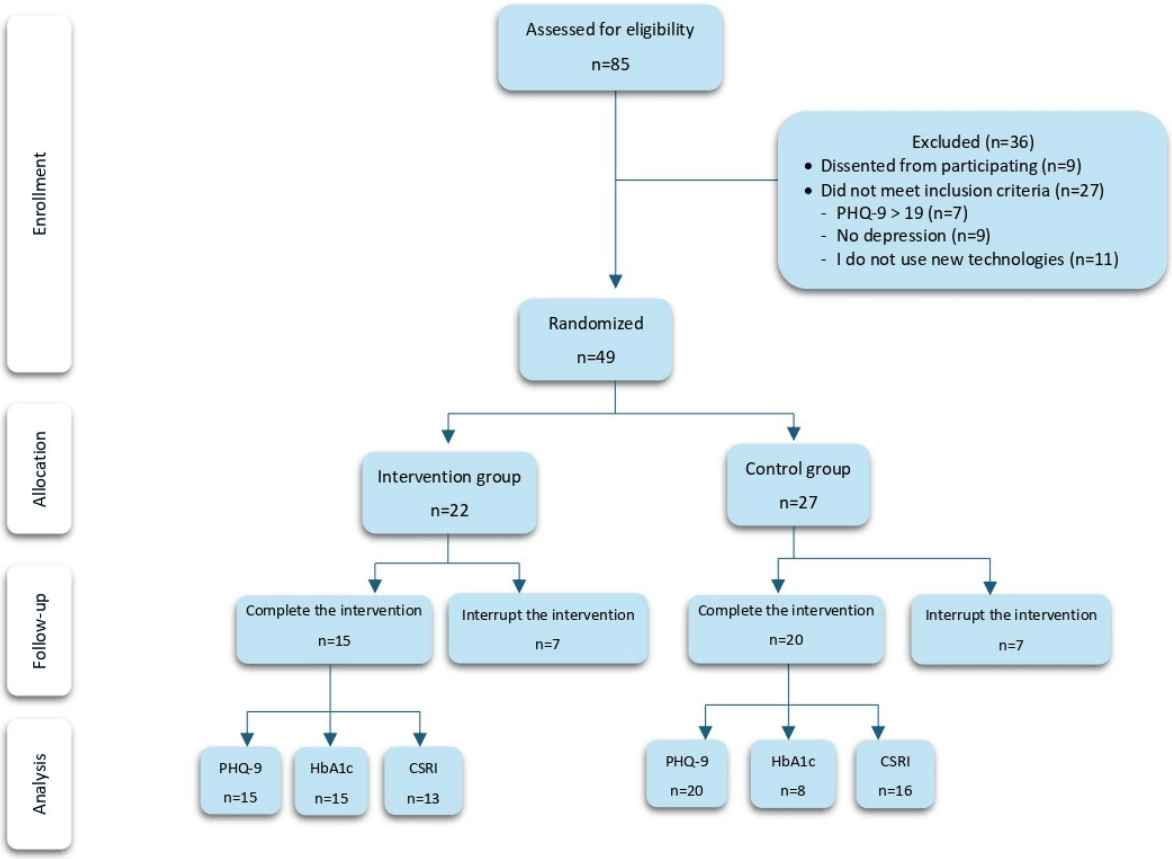
A multicenter randomized controlled trial was conducted. Participants were recruited by family physicians from PC centers in 3 Spanish regions: Andalusia, Aragon, and the Balearic Islands and were randomly assigned to either the intervention group (IG), which included a web-based treatment program, or the control group (CG) that only received TAU.

Study Procedure

A total of 49 patients with T2DM and depression were recruited. Figure 1 presents the flow diagram of the randomization and patient assessment process from patient selection by PC physicians to 6-month follow-up. Each participant, after being identified by his or her PC physician and signing the informed consent form, was referred to the study investigator for baseline assessment. If they met the criteria, randomization was performed independently by a person outside the study. The inclusion period was from December 1, 2018, to December 31, 2019. Inclusion criteria were adults older than 18 years old, diagnosis of depression (*Diagnostic and Statistical Manual of Mental Disorders fifth edition* [*DMS-5*] criteria) with mild or moderate severity (≤19 points on the Patient Health

Questionnaire-9 [PHQ-9]), diagnosis of T2DM (American Diabetes Association), and having an internet connection.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram. CSRI: Client Service Receipt Inventory; HbA1c: glycosylated hemoglobin; PHQ-9: Patient Health Questionnaire–9.



Ethical Considerations

The research study was approved by the Human Research Ethics Committee of the Regional Health Authority of Aragon (CEICA; PI16/0259) and was designed in accordance with the ethical standards laid down in the Declaration of Helsinki and its later amendments. The research study followed the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) guidelines (Multimedia Appendix 1). All participants signed informed consent forms after being informed of the nature, objectives, potential benefits, and risks associated with participation in the study, as well as the confidentiality of the data collected.

Interventions

The intervention was based on the cognitive behavioral therapy (CBT) and mindfulness self-help program applied through the internet for the treatment of depression “Smiling is fun” [33], which consists of different therapeutic modules. For this study, in addition to the modules previously designed for “Smiling is fun” [33], a specific module for the promotion of diabetes self-care behaviors, a welcome module, and 2 face-to-face sessions were included. The efficacy of this program has been demonstrated in previous studies [33-36], and the study protocol [37] has been published elsewhere. The CG received only TAU, which refers to treatment administered from PC to patients with depression and T2DM.

Study Measures

The PHQ-9 Questionnaire

Depressive symptomatology was assessed using the PHQ-9 [38], Spanish version [39]. The sum of the responses indicates different levels of depression (0-27). In general, scores above 5 suggest the presence of depressive symptomatology. It presents good internal consistency with a Cronbach α coefficient of 0.89.

Glycosylated Hemoglobin

Glycosylated hemoglobin (HbA_{1c}) obtained from blood samples was used as an outcome measure of T2DM control, indicating the average blood glucose level during the last 2 or 3 months [40].

The 12-Item Short Form Survey Health Questionnaire

To assess the quality of life, the 12-Item Short Form Survey (SF-12) [41], Spanish version [42] of this instrument, was used, which provides a profile of health status and consists of 8 dimensions ranging from 0 (the worst health status for that

dimension) to 100 (the best health status). Thus, the higher the score, the higher the perceived quality of life. For this study, the quality-adjusted life years (QALYs) were calculated from the scores of this questionnaire.

Consumption of Health Resources and Cost Procedure

The consumption of health services and the social impact were recorded using the Spanish version of the Client Service Receipt Inventory [43] in a self-reported manner by the patient or using the electronic medical record. Data were collected on those resources derived exclusively from depressive symptomatology and T2DM used during the 6 months before and 6 months after the start of the intervention.

Economic Evaluation

Cost Analysis

The economic evaluation was carried out from a social perspective, including indirect and direct health care costs expressed in euros for the year 2018. Direct health care costs were estimated based on the use of health care services according to Andalusian public prices [44] (Table 1). The costs of developing and maintaining the web page were calculated using the equivalent annual cost method. The intervention program included two 25-minute face-to-face sessions with a psychologist, and this cost was estimated according to the minimum interprofessional salary for a psychologist in Spain [45]. The costs of lost productivity (indirect costs) were estimated using the human capital approach, multiplying the minimum interprofessional wage by the number of days of sick leave [46].

Table 1. Direct health care costs (financial year 2018; values in €[a]).

Health resources	IG[b] (€), mean (SD)	CG[c] (€), mean (SD)
Medical PC[d]	248.08 (364.24)	248.59 (398.31)
Nurse PC	32.29 (82.74)	23.14 (42.73)
Medical PC home	N/A[e]	23.98 (95.92)
Nurse PC home	N/A	5.64 (22.57)
Endocrinology	21.75 (54.26)	21.40 (46.00)
Mental health	30.15 (80.83)	7.13 (28.53)
Emergencies	55.47 (73.04)	27.04 (78.45)
Hospitalizations	N/A	N/A
Total health care cost	387.74 (508.91)	356.94 (500.49)

[a]€1=US $1.18 in 2018.

[b]IG: intervention group.

[c]CG: control group.

[d]PC: primary care.

[e]N/A: not applicable.

Efficacy, Cost-Effectiveness, and Cost-Utility

The outcome measures to assess the efficacy of the psychological web-based treatment program were improvements in depressive symptomatology and HbA_{1c}. Improvement in depressive symptomatology was estimated based on an improvement in PHQ-9 scores of 3, 5, and 50 percentage points. Efficacy for diabetes control was estimated based on a 0.5% reduction in HbA_{1c}. These criteria were determined based on previous studies [28,31,47-51] in the absence of a gold standard criterion.

For each group, cost, incremental cost, efficacy, incremental efficacy, and dominance were calculated, and in the absence of dominance, the results were expressed in terms of incremental cost-effectiveness ratio (ICER).

The unit of measurement for the cost-utility analysis was QALYs, estimated from the SF-12 questionnaire. In addition to QALY, QALY gain was calculated by considering baseline imbalances in utility levels [52]. Similarly, as in the cost-effectiveness analysis (CEA), cost, incremental cost, QALY, incremental QALY, and dominance were calculated for each group, and in the absence of dominance, the results were expressed in terms of incremental cost-utility ratio (ICUR).

The results of the base case were presented in the cost-effectiveness plane that allows us to outline 4 possible scenarios or outcomes after economic evaluation, corresponding to each one of the quadrants of this plan: (1) southeast quadrant—the evaluated technology or new treatment is more effective and less costly than the reference treatment; (2) upper left quadrant—the evaluated technology is less effective and more costly than the reference treatment; (3) southwest quadrant—the evaluated technology is less effective and less costly than the reference treatment; and (4) northeast quadrant—the evaluated technology provides a gain in effectiveness in exchange for equally higher costs.

Sensitivity Analysis

A univariate sensitivity analysis was performed to analyze the robustness of the results obtained after cost-effectiveness and cost-utility analysis, assuming a variability of ±20% in the main components of the economic evaluation: health costs, direct costs associated with the intervention, indirect costs, effectiveness of depression (PHQ-9), effectiveness of diabetes (HbA_{1c}), and QALYs. These results were presented using a tornado diagram.

Statistical Analysis

Data collection was performed with Excel (Microsoft Corp), and statistical analysis was performed with SPSS (version 20; IBM Corp), licensed by the University of Malaga. A descriptive analysis of categorical and qualitative variables was performed, using frequencies and proportions. Means and SDs were calculated for quantitative variables. Comparisons between groups were performed using χ^2 tests and the McNemar test for qualitative variables and the 2-tailed Student *t* test or Mann-Whitney *U* test bilaterally for quantitative variables. In all cases, statistical significance corresponded to a P value of <.05.

Results

Baseline Characteristics of the Sample

The sociodemographic and clinical characteristics are shown in Table 2; there were no significant differences between the groups before the intervention. At the baseline assessment, moderate depressive symptoms (total score between 10 and 14 on the PHQ-9) were observed in both the IG (mean 12.71, SD 3.60) and the CG (mean 11.81, SD 3.14; P=.37). Regarding the treatment for depressive symptoms (N=49), only 12% (n=6) of the patients had attended mental health consultations, 31% (n=15) of the participants were using antidepressants, and 24% (n=12) of the participants were prescribed anxiolytics. In terms of biomedical variables or diabetes control, the IG had an HbA_{1c} level of 7.16%, while the CG had a baseline HbA_{1c} level of 7.78% (P=.29; P=.51). As for the treatment for diabetes control, 45% (n=22) of the participants were using oral antidiabetic drugs and 12% (n=6) of the participants were using insulin.

Table 2. Baseline characteristics of the sample.[a]

Characteristics	Intervention group (n=22)	Control group (n=27)
Sociodemographic		
Age (years), mean (SD)	58.27 (8.01)	56.52 (9.04)
Female, n (%)	16 (73)	12 (44)
Married or in a relationship, n (%)	15 (68)	18 (67)
Educational level, n (%)		
No qualification	6 (27)	6 (22)
High school	12 (54)	11 (41)
College qualification or more	4 (18)	10 (37)
Employment status, n (%)		
Employed	6 (27)	11 (41)
Unemployed	7 (32)	10 (37)
Retired	5 (23)	4 (15)
Depressive symptoms: PHQ-9[b] (range 5-27), mean (SD)	12.71 (3.60)	11.81 (3.14)
HbA_{1c}[c] (%)[d]	7.16	7.78

[a]Intervention and control groups did not significantly differ (P>.05 in all cases) on any of the sociodemographic or clinical baseline characteristics. Values >5 on the PHQ-9 indicate the presence of depressive symptoms.

[b]PHQ-9: Patient Health Questionnaire-9.

[c]HbA_{1c}: glycosylated hemoglobin.

[d]Percentage of glycosylated hemoglobin, absolute values do not apply.

After 6 months from the start of the study, of the total number of patients included, 71% (25/35 participants) of patients with T2DM completed follow-up. The study dropout rate was very similar between both groups, being 36% (8/22) for IG versus 33% (9/27) for CG, with no statistically significant differences. Among the patients in IG (n=22) who dropped out, 14% (n=3) stated that they dropped out because of "lack of time," 4% (n=1) reported that they dropped out because they did not like the web program, and 18% (n=4) dropped out for "other reasons." With respect to the number of therapeutic modules completed, 41% (n=9) of the patients completed all modules, 18% (4/22) did not complete any module, and 4% (n=1) completed only 1 module. No statistically significant differences in sociodemographic and clinical characteristics were found between patients who dropped out and those who completed follow-up, as well as between those who completed all modules and those who did not.

Economic Evaluation

Cost Analysis

The mean health care costs associated with PC consultations (medical and nursing consultations in person and at home), endocrinology, mental health, emergency room visits, and hospital admissions were very similar between the 2 groups, being €387.75 (€1=US $1.18 in 2018) in the IG and €356.94 for the CG, with no statistically significant differences between the groups. The development of the web platform had a total cost of €130,123. However, considering that the complete duration of the treatment, including follow-up, is a total of 6 months, the cost of developing the web platform per patient would be €65.06. On the other hand, the implementation of the intervention had associated personnel costs for the development of 2 face-to-face sessions, estimated at €51.10 per patient. The cost associated with productivity losses for the CG or group that received only the TAU from PC was €61.67 per patient. The total costs for the IG were €503.91 per patient and for the CG €418.61 per patient (Table 3).

Table 3. Estimated total direct and indirect costs for each study group.

	Intervention group (€[a]), mean (SD)	Control group (€), mean (SD)
Health care costs	387.75 (508.91)	356.94 (500.49)
Web development costs	65.06 (0.00)	N/A[b]
Face-to-face psychological intervention	51.10 (0.00)	N/A
Productivity losses	N/A	61.67 (246.67)
Total costs	503.91 (508.91)	418.61 (567.42)

[a] €1=US $1.18 in 2018.

[b]N/A: not applicable.

CEA as an Outcome Measure for the Improvement of Depressive Symptomatology

The web-based psychological intervention proved to be more effective than the TAU in all scenarios analyzed: reduction of 3 points (76.92% vs 31.25%), 5 points, and 50 percentage points in PHQ-9 (53.85% vs 12.50%). The results of the CEA show that this web-based psychological treatment program can be considered an efficient intervention for the control of depressive symptomatology in people with T2DM. In addition, although the IG had a slightly higher mean cost per patient than the CG (€503.91 vs €418.61) mainly due to the costs of the development of the intervention itself, the ICER was €186.76 per patient with no symptoms (for the 3-point scenario) and €206.31 per patient with no symptoms for the 5- and 50-point scenarios (Table 4). In the cost-effectiveness plane, the ICER for the 3 criteria was in the northeast quadrant (upper right), indicating that the web-based intervention was more effective than TAU from PC and at a higher cost (Figure 2).

Table 4. Results of the cost-effectiveness analysis of the web-based psychological intervention program to treat depressive symptomatology versus usual treatment in primary care.

	Cost, €[a], (95% CI)	Efficacy, % (95% CI)	CER[b] (€)
3-point reduction in the PHQ-9[c]			
Psychological web-based intervention	503.91 (266.65 to 794.84)	76.92 (54.00 to 99.80)	655.08
TAU[d]	418.61 (179.75 to 725.94)	31.25 (8.50 to 54.00)	1339.55
Incremental	85.30 (–325.51 to 496.11)	45.67 (13.40 to 77.90)	186.76
5-point reduction in the PHQ-9			
Psychological web-based intervention	503.91 (266.65 to 794.84)	53.85 (26.70 to 80.90)	935.83
TAU	418.61 (179.75 to 725.94)	12.50 (–3.70 to 28.70)	3348.87
Incremental	85.30 (–325.51 to 496.11)	41.35 (9.80 to 72.90)	206.31
50 percentage point reduction PHQ-9			
Psychological web-based intervention	503.91 (266.65 to 794.84)	53.85 (26.70 to 80.90)	935.83
TAU	418.61 (179.75 to 725.94)	12.50 (–3.70 to 28.70)	3348.87
Incremental	85.30 (–325.51 to 496.11)	41.35 (9.80 to 72.90)	206.31
0.5 reduction in HbA_{1c}[e]			
Psychological web-based intervention	481.59 (231.05 to 801.47)	8.33 (–7.30 to 24.00)	5779.13
TAU	571.53 (179.44 to 1177.61)	14.29 (–11.60 to 40.20)	4000.70
Incremental	–89.93 (–773.18 to 593.31)	–5.95 (–36.20 to 24.30)	1510.90

[a] €1=US $1.18 in 2018.

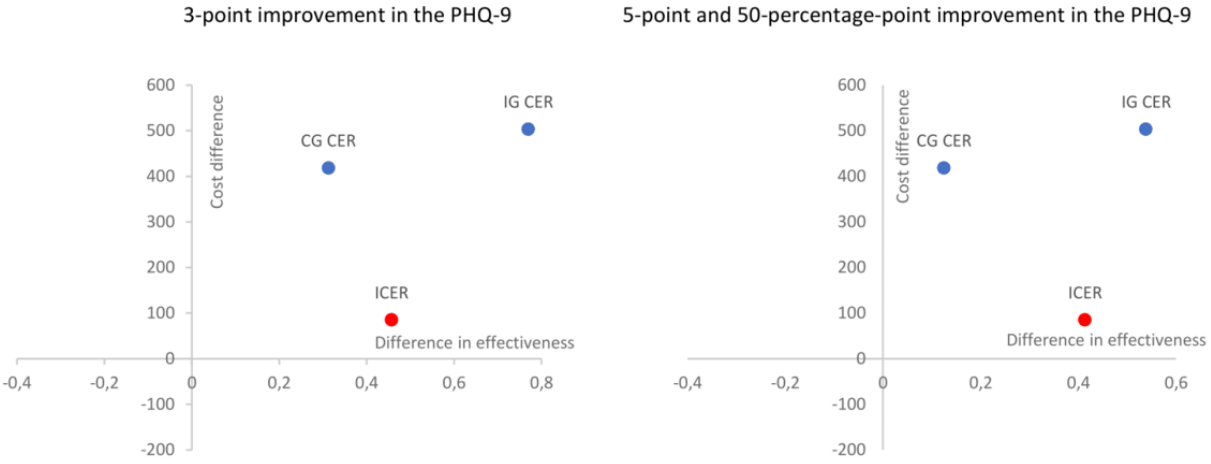
[b]CER: cost-effectiveness ratio.

[c]PHQ-9: Patient Health Questionnaire-9.

[d]TAU: treatment as usual.

[e]HbA_{1c}: glycosylated hemoglobin.

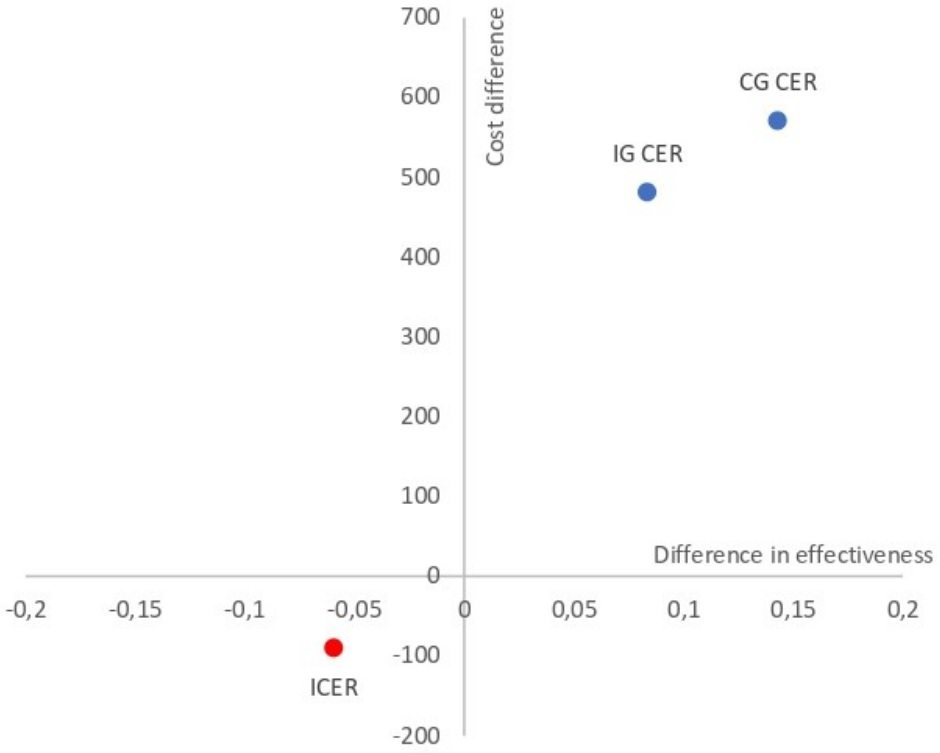
Figure 2. Cost-effectiveness plan for the improvement of depressive symptomatology in patients with type 2 diabetes mellitus after web-based psychological intervention. CG CER: control group cost-effectiveness ratio; ICER: incremental cost-effectiveness ratio; IG CER: intervention group cost-effectiveness ratio; PHQ-9: Patient Health Questionnaire-9.



CEA as an Outcome Measure of Improvement in HbA1c Levels

The web-based psychological intervention to improve HbA_{1c} levels in people with T2DM is reduced in IG compared with CG (8.33% vs 14.29%). Furthermore, although IG had a slightly lower cost per patient than CG (€481.59 vs €571.53), the ICER was €1510.90 (Table 4). In the cost-effectiveness plane, the ICER is in the southwest quadrant (lower left), indicating that the web-based intervention was less effective and less costly than the TAU from PC (Figure 3).

Figure 3. Cost-effectiveness plan for the improvement of HbA1c control in patients with type 2 diabetes mellitus after web-based psychological intervention. CG CER: control group cost-effectiveness ratio; ICER: incremental cost-effectiveness ratio; IG CER: intervention group cost-effectiveness ratio.



Cost-Utility Analysis

Both study groups started from a baseline level of utility that was practically similar (QALY 0.5898 vs 0.5935). The ICUR was €4119.33 per QALY. Therefore, the ICUR shows that the group that received the web-based psychological intervention program from PC achieved greater health gains (incremental QALY of 0.0207) and a higher cost compared to the group that only received TAU. Regarding the effect on QALY gained, this was higher in the IG (0.0321) than in the CG (0.0095). The ICUR resulted in 4174.92 per QALY gained. Therefore, the CUA shows that the group receiving the web-based psychological intervention program from PC achieved greater health gains (incremental QALY gain of 0.0225) and a higher cost compared to the group receiving only TAU (Table 5). Figure 4 shows the results of the cost-utility plane using QALY and QALY gained as the benefit outcome measure. ICUR is in the northwest quadrant (lower left), indicating that the web-based psychological intervention is more costly but contributes to increased QALYs.

Table 5. Results of the cost-utility analysis of the web-based psychological intervention program for the improvement of depressive symptomatology versus usual treatment.

	Cost, €[a] (95% CI	Gain (95% CI)	CUR[b], €

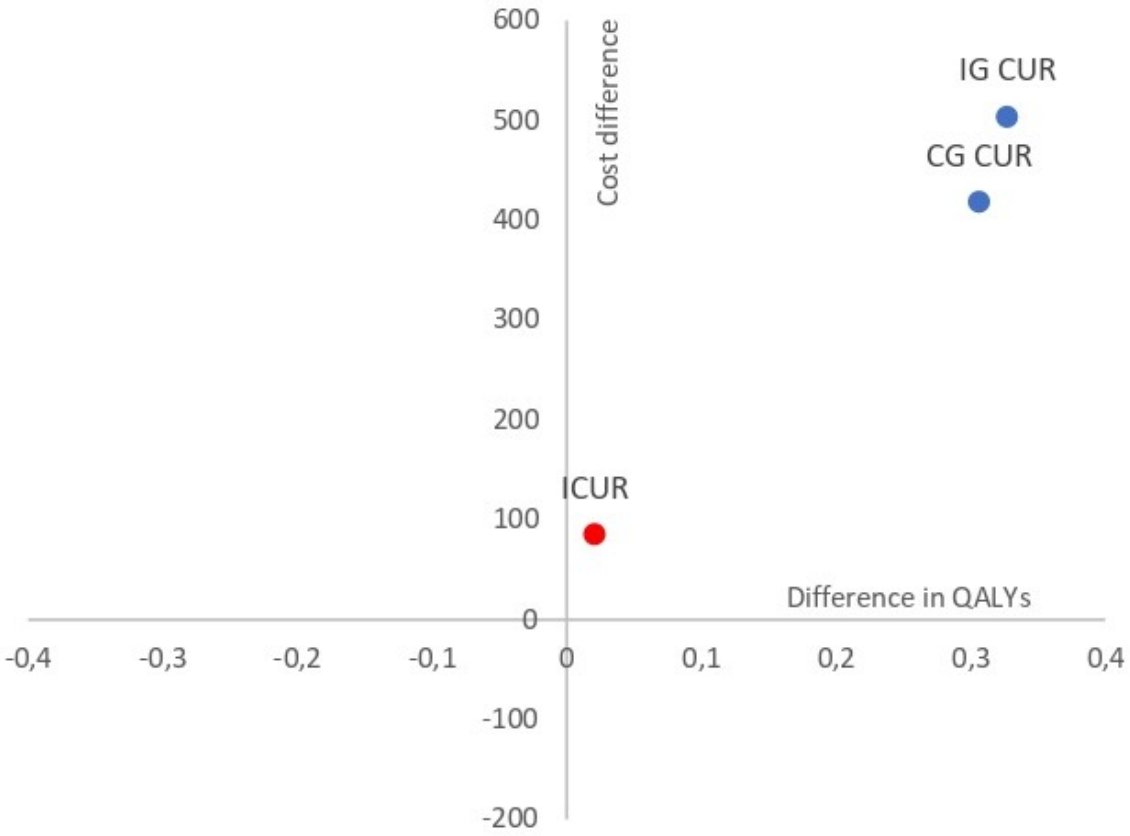
[a] €1=US $1.18 in 2018.

[b]CUR: cost-utility ratio.

[c]QALYs: quality-adjusted life year.

[d]TAU: treatment as usual.

Figure 4. Cost-utility per QALY of the web-based psychological intervention program for the improvement of depressive symptomatology in people with type 2 diabetes mellitus. CG CUR: control group cost-utility ratio; ICUR: incremental cost-utility ratio; IG CUR: intervention group cost-utility ratio; QALYs: quality-adjusted life years.

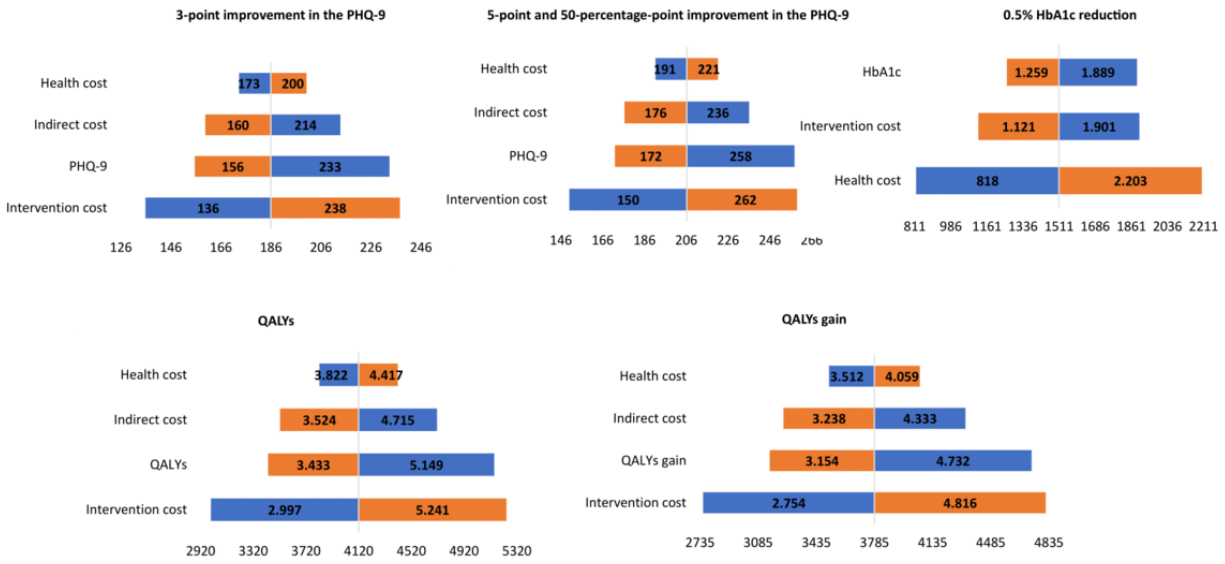


Sensitivity Analysis

Sensitivity analysis again showed that the ICER was cost-effective and that the results obtained were robust with respect to the base case. The variable that generated the most uncertainty in almost all cases was the costs of the intervention. However, taking a reduction in HbA_{1c} as a reference, the variable that generated the most uncertainty was health care

costs. These results can be seen in Figure 5. Taking as a reference the results obtained based on a reduction in the PHQ-9 as a criterion for improving depressive symptomatology, the variable that generated the most uncertainty was the costs of the intervention, as shown in Figure 5. The results were obtained based on a reduction of 3 points on the PHQ-9 as a criterion for improving depressive symptomatology, and the variable that generated the most uncertainty was the costs of the intervention, with oscillations of between €136 per patient with no depressive symptomatology and €238 per patient with no depressive symptomatology, considering the best- and worst-case scenarios. In criterion B and C, reduction of 5 points and 50 percentage points on the PHQ-9. The variable that generated the most uncertainty was also the cost of the intervention, with oscillations of between €150 per patient without depressive symptomatology and €262 per patient without depressive symptomatology.

Figure 5. Sensitivity analysis for a web-based psychological intervention program. HbA1c: glycosylated hemoglobin; PHQ-9: Patient Health Questionnaire-9; QALYs: quality-adjusted life years.



The results of the sensitivity analysis for the ICUR, using QALYs as a measure of benefit, were also robust to the base case. Figure 5 shows how variations are associated with oscillations between €2997 per QALY and €5241 per QALY for patients with no depressive symptomatology. On the other hand, variations in health care costs ranged from €3822 per QALY to €4417 per QALY for patients with no depressive symptomatology. The results of this analysis for the ICUR using the QALY gain as a measure of benefit obtained results are similar to those described in the case of QALYs. These results show that they are cost-utility (Figure 5).

Discussion

Principal Findings

This study performed the economic evaluation of a psychological intervention based on a web-based treatment with CBT and mindfulness to reduce depressive symptomatology and improve diabetes control. Although this type of intervention has been analyzed in other studies [26,28,30,31,53-56], this is the first study developed specifically for people with T2DM, not including patients with other types of diabetes (eg, patients with type 1 diabetes mellitus together with patients with T2DM) who, therefore, have different treatments and characteristics. It also includes a specific module aimed at promoting diabetes self-care behaviors and implemented directly by the Spanish PC health system.

The results of the CEA show that the intervention proved to be more effective and more costly in reducing the symptoms of depression compared to the TAU group. These results are to be expected after analyzing novel interventions developed using information and communication technologies and are in line with previous studies designed for the general population [36,57-61]. For a population with diabetes, only the study presented by Nobis et al [62] published results of CEA and CUA of a similar intervention, obtaining results that are equally in line with those obtained by this study.

Finally, the CUA results show that the intervention improved quality of life, measured in terms of QALYs, compared with TAU in PC. These results, with ICUR of €4119 per QALY and €3785 per QALY gained, are below the threshold value of between €22,000 and €25,000 per QALY estimated in Spain [63,64] as the maximum willingness to pay per QALY gained. Compared with previous studies, our results are very promising. Warmerdam et al [65] found that the additional cost of obtaining a QALY after the use of web-based CBT was €22,609 compared with the waiting list group, which is much higher than the results obtained in this study. Nobis et al [62] concluded that treatment response was not reflected in QALY gains, and the extra cost of obtaining a QALY amounted to €14,000. Romero-Sanchiz

et al [36] have been the only economic analysis study on a web-based psychological intervention performed so far in Spain in the PC setting in depression and showed a reduction in the cost of €11,390.

This study has limitations. First, difficulties were encountered in obtaining blood samples and determining HbA_{1c} during the follow-up phase. These difficulties were generated by the COVID-19 confinement. However, despite this circumstance, the results obtained are similar to those reported in previous studies [28-31,53,54] on face-to-face psychological interventions. Second, the cost analysis did not include the consumption associated with drugs for depression or diabetes. However, the reported medication costs were equally distributed between the 2 groups, so they would not make much difference to the results of the economic evaluation [36]. Finally, there were limitations in defining the criteria for the efficacy of the intervention because there was no gold standard for improvements in depressive symptomatology or HbA_{1c}.

Although the results are promising, more studies are needed because the evidence on the cost-effectiveness of these interventions is scarce. Therefore, studies are needed to replicate this intervention, increasing the sample size to be able to compare and generalize the results obtained. Likewise, the current challenge is directed toward the design of web-based psychological interventions in a personalized way according to the pathology to be treated to achieve better results and better adherence to them [66,67].

Conclusions

This intervention, devised to reduce depressive symptoms and enhance glycemic control among individuals with T2DM through a series of online web-based modules incorporating CBT tools, promotion of diabetes self-care behaviors, and mindfulness, has proven to be both effective and efficient. This effectiveness extends to both clinical outcomes and economic considerations. Consequently, these eHealth interventions not only facilitate clinical improvements for patients but also demonstrate cost-effectiveness for health care systems.

The findings of this study underscore the significance of incorporating a specific module focused on enhancing diabetes self-care behaviors. This element is deemed indispensable for the future development of web-based psychological interventions, ensuring their personalization and adaptation to the unique needs of individuals within this diabetic population. Moreover, the study supports the notion that interventions targeting the improvement of depressive symptoms in individuals with diabetes, while essential, may not be adequate in isolation for optimizing the overall clinical management of diabetes [25,30,68-71].

In summary, this intervention not only directly benefits patients by improving their mental and physical health but also brings efficiency and adaptability to health care settings, highlighting its importance in the effective management of diabetes in diverse health care settings.

Acknowledgments

The authors thank all the health care staff of the primary care centers who participated in this study for their outstanding collaboration in the recruitment and referral of participants. They also thank all the researchers who participated in the fieldwork. AM-B has a Margarita Salas postdoctoral fellowship at the University of Zaragoza, funded by the NextGeneration EU. This study has been funded by Carlos III Health Institute through the project PI19/01131 and was cofunded by the European Union. AMB had an FI predoctoral contract awarded by the Carlos III Health Institute (FI17/00180) at the Institute for Health Research of Aragon to conduct this study.

KEYWORDS

aortic valve; implantation functional; wearable devices

I read with great interest the recent article by Eerdekens et al [1] titled "Cardiac Health Assessment Using a Wearable Device Before and After Transcatheter Aortic Valve Implantation: Prospective Study," published in *JMIR mHealth and uHealth*. The study presented an innovative approach by using a wearable device to assess cardiac health outcomes before and after transcatheter aortic valve implantation (TAVI), addressing an important gap in the objective evaluation of functional improvement post TAVI.

While the findings of the study were significant, particularly the introduction of the Cardiac Energy Expenditure Slope (CEES) as a potential metric for assessing cardiovascular efficiency, there were some critical considerations that merited discussion.

First, the study's conclusion that wearable device parameters, such as step count and total activity time, did not significantly change post TAVI, raised questions about the sensitivity of these devices in capturing subtle improvements in daily activity. It is well established that older populations, especially those undergoing TAVI, may not exhibit dramatic changes in physical activity due to a combination of frailty, preexisting comorbidities, and lifestyle factors [2-5]. However, the lack of significant change in these parameters might also reflect limitations in the wearable device's ability to capture variations in physical activity that are clinically meaningful but subtle. For instance, improvements in quality of life and functional capacity may have manifested in ways that were not fully captured by metrics like step count alone.

Second, the study's reliance on a 3-month follow-up period to assess post-TAVI outcomes could be seen as a limitation. While the authors argued that most patients reach full capacity by this time, it is possible that some patients might show delayed improvements in physical activity and cardiovascular efficiency. Extending the follow-up period to 6 months or even a year could have provided a more comprehensive view of the long-term impact of TAVI on patient activity levels and cardiac health.

Additionally, the introduction of CEES as a novel metric was intriguing, yet its application and utility needed further validation in larger, diverse cohorts. The metric's correlation with traditional measures of functional improvement, such as the 6-minute walking test, and its predictive value in long-term outcomes post TAVI, should be explored in future studies. This would help establish CEES as a reliable tool in both clinical practice and research settings.

In conclusion, while the study by Eerdekens et al [1] contributed valuable insights into the use of wearable devices for cardiac health assessment, it also highlighted the need for further research to optimize these tools for older, comorbid populations. Continued exploration into novel metrics like CEES and longer follow-up periods could enhance our understanding of post-TAVI recovery and guide personalized treatment strategies.

In "The Importance of Activating Factors in Physical Activity Interventions for Older Adults Using Information and Communication Technologies: Systematic Review" (JMIR Mhealth Uhealth 2023; 11(1): e42968) the authors noted some errors].

In the "Conclusions" section of the Abstract, the following phrase:

> *So far, only a limited number of available BCTs (21/99, 21%) have been integrated.*

Has been changed to:

> *So far, only a limited number of available BCTs (21/102, 21%) have been integrated.*

In the "Introduction" subsection "Activation Using Information and Communication Technology," the following sentence:

> *Dugas and colleagues [12] added 2 more categories (ie, gamification and personalization).*

Has been changed to:

> *Dugas and colleagues [12] added 2 more categories (ie, personalization and gamification), including 9 BCTs in total.*

In the "Methods" subsection "Selection of Studies and Data Extraction," the line:

> *Additionally, the two categories suggested by Dugas and colleagues [12]—gamification and personalization—were incorporated as categories 17 and 18.*

Has been changed to:

> *Additionally, the two categories suggested by Dugas and colleagues [12]—personalization and gamification—were incorporated as categories 17 and 18.*

In Table 1, under the "Skills (ability)" column, the following text:

- *Category 7: Repetition and substitution*

Has been changed to:

- *Category 8: Repetition and substitution*

Elsewhere in Table 1, under the "Knowledge (awareness)" column, the following content:

- *Category 5: Natural consequences*
- *Category 9: Comparison of outcomes*
- *Category 11: Regulation*
- *Category 14: Scheduled consequences*
- *Category 16: Covert learning*

Has been changed to:

- *Category 5: Natural consequences*
- *Category 9: Comparison of outcomes*
- *Category 11: Regulation*

In Table 1, under the "Motivation (triggers)" column, the following text:

- *Category 1: Goals and planning*
- *Category 2: Feedback and monitoring*
- *Category 3: Social support*
- *Category 8: Associations*
- *Category 10: Reward and thread*
- *Category 12: Antecedents*
- *Category 17: Gamefication*
- *Category 18: Personalization*

Has been changed to:

- *Category 1: Goals and planning*
- *Category 2: Feedback and monitoring*
- *Category 3: Social support*
- *Category 7: Associations*
- *Category 10: Reward and thread*
- *Category 12: Antecedents*
- *Category 14: Scheduled consequences*
- *Category 16: Covert learning*
- *Category 17: Personalization*
- *Category 18: Gamification*

In the "Results" subsection "Delivering Activation Factors", the following sentence:

> *Of the 22 available BCTs [11,12] that target skills, the aforementioned 5 (23%) were used among all included articles.*

Has been changed to:

> *Of the 23 available BCTs [11,12] that target skills, the aforementioned 6 (23%) were used among all included articles.*

Further in the same section, the following paragraphs:

> *Others were prompts and cues (4 intervention groups), social comparison (1 intervention group), and problem-solving discussions for finding ways to overcome barriers (1 intervention group). Of the 64 available BCTs [11,12] that target motivation, 12 (19%; inclusive of the 7 aforementioned BCTs) were used among all included articles.*
>
> *Altogether, of the 99 potential BCTs [11,12], 21 (21%) were integrated in all articles.*

Have been changed to:

> *Others were prompts and cues (4 intervention groups), adjustment of intervention content to the performance (4 intervention groups), action planning (2 intervention groups) and problem-solving discussions for finding ways to overcome barriers (1 intervention group). Of the 66 available BCTs [11,12] that target motivation, 11 were used among all included articles.*
>
> *Altogether, of the 102 potential BCTs [11,12], 21 (21%) were integrated in all articles.*

Within Textbox 1, the "Skills" subheading which previously appeared as:

Skills

- *Promoted in 19 of 20 interventions*
- *Five BCTs were used; main behavior change techniques (BCTs) were the instruction of optimal behavior performance and the demonstration of behavior*

Has been changed to:

Skills

- *Promoted in 19 of 20 interventions*
- *Six BCTs were used; main behavior change techniques (BCTs) were the instruction of optimal behavior performance and the demonstration of behavior*

Further within Textbox 1, the "Motivation" subheading previously read as:

Motivation

- *Promoted in 17 of 20 interventions*
- *Twelve BCTs were used; main BCTs were self-monitoring, feedback on behavior, social support, and goal setting*

And will now appear as:

Motivation

- *Promoted in 17 of 20 interventions*
- *Eleven BCTs were used; main BCTs were self-monitoring, feedback on behavior, social support, and goal setting*

Within the "Discussion" subsection "Delivering Activation Factors," the sentence:

> *To target participants' motivation, 12 BCTs, such as self-monitoring, feedback on behavior, social support, and goal setting, were used.*

Was changed to:

> *To target participants' motivation, 11 BCTs, such as self-monitoring, feedback on behavior, social support, adjusting intervention content to the performance and goal setting, were used.*

The "Discussion" subsection "Conclusions" includes the claim that:

> *Although a broad variety of BCTs were used in the articles, they were limited to about 21% (21/99) of available BCTs.*

This has been adjusted to appear as:

> *Although a broad variety of BCTs were used in the articles, they were limited to about 21% (21/102) of available BCTs.*

In Multimedia Appendix 1, the rows "Li, 2020," "Mansson, 2020," "Rowley, 2019," and "Van Dyck, 2016" have been amended from:

> *18 Personalization*

And now appear as:

> *17.4 Adjusting intervention content to performance*

Finally, Multimedia Appendix 2 has been changed to match the main manuscript in the ways listed below.

The "Skills" column has been changed from:

Skills (30 BCTs)

5 BCTs

To read as:

Skills (23 BCTs)

6 BCTs

The "Knowledge" column has been changed from:

Knowledge (27 BCTs)

4 BCTs

To read as:

Knowledge (13 BCTs)

4 BCTs

The "Motivation" column has been changed from:

Motivation (50 BCTs)

12 BCTs

To appear as:

Motivation (66 BCTs)

11 BCTs

The correction will appear in the online version of the paper on the JMIR Publications website on February 1, 2024, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Correction of: https://mhealth.jmir.org/2024/1/e45942

(JMIR Mhealth Uhealth 2024;12:e58507) doi:10.2196/58507

In "Mobile App Intervention of a Randomized Controlled Trial for Patients With Obesity and Those Who Are Overweight in General Practice: User Engagement Analysis Quantitative Study" (JMIR Mhealth Uhealth 2024;12:e45942), the authors noted two errors. The following corrections have been made:

Under "Methods", the third paragraph of the "Outcome Measures" subsection has been changed from:

> *Specifically, the Health Literacy Questionnaire domain 8 questions were the following [11]: please indicate how difficult or easy the following tasks are for you now: (1) find information about health problems; (2) find health information from several different places; (3) get information about health so you are up to date with the best information; (4) get health information in words you understand; and (5) get health information by yourself. There is a 5-point response option scale for each question (cannot do or always difficult, usually difficult, sometimes difficult, usually easy or always easy). The scores are reported as averages for the domain (with a range between 1 and 5) with high scores representing higher health literacy.*

And now reads as follows:

> *The Health Literacy Questionnaire domain 8 questions were used [11]:(1) find information about health problems; (2) find health information from several …. ; (3) get information about health so you…; (4) get health information in words you…; and (5) get health information by yourself. There is a 5-point response option scale for each question (cannot do or always difficult, usually difficult, sometimes difficult, usually easy or always easy). The scores are reported as averages for the domain (with a range between 1 and 5) with high scores representing higher health literacy.*

Additionally, in Table 1 the definition of the "Health literary" row has been changed from:

> *Health literacy, specifically the self-reported ability to find good quality health information, according to domain 8 of the Health Literacy Questionnaire [9], at baseline and 6-month follow-up.*

To reference a different source, this now appears as:

> *Health literacy, specifically the self-reported ability to find good quality health information, according to domain 8 of the Health Literacy Questionnaire [11], at baseline and 6-month follow-up.*

The correction will appear in the online version of the paper on the JMIR Publications website on April 2, 2024, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Abstract

Background: Despite the increasing need for digital services to support geriatric mental health, the development and implementation of digital mental health care systems for older adults have been hindered by a lack of studies involving socially vulnerable older adult users and their caregivers in natural living environments.

Objective: This study aims to determine whether digital sensing data on heart rate variability, sleep quality, and physical activity can predict same-day or next-day depressive symptoms among socially vulnerable older adults in their everyday living environments. In addition, this study tested the feasibility of a digital mental health monitoring platform designed to inform older adult users and their community caregivers about day-to-day changes in the health status of older adults.

Methods: A single-arm, nonrandomized living lab pilot study was conducted with socially vulnerable older adults (n=25), their community caregivers (n=16), and a managerial social worker over a 6-week period during and after the COVID-19 pandemic. Depressive symptoms were assessed daily using the 9-item Patient Health Questionnaire via scripted verbal conversations with a mobile chatbot. Digital biomarkers for depression, including heart rate variability, sleep, and physical activity, were measured using a wearable sensor (Fitbit Sense) that was worn continuously, except during charging times. Daily individualized feedback, using traffic signal signs, on the health status of older adult users regarding stress, sleep, physical activity, and health emergency status was displayed on a mobile app for the users and on a web application for their community caregivers. Multilevel modeling was used to examine whether the digital biomarkers predicted same-day or next-day depressive symptoms. Study staff conducted pre- and postsurveys in person at the homes of older adult users to monitor changes in depressive symptoms, sleep quality, and system usability.

Results: Among the 31 older adult participants, 25 provided data for the living lab and 24 provided data for the pre-post test analysis. The multilevel modeling results showed that increases in daily sleep fragmentation (P=.003) and sleep efficiency (P=.001) compared with one's average were associated with an increased risk of daily depressive symptoms in older adults. The pre-post

test results indicated improvements in depressive symptoms (*P*=.048) and sleep quality (*P*=.02), but not in the system usability (*P*=.18).

Conclusions: The findings suggest that wearable sensors assessing sleep quality may be utilized to predict daily fluctuations in depressive symptoms among socially vulnerable older adults. The results also imply that receiving individualized health feedback and sharing it with community caregivers may help improve the mental health of older adults. However, additional in-person training may be necessary to enhance usability.

KEYWORDS

depression; monitoring system; IoT; AI; wearable device; digital mental health phenotyping; living lab; senior care; Internet of Things; artificial intelligence

Introduction

Over the past 2 decades, there has been a notable increase in geriatric depression and other psychiatric disorders, coinciding with a global rise in life expectancy and population aging [1-4]. Since 2009, South Korea has had the highest suicide rate for older adults among the Organisation for Economic Co-operation and Development (OECD) countries. This is attributed to elevated levels of geriatric depression, economic poverty, and social isolation resulting from the rapid nuclearization of the family [5]. With the rapid aging of the global population, caring for older family members with mental disorders has become an overwhelming task for younger generations [6]. Despite the increasing role of community services, there are significant budget shortages in local communities and government health departments, as well as a lack of skilled geriatric labor to meet the needs of these older adults with mental disorders.

The digitalization of mental health screening and intervention is expected to provide innovative solutions to the challenges in mental health care for older adults. For example, digital phenotyping can facilitate the early detection of depression and help reduce the high rate of undiagnosed depression (50%) among older adults [7]. Digital phenotyping of mental health is defined as the "moment-to-moment quantification of the individual-level human phenotype of mental health status in real-life contexts using data collected from personal digital devices" [8]. Recent studies have suggested the potential of digital phenotyping for depressive symptoms using ecological momentary assessments, including self-reports of depressive mood [9]. Beyond momentary self-reports, digital sensing technologies enable unobtrusive passive sensing of depressive symptoms through smartphone apps, wearable sensors, and the Internet of Things. The Internet of Things, a ubiquitous network of interconnected devices, facilitates seamless data collection and intelligent monitoring and management to ensure users' health and safety [10-13]. However, previous studies have primarily examined digital phenotypes of depressive symptoms in young adults or small groups of patients with depression. This has created challenges in applying digital phenotyping technologies to older adults [3].

The underrepresentation of older adults in digital mental health care research is due to several barriers hindering their participation in studies involving novel digital technologies. First, older adults often have sensory and cognitive impairments that necessitate the use of different design principles than those effective for young or middle-aged adults [14-16]. For example, older adults generally prefer displays with simple layouts and multimodal command functions, such as voice commands in addition to touch screens. Second, implementing digital health care services for older adults should involve both family and community caregivers, who often do not live with the older adult, as well as support from multiple community health care institutions [17,18]. When learning to use new technology, older adults require repeated in-person assistance and educational materials tailored to low digital literacy levels [14,15]. Digital health care services are most likely to benefit older adults when they can connect them to the necessary health care services within the community. Third, the living environments of older adults often hinder their use of digital mental health care services, as a significant proportion (40%-60%) may not have an internet connection or access to personal computers and other mobile devices [19,20].

These functional, social, and environmental barriers underscore the necessity for proof-of-concept and feasibility trials for geriatric mental health care services among older adults and community caregivers in their natural living environments, utilizing living labs [3,18]. Living labs are defined as "user-centered, open innovation ecosystems based on a systematic user co-creation approach, integrating research and innovation processes in real-life communities and settings to create sustainable impact" [21]. Living labs are essential for designing solutions tailored to the needs of older adults. Digital mental health services will not be acceptable or sustainable unless they are designed to be compatible with the cognitive and physical capacities of older adults, as well as their natural living environments, and the working environments of community caregivers. This compatibility can be ensured through living lab testing [22,23].

This study aims to address the gap in current geriatric health literature by testing the feasibility of a digital mental health monitoring platform. This platform could be integrated with existing community senior care services, aiming to prevent and detect early signs of mental health decline in socially isolated older adults. We conducted a single-arm, nonrandomized living lab pilot study involving 25 socially vulnerable older adults. These individuals received personalized daily health monitoring in their natural living environments, both during and after the

COVID-19 pandemic. Additionally, the monitoring results of the older adult participants were shared with their community caregivers (n=16) and a managerial social worker at a community senior welfare center (hereafter referred to as the "community center"). This information was utilized by caregivers during their regular in-person senior caregiving services and emergency responses. The study assessed pre- and postintervention changes in mental health indicators (eg, depressive symptoms and sleep quality) and the usability of the monitoring platform among older adults. This evaluation aimed to test both the health-enhancing effects and the usability of the platform. Additionally, beyond feasibility testing, the research investigated whether utilizing digital biomarkers of geriatric depression detected by a wearable sensor could predict daily fluctuations in depressive symptoms among older adults.

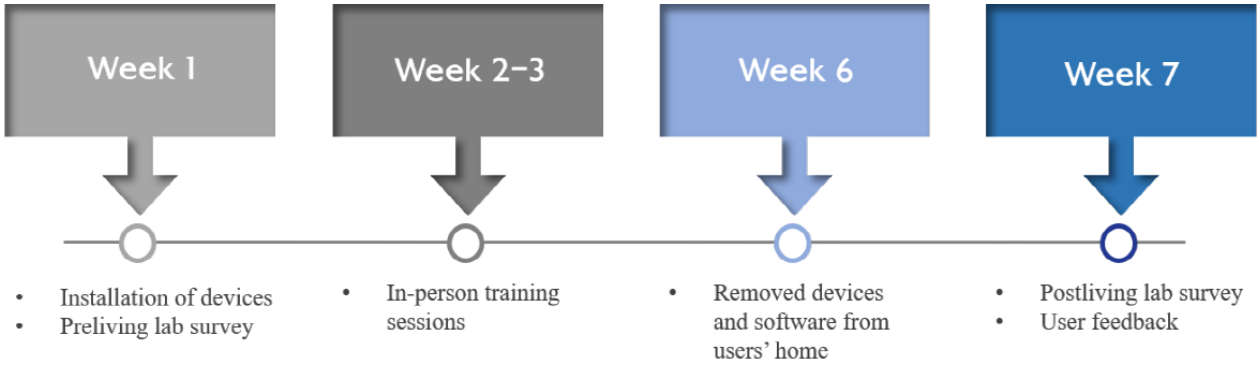
Methods

Overview

This single-arm, nonrandomized living lab pilot study was undertaken as part of a broader research endeavor aimed at developing a sustainable digital health monitoring platform. The platform is designed to be integrated with a community-based public senior care service, with the goal of enhancing the mental and physical well-being of older adults, both during and following the COVID-19 pandemic. Previously, we conducted formative research using surveys with older adults (n=99) and focused group interviews involving older adults (n=16), community caregivers (n=12), and social workers (n=3) at the community center. The objective was to identify the primary health concerns among older adults, understand the workflow of community caregiving services, and determine the necessary structures and features for the health monitoring service platform. The present digital health monitoring platform incorporates a smartphone chatbot, a smartwatch (Fitbit Sense; Google Inc.), and a motion-sensing camera (Azure Kinect SDK 1.3.0; Microsoft Corporation) installed in the home environment. This platform is designed to enhance the self-care capabilities of older adults by delivering daily updates on their mental and physical health status compared with their baseline averages established during the initial week of the living lab. Additionally, the platform aims to bolster the social support network of older adults by sharing their daily health status information and health emergency alerts with their community caregivers. These caregivers offer regular in-person senior caregiving services to older adult users through the community center. Furthermore, the information was shared with the managerial social worker at the community center to provide assistance in case of any health emergencies during and after the COVID-19 pandemic. Before the pilot study, we conducted an informal prepilot test involving study staff (n=6) to ensure the overall functionality of mobile apps and processing algorithms. The results from the motion-sensing camera, which was integrated with experimental sessions outside the living lab, are reported separately from this study [24]. Trained research assistants, along with a community caregiver, visited older adult participants in their homes to obtain informed consent and install a mobile app on the users' smartphones and digital devices. Participants were requested to complete surveys at home both before and after the living lab activities, aimed at gauging the usability of the platform and assessing their mental and physical health status. The primary randomized controlled trials featuring both intervention and comparison groups have been registered (registered with Clinicaltrials.gov; registration number NCT06270121); however, this pilot study did not include a control group.

Figure 1 illustrates the timeline of the living lab study procedure, conducted from September 2022 to August 2023. The living lab spanned 6 weeks, commencing with a 1-week adaptation period. Older adults were instructed to launch the smartphone app in the morning, which would prompt them to engage with a chatbot inquiring about their well-being and presenting 2 questions regarding daily depressive symptoms. Following interaction with the chatbot, participants could access their daily health status information, including stress levels (measured via the high frequency [HF] measure of heart rate variability [HRV]), sleep quality (indicated by total sleep time and sleep fragmentation), and physical activity (PA) levels (tracked by step count) from the previous day. This information was compared with their own average during the initial week of the living lab. Voice recordings, daily health status updates, and real-time emergency alerts of the older adult participants were transmitted to their corresponding community caregivers and the managerial social worker through the web or app interface. Throughout the duration of the living lab, participants were instructed to wear a smartwatch continuously, except during battery charging periods.

Figure 1. Timeline of the 6-week pilot living lab procedure.



Trained research assistants conducted surveys at the homes of older adults, both before and after the living lab, to assess significant changes in pilot trial outcomes, such as depressive symptoms, sleep quality, and system usability. During the

posttest survey, participants were also queried about the frequency and types of functions they utilized on the platform during the living lab period, and any additional feedback to enhance the platform for the main trials.

To facilitate participants' acclimatization to the digital monitoring app and devices, and to mitigate the risk of missing data, a member of the research staff visited participants in their homes for 2-3 additional in-person training sessions. These sessions focused on guiding participants on how to use the verbal surveys (Textbox 1) and digital devices effectively, as well as how to check their daily health status. These training sessions were conducted during the second and third weeks of the living lab. If a participant's data were missed for 3 consecutive days, study staff promptly contacted the participant via phone to emphasize the significance of responding to verbal surveys or wearing the smartwatch. Additionally, they offered assistance in resolving any technical issues hindering the older adult's participation. Furthermore, community caregivers played a vital role in assisting older adults in adapting to the platform's usage.

Textbox 1. The methods for assessing daily depressive symptoms via the mobile app chatbot.

The 9-Item Patient Health Questionnaire on depressive symptoms

- Do you feel down, depressed, or hopeless today?
- Do you feel little interest or pleasure in doing things today?
- Have you had trouble falling or staying asleep, or sleeping too much today?
- Are you feeling tired or having little energy today?
- Have you experienced poor appetite or overeating today?
- Do you experience trouble concentrating on things today?
- Are you feeling bad about yourself or that you are a failure or have let yourself or your family down?
- Are you moving or speaking so slowly that other people could have noticed?

5 items on daily greetings (recommended by community caregivers during the formative research)

- Did you sleep well last night?
- Have you eaten your meal?
- How are you feeling? Are you feeling pain in any part of your body?
- What are you planning to do today?
- Do you need to go to the hospital today?

An example daily voice survey scenario combining 1 randomly selected greeting item and 2 randomly selected items from the 9-Item Patient Health Questionnaire

Good morning, Ma'am!

[Greeting item] Did you sleep well last night? (Recording)

[PHQ-9 #1] Do you feel down, depressed, or hopeless today? (Recording)

[PHQ-9 #2] Are you moving or speaking so slowly that other people could have noticed? (Recording)

Thank you! Have a good day.

Ethics Approval

The study protocol received approval from the Institutional Review Board of Korea University (approval number KUIRB-2021-0324-02).

Recruitment

Adults older than 65 years, along with their community caregivers, were recruited from a community center in Seoul, South Korea. A meeting was convened with the community caregivers and managers at the community center to elucidate the study's objectives and procedures, solicit participation as community caregivers, and seek assistance in recruiting older adult participants. Based on the formative research findings, community caregivers can be described as predominantly middle-aged women (mean age 58.04, SD 3.17 years), with a gender composition of women only. On average, they possessed 1-2 years of work experience. Each caregiver was responsible for providing in-person caregiving services to multiple older adults, with a maximum caseload of 16 individuals. Caregivers who expressed interest in participating in the study with their older adult service recipients explained the study protocol to the older adult during their subsequent regular in-person visits. If both the older adult and their community caregiver were interested in participating, the study staff arranged a home visit to obtain informed consent from the older adult, accompanied by their caregiver.

The inclusion criteria encompassed older adults receiving in-person senior care services due to socioeconomic vulnerability, particularly those living alone with low income. Additionally, participants were required to use a Samsung

Galaxy smartphone, as the mobile app was exclusively developed for Android smartphones, which are widely utilized by older adults in South Korea. Exclusion criteria encompassed cognitive and functional impairments that could impede study participation (such as hearing loss), as well as individuals residing with others in the same household. This exclusion was due to technical challenges associated with motion-sensing camera detection, which were pertinent to the broader study. Community caregivers offering in-person public senior care services at the community center were deemed eligible to participate in the study. A managerial social worker responsible for overseeing the in-person senior care service at the community center was also recruited to evaluate the website of the monitoring platform.

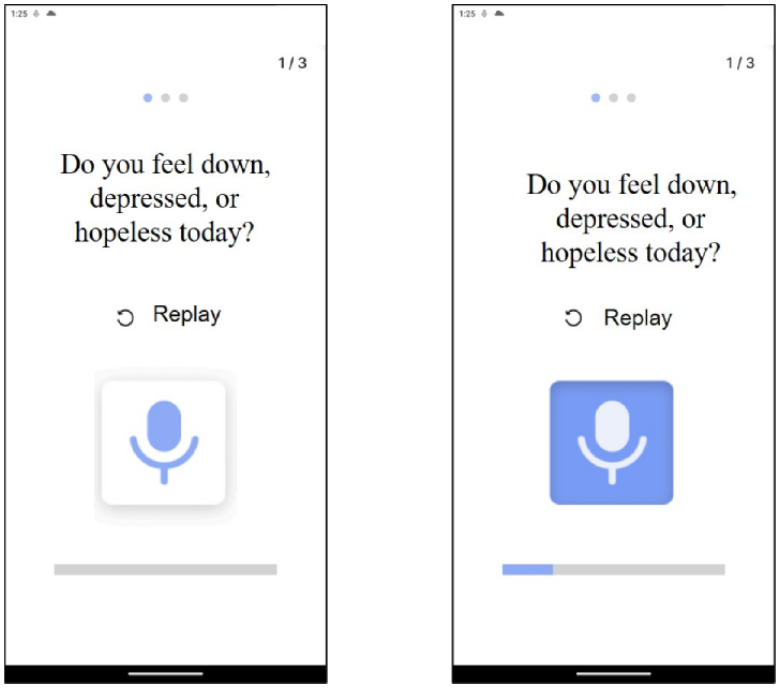
Of the 39 older adults initially recruited for the study, 8 declined participation, primarily citing busyness and concerns about the long-term use of the platform as reasons. Consequently, the study proceeded with the consented participation of the remaining 31 older adults.

Patient Health Questionnaire-9

The 9-item Patient Health Questionnaire-9 (PHQ-9) was used to evaluate daily depressive symptoms through the smartphone app chatbot, reflecting insights from the formative research of the larger study. This decision was informed by older adult users' challenges with touch screen usage and their preference for verbal communication features over visual displays. The PHQ-9 is a widely recognized tool utilized to identify mild and clinical depressive symptoms in nonpsychiatric settings [25,26]. One item from the PHQ-9 questionnaire, specifically concerning suicidal thoughts ("Have you had thoughts that you would be better off dead, or of hurting yourself?"), was omitted due to the potential risk of eliciting negative thoughts, particularly among individuals who may be at risk for depression.

In addition to the PHQ-9 items, we created a chatbot script for daily greetings and safety checks, incorporating 5 commonly used questions recommended by community caregivers. Older adult participants were instructed to open the mobile app every morning, triggering an automated conversation with the chatbot (upon the first daily app launch). Voice recording was activated for 30 seconds after each question, and the recorded file was instantly uploaded to the website accessible to community caregivers (Figure 2). These voice recording files were monitored during the living lab and coded later to identify the presence of daily depressive symptoms (1=depressive symptoms indicated on at least one PHQ-9 item, 0=no reports of depressive symptoms) by 2 research assistants (YBS and SYH) independently. Any discrepancies were resolved through discussions among the 2 coders and an experienced supervisor.

Figure 2. Mobile app function for collecting daily depressive symptoms; the chatbot voice asked 2 randomly selected PHQ-9 items and older adult participants' answers were automatically recorded. The blue bar and the blue microphone icon indicate that voice recording has been activated. PHQ-9: 9-item Patient Health Questionnaire.



Smartwatch-Derived Measures

Daily Sleep Quality

Sleep quality was evaluated using several metrics, including total sleep time, sleep fragmentation index, and the number of long fragmentation episodes. To validate our sleep calculation algorithm, we examined baseline data on participants' usual sleep time and wake time using items from the Pittsburg Sleep Quality Index (PSQI). Our algorithm commenced at 6 PM and concluded at noon the following day to encompass all sleep periods. Additional adjustments were implemented for 1 older adult whose day and night cycles had reversed, allowing for the capture of daytime sleep periods (n=1). The Fitbit algorithm categorized the activity level for each minute the older adult wore the sensor as either asleep or awake. Furthermore, the classification data were prescreened using the following 7

criteria to improve the accuracy of actigraphy-assessed sleep detection based on previous studies [27,28]: (1) if the previous 4 minutes were categorized as awake, the initial minute of the sleep period was adjusted to sleep; (2) if the previous 10 minutes were identified as awake, the subsequent 3 minutes were adjusted to awake; if more than (3) 15 minutes before and (4) after a sleep period lasting less than 6 minutes were classified as awake, then the period of less than 6 minutes of sleep was adjusted to awake; (5) if more than 20 minutes before and after a sleep period lasting less than 10 minutes were categorized as awake, the period of less than 10 minutes of sleep was adjusted to awake. The total time in bed was computed as the duration between the initiation and cessation of the sleep cycle; (6) the sleep onset time was determined as the first time block featuring at least 10 minutes of uninterrupted sleep; and (7) the sleep offset time was determined as the final 10 minutes of uninterrupted sleep before rising from bed. The total sleep time was computed by aggregating the minutes spent asleep from the sleep onset to the sleep offset. The sleep fragmentation index was determined by dividing the number of times the participant awakened for more than 1 minute by the total sleep time [27]. Sleep efficiency was calculated by dividing the total sleep time by the duration of time spent in bed [27].

Heart Rate Variability

HRV was evaluated using both time and frequency domain indicators. These indicators were computed every 5 minutes, around the clock, using the Python-based (Python Foundation) open-source program code Aura-healthcare [29]. The code converted heart rate data to R-R intervals, which represent the time elapsed between 2 successive R-waves in the QRS signal on the electrocardiogram. These intervals are known to be influenced by the activity of the sinus node and autonomic nerve stimulation [30]. Next, the code was used to compute the time domain indicators, which included the SD of the N-N intervals, the normalized or filtered R-R intervals, and the root mean square of successive differences. Additionally, frequency domain indicators were derived, such as the ratio of low frequency (LF) to HF, and HF after applying fast Fourier transformation. This transformation categorized the power of heart rate into HF, LF, and very-low-frequency components. The characteristics and reliability of HRV assessments using Fitbit have been documented in a previous study involving a diverse population [31].

Physical Activity Indices

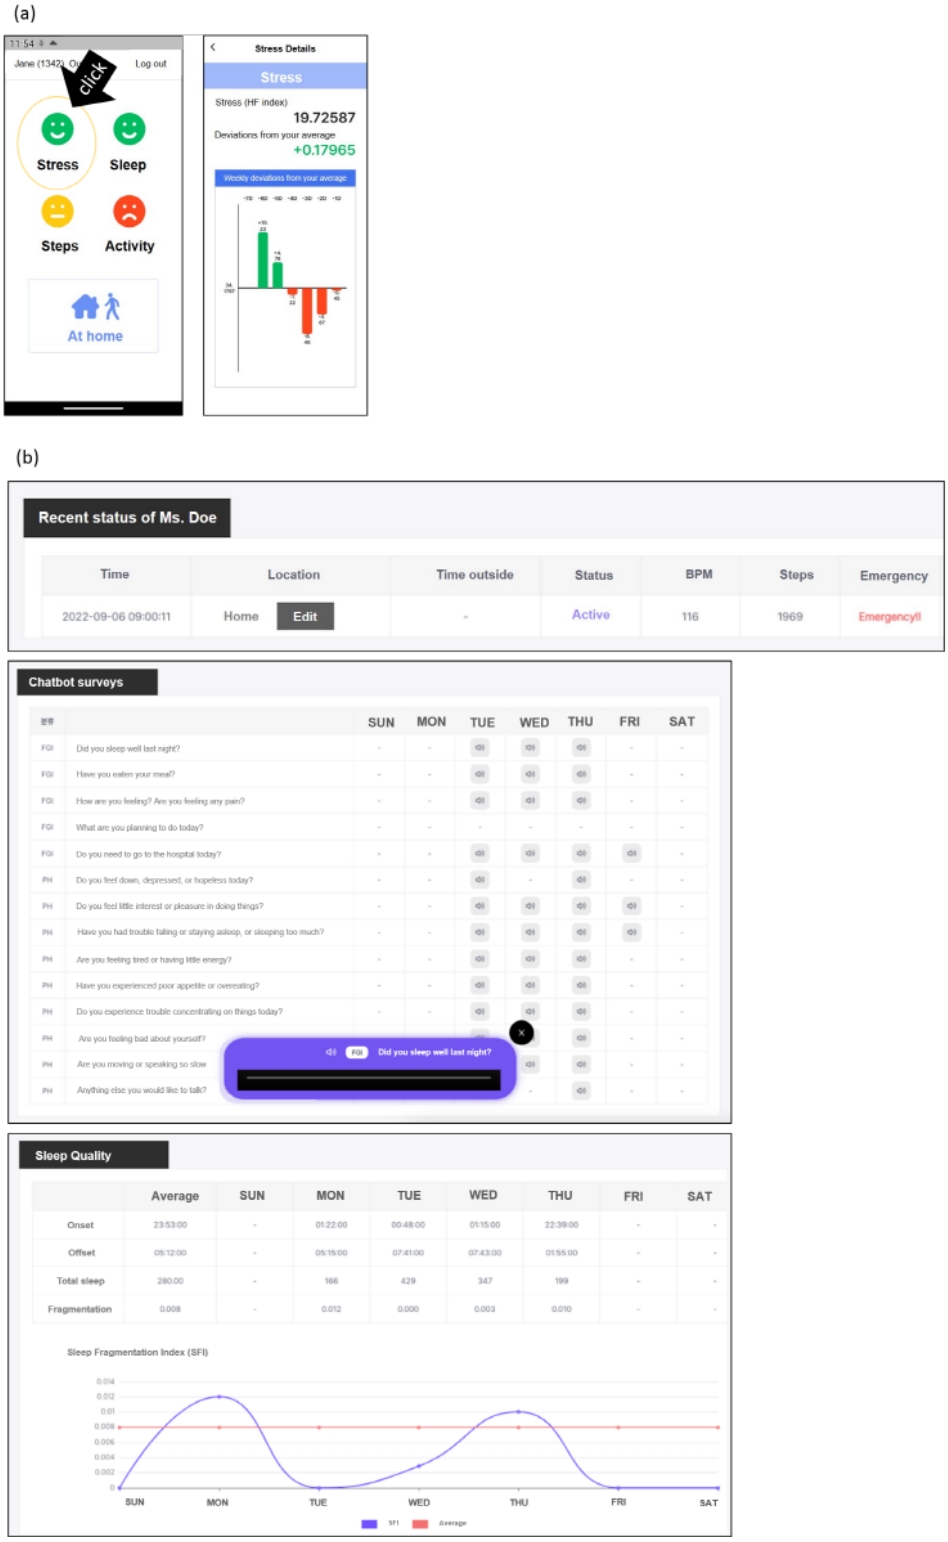
PA levels were evaluated using Fitbit's indicators for steps taken and minutes spent engaging in light, moderate, and intense activity each day throughout the living lab participation. Fitbit uses a 3-axis accelerometer to track steps and PA by analyzing the frequency, duration, intensity, and patterns of movements. Previous studies have confirmed the accuracy of Fitbit activity data [32-34].

Provision of Individualized Daily Health Status Feedback Via the Mobile App

The mobile app designed for older adults and their community caregivers delivered personalized daily health status feedback on stress, sleep, steps, and activity. This feedback was presented using traffic signal colors and accompanied by detailed information, as depicted in Figure 3A. Using the traffic signal colors, a green face within the health status for stress, steps, and activity domain indicated a value higher than 1 SD of the user's average in that domain. A yellow face denoted a value within +1 SD or –1 SD of the average of the health status domain score. A red face indicated a value lower than 1 SD of the average level. The ranges for the green and red faces were inverted for sleep (as measured by sleep fragmentation) compared with the other measurable categories, as a higher value indicates more fragmented sleep. Clicking each face on the initial page (Figure 3A on the left side) advanced the user to the next page, where details (Figure 3A on the right side) were provided regarding the differences between today's value in the domain compared with the average during the first week. Additionally, a weekly graph was included to illustrate the pattern of changes in the weekly values.

The web application designed for the community caregiver and the managerial social worker (Figure 3B) facilitated centralized monitoring by community caregivers, allowing for swift emergency responses to older adults during and after the COVID-19 pandemic. Additionally, it enabled the sharing of daily health status updates. The emergency signal would be triggered if an older adult remained inactive for over 8 hours and/or if their heart rate fell below 30 bpm or rose above 140 bpm.

Figure 3. Example of customized daily health status feedback on stress, sleep, steps, and activity using traffic signal colors and detailed information via the mobile app for (A) the older adult users and (B) the web application for the community caregivers and the managerial social worker.



Pre- and Postsurvey Measures

Geriatric Depression Scale

The 15-item version of the Geriatric Depression Scale (GDS) [35,36] was used to evaluate levels of depressive symptoms in older adults during the pre- and postliving lab surveys. Scores ranged from 0 to 15, with cutoff scores of ≥5 and ≥10 indicating a risk for mild and severe depression, respectively.

Pittsburgh Sleep Quality Index

Subjective sleep quality was evaluated using the Pittsburgh Sleep Quality Index (PSQI) in the pre- and postliving lab surveys [37,38]. The PSQI comprises 19 items and assesses 7 components of sleep over the past month. The total PSQI score was utilized to indicate the overall level of subjective sleep quality, with a cutoff score of 5 or more indicating a risk for sleep disorders.

System Usability Scale

The *System Usability Scale* (SUS) was used to gauge the older adults' experience levels and perceived difficulty in using the digital monitoring platform during the pre- and postliving lab surveys [39]. The scale includes questions regarding the participant's frequency of digital technology usage and their perception of its ease of use, among others. Responses are rated on a 5-point scale ranging from 0=strongly disagree to 4=strongly agree.

Many older adult participants encountered challenges in identifying digital technology to base their answers on for this scale during the preliving lab survey. This survey was conducted on the day when the digital health monitoring platform was installed. To assist participants in answering the survey, examples of digital devices such as smartphones or kiosks at hospitals were provided. Postliving lab assessments of the SUS were conducted based on the participants' experiences with the developed health monitoring platform.

In addition to the SUS, participants were queried about the number of days per week they utilized the platform and the number of functions they accessed on the platform during the postliving lab survey. Furthermore, at the posttest, participants were requested to offer qualitative feedback aimed at enhancing the platform for future trials. This feedback was transcribed verbatim by a research assistant.

Covariates

Covariates were selected a priori, drawing from existing literature that outlines demographic and health risk factors associated with daily depressive symptoms among older adults [7,40]. Alongside baseline depression levels, demographic and health factors known to be correlated with depression (eg, age, sex, and chronic health conditions) were utilized as covariates.

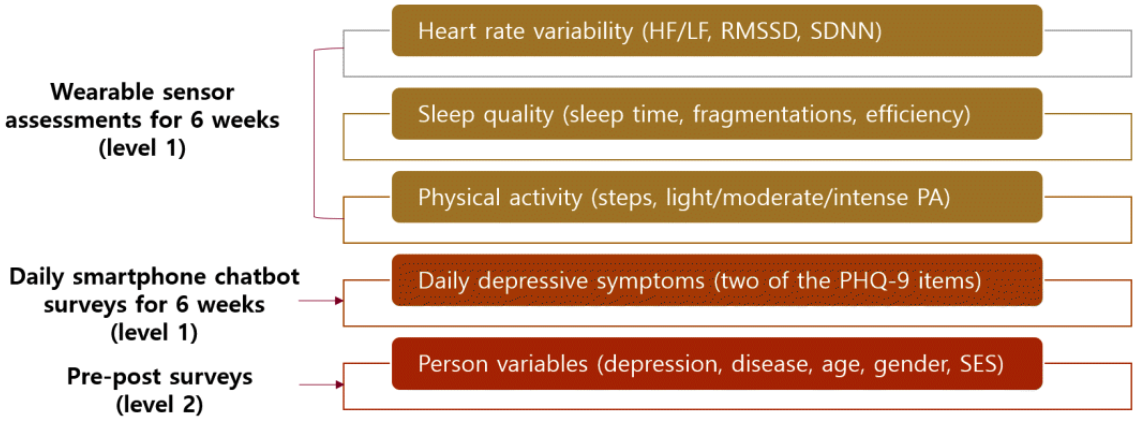
Statistical Analysis

After analyzing missing data and assessing the distributions of key variables, descriptive analyses were performed. Group comparisons between depressed and nondepressed older adults were conducted using *t* tests for continuous variables (eg, age, BMI, PSQI total score, daily depressive symptoms, wearable sensor assessments of HRV, sleep, and PA indicators), chi-square tests for categorical variables (eg, sex, education, income, chronic disease, sleep disorder categories), and Fisher exact tests for smoking status. Subsequently, bivariate correlations were explored between baseline depression and person mean variables (daily depressive symptoms and wearable sensor assessments) over 5 weeks, excluding the initial week for adaptation.

To identify digital biomarkers for daily depressive symptoms in older adults, we used multilevel modeling (MLM) analysis. This method allowed us to scrutinize the daily shifts in depressive symptoms, as well as the smartwatch-detected metrics of sleep quality, HRV, and activity levels over time. We utilized SAS PROC MIXED (SAS Institute) for this analysis. Applying MLM analysis to daily depression and smartwatch data facilitates the identification of antecedents and correlates of daily depressive symptoms. It also allows for the use of participants as their own controls [41]. In the multilevel models, the level 1 equation investigated whether daily sleep, HRV, and PA indices predicted the likelihood of reporting any depressive symptoms on the same day and the following day. To assess the primary impact of smartwatch indices on daily depressive symptoms, the main effect models for each of the sleep/HRV/activity model indices were utilized as level 1 predictors, with daily depressive symptoms on the same day or the next day serving as level 1 outcome variables. In all MLM analyses, the level 2 equations incorporated personal characteristics, including participants' demographic and health covariates. Daily measures were person mean centered, while level 2 covariates were grand mean centered. This approach allows for the interpretation of estimates as the probability of daily depressive symptoms when there are deviations in the predicting digital biomarker variable from the participant's own average across the 5-week living lab period. The multilevel data structure of this study is illustrated in Figure 4. A type I error rate of 0.05 was established for statistical analyses, except for the MLM analyses, where Bonferroni and Holm corrections for multiple testing were applied, resulting in a type I error rate of 0.005.

The pre- and posttest results were assessed using a paired *t* test for variables demonstrating normal distributions, such as system usability. However, because of their skewed distributions, depressive symptoms and sleep quality were analyzed using the Wilcoxon signed rank test. To delve deeper into the age moderation effects on the pre- and posttest results for usability, repeated-measure ANOVA was applied to examine potential differences in system usability between the oldest group (>75 years old) and the rest (65-74 years old).

Figure 4. Multilevel data structure of this study with wearable sensor and daily depressive symptom chatbot survey data as level 1 and pre- and posttest survey data as level 2. HF: high frequency; LF: low frequency; PA: physical activity; PHQ-9: 9-item Patient Health Questionnaire; RMSSD: root mean square of successive differences; SDNN: standard deviation of N-N intervals; SES: socioeconomic status.



Power Analysis

Power analysis for multilevel model design is recognized for its complexity. Previous studies have revealed a compensatory relationship between the number of participants and the number of observations per participant [42,43]. We gathered 807 days of observational data from 25 older adults, averaging 32.28 days per participant (range 8-40 days). The variability in the number of available days stemmed primarily from 2 reasons: participants' nonadherence to data collection protocols (eg, forgetting to wear the Fitbit) and the scheduling preferences for installing and removing digital devices from their homes (eg, 1 participant needed to schedule device removal 1 week later than others because of personal reasons). A recent simulation study proposed that a sample size of 25 combined with continuous data collection over 30 days yields acceptable performance levels in terms of parameter estimations [42].

Data Exclusion and Missing Data

Out of the initial 31 adults who participated, data from 6 participants were excluded from the study. They dropped out after the installation of sensing devices due to experiencing inconvenience and difficulties in using mobile apps and digital devices. Among the initial group, 25 older adults provided their responses to daily verbal surveys and wearable sensor data. These data were included in the multilevel analyses, focusing on the primary outcome of daily depressive symptoms. Of 808 days of assessments (with a mean of 32.32 days per participant), there were 186 days (23% of total days) with missing daily verbal survey data, primarily as a result of participants forgetting to respond or no responses being recorded. Additionally, there were 269 days (33.3%) with missing HRV data, 440 days (54.5%) with missing sleep measures, and 298 days (36.9%) with missing steps data. These missing data were primarily attributed to participants forgetting to wear a smartwatch during the day or night, or experiencing issues with charging the device. Previous studies on missing data analysis suggest that multilevel analyses using full information maximum likelihood estimation methods are generally robust against estimation biases arising from data with partial missingness [44]. Regarding pre-post test effects, 1 participant did not complete the posttest survey as a result of long-term travel for family matters, resulting in data from 24 older adults being included in the analyses.

Results

Descriptive Overview

The demographic and health characteristics of the older adult living lab participants are detailed in Table 1. The participants exhibited characteristics typical of older adults, with a mean age of 76.40 (SD 4.23) years. Additionally, they displayed social vulnerabilities concerning education and income levels. Among the participants, there were more women (n=19) than men (n=6). On average, participants reported having 4 chronic disease conditions, with 3 (12%) of the 25 participants reporting depressive disorders and 10 (40%) reporting arthritis or diabetes. The average level of sleep quality was poor, with 22 (88%) participants at high risk for sleep disorders.

Compared with individuals with a low risk of depression at baseline, those with a high risk were more likely to report daily depressive symptoms via verbal surveys. Additionally, they tended to sleep longer but with lower efficiency and were less likely to engage in light, moderate, and intense PA (*P* values ranged from <.001 to.02).

Figure 5 illustrates the 24-hour profile of heart rate on both total days and days when older adults reported depressive symptoms. The patterns of heart rate on days with depressive symptoms seemed to exhibit more variability throughout the day compared with total days.

Table 1. Characteristics of older adult living lab participants.

Characteristics	Total (n=25)	Baseline depressive symptoms[a]		*P* value
		No (n=15)	Yes (n=10)

[a]The presence or absence of depressive symptoms was determined based on a score of 5 or higher on the Geriatric Depression Scale.

[b]US $1=1344 Korean won.

[c]PSQI: Pittsburg Sleep Quality Index.

[d]Higher scores indicate worse sleep quality.

Figure 5. The average 24-hour profiles of heart rate on (A) total days and (B) days with depressive symptoms.

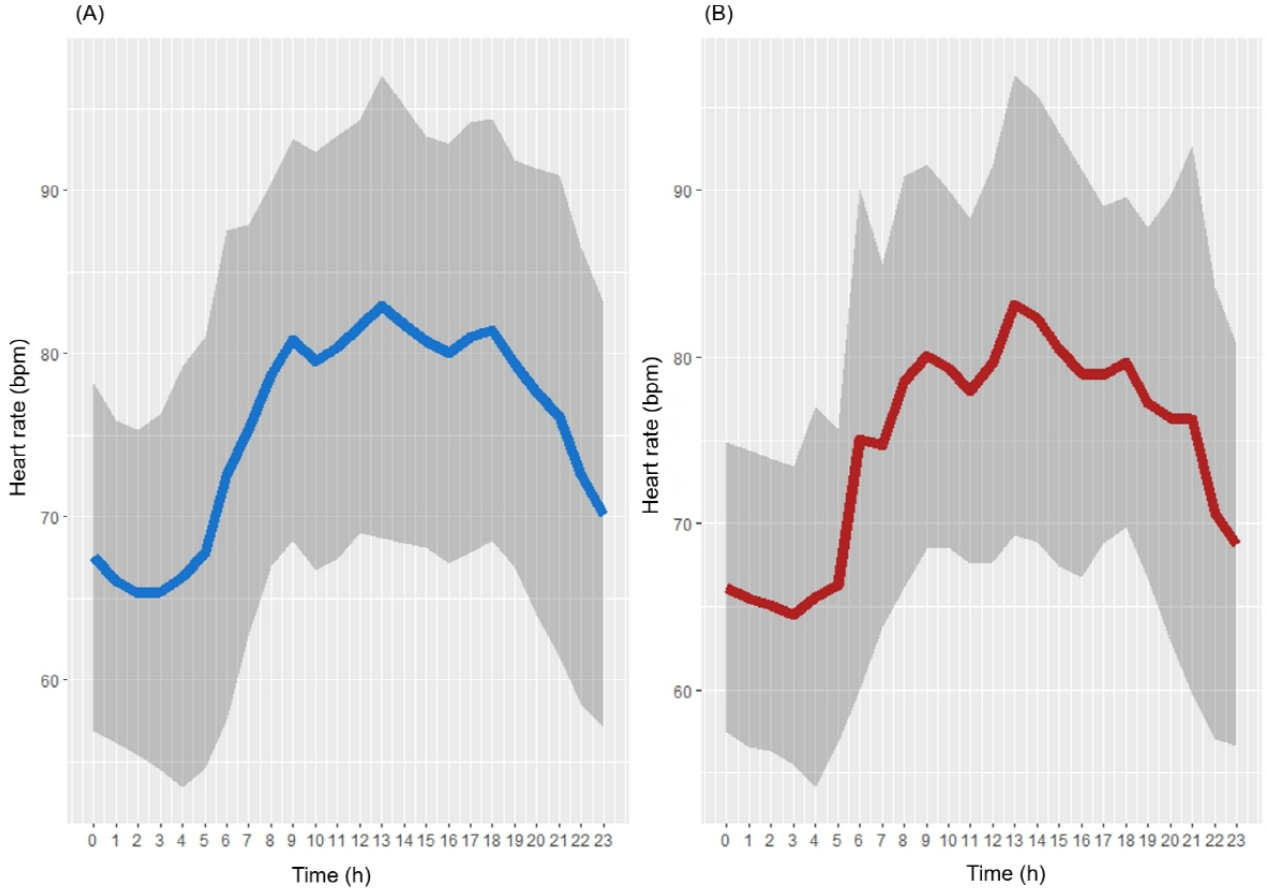

Figure 6 displays the results of bivariate correlation analysis among baseline depression measures; the person mean score of daily depressive symptoms; and the smartwatch measures of HRV, sleep quality, and PA. Additionally, distributions of the variables are presented on the diagonals. As anticipated, baseline depressive symptoms were significantly correlated with the person mean variable of daily depressive symptoms (r=0.43, P=.03). Interestingly, the person mean of daily depressive symptoms exhibited a negative association with daily sleep efficiency (r=–0.47, P=.02) and the amount of moderate PA (r=–0.50, P=.02). Furthermore, HRV, sleep, and PA indicators exhibited correlations with each other. Specifically, person mean variables of daily HF and root mean square of successive differences were associated with daily sleep efficiency (r=0.58, P=.003 and r=–0.51, P=.009, respectively). Additionally, the person mean levels of daily HRV indicators were associated with the person mean levels of daily PA. HF exhibited a positive correlation with light PA (r=0.49, P=.03), whereas SD of the N-N intervals was positively associated with light (r=0.45, P=.05), moderate (r=0.54, P=.01), and intense PA (r=0.59, P=.006).

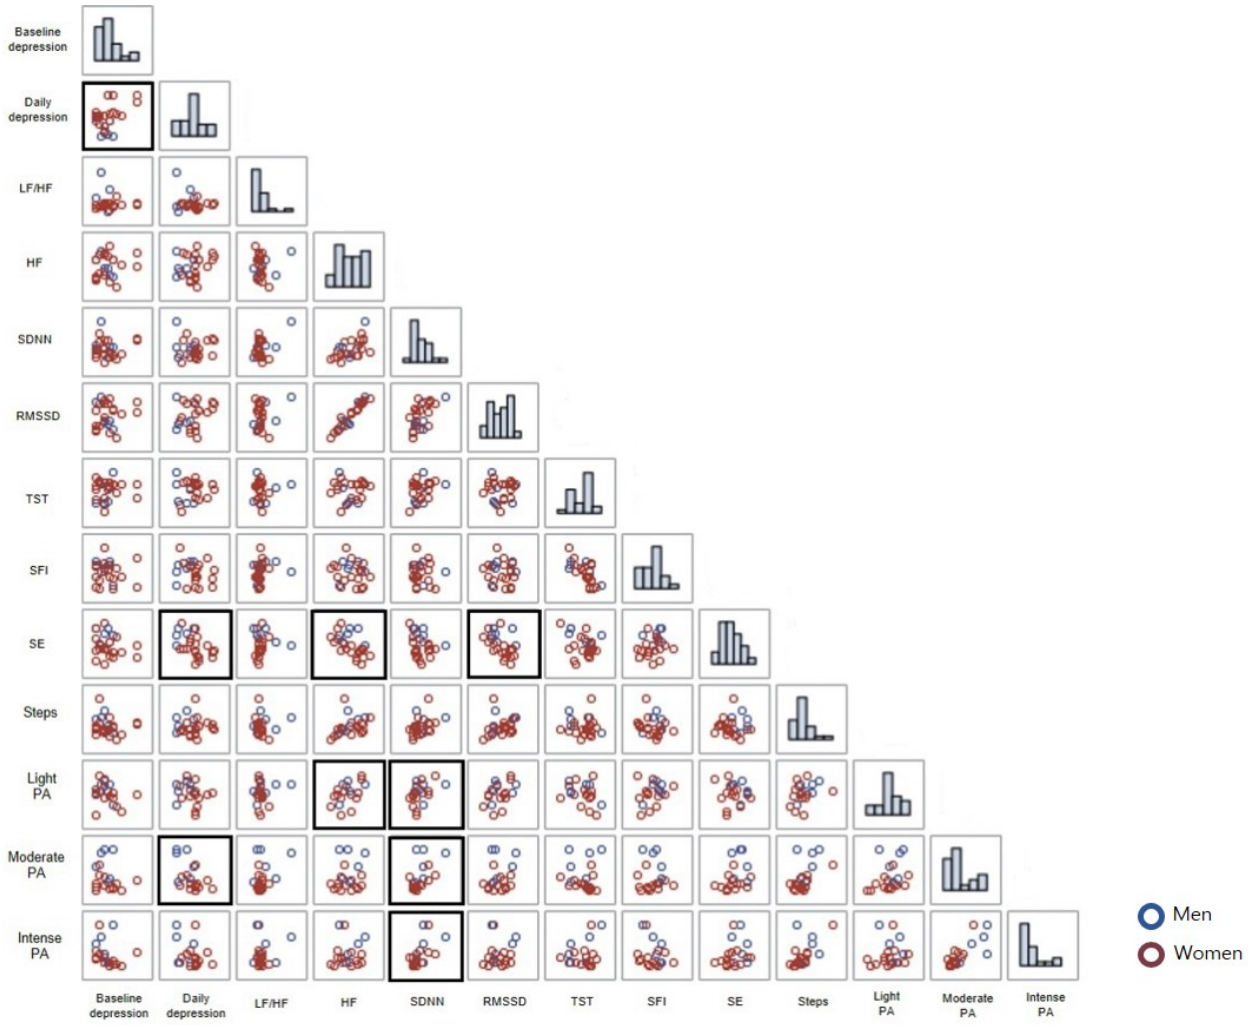
Figure 6. Bidirectional correlations among baseline depression; person mean of daily depression; and digital markers of heart rate variability indicators, sleep indicators, and physical activity measures (bold box indicates significance at $P<.05$; red dots represent women, blue dots represent men. HF: high frequency; LF/HF: low frequency-to-high frequency power ratio; PA: physical activity; RMSSD: root mean square of successive differences; SDNN: standard deviation of N-N intervals; SE: sleep efficiency; SFI: sleep fragmentation index; TST: total sleep time.



Primary Outcomes

As depicted in Table 2, the MLM results indicated that both the daily sleep fragmentation index and sleep efficiency significantly predicted the occurrence of daily depressive symptoms measured on the subsequent day, even after adjusting for baseline depression, age, sex, and chronic disease conditions (odds ratio 2.066, 95% CI 1.252-3.411; P=.003 for daily sleep fragmentation and odds ratio 0.972, 95% CI 0.955-0.989; P=.001 for daily sleep efficiency). In essence, on days following more fragmented sleep or lower sleep efficiency compared with their own average, older adult participants were more inclined to report depressive symptoms via the chatbot survey. Notably, the effects of daily sleep fragmentation and efficiency on daily depressive symptoms remained significant even after applying Bonferroni-Holm corrections for multiple testing. However, none of the daily assessments in HRV, sleep quality, or PA predicted the occurrence of depressive symptoms the following day.

Table 2. The concurrent and lagged effect models of daily digital indicators on daily depressive symptoms[a,b,c].

Digital predictors	Same-day depressive symptoms		Next-day depressive symptoms	
	Odds ratio (95% CI)	*P* value	Odds ratio (95% CI)	*P* value
Heart rate variability				
High frequency/low frequency	0.975 (0.790-1.204)	.82	0.929 (0.751-1.148)	.49
High frequency	0.987 (0.617-1.579)	.96	0.978 (0.632-1.513)	.92
SD of the N-N intervals	0.998 (0.990-1.005)	.57	1.001 (0.994-1.008)	.84
Root mean square of successive differences	0.954 (0.866-1.051)	.34	0.998 (0.924-1.078)	.96
Sleep				
Total sleep time	0.999 (0.996-1.001)	.16	1.001 (0.999-1.003)	.35
Sleep fragmentation index	2.066 (1.252-3.411)	.003[c]	1.149 (0.750-1.759)	.77
Sleep efficiency (%)	0.972 (0.955-0.989)	.001[c]	0.999 (0.983-1.016)	.93
Physical activity				
Steps	1.000 (1.000-1.000)	.28	1.000 (1.000-1.000)	.21
Light physical activity	0.999(0.996-1.002)	.48	1.002 (0.998-1.005)	.33
Moderate physical activity	0.992 (0.971-1.014)	.48	0.985 (0.964-1.006)	.16
Intense physical activity	0.998 (0.985-1.011)	.73	1.002 (0.989-1.015)	.75

[a]All analyses were adjusted for age, sex, chronic disease conditions, and baseline depression.

[b]All digital predictors were person mean centered so that daily values represent deviations from the individuals' own means across the participation days.

[c]The Bonferroni-Holm correction suggests that *P* values indicating significance should be <.005, with 11 multiple tests for each of the 2 outcome variables.

Pre- and Posttest Results

As presented in Table 3, the pre- and posttest results showed significant decreases in depressive symptoms (pre-post difference –1.000, 95% CI –2.000 to 0.000, W=143.500, z=–1.976, P=.048) and improvements in sleep quality (pre-post difference –1.500, 95% CI –3.000 to 0.000, W=165.000, z=–2.252, P=.02) after the 6-week living lab than before. However, there were no significant changes in the levels of usability (pre-post difference –6.354, 95% CI –15.969 to 3.261, t_{23}=–1.376, P=.18). Age moderation was also not significant in the pre- and posttest changes in usability ($F_{1,22}$=437.682, P=.20). At the posttest survey, participants reported using the monitoring app a mean of 6.68 (SD 1.44) days per week and utilizing 1.58 functions (SD 1.91) out of a possible 5. These functions included recording verbal surveys for daily depressive symptoms and checking individualized health feedback for stress, steps, physical functions, and sleep time.

In the posttest survey, older adults expressed satisfaction with the chatbot survey, particularly appreciating its inquiries about their daily lives and health conditions. They felt cared for and safe, knowing that their voice message would be delivered to their community caregiver daily. However, older adults also voiced frustrations with smartwatch malfunctions. They experienced technical issues during the living lab period as a result of difficulties in regularly charging the smartwatch, accidentally turning off the smartphone's Bluetooth connection, and overloading of the central server.

Table 3. Changes in depressive symptoms, sleep quality, and usability levels from pre- to posttests.

Variables	Pretest	Posttest	*P* value
Depressive symptoms (Geriatric Depression Scale), median (IQR)[a]	3.000 (1.000-6.000)	1.500 (0.250-5.000)	.048
Sleep quality (Pittsburg Sleep Quality Index), median (IQR)[a]	8.000 (6.000-10.000)	6.000 (4.000-7.750)	.02
Usability (System Usability Scale), mean (SD)[b]	53.333 (24.524)	59.688 (19.620)	.18

[a]Wilcoxon signed rank test was used to analyze depressive symptoms and sleep quality due to their skewed distributions.

[b]Paired *t* test was used to evaluate usability based on a normal distribution of the usability scores.

Discussion

Principal Findings

This study explored the viability of digitally phenotyping depressive symptoms and implementing continuous digital mental health monitoring among a small cohort of socially vulnerable older adults (n=25) in their everyday living settings. By conducting daily verbal assessments of depressive symptoms via a chatbot and monitoring daily fluctuations in digital biomarkers using a smartwatch, this study indicates that 2 digital measures of daily sleep quality, namely, sleep fragmentation and sleep efficiency, predicted the occurrence of daily depressive symptoms on the subsequent day. These associations remained significant even after adjusting for potential confounders such as baseline depression, age, gender, and chronic disease conditions. To the best of our knowledge, this study represents the first attempt to explore the digital phenotyping of depressive symptoms in socially vulnerable older adults within their own living environments over an extended duration. Furthermore, the pre- and posttest findings revealed that while depressive symptoms and sleep issues improved following the 6-week platform utilization alongside community caregiver support, no significant enhancement was observed in system usability. Although the current findings are preliminary and lack a comparison group, they suggest the potential health advantages of integrating a digital health monitoring platform for older adults in conjunction with in-person community senior care services.

Comparison With Prior Work

Through the development of analytic algorithms for continuous sensing of sleep time, fragmentation, and efficiency, this study unveiled that daily alterations in sleep fragmentation and efficiency during the night, relative to an individual's average, were predictive of daily depressive symptoms among older adults on the subsequent day. These findings are consistent with prior studies that have demonstrated a significant correlation between actigraphy-assessed wake time after sleep onset, sleep efficiency, and 1-time survey assessments of depressive symptoms among adults with a history of clinical depression [12,40,45]. A meta-analysis of 38 studies incorporating actigraphy assessments similarly found significant disparities in longer wake time after sleep onset between patients with depression and healthy controls [46]. Our findings contribute to the existing literature by investigating daily variations in depressive symptoms among socially isolated older adults over an extended period. Moreover, this study examines whether within-person fluctuations in sleep quality forecast ongoing changes in depressive symptoms across consecutive days.

The current findings revealed that neither actigraphy-assessed HRV nor PA measures significantly predicted daily depressive symptoms. Prior research has demonstrated varied associations between HRV and depressive symptoms, depending on factors such as the diagnosis or severity of depression and the cardiovascular health of the population under study. Indeed, a meta-analysis of 21 studies highlighted significant distinctions between individuals with depression and healthy controls [47]. Additionally, a previous investigation involving patients with depression documented a negative correlation between HRV (eg, root mean square of successive differences) and cognitive symptoms of depression (eg, rumination) on the same day [48]. However, such relationships between HRV and depressive symptoms were not observed in adults without clinical depression or those with cardiovascular health issues. For instance, depressive symptoms were not significantly correlated with electrocardiogram-measured HRV in healthy adults [49] or adults at risk of coronary artery disease [50]. The majority of older adults (18/25, 72%) in this study had cardiovascular disease conditions, a prevalence higher than the national average in South Korea (40.36%) and the global prevalence (31.0%-70%) for adults over 70 years [51-53]. Future research with a larger sample of older adults is warranted to investigate the associations between depressive symptoms and HRV among older adults with diverse chronic disease conditions.

Regarding the association between depressive symptoms and PA, in contrast to previous findings, daily fluctuations in PA did not predict daily depressive symptoms in this study. Indeed, a meta-analysis comprising 42 studies utilizing actigraphy or pedometer assessments of PA demonstrated significant associations between average PA levels and depressive symptom severity among adults, regardless of clinical depression status [54]. Additionally, intervention programs aimed at increasing PA were associated with lower levels of depressive symptoms compared with control groups in adult populations without clinical depression [55]. There could be several potential explanations for the lack of association between daily PA and daily depressive symptoms observed in our study. It is plausible that long-term patterns of PA, rather than day-to-day fluctuations, may better explain changes in depressive symptoms. Consistent with this hypothesis, the present findings demonstrated a significant negative correlation between the average levels of depressive symptoms and the average levels of moderate PA across individuals. Future research is warranted to explore potential factors that might elucidate the relationship between daily depressive symptoms and PA. This could include investigating cumulative patterns of PA, the impact of specific types of PA (such as group exercise), or external circumstances that may impede physical activities (such as the COVID-19 pandemic).

Finally, the pre- and posttest findings indicated that older adults exhibited enhancements in depressive symptoms and sleep quality following their utilization of the platform alongside their community caregivers. It is important to note that the participating older adults had previously been receiving in-person senior caregiving services, which entailed regular phone calls and weekly in-person visits for safety checks, as well as assistance with hospital visits if necessary. However, the utilization of the present digital monitoring platform may have empowered community caregivers to optimize the timing of service provision based on when older adults were most in need. For example, an older adult user received red lights on sleep and physical activity via the user app when they had poor sleep and skipped exercise due to a flare-up of chronic disease conditions. Their community caregiver received the same daily feedback and voice recordings (from the respective user) about health issues via the caregiver app. Subsequently, the caregiver

phoned or visited each participant to check on the negative health changes for that day. The current findings align with recent studies demonstrating the health-improving effects of digital health care services for older adults. These effects were observed when mental health professionals provided in-person services [56,57] or when community health workers with intensive training [58,59] were connected to the digital service. However, this study makes a unique contribution to the literature by presenting preliminary findings suggesting that community caregivers without a health care specialty or intensive training in mental health care can potentially enhance the mental health of socially vulnerable older adults through the utilization of a digital health monitoring platform.

Contrary to expectations, the results of the usability test in this study suggest that older adults experienced difficulties in using the mental health monitoring system, and these challenges did not improve over time. These findings underscore the importance of offering adequate in-person assistance, including group lessons, in-person training sessions, and troubleshooting visits for older adults when introducing a new digital health care service.

Limitations

Our findings should be interpreted with caution due to several limitations. First, the sample size was limited to 25 older adults, which may not have provided sufficient power to detect small effect sizes of associations between daily depressive symptoms and sensor-based daily indicators, as well as changes in outcome measures pre- to posttest. The current results may not be generalizable to other older adult populations or other countries due to our deliberate selection of older adults with social vulnerabilities, including those living alone with low income. These individuals may experience greater challenges in accessing digital technologies compared with the overall older adult population [60]. We used MLM to investigate the concurrent digital biomarkers of daily depressive symptoms. However, future studies may benefit from exploring alternative analytic approaches such as machine learning to classify older adults into high- and low-risk groups for depression. Additionally, it is important to acknowledge that the strict implementation of COVID-19–related social restriction policies in 2022 may have influenced the findings of this study.

Conclusions

This study investigated the feasibility of mental and physical health monitoring platforms for socially vulnerable older adults and their community caregivers in their everyday living environments. Additionally, it explored whether passively sensed measurements of HRV, sleep, and PA predicted daily fluctuations of depressive symptoms in older adults. The findings indicate that older adults successfully utilized the monitoring platform throughout the 6-week study to monitor their daily health status. This information was also shared with community caregivers to enhance the existing senior care service. Additionally, the MLM results revealed same-day associations between daily sleep quality indicators (sleep fragmentation index and sleep efficiency from the previous night) and daily depressive symptoms. The pre- and posttest results indicate that older adults exhibited enhancements in depressive symptoms and sleep quality following the utilization of the monitoring platform, which was integrated with their existing community care services. These findings offer preliminary support for the digital phenotyping of geriatric depressive symptoms using sleep measures obtained from a wearable sensor. We also propose a potential service delivery model for developing a hybrid senior care service that integrates online and offline components. This model leverages existing community-based senior care services to facilitate the early detection and prevention of mental health declines in socially vulnerable older adults.

Acknowledgments

We are very grateful for the support of the staff at the Seong-buk City Senior Welfare Center, who assisted with the recruitment of participants and in-person data collection during the pandemic period. This study was supported by a grant from the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (grant number H21C0572); the Basic Science Research Program through the National Research Foundation of Korea (NRF), funded by the Ministry of Education (grant number NRF2020R1A6A3A0110041011); and the Pioneer Research Center Program through the National Research Foundation of Korea, funded by the Ministry of Science, ICT & Future Planning (grant number 2022M3C1A3081294).

Conflicts of Interest

JK and SS developed the health monitoring platform software in collaboration with M2S+ Co. and owned the intellectual property rights. The Department of Health and Welfare of the Korean Government provided funding for the development of this platform and owned the right to utilize the developed platform as a public service for older adults.

Abstract

Background: Attention-deficit/hyperactivity disorder (ADHD) is a common neurodevelopmental disorder in school-aged children. The lack of objective biomarkers for ADHD often results in missed diagnoses or misdiagnoses, which lead to inappropriate or delayed interventions. Eye-tracking technology provides an objective method to assess children's neuropsychological behavior.

Objective: The aim of this study was to develop an objective and reliable auxiliary diagnostic system for ADHD using eye-tracking technology. This system would be valuable for screening for ADHD in schools and communities and may help identify objective biomarkers for the clinical diagnosis of ADHD.

Methods: We conducted a case-control study of children with ADHD and typically developing (TD) children. We designed an eye-tracking assessment paradigm based on the core cognitive deficits of ADHD and extracted various digital biomarkers that represented participant behaviors. These biomarkers and developmental patterns were compared between the ADHD and TD groups. Machine learning (ML) was implemented to validate the ability of the extracted eye-tracking biomarkers to predict ADHD. The performance of the ML models was evaluated using 5-fold cross-validation.

Results: We recruited 216 participants, of whom 94 (43.5%) were children with ADHD and 122 (56.5%) were TD children. The ADHD group showed significantly poorer performance (for accuracy and completion time) than the TD group in the prosaccade, antisaccade, and delayed saccade tasks. In addition, there were substantial group differences in digital biomarkers, such as pupil diameter fluctuation, regularity of gaze trajectory, and fixations on unrelated areas. Although the accuracy and task completion speed of the ADHD group increased over time, their eye-movement patterns remained irregular. The TD group with children aged 5 to 6 years outperformed the ADHD group with children aged 9 to 10 years, and this difference remained relatively stable over time, which indicated that the ADHD group followed a unique developmental pattern. The ML model was effective in discriminating the groups, achieving an area under the curve of 0.965 and an accuracy of 0.908.

Conclusions: The eye-tracking biomarkers proposed in this study effectively identified differences in various aspects of eye-movement patterns between the ADHD and TD groups. In addition, the ML model constructed using these digital biomarkers achieved high accuracy and reliability in identifying ADHD. Our system can facilitate early screening for ADHD in schools and communities and provide clinicians with objective biomarkers as a reference.

Introduction

Background

Attention-deficit/hyperactivity disorder (ADHD) is a common neurodevelopmental disorder in school-aged children, characterized by deficits in attention, hyperactivity, and impulsivity. Globally, the estimated prevalence of ADHD in children and adolescents is approximately 5.29% [1]; in China, the prevalence is approximately 6.4% [2]. People with ADHD typically exhibit deficiencies in various cognitive domains, and these symptoms can persist into adolescence and adulthood, which can result in academic underachievement and societal issues, such as substance abuse and violence [3]. Therefore, early identification, diagnosis, and intervention for ADHD are essential.

Despite recent advances, the diagnosis of ADHD relies heavily on subjective judgments based on the observations of children's behavior. Consequently, this can lead to both over and underdiagnosis, as well as inappropriate treatments. Therefore, there is an urgent need to develop methods to identify reliable ADHD biomarkers. Furthermore, given that poor academic performance is the most common concern of individuals with ADHD, it is crucial that we improve awareness and understanding of ADHD among parents and teachers to ensure timely identification of ADHD. However, on the one hand, most nonmedical professionals cannot be expected to gain specialized medical expertise, and on the other hand, physicians cannot frequently visit campuses to aid in ADHD assessment. This situation has resulted in delays in diagnosing children with ADHD. Developing mobile screening equipment will enable on-campus ADHD screening to facilitate timely identification and diagnosis of ADHD.

Eye-tracking technology is particularly suited for the assessment and diagnosis of ADHD because it offers an objective measurement of children's neuropsychological behavior. Studies have shown that there is a significant overlap between the neural networks responsible for attention and those responsible for eye-movement control [4]. Children with ADHD experience difficulties with spatial perception and visual-motor integration [5], and these neurophysiological features associated with ADHD can be identified using eye-tracking assessments. In addition, children with ADHD often find lengthy and complex assessments challenging, particularly if they are required to wear additional equipment. Eye-tracking technology surpasses other neurophysiological techniques in its ability to record the neuropsychological activity of participants in a more natural setting [6]. This leads to better cooperation of children during assessments and higher reliability and generalizability of results.

Recent advances in computational psychiatry have enabled the extraction of eye-tracking metrics to discern behavioral alterations in children with ADHD [7-9]. These metrics encompass various aspects of visual attention, such as fixation duration, saccade velocity, and gaze entropy [10-12], which may serve as digital biomarkers for neurodevelopmental disorders [13,14]. By analyzing the temporal and spatial characteristics of eye movements, computational models can capture differences in visual behaviors between ADHD and typically developing (TD) children. Machine learning (ML) techniques have emerged as powerful tools for processing and interpreting large amounts of eye-tracking data [15-17]. Training ML models on labeled eye-tracking metrics has allowed the construction of robust and accurate classifiers to identify whether individuals belong to an ADHD or a TD group. Precise eye-tracking measurements and digital biomarkers hold great promise as objective and automated screening tools for ADHD, which will facilitate the development of early intervention strategies and improve the clinical outcomes of affected children [7,18,19]. Moreover, the evolution of mobile eye-tracking technology and devices, coupled with portable computing sources, such as smartphones and tablets, will allow the implementation of eye-tracking assessments in various scenarios and thus address the need for ADHD screening in the community [20-22].

Related Work

Neuroimaging studies have shown that children with ADHD have multidimensional brain function abnormalities. The impairment of inhibitory control is a fundamental factor contributing to cognitive and executive functioning deficiencies in individuals with ADHD [23]. However, these individuals also have motor coordination difficulties, poorer spatial perception [24-26], reduced auditory sensitivity, and problems with attentional integration of audiovisual stimuli [27].

Recently, there has been a growing interest in exploring the use of eye-tracking technology to study the neurophysiological features of ADHD. A meta-analysis of the various behavioral tests developed over the last 5 decades to evaluate eye movement and cognitive control [28] revealed that eye-tracking evaluations of children with ADHD yielded the most reliable and consistent outcomes when eliminating bias. Most of these tests focused on saccade, which is one of the most crucial type of eye movement. Children with ADHD perform significantly worse than TD children across all tasks, with greater variability for each metric in the antisaccade task [29].

To ensure that the screening method is appropriate for children with ADHD, we must use a paradigm that is brief and simple

to perform yet capable of highlighting cognitive deficits. In addition, the extracted eye-movement metrics should be able to comprehensively characterize children's task performance. Several recent studies have used eye tracking to explore the characteristics of ADHD. Lemel et al [30] incorporated spoken-word recognition accuracy, gaze duration, and the number of transitions in response to a phonological competitor to analyze spoken-word processing in adverse listening conditions in individuals with ADHD. However, this paradigm was complex and required word recognition and was thus more suited to adult patients. Another study used a paradigm to assess children's working memory; however, the task took 30 minutes to complete [31], which is not conducive to task completion in children with ADHD. Siqueiros et al [32] used the antisaccade task, which is a simple and reliable paradigm that suits children. However, only directional errors and expected eye movements were assessed; moreover, the paradigm was not sufficiently comprehensive to assess children's task performance.

Objectives

Studies conducted to date have provided valuable insight into automatic screening approaches for ADHD in children using eye-tracking devices. However, these studies have drawbacks that have hindered the development of a more robust and accurate auxiliary diagnostic system. For example, the paradigms were too time-consuming or complex for clinical ADHD screening, and the extracted metrics were not sufficiently comprehensive. ML models used in previous studies have typically achieved only modest accuracy and sensitivity, which limits clinical applicability. Furthermore, small sample sizes have limited the robustness of the results.

To address the aforementioned challenges, we aimed to develop an accurate and reliable auxiliary diagnostic system for ADHD in children using eye-tracking technology. Specifically, the objectives of this study were as follows:

1. To design an eye-tracking assessment paradigm that is easy to implement and can identify differences in eye-movement patterns between children with ADHD and TD children.
2. To extract effective eye-tracking metrics as digital biomarkers that quantitatively represent various aspects of eye-movement behaviors and use these biomarkers to construct and validate ML models to enable automatic screening of children for ADHD.
3. To achieve high accuracy and reliability of the ML model using a large dataset, which will facilitate early screening for ADHD and timely intervention for children with ADHD and thus contribute to improving the effectiveness of the health care system.

Methods

Participants

To ensure the representativeness of the ADHD and TD groups in this case-control study, we recruited participants from hospitals and schools separately. Children with ADHD were recruited from an outpatient clinic at a public pediatric hospital in Shanghai, China, whereas TD children were recruited from 2 general public elementary schools in Shanghai (one from an urban area and another from a suburban area). The children were divided into 3 age groups: group 1 (5-6 years), group 2 (7-8 years), and group 3 (9-10 years).

The inclusion criteria for the ADHD group were children in grades 1 to 3 with a clinical diagnosis of ADHD who were not currently receiving treatment. The inclusion criteria for the TD group were children in grades 1 to 3 with a negative assessment on the Swanson, Nolan, and Pelham Rating Scale (SNAP-IV) [33].

The exclusion criteria were children with a full-scale score of <75 on the Wechsler Intelligence Scale for Children; children who had a history of severe traumatic brain injury, neurological disorders, severe physical illnesses, and psychiatric illnesses (eg, mood disorders and schizophrenia); and those unable to undergo eye-tracking examinations.

From December 2022 to April 2023, a total of 100 children with a clinical diagnosis of ADHD were recruited. Of these, 4 participants with a history of severe traumatic brain injury, neurological disorders, and other severe physical and psychiatric disorders and 2 participants who were unable to tolerate the eye-tracking assessment were excluded. This resulted in 94 participants in the ADHD group.

A total of 150 children were randomly selected as the TD group. Of these, 15 children refused to participate in the program. In addition, 2 children with a history of severe traumatic brain injury, neurological disorders, and other severe physical and psychiatric disorders and 11 children who were considered to have ADHD after the interviews and evaluations were excluded. Finally, 122 children were included in the study as the TD control group.

All personnel involved in administering the assessments in this study were full-time child health practitioners who had been working in child health care for more than 3 years. Standardized survey administration training was provided before the tests were administered.

Ethical Considerations

Before the assessment began, the purpose of the project was explained to the children and their guardians, and written informed consent was obtained from the guardians. All participants could withdraw at any stage of the study. Interviews were then conducted with the guardians to gather data on the basic conditions of the children. Children who fulfilled the inclusion and exclusion criteria were formally enrolled in the study and underwent the SNAP-IV and eye-tracking assessments. All data will be stored in a deidentified form. No participants will receive any benefit from participating in this study, but they will receive a booklet reporting the results of the assessments involved in this study as a souvenir.

The study protocol and informed consent form were approved by the Shanghai Children's Hospital Institutional Review Board (2022R126-F01).

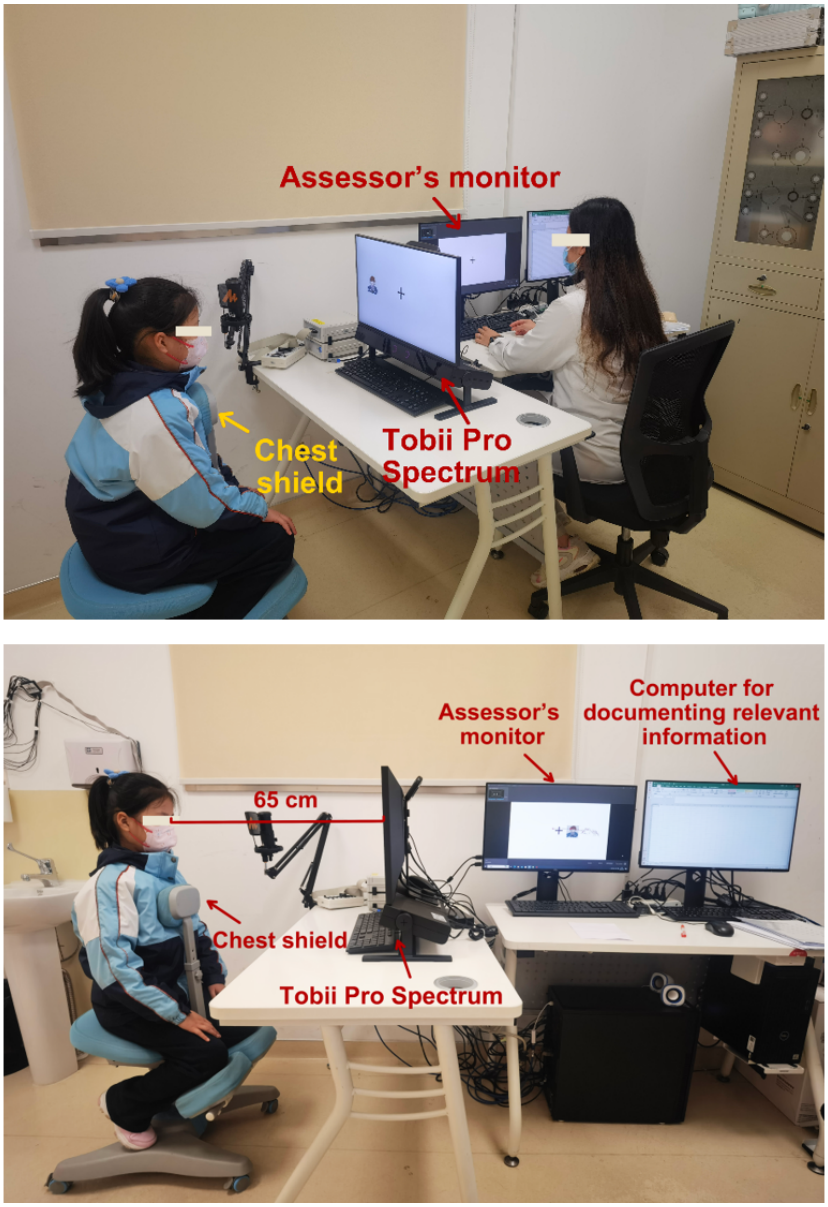
Paradigm Design

Overview

Eye movements were recorded at a sampling rate of 1200 Hz using the Tobii Pro Spectrum eye tracker (Tobii Pro AB), a screen-based eye tracker that captures eye movements and pupillary responses. Visual stimuli were presented at a screen response rate of <5 milliseconds on a 24-inch monitor with a resolution of 1920×1080 pixels (16:9 ratio). The Tobii Pro Lab software (version 1.194; Tobii Pro AB) was used to set up the experiment.

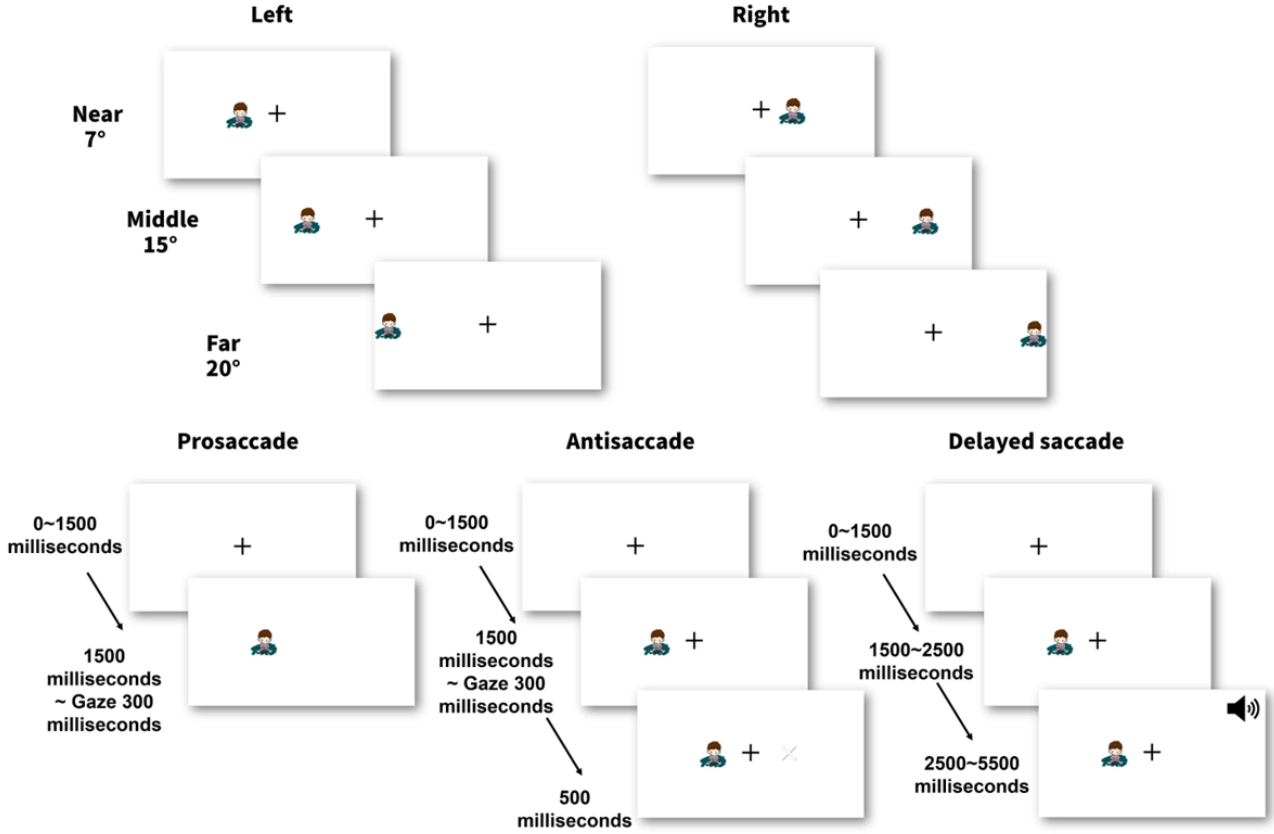
The assessment procedure was performed in a quiet room with only 1 overhead light source (Figure 1). Participants were seated in a special seat with a chest shield to limit upper body movement and help stabilize the head. The cushion was adjusted to ensure that the center of the screen was at the same level as the participant's head. The participant was seated in a position in which they were unable to observe the assessor's screen or operations to minimize distractions. Participants maintained a distance of 65 cm from the screen and began the formal assessment following a 5-point calibration. Before each task, a prompt screen appeared, and the assessor provided detailed instructions to ensure that the participant fully understood the task content before proceeding with formal testing.

Figure 1. Eye-tracking assessment scenario settings.



During the assessment, participants were asked to complete 3 saccade tasks sequentially (Figure 2): prosaccade, antisaccade, and delayed saccade. The stimulus was 5 cm high and 5 cm wide and randomly appeared on the left or right side of the screen. There was a central fixation cross in the middle of the screen, and the stimuli were set at 7°, 15°, and 20° away from the central cross for the different eccentricities. For each trial, a stimulus would randomly appear twice at one of the aforementioned 6 positions.

Figure 2. The eye-tracking assessment paradigm.



Prosaccade Task

Prosaccade, also known as reflexive saccade or visually guided saccade, is an abrupt eye movement triggered by the sudden appearance of a stimulus [34]. It is primarily induced by exogenous stimuli and serves as a baseline measure. In the prosaccade task, participants were instructed to initially fixate on the central fixation cross. After 1500 milliseconds, a stimulus appeared randomly in one of the aforementioned 6 positions. Participants were required to quickly shift their gaze toward the stimulus. Once participants fixated on the stimulus area (SA) for more than 300 milliseconds, the next trial was started automatically.

Antisaccade Task

In the antisaccade task, participants were required to first fixate on the central fixation cross. After 1500 milliseconds, 1 stimulus appeared randomly in one of the 6 aforementioned positions. Participants were required to quickly shift their gaze to the target area (TA), which was the location symmetrically opposite to the stimulus relative to the central fixation cross. Upon maintaining fixation at the TA for more than 300 milliseconds, a white feedback cross automatically appeared at the TA position to indicate success before proceeding to the next trial. If the participant decided to abandon the trial, the assessor pressed the space bar to skip the trial, and a white cross was displayed at the TA before moving on to the next trial. Previous studies have used a paradigm in which the central fixation cross disappears when the stimulus is presented [28]. However, this can make accurately localizing the TA more challenging, which may result in children being unable to complete the task. Therefore, in this study, the central cross was retained to assist participants in locating the TA.

Delayed Saccade Task

The delayed saccade task, based on the go–no-go paradigm [35], was adapted to the cognitive abilities of children with ADHD. This task not only directly assesses inhibition but also requires participants to combine auditory discrimination and visuomotor modulation. Thus, the task assesses the multisensory integration and coordination capacity of individuals with ADHD. During the task, participants were instructed to fixate on the central fixation cross. After 1500 milliseconds, 1 stimulus appeared randomly in one of the 6 aforementioned positions. Participants were asked to maintain fixation on the central cross until they heard a sound cue after 1000 milliseconds, after which they were required to shift their gaze toward the SA as fast as possible. Then, after another 3000 milliseconds, the next trial was started automatically.

For each saccade task, there were 12 formal trials (2 trials for each position). Before the formal test, practice trials were provided, where stimuli were presented randomly in the 6 positions, to allow participants to familiarize themselves with the task.

Area of Interest Division Across Tasks

To quantify the eye movements made during the different tasks, we divided the area viewed by participants into different areas (Figure 3): the TA, the SA, the center area (CA), the unrelated area (UA), the proper-side area (PSA), and the wrong-side area (WSA). The TA represented the area that participants were

required to fixate on, and the SA represented the area of the stimulus. For the delayed saccade task, we further divided TA into TA during the proper period (TA-P) and TA during the wrong period (TA-W) to represent the TA area in the proper or wrong time periods, respectively (Figure 4). The TA and SA were the same in the prosaccade and delayed saccade tasks, whereas in the antisaccade task, they were horizontally symmetrical. The CA represented a 5 cm × 5 cm area around the central fixation cross. The UA was unrelated to the task requirements and expected to attract minimal attention during the tasks. The PSA and WSA were defined for the antisaccade task only and represented the proper and wrong areas, respectively, besides the CA.

Figure 3. Illustration of the division of areas for extracting area-based eye-tracking metrics. CA: center area; PSA: proper-side area; SA: stimulus area; TA: target area; UA: unrelated area; WSA: wrong-side area.

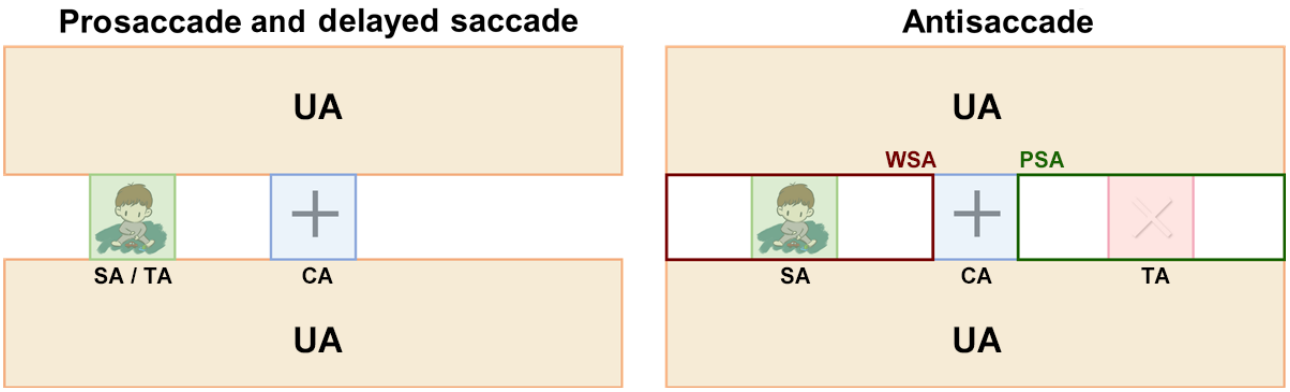


Figure 4. The different completion statuses in the delayed saccade task. From 0 to 1500 milliseconds, participants were asked to gaze at the center area (shaded area in a). If fixation fell into the shaded area in b, this indicated the occurrence of an intrusive saccade. From 1500 to 2500 milliseconds, participants were asked to maintain their fixation on the center area (shaded area in c) until they heard the cue. Thus, if fixation fell into the shaded area in d during this period, this was defined as a target area during the wrong period fixation (ie, saccade to the target area (TA) but during the wrong period). At 2500 milliseconds, the sound cue was presented, and participants were required to fixate on the TA (shaded area in e) as fast as possible. Fixation on the shaded area after 2500 milliseconds was defined as a target area during the proper period fixation (ie, saccade to the TA during the proper period).

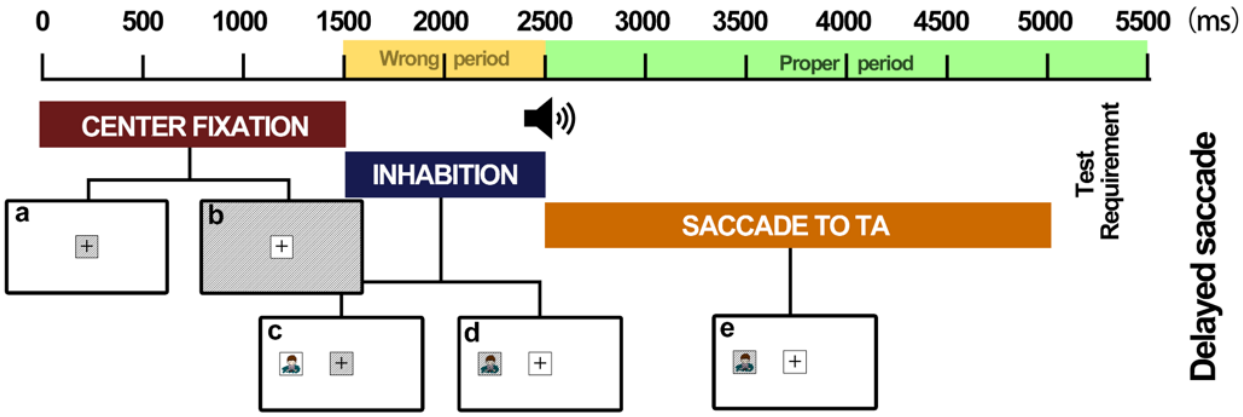


Extraction of Digital Biomarkers

Overview

On the basis of the eye-tracking paradigm, we calculated 28 digital biomarkers from the raw data recorded by the eye tracker. These biomarkers quantitatively reflect various behaviors of participants during the task, which were divided into 5 categories: general metrics (8/28, 29%), pupil-based metrics (4/28, 14%), area-based metrics (11/28, 39%), search-based metrics (3/28, 11%), and entropy-based metrics (2/28, 7%). For each assessment trial, we recorded 4 trial attributes (ie, task: prosaccades, antisaccades, and delayed saccades, target side: left and right, target eccentricity: 7°, 15°, and 20°, and trial order: first and second) and 6 participant attributes (ie, name, ID, category [ADHD and TD], sex [male and female], age, and age group). Table 1 summarizes these biomarkers in terms of category, symbol, description, and task.

Table 1. Descriptions of the digital biomarkers.

Category and symbol	Description	Task
General metrics		
$N_{Fix.}$	Total number of fixations	All[a]
$N_{Sac.}$	Total number of saccades	All
T_{Total}	Total duration of the trial	All
$T_{Fix.\ Avg.}$	Average fixation duration	All
$T_{Sac.\ Avg.}$	Average saccade duration	All
$V_{Sac.\ Avg.}$	Average saccade velocity	All
$V_{Sac.\ Peak}$	Peak value of saccade velocity	All
$A_{Sac.\ Avg.}$	Average saccade amplitude	All
Pupil-based metrics		
$D_{Pupil\ Avg.}$	Average pupil diameter	All
$D_{Pupil\ Max.}$	Maximum pupil diameter	All
$D_{Pupil\ Min.}$	Minimum pupil diameter	All
$D_{Pupil\ Sd.}$	SD of pupil diameter	All
Area-based metrics		
$B_{TA\ Fix.}$	Boolean value to signify the occurrence of fixations in the TA[b] (TA-P[c] for the delayed saccade task)	All
$L_{TA\ Fix.}$	Fixation latency of the TA (TA-P for the delayed saccade task)	All
$N_{UA\ Fix.}$	Number of fixations in the UA[d]	P[e] and A[f]
$N_{TA\ Fix.}$	Number of fixations in the TA for the whole period	D[g]
$N_{TA\text{-}P\ Fix.}$	Number of fixations in the TA for the proper period	D
$N_{TA\text{-}W\ Fix.}$	Number of fixations in the TA for the wrong period	D
$N_{SA\ Fix.}$	Number of fixations in the SA[h]	A
$B_{PSA\ Fix.}$	Boolean value to signify the occurrence of fixations in the PSA[i]	A
$B_{WSA\ Fix.}$	Boolean value to signify the occurrence of fixations in the WSA[j]	A
$B_{PSA\ Fix.\ 1st}$	Boolean value to signify if the first fixation located in the PSA	A
$B_{Intrusive\ Sac.}$	Boolean value to signify the occurrence of intrusive saccade during the center fixation period	D
Search-based metrics		
B_{Search}	Boolean value to signify the occurrence of the search behavior	A
N_{Search}	Number of search behavior occurrences	A
T_{Search}	Total duration of search behavior	A
Entropy-based metrics		
SGE_{norm}	Normalized stationary gaze entropy	All
GTE_{norm}	Normalized gaze transition entropy	All

[a]All: all tasks, including prosaccade, antisaccade, and delayed saccade tasks.

[b]TA: target area.

[c]TA-P: target area during the proper period in the delayed saccade task.

[d]UA: unrelated area.

[e]P: prosaccade task.

[f]A: antisaccade task.

[g]D: delayed saccade task.

[h]SA: stimulus area.

[i]PSA: proper-side area.

[j]WSA: wrong-side area.

General Metrics

Human eye-movement patterns can be divided into fixations, saccades, and pursuits [36], of which the former 2 patterns are the focus of our paradigm. Using the Tobii Pro Lab software, we extracted the fixations and saccades of participants in chronological order from the raw gaze data. Subsequently, we calculated the total number of fixations ($N_{Fix.}$) and saccades ($N_{Sac.}$) and their average durations ($T_{Fix.\,Avg.}$ and $T_{Sac.\,Avg.}$), which reflects participants' holistic visual behavior. The velocity and amplitude of saccades were automatically recorded by the software. We calculated the average and peak saccade velocity ($V_{Sac.\,Avg.}$ and $V_{Sac.\,Peak}$) and the average saccade amplitude ($A_{Sac.\,Avg.}$) for each trial. These values reflect the scanning and information retrieval process, respectively. In addition, the total time taken for each trial (T_{Total}) was recorded.

Pupil-Based Metrics

Pupil size is a crucial physiological measure that reflects autonomic nervous system activity, cognitive load, and emotional arousal. It has been applied extensively to various research fields [37-40]. The eye tracker continuously recorded participants' pupil diameter during each trial. We preprocessed the raw data and extracted pupil-based metrics following 5 steps (Textbox 1) [41].

Textbox 1. Preprocessed raw data and extracted pupil-based metrics.

Step 1: We removed samples labeled by the eye tracker as "invalid" and pupil diameters that fell outside the feasible range of 1.5 to 9.0 mm.

Step 2: We calculated pupil dilation speed to remove samples with a disproportionately large change in pupil size, which was usually caused by blinks or system errors. Because of the inconsistent sampling intervals, pupil diameter changes were not directly comparable between adjacent samples. Therefore, we calculated the normalized dilation speed between samples using the formula:

$$s_i = \max\left(\left| \frac{(p_i - p_{i-1})}{(t_i - t_{i-1})} \right|, \left| \frac{(p_{i+1} - p_i)}{(t_{i+1} - t_i)} \right| \right), \textbf{(1)}$$

where p_i and t_i are the pupil diameter sequence and timestamp sequence, respectively. To detect outliers in the dilation speed sequence (s_i), we calculated the threshold, T, using the median absolute deviation (MAD):

$$MAD = \text{median}\left(\left| s_i - \text{median}\left(s_i \right) \right| \right), \textbf{(2)}$$

$$T = \text{median}\left(s_i \right) + n \cdot MAD, \textbf{(3)}$$

where the scalar n was chosen as 1.5. Samples with an s_i larger than T were removed as outliers. Because the eye tracker simultaneously collected data from both the left and right pupils, we performed steps 1 and 2 for each pupil separately.

Step 3: We excluded samples in which data of 1 pupil was missing and calculated the mean data sequence of the left and right pupil diameters.

Step 4: Because of nonuniform sampling and the presence of noise, we used a size 20 sliding window to resample and smooth the data sequence at 500 Hz. This involved an exponential moving average based on the timestamp and skipped data gaps ≥50 milliseconds.

Step 5: Following the above preprocessing steps, we obtained a valid, uniform, and smooth sequence of pupil diameter data. We then calculated the average ($D_{Pupil\,Avg.}$), maximum ($D_{Pupil\,Max.}$), minimum ($D_{Pupil\,Min.}$), and SD ($D_{Pupil\,Sd.}$) pupil diameter values of the sequence for each trial, which reflect various aspects of the pupil state of participants.

Area-Based Metrics

We extracted a range of metrics according to the area of interest (AOI) divisions. A Boolean value for fixation incidence ($B_{TA\,Fix.}$) was recorded to signify the completion of the task by detecting whether the TA (or TA-P for the delayed saccade task) contained any fixations. The latency of the first fixation in the TA (or TA-P) was recorded as the fixation latency ($L_{TA\,Fix.}$). The number of fixations was counted for the SA (only in the antisaccade task), UA (in the prosaccade and antisaccade tasks), TA-P (only in the delayed saccade task), and TA-W (only in the delayed saccade task), which were denoted as $N_{SA\,Fix.}$, $N_{UA\,Fix.}$, $N_{TA\text{-}P\,Fix.}$, and $N_{TA\text{-}W\,Fix.}$, respectively. For the delayed saccade task, fixations outside of the CA during the center fixation period were defined as intrusive saccades and thus recorded as a Boolean value ($B_{Intrusive\,Sac.}$). For the antisaccade task, if fixations were detected in the PSA ($B_{PSA\,Fix.}$) or WSA ($B_{WSA\,Fix.}$), these were recorded as Boolean values. We also used a Boolean metric to signify that the first fixation that occurred after the stimulus appeared was located in the PSA ($B_{PSA\,Fix.\,1st}$).

Search-Based Metrics

During the antisaccade task, participants may have had difficulty determining the correct fixation position, which may have led to a series of consecutive fixations around the TA before finally reaching the TA. In practice, we detected fixations in the surrounding area outside the TA and within a distance of $1.5 \cdot L_{TA}$ from the TA center, where L_{TA} is the length of the TA edge. Therefore, the consecutive sequences of ≥2 detected fixations were extracted as search behaviors. For each antisaccade trial, we recorded the following search-based metrics: the occurrence of search behaviors (B_{Search}), the number of search behaviors (N_{Search}), and their total duration (T_{Search}).

Successful antisaccade trials required both a reversed saccade as well as an accurate landing position. Therefore, these metrics based on search behavior represent participants' vision control and distance perception abilities.

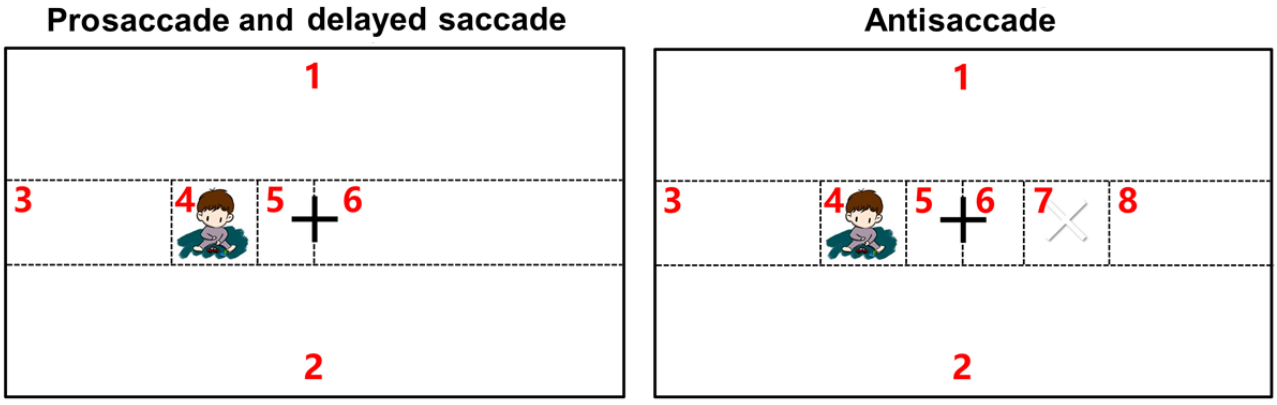
Entropy-Based Metrics

Entropy in information theory [42] suggests that gaze entropy reflects the degree of uncertainty or predictability exhibited by the human eye during visual exploration. Thus, gaze entropy can provide valuable insight into the cognitive processes involved in visual perception and attention. There are 2 types of gaze entropy: stationary gaze entropy (SGE) and gaze transition entropy (GTE) [43]. SGE evaluates the spatial distribution of fixations, with a higher value indicating a more dispersed eye-movement pattern [44]. GTE focuses on the randomness of eye movements between fixations and reflects the flexibility and complexity of the scanning pattern.

As shown in Figure 5, the images were divided into n different areas, which served as the individual state spaces of a discrete system. We calculated the proportion of fixations located in each area, denoted as p_i for the i-th area, which formed the approximate probability distribution of the states [45,46]. On the basis of the entropy equation by Shannon [42], SGE was calculated as follows:

$$SGE = -\text{sum}_i\,(\,p_i \cdot \log_2 p_i\,). \textbf{ (4)}$$

Figure 5. Division of areas for the calculation of gaze entropy metrics. It should be noted that the areas here are different from those for the area-based metrics shown in Figure 3.



Applying the first-order Markov transition matrix [47], we derived $p(j|i)$ from the fixation sequence, which represented the conditional probability of a gaze transitioning from the i-th to the j-th area. Then, GTE was computed based on the conditional entropy equation [47,48] as follows:

$$GTE = -\text{sum}_i\,(\,p_i \cdot \text{sum}_j\,(\,p(j|i) \cdot \log_2 p(j|i)\,)\,). \textbf{ (5)}$$

The maximum entropy of a system is determined by the number of available state spaces, which occurs when they are equally distributed [49]. To enable a comparison between different tasks, we used the corresponding maximum value, $H_{max} = \log_2 n$, to normalize the computed SGE and GTE into a range from 0 to 1:

$$SGE_{norm} = SGE / \log_2 n, \textbf{ (6)}$$

$$GTE_{norm} = GTE / \log_2 n. \textbf{ (7)}$$

As introduced earlier, n represents the number of areas, where n=6 for the prosaccade and delayed saccade tasks, and n=8 for the antisaccade task.

Statistical Analysis

We reviewed and uniformly numbered basic information and scale data. After eliminating data with incomplete information, data were entered in duplicate using the Chinese version of EpiData 3.1 (The EpiData Association), and Excel (version 2019; Microsoft Corp) was used to clean and organize the data.

The Tobii Pro Lab software was used to analyze basic eye-movement metrics and export data. Participants with >80% valid data were included in the analysis. Python (version 3.8) was used to extract the eye-tracking metrics.

All data were tested for normality and homogeneity of variance. Samples conforming to a normal or approximately normal distribution are represented as means and SDs, and nonnormally distributed data are described as means and 95% CIs. Count data are expressed as n (%), and differences between groups were calculated using the chi-square test. For visual harmonization, 4 valid digits were retained for the eye-tracking metrics. We used independent samples 2-tailed t tests to compare normally distributed data between the 2 groups. To compare nonnormally distributed data between the 2 groups, we used the Wilcoxon Mann-Whitney U test, and the Kruskal-Wallis test was used to compare among multiple groups. Paired comparisons for significant multiple-group comparisons were performed using the Bonferroni method. A 2-sided $P<.05$ was considered statistically significant.

ML Analysis

Overview

To validate the effectiveness of the proposed digital biomarkers, we conducted an ML analysis of the eye-tracking metrics to classify the ADHD and TD groups. First, we preprocessed the extracted metrics to meet the requirements of ML analysis and sequentially performed variable filtering, model construction, and model evaluation to verify the effectiveness of the extracted biomarkers. To ensure the reliability and generalizability of the model, we applied 5-fold cross-validation.

Data Preprocessing

The eye-tracking metrics were subdivided into multiple variables according to trial attributes (ie, task, target eccentricity, target side, and trial order). For each metric, we performed an average calculation for the target side and trial order, while maintaining different values for different task types and target eccentricities. For example, the metric $N_{Fix.}$ was obtained from the prosaccade, antisaccade, and delayed saccade tasks with 7°, 15°, and 20° target eccentricities, respectively, which were subdivided into 9 variables as follows: ${}^{P7}N_{Fix.}$, ${}^{P15}N_{Fix.}$, ${}^{P20}N_{Fix.}$, ${}^{A7}N_{Fix.}$, ${}^{A15}N_{Fix.}$, ${}^{A20}N_{Fix.}$, ${}^{D7}N_{Fix.}$, ${}^{D15}N_{Fix.}$, and ${}^{D20}N_{Fix}$. This ensured that the variability of the metrics would be reasonably preserved. The preprocessing resulted in 183 eye-tracking variables, and each participant became 1 data point for the ML analysis.

Model Construction

Before model training, we performed filtering to remove redundant variables and enhance computational efficiency. Variables that were significantly different between groups, compared using the Mann-Whitney *U* test, were retained.

To predict the categories of participants, we used the extreme gradient boosting (XGBoost) algorithm as the classification model. XGBoost is an advanced implementation of the gradient boosting decision tree framework, which sequentially builds an ensemble of decision trees to refine the prediction. The learning process minimizes the gradient of the loss function, thereby enhancing the model's performance. The XGBoost algorithm applies regularization techniques to efficiently boost the model and has thus demonstrated superior performance than the conventional gradient boosting decision tree framework in similar studies [50,51]. We implemented the XGBoost model in Python (version 3.8) using the packages *xgboost* (version 2.0.1) and *scikit-learn* (version 1.3.0). The hyperparameter settings of the model are listed in Multimedia Appendix 1, which are mainly the default values without adjustment to objectively illustrate the model's performance.

Model Evaluation

The 5-fold cross-validation method with 500 repeats was applied to evaluate classification performance. The model was trained with 173 samples and tested with 43 samples for each fold. To evaluate the models, we used the receiver operating characteristic (ROC) curve and the area under the ROC curve (AUC), which consider the trade-off between the true positive rate and false positive rate at various classification thresholds and provide a holistic assessment of the model's classification performance. We used the evaluation metrics of accuracy, sensitivity, specificity, precision, and F_1-score to quantify classification performance.

Variable Importance

When training the XGBoost model, the split gain was calculated at each node of the decision tree, which indicated the contribution of variables to the model. After the training process, the split gain was aggregated for each variable among all the decision trees to provide a comprehensive measure of the variable's relative importance in the classification of ADHD or TD groups.

Results

Characteristics of the Participants

A total of 216 participants (n=122, 56.5% in the TD group and n=94, 43.5% in the ADHD group) were enrolled in the study (Table 2). Overall, there was no significant difference in age (t_{214}=–0.30; P=.76); full-scale IQ (t_{214}=1.14; P=.25); or verbal IQ (t_{214}=0.03; P=.98) between the TD and ADHD groups. However, the ADHD group scored significantly lower than the TD group for performance IQ (t_{214}=2.08; P=.04). On the SNAP-IV, children in the TD group scored within the normal range, whereas the ADHD group scored significantly higher than the TD group on all 3 core symptoms (all P<.001).

Table 2. The basic information of the participants.

Variables	TD[a] (n=122)	ADHD[b] (n=94)	*t* test or chi-square test (*df*)[c]	*P* value
Sex, n (%)			37.28 (1)	<.001
Male	61 (50)	84 (89.4)		
Female	61 (50)	10 (10.6)		
Age (y), mean (SD)	7.18 (1.19)	7.24 (1.39)	–0.30 (214)	.76
Age group, n (%)			0.63 (2)	.73
Group 1 (5-6 y)	44 (36.1)	36 (38.3)		
Group 2 (7-8 y)	45 (36.9)	37 (39.4)		
Group 3 (9-10 y)	33 (27)	21 (22.3)		
IQ, mean (SD)				
Verbal IQ	97.36 (12.51)	97.41 (12.90)	0.03 (214)	.98
Performance IQ	103.02 (13.25)	99.01 (15.02)	2.08 (214)	.04
Full-scale IQ	100.06 (12.44)	98.11 (12.43)	1.14 (214)	.25
SNAP-IV [d], mean (SD)				
Inattentive	0.63 (0.25)	15.09 (0.75)	–199.20 (214)	<.001
Hyperactivity or impulsive	0.50 (0.30)	11.59 (0.82)	–137.43 (214)	<.001
Oppositional defiant	0.36 (0.12)	7.66 (0.56)	–118.54 (214)	<.001

[a]TD: typically developing.

[b]ADHD: attention-deficit/hyperactivity disorder.

[c]*t*-tests were used for variables presenting means and standard deviations (Age, IQ, and SNAP-IV scores), and chi-square tests were used for variables presenting numbers and percentages (Sex and Age group).

[d]SNAP-IV: Swanson, Nolan, and Pelham Rating Scale.

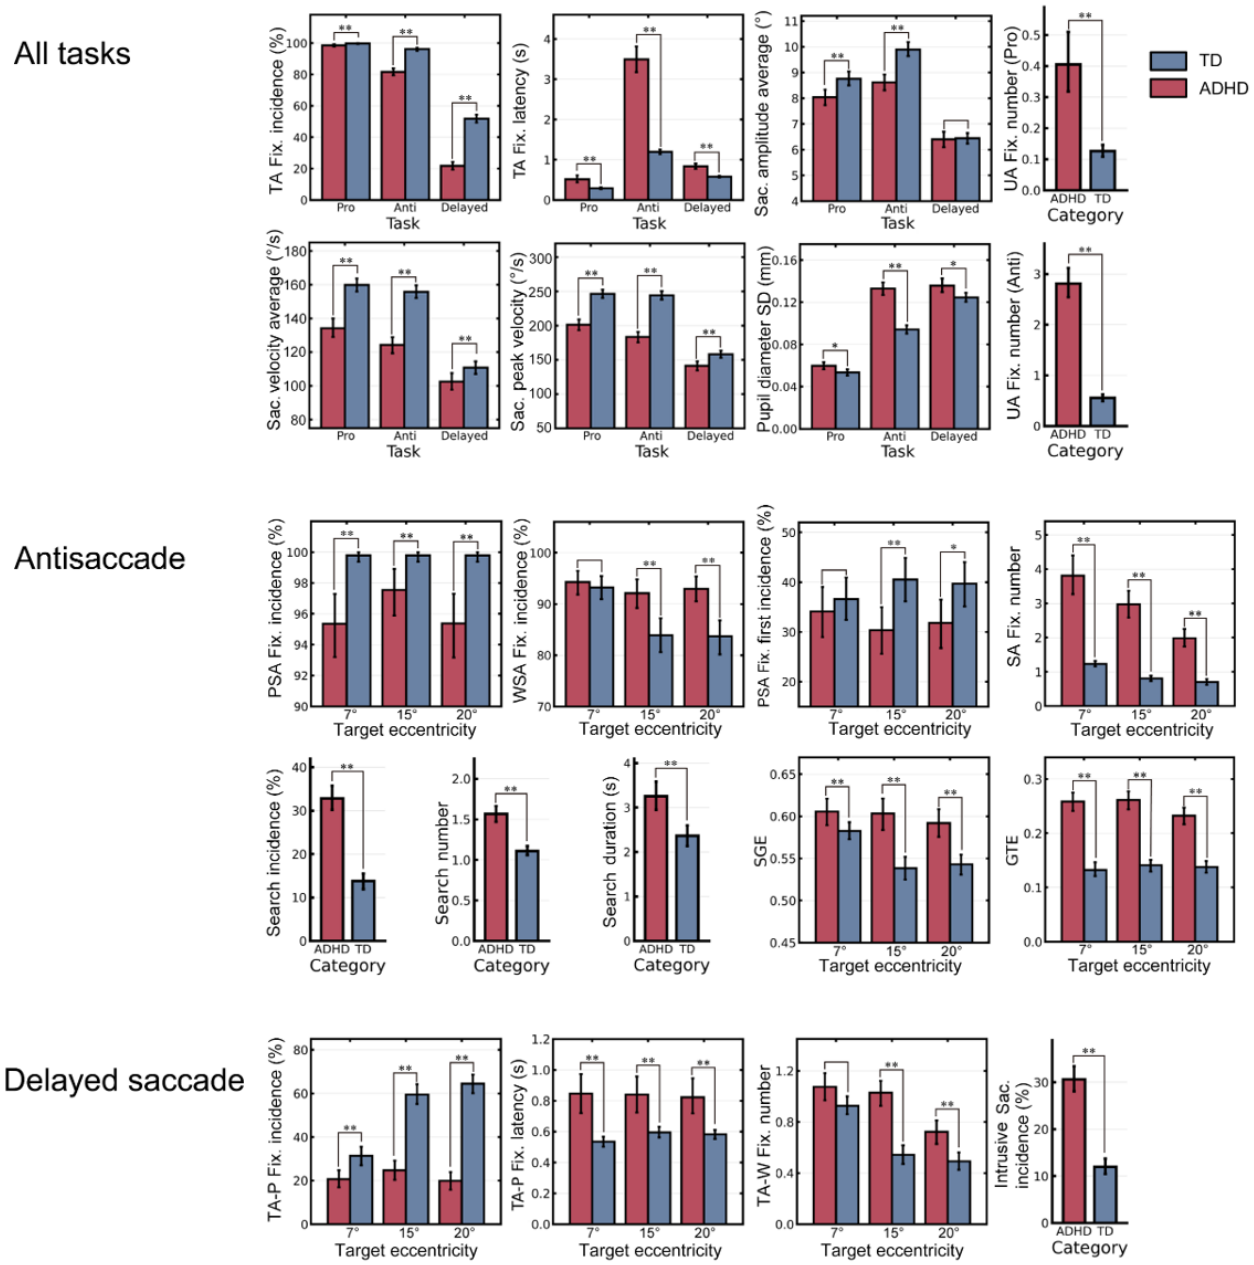
Comparison of Digital Biomarkers Between the ADHD and TD Groups

Eye-Tracking Metrics Across the 3 Tasks

The analysis of the biomarkers identified for all 3 tasks (Figure 6; Multimedia Appendices 2 and 3) showed that for completion, there were significant differences in TA fixation incidence (calculated based on $B_{TA\ Fix.}$) and $L_{TA\ Fix.}$ between the ADHD and TD groups for all 3 tasks (both P<.001). $A_{Sac.\ Avg.}$ of the ADHD group was significantly smaller than that of the TD group in the prosaccade and antisaccade tasks (all P<.001), whereas $V_{Sac.\ Avg}$ and $V_{Sac.\ Peak}$ of the ADHD group was significantly slower than those of the TD group for all tasks (all P<.001). $D_{Pupil\ Sd.}$ of the ADHD group was significantly greater than that of the TD group for all tasks (P=.03 for the prosaccade task, P<.001 for the antisaccade task, and P=.02 for the delayed saccade task).

In terms of attention control, in both the prosaccade and antisaccade tasks, more irrelevant fixations (ie, $N_{UA\ Fix.}$) occurred in the ADHD group than in the TD group (all P<.001). In addition, the ADHD group fixated more frequently on the UA during the antisaccade task than in the prosaccade task.

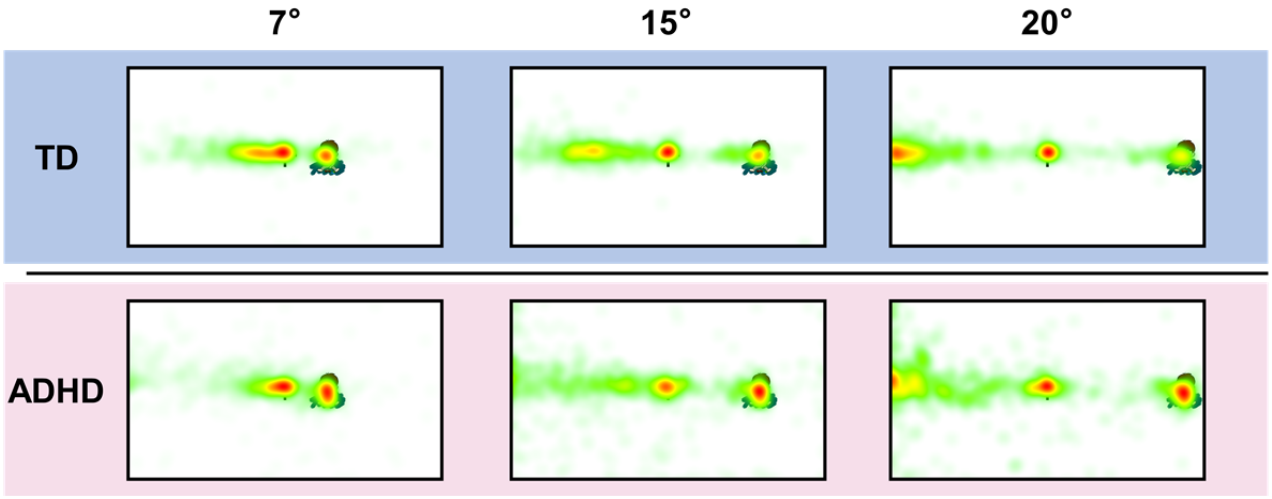
Figure 6. Comparisons of eye-tracking metrics between the attention-deficit/hyperactivity disorder (ADHD) and typically developing (TD) groups. Results of the corresponding data analyses are presented in Multimedia Appendices 3 and 4. *P<.05, **P<.01. Fix.; fixation; GTE: gaze transition entropy; PSA: proper-side area; SA: stimulus area; Sac.: saccade; SGE: stationary gaze entropy; TA: target area; UA: unrelated area; WSA: wrong-side area.



Eye-Tracking Metrics of the Antisaccade Task

The heat maps (Figure 7) of the analysis of the different target eccentricities (Multimedia Appendix 4) revealed that the TD group's fixations were concentrated along the horizontal position where the SA and TA were located, whereas the ADHD group's fixations were more widespread. Moreover, the TD group was more accurate than the ADHD group in fixating on the TA, whereas the ADHD group showed more erroneous localization deviations in both the 7° and 15° trials. Interestingly, in the 20° trial, we noted that the fixation concentration of the ADHD group deviated from the stimulus: there was a longitudinal distribution of fixations along the edge of the correct side of the screen, which suggested that the ADHD group did not localize fixation according to the logic of symmetry; rather, they relied purely on the edge of the screen to assist in their fixation positioning.

Figure 7. Heat maps of fixations of the typically developing (TD) and attention-deficit/hyperactivity disorder (ADHD) groups for stimuli of different target eccentricities in the antisaccade task.



As shown in Figure 6 and Multimedia Appendix 4, the ADHD group had more WSA fixations (calculated from $B_{WSA\ Fix.}$) and fewer PSA fixations (calculated from $B_{PSA\ Fix.}$) than the TD group (all P<.001). Among the 3 eccentricities, the number of WSA fixations during the 15° and 20° trials were significantly different between the groups (U=81,316 for 15°, U=80,812 for 20°, all P<.001), whereas in the 7° trials, both groups showed a higher number of WSA fixations (U=87,841, P=.52) than PSA fixations. However, the TD group had more PSA fixations in the 7° trials and a higher incidence of the first fixation in the PSA (calculated from $B_{PSA\ Fix.\ 1st}$) than the ADHD group (all P<.001).

Comparisons of search incidence (calculated from B_{Search}), N_{Search}, and T_{Search} between the ADHD and TD groups showed that the ADHD group was significantly higher than the TD group for all 3 metrics (P<.001, P<.001, and P=.008, respectively). Both SGE and GTE were significantly higher in the ADHD group than in the TD group (all P<.001).

Eye-Tracking Metrics in the Delayed Saccade Task

As shown in Figure 6 and Multimedia Appendix 4, TA-P fixation incidence (calculated from $B_{TA\ Fix.}$) and $L_{TA\ Fix.}$ were significantly different between the 2 groups at all eccentricities. Moreover, the TD group had a lower $N_{TA\text{-}W\ Fix.}$ than the ADHD group (all P<.001).

As the stimulus eccentricity increased from the center point, only the TD group showed an improvement in performance. The TD group showed a lower $N_{TA\text{-}W\ Fix}$ when the eccentricity was 15° than when the eccentricity was 7°, whereas the decrease in $N_{TA\text{-}W\ Fix}$ in the ADHD group from an eccentricity of 15° to 20° was more gradual than that in the TD group.

The assessment of intrusive saccades for stability of eye movements showed that the ADHD group had more intrusive saccades (calculated from $B_{Intrusive\ \ Sac.}$) and less stable eye-movement patterns than the TD group (P<.001).

Comparisons of Digital Biomarkers Among Age Groups

We discovered that several digital biomarkers showed consistent changes with age (Figure 8; Multimedia Appendices 5 and 6). In the prosaccade task, the overall T_{Total} of both groups showed a decreasing trend with age (P=.02 for ADHD, P<.001 for TD). In addition, an age-related decrease in $A_{Sac.\ Avg.}$ was observed in the TD group only (P=.007), whereas $V_{Sac.\ Avg.}$ and $V_{Sac.\ Peak}$ remained stable in both groups (P=.71 for $V_{Sac.\ Avg.}$ and P=.46 for $V_{Sac.\ Peak}$). In the antisaccade task, both the TD and ADHD groups showed an increasing trend for accuracy (P<.001 for ADHD, P=.63 for TD) and efficiency (P<.001 for ADHD and TD) in completing the task. In fact, the ADHD group showed significantly greater improvement than the TD group (P<.001). The ADHD group also exhibited a propensity for $D_{Pupil\ Sd.}$ to decrease with age (P<.001). Across all age groups, the ADHD group had a higher $N_{UA\ Fix.}$ than the TD group (P<.001), and this did not significantly improve with age; although the $N_{SA\ Fix.}$ significantly dropped with age (P<.001). We also found that there was a greater tendency for SGE and GTE to decline with age in the TD group than in the ADHD group (P<.001 for SGE and P=.001 for GTE).

The TA-P fixation incidence (P=.06) did not significantly differ with age in the ADHD group for the delayed saccade task. This was true despite the ADHD group showing improvements in $L_{TA\ Fix.}$ (P=.01), $N_{TA\text{-}W\ Fix.}$ (P=.005), and intrusive saccade incidence (calculated from $B_{Intrusive\ Sac.}$; P=.003) with age.

Figure 8. Comparisons of eye-tracking metrics among age groups. Letters above the bars indicate the results of the post hoc tests using Bonferroni correction among different age groups in the attention-deficit/hyperactivity disorder (ADHD) and typically developing (TD) groups. Lower case letters indicate $P<.05$; upper case letters indicate $P<.01$. *$P<.05$, **$P<.01$. ML Analysis With the Proposed Digital Biomarkers

The evaluation metrics (AUC, accuracy, sensitivity, specificity, precision, and F_1-score) are reported as means (95% CIs). The XGBoost model trained on the eye-tracking variables achieved an AUC of 0.965 (0.964-0.966), an accuracy of 0.908 (0.907-0.910), a sensitivity of 0.877 (0.874-0.880), a specificity of 0.932 (0.930-0.934), a precision of 0.913 (0.910-0.915), and an F_1-score of 0.892 (0.890-0.894). The averaged ROC curve is shown in Figure 9, which illustrates the effectiveness of the proposed digital biomarkers for discriminating the ADHD and TD groups. The 10 most important variables for the model are reported with their scores in Figure 10.

Figure 9. Receiver operating characteristic curve of the classification model. AUC: area under the receiver operating characteristic curve.

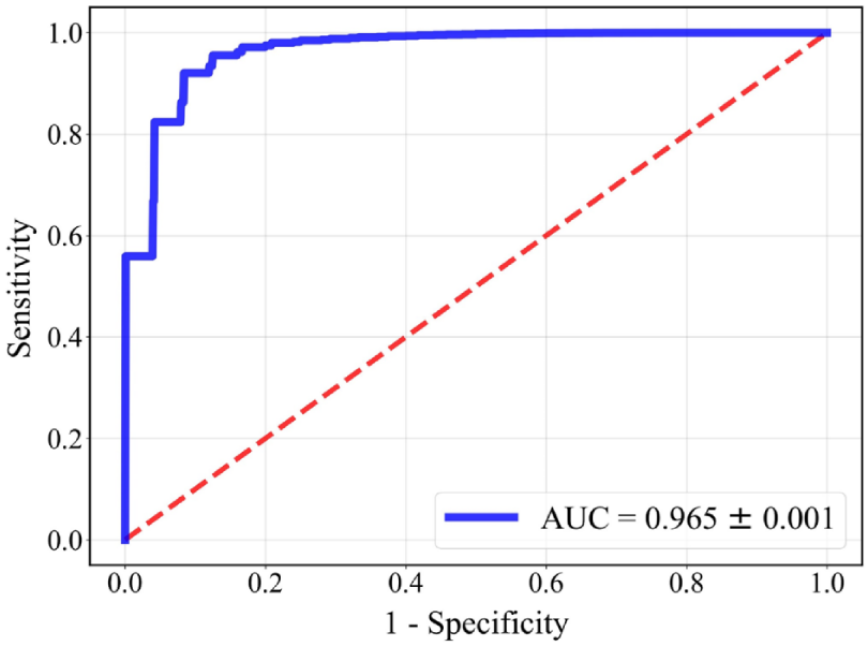

Figure 10. Importance scores of the top 10 most important variables. $N_{Sac.}$: total number of saccades; $N_{Fix.}$: total number of fixations; $L_{TA\ Fix.}$: fixation latency of the TA; $N_{SA\ Fix.}$: number of fixations in the stimulus area; $B_{TA\ Fix.}$: Boolean value to signify the occurrence of fixations in the TA (TA-P for the delayed-saccade task); $N_{UA\ Fix.}$: number of fixations in the UA; $N_{TA\text{-}W\ Fix.}$: number of fixations in the TA for the wrong period; $T_{Sac.\ Avg.}$: average of saccade duration.

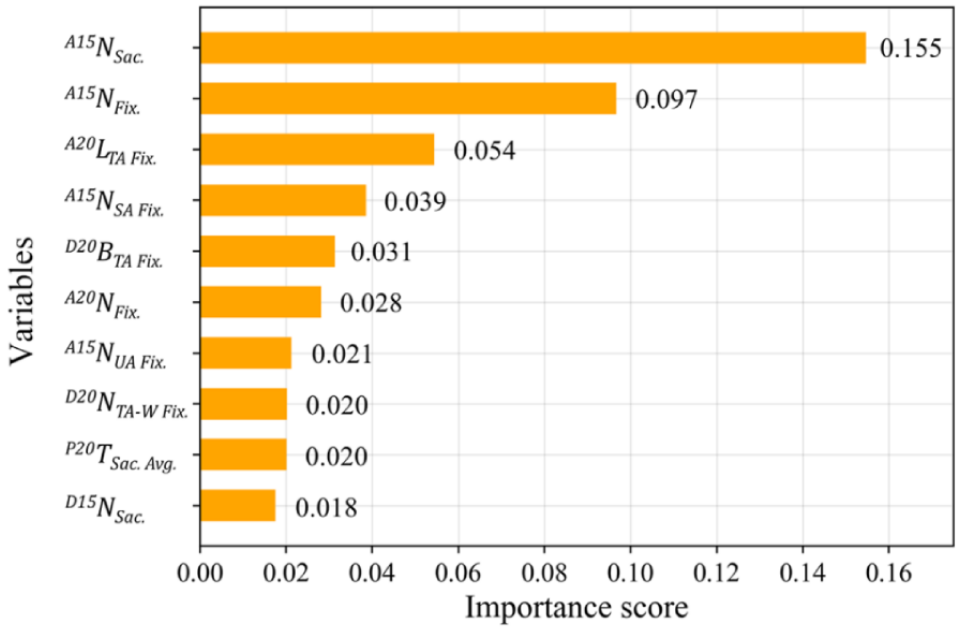

Discussion

Principal Findings

Clinical Behavioral Performance

The 3 saccade tasks consistently showed that the performance of the ADHD group was poorer than that of the TD group, which suggests that the paradigm serves as a reliable and objective measure of cognitive and executive functioning. Furthermore, the ADHD group exhibited a pattern of amelioration with aging, whereas the TD group showed consistent performance across the different age groups. This may be because TD individuals had already achieved a higher cognitive skill level and a relatively stable state of corresponding biomarkers than ADHD individuals of the same age. Therefore, despite the ADHD group showing a faster rate of improvement, they performed significantly worse than TD individuals across all age groups. This finding demonstrates distinct developmental eye-movement patterns associated with ADHD.

Attention and Inhibitory Control

The ADHD group exhibited a significant lag in the ability to inhibit stimuli, which was characterized by poorer performance than the TD group on tasks with a weaker perceptual load.

Previous studies have confirmed that human visual features are divided into 3 regions–the foveal region at a viewing angle of 2.5° from the gaze point has the highest visual sensitivity, followed by the parafoveal region from 2.5° to 4.2°, and the peripheral region from 4.2° to 9.2° has the lowest visual sensitivity [52]. In this study, the 7° eccentricity stimulus was closest to the central cross and within the peripheral region, whereas the other 2 stimulus types were located outside the peripheral region. Thus, the task of inhibiting the 15° and 20° eccentricity stimuli was a low perceptual load task, which was relatively easy for the TD group. However, the performance of the PSA first incidence showed that the ADHD group had poorer inhibitory control for the lower perceptual load task of inhibiting stimuli that were located outside of the peripheral region (ie, the 15° and 20° eccentricity stimuli, as shown in Figure 6). This confirms the existence of up-down attention control impairment in individuals with ADHD [53] and emphasizes that children with ADHD may be more prone to distraction in low perceptual load environments because of a higher central threshold of response to perceptual load [54]. This finding also corroborates previous reports that individuals with ADHD are more sensitive to stimuli located in peripheral regions.

Furthermore, although individuals with ADHD had difficulty suppressing the sudden appearance of distracting stimuli, they also had a longer completion time than the TD group for the prosaccade task with a single instruction. This may be attributed to the low load of the prosaccade task, which may not have elicited sufficient cognitive arousal in the ADHD group, leading to poorer task performance. In addition, in the delayed saccade tasks that involved sequential instructions (ie, “do not look at the stimulus until you hear the cue, and then quickly look at the stimulus”), the weak task-switching ability of the ADHD group may have also prolonged fixation latency.

Organizing and Planning

In the antisaccade task, the ADHD group exhibited significantly lower TA fixation incidence and longer $L_{TA\ Fix.}$ compared with the TD group (Figure 6). This suggests that most children in the ADHD group were unable to accurately localize the TA, and those who succeeded took longer. On the basis of the heat map and UA fixation (Figures 6 and 7), the ADHD group exhibited greater fixation deviation and more frequent search behaviors.

In addition, the ADHD group had much higher SGE and GTE than the TD group for overall eye-movement trajectory, which indicated that they exhibited more eye-movement pattern shifts and spatial dispersion of fixations. This suggests that patients with ADHD favor an irregular search pattern and lack forethought when organizing and coordinating eye movements during symmetrical localization, resulting in prolonged search time to accurately locate the target. Furthermore, the positive correlation between SGE and GTE in the ADHD group supports the impact of top-down interference on visual scanning in ADHD [43].

The TD group followed a significant declining trend in SGE (P<.001) and GTE (P=.001) with age, whereas the ADHD group maintained high entropy values. We also observed that the frequent UA fixation in the ADHD group did not improve with age. These findings suggest that with age, the TD group better localized the landing point, which led to a more regular eye-movement trajectory. In contrast, the irregular eye-movement pattern of the ADHD group was exhibited across all age groups.

Eye-Movement Coordination With Age

Previous studies have mainly focused on age-related changes in the general population by comparing individuals among different age groups. However, few studies have examined variations in eye movement among younger individuals with ADHD and TD individuals. A recent study evaluating the performance of visually guided horizontal prosaccades in healthy people aged 3 years to >80 years found that peak saccade velocity increases until the age of 6 years, after which it remains relatively stable until 10 years of age [55]. The results of our prosaccade task similarly demonstrated that $V_{Sac.\ Avg.}$ and $V_{Sac.\ Peak}$ remained stable from ages 5 to 10 years in both the ADHD and TD groups, which indicates that the developmental pattern of saccade velocity is similar across both groups.

We also discovered that the ADHD group was more likely to experience intrusive saccades during the central fixation stage. The percentage of intrusive saccades decreased with age in the ADHD group, whereas that in the TD group remained at a well-performing and stable level across age groups. This further highlights the overall impairment in eye-movement control in the ADHD group.

The TD group showed a consistently higher $V_{Sac.\ Avg.}$ than the ADHD group. However, it showed a decreasing trend with age for $A_{Sac.\ Avg}$ than the ADHD group. In addition to speed, accurate localization is also required to successfully perform the prosaccade task. With age, children may modulate their eye movements to a lower speed for greater controllability, rather than simply sweeping their eyes rapidly toward the target, and thus, increase task efficiency.

Previous research has reported that the cerebellum is a crucial hub of the motor network that interacts with the executive control circuits of the frontoparietal lobe, which are involved in inhibition and stimulus response [56]. Furthermore, studies have demonstrated reduced volume and under activation of the cerebellum in individuals with ADHD [57], which suggests that impairment of the cerebellum contributes to poor control and coordination of eye movements in patients with ADHD.

Variations in Pupil Diameter and Cognitive Stress

It is well-established that when humans encounter stressful situations, they dilate their pupils to improve vision [58]. Previous research using eye-tracking technology has also revealed that when people are engaged in an active coping task, their pupils enlarge significantly. These findings suggest that a larger pupil diameter is linked to higher cognitive load while preparing for challenging tasks [58]. According to previous research examining the relationship between pupil diameter and attention, there is an inverted U–shaped pattern between pupil diameter and attentional performance; that is, when pupil diameter becomes too small or large, error rates are higher and response times are slower [59]. In our study, we discovered that

for all tasks, children with ADHD displayed greater pupil diameter variation than TD individuals. This finding supports the theory that excessively large or small pupil diameter is an indicator of inattentiveness when completing tasks requiring active responses. Alternatively, executive function deficiencies at the functional level of the brain and inefficient brain network connectivity in the ADHD group may account for the higher cognitive load when responding to complex task demands [60].

ML Analysis

For the classification of ADHD and TD children, the ML model achieved an AUC of 0.965 and an accuracy of 0.908, which demonstrates promise for the model to serve as an automated screening tool for ADHD children. Moreover, the high performance of the model highlights the effectiveness of the paradigm and its ability to extract digital eye-tracking biomarkers. In a previous study focused on screening for ADHD using eye-tracking and ML methods, Lev et al [18] conducted continuous performance tests in 66 participants (33 adult patients with ADHD and 33 healthy controls) and used eye-movement metrics during the tests to classify patients and controls. They applied a regression model to combine the relative gaze durations of 4 AOIs as the diagnostic scale and achieved an AUC of 0.826. Das and Khanna [19] extracted pupil size dynamics features as an objective biomarker and trained 5 types of commonly used classification models to detect ADHD. Using the data of 50 participants (28 patients with ADHD and 22 healthy controls) and 10-fold cross-validation, they attained an AUC of 0.856. Deng et al [61] built an eye-tracking ML classifier for ADHD using the natural reading paradigm; however, the model was difficult to interpret, and the classification performance (AUC of 0.646) was not as high as the performance achieved by our model.

Compared with previous work, we recruited a larger number of participants (ie, 94 ADHD and 122 TD individuals), obtained higher evaluation metrics, and achieved better classification performance for children with ADHD. Moreover, we extracted a larger variety of eye-tracking metrics and provided a more comprehensive description of participants' eye-movement behaviors. These advantages emphasize the effectiveness, reliability, and potential practical applications of the model. Furthermore, our findings offer valuable insight into the field of ADHD diagnosis using ML.

Because we plan to extend our findings using portable eye-tracking devices in the future, we validated the performance of our model at lower sampling frequencies using external samples. Results demonstrated that the model adapted well to low-sampling rate data, which further confirmed its high generalizability and applicability to portable devices (Multimedia Appendix 7).

Advantages of the Study

First, we used eye-tracking technology in a natural and straightforward assessment setting, which enabled direct visual and on-screen interactions without complicated rules or restrictions on head motion. Unlike the paradigms used in previous studies, our approach did not require participants to wear additional equipment [7] or make additional keystrokes [18]. In addition, our method avoided interference from other environments and devices, facilitated children's participation, and minimized inaccuracies in eye-movement measurement due to excessive head movement.

Second, our paradigm allowed a more comprehensive exploration of children's cognitive skills. In addition to testing attentional and inhibitory ability, our paradigm included audiovisual integration, which has been shown to be effective in evaluating children with ADHD.

Third, we provided a more comprehensive scheme for extracting digital eye-tracking biomarkers by expanding the evaluation system of classical paradigms. The presentation of stimuli was further divided into defined areas of fixation for quantitative analyses; moreover, behaviors, such as search behaviors that are typically observed in the clinic, were quantified alongside numerous metrics based on the AOI, such as fixation duration, saccade velocity and amplitude, and pupil diameter change. This enabled the extraction of more detailed eye-movement metrics during different saccade tests than those used in previous studies [8,18,19,62] while ensuring that the extracted digital biomarkers were interpretable and objectively reflected cognitive deficits. As a result, we were able to provide a practical and thorough description of children's performance in completing the various tasks.

In addition, we applied ML modeling using the extracted digital biomarkers and achieved promising results, which confirmed that these biomarkers are highly valuable for the future development of screening and auxiliary diagnostic tools. We also investigated age-related developmental patterns of eye movement in addition to simple eye-movement metrics in children with ADHD in a larger, more trustworthy, and more representative dataset than previous research. In terms of practical applications, the implementation of the paradigm is straightforward, and the 7-minute duration of the assessment is suitable for children with ADHD. These features will increase the likelihood that the assessment can be completed successfully by children with ADHD. Taken together, we have provided a reliable and practical solution for auxiliary diagnosis and screening for ADHD at the primary care level.

Limitations

Although our sample size was larger than previous studies, we only recruited from 1 city in China. Therefore, the representativeness of the sample can be improved. There was also a sex imbalance between the TD and ADHD groups. The TD group had a 1:1 sex ratio, whereas the ADHD group had considerably more boys (84/94, 89%) than girls (10/94, 11%). Although this was attributed to morbidity bias, our modeling would have benefited from a balanced sex ratio, especially because previous studies have reported sex differences in comorbidity and cognitive impairment in children with ADHD [63]. To verify the effect of sex on the validity of the model, 2 models were trained using data from boys and girls separately and validated using data from the opposite sex. Results showed that the 2 models performed well, which suggested that sex does not significantly affect modeling and that the current model trained with predominantly male data can also be applied to predict female participants' behavior (Multimedia Appendix

8). Nevertheless, we must consider recruiting participants with various presentations (eg, different geography and balanced sex ratios) in future studies to ensure the generalizability of the ML model. Finally, our eye-tracking instrument is heavy and difficult to carry. Thus, in the future, a portable eye-tracking instrument could be used.

Conclusions and Future Research

We successfully adapted eye-tracking technology for clinical use as a tool for auxiliary diagnosis and campus and community screening for ADHD. The system includes standard paradigms and a reliable digital biomarker extraction process. We validated the use of digital biomarkers to build robust ML models. In addition, the entire assessment process was conducted in a natural setting without the need for extra equipment to be worn by participants. The assessment is also brief and simple, which makes it particularly suitable for clinical applications and ensures completion of the assessment.

For the next steps of our research, we plan to further expand the sample size and implement multicenter data collection using the proposed paradigm and digital biomarker extraction scheme. We aim to build a robust ML model and externally validate classifiers to improve their predictive accuracy and stability. This will ensure that the auxiliary diagnosis model can be effectively applied to real clinical scenarios and improve primary care–level screening and diagnosis of ADHD.

Acknowledgments

This study was financially supported by the Joint Project on Emerging Frontier Technologies for Municipal Hospitals of Shanghai Hospital Development Center (grant SHDC12022114), Exemplary Research Physician Training Program on Innovation and Transformation Capabilities Special Project on Transformation of Innovation Results of Medical-Enterprise Integration of SHDC (grant SHDC2022CRD012), National Natural and Science Foundation of China (grant 62203296), Shanghai Pujiang Program (grant 22PJ1405500), Shanghai Jiao Tong University Medical-Industrial Crossroads Center Project, National Program on Key Research Program (grant 2022YFC2705203), Shanghai 2022 “Science and Technology Innovation Action Plan” Technical Standards Project (grant 22DZ2203500), the Three-year Action Plan for Strengthening the Construction of Shanghai Public Health System (2023-2025) Outstanding Young Talents (grant GWVI-11.2-YQ23), Shanghai Pilot Program for Basic Research—Shanghai Jiao Tong University (grant 21TQ1400203), the Science and Technology Commission of Shanghai Municipality (grant 20DZ2220400), the National Natural Science Foundation of China (grant 81703235), and the Fundamental Research Funds for the Central Universities (grant YG2022QN100).

The authors thank Tianbao Chen, Ruoya Qian, and Ruihan Wang from Shanghai Jiao Tong University School of Medicine for their help with data processing.

They thank Sarina Iwabuchi, PhD, from Liwen Bianji (Edanz), for editing the English text of a draft of this paper.

Authors' Contributions

ZL performed the data collection and data analysis of the clinical part, and wrote the paper; JL performed the construction of the biomarker extraction scheme and machine learning modeling, and wrote the paper; YZ, DW, and YH were involved in the analysis of the clinical data; JY and MZ were involved in the feature extraction and machine learning modeling; CD, LJ, RS, and RZ implemented the patient interviews and assessments; FL, XY, and DZ reviewed and revised the paper; YG and JC set the topic, critically revised the article, and funded the study.
YG and JC contributed equally as cocorresponding authors.
All authors reviewed the final paper.

Abbreviations

ADHD: attention-deficit/hyperactivity disorder
AOI: area of interest
AUC: area under the receiver operating characteristic curve
CA: center area
GTE: gaze transition entropy
ML: machine learning
PSA: proper-side area
ROC: receiver operating characteristic
SA: stimulus area
SGE: stationary gaze entropy
SNAP-IV: Swanson, Nolan, and Pelham Rating Scale
TA: target area
TA-P: target area during the proper period
TA-W: target area during the wrong period
TD: typically developing
UA: unrelated area
WSA: wrong-side area
XGBoost: extreme gradient boosting

Abstract

Background: Ecological momentary assessment (EMA) is an increasingly used tool for data collection in behavioral research, including smoking cessation studies. As previous addiction research suggests, EMA has the potential to elicit cue reactivity by triggering craving and increasing behavioral awareness. However, there has been limited evaluation of its potential influence on behavior.

Objective: By examining the perspectives of research participants enrolled in a tobacco treatment intervention trial, this qualitative analysis aims to understand the potential impact that EMA use may have had on smoking behaviors that may not have otherwise been captured through other study measures.

Methods: We performed a qualitative analysis of in-depth interviews with participants enrolled in a pilot randomized controlled trial of a tobacco treatment intervention that used SMS text messaging to collect EMA data on smoking behaviors. In the pilot randomized controlled trial, combustible cigarette and e-cigarette use and smoking-related cravings were measured as part of an EMA protocol, in which SMS text messaging served as a smoking diary. SMS text messaging was intended for data collection only and not designed to serve as part of the intervention. After a baseline assessment, participants were asked to record daily nicotine use for 12 weeks by responding to text message prompts that they received 4 times per day. Participants were prompted to share their experiences with the EMA text messaging component of the trial but were not directly asked about the influence of EMA on their behaviors. Transcripts were coded according to the principles of the framework for applied research. The codes were then examined, summarized, and grouped into themes based on the principles of grounded theory.

Results: Interviews were analyzed for 26 participants. The themes developed from the analysis suggested the potential for EMA, in the form of an SMS text messaging smoking diary, to influence participants' smoking behaviors. The perceived impacts of EMA text messaging on smoking behaviors were polarized; some participants emphasized the positive impacts of text messages on their efforts to reduce smoking, while others stressed the ways that text messaging negatively impacted their smoking reduction efforts. These contrasting experiences were captured by themes reflecting the positive impacts on smoking behaviors, including increased awareness of smoking behaviors and a sense of accountability, and the negative impacts on emotions and smoking behaviors, including provoking a sense of guilt and triggering smoking behaviors.

Conclusions: The collection of EMA smoking behavior data via SMS text messaging may influence the behaviors and perceptions of participants in tobacco treatment interventions. More research is needed to determine the magnitude of impact and mechanisms, to account for the potential effects of EMA. A broader discussion of the unintended effects introduced by EMA use is warranted among the research community.

Introduction

Ecological momentary assessment (EMA) is a data collection method that is increasingly being used in health and behavioral sciences [1,2]. EMA has been shown to be a useful tool for measuring behaviors associated with substance use [3]. Consequently, there has been a strong interest in the use of EMA in smoking cessation studies [4]. However, as indicated in previous addiction research, EMA has the potential to elicit cue reactivity by triggering craving and increasing behavioral awareness [5-8]. As such, there is potential for the use of EMA to create an assessment effect and inadvertently influence behaviors in some settings.

Assessment effects refer to the phenomenon in which the outcome of interest (eg, a behavior) is modified simply by assessing it, arising due to the assessment method or its interaction with the intervention [9,10]. The frequent prompts for self-reporting that are often required by EMA might inadvertently influence participants' behaviors by, among other mechanisms, increasing their self-awareness, altering an emotional response, or serving as reminders of the behavior [2,8,11,12]. Depending on the behavior of interest, these EMA consequences may differentially impact outcomes. These assessment effects can have a significant impact on the interpretation of trial results but are rarely considered in trial design [13].

Despite its potential importance to the interpretation of research results, there are a limited number of studies investigating the potential for EMA to produce an assessment effect. Within the research that does exist, there have been mixed results reported, with some studies reporting no impact on behavior [11,14,15] and others indicating that EMA likely has an impact [2,5-8,11,12,14]. For this reason, it is important to understand if and how the use of EMA data collection in smoking research could impact smoking behaviors.

To better understand the potential impact of using EMA to measure smoking behaviors, we performed a qualitative analysis of in-depth interviews with participants in a randomized controlled trial (RCT) pilot study of a smoking intervention that used SMS text messaging–based EMA as a data collection strategy [16]. By examining the perspectives of the trial participants, this qualitative analysis aims to understand the potential impact that the use of EMA may have had on smoking behaviors that may not have otherwise been captured through other means of data collection.

Methods

Study Design

For the purposes of assessing the acceptability of a smoking intervention and determining points for potential program improvement, we performed a qualitative analysis of in-depth interviews conducted with participants of an RCT pilot study that compared the effectiveness of behavioral counseling and the use of e-cigarettes on smoking outcomes to that of behavioral counseling and nicotine replacement therapy (NRT).

Ethical Considerations

The interviews and analysis procedures were reported in accordance with the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist (Checklist 1), as applicable [17]. The study protocol was approved by the New York University Langone Health Institutional Review Board (approval number i20-00839), and written documentation of informed consent was received prior to starting data collection. Participants were provided with a US $20 incentive for their participation. Participant data were maintained on a secure server. After transcription, all participant data were deidentified prior to data analysis.

Setting and Participants

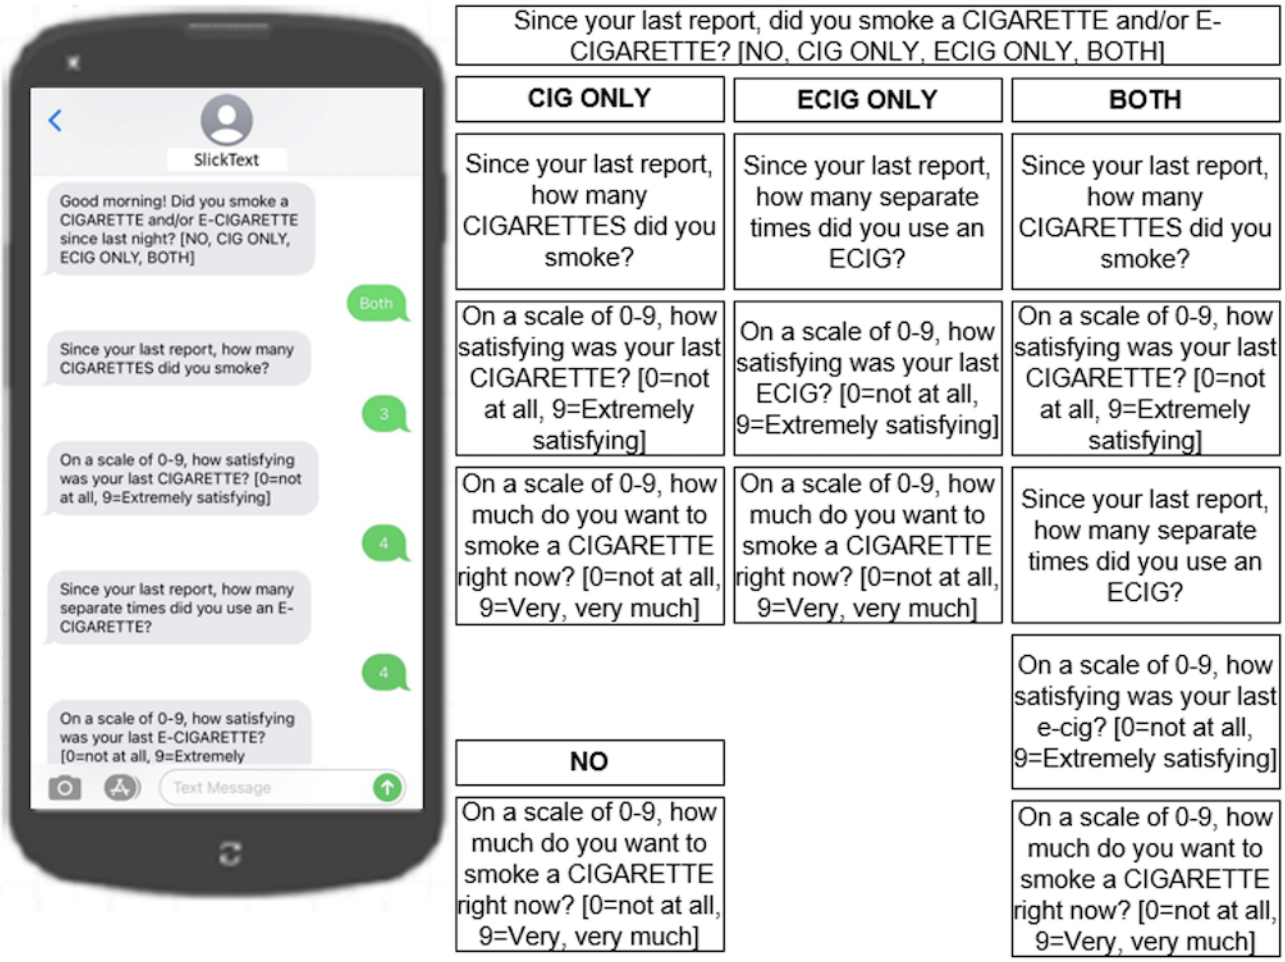
Interview participants were recruited upon completion of the intervention phase of the RCT at the 12-week follow-up study visit. All RCT participants were invited to participate in an in-depth interview to discuss their experiences with the intervention and other aspects of the trial. Interview recruitment ended once thematic saturation was reached. Interviews lasted approximately 30 minutes and were performed between April 2021 and November 2022.

The pilot RCT was performed to determine the feasibility and acceptability of an e-cigarette–based smoking intervention and to compare the effectiveness of counseling and e-cigarette use on smoking outcomes to that of counseling and NRT [16]. Text message–based EMA data collection was used to record smoking patterns. Patients from the electronic health record system of New York University Langone Health—a private hospital system serving New York, New Jersey, and Connecticut—were recruited as RCT participants. The RCT participant sample was initially restricted to patients with a diagnosis of chronic obstructive pulmonary disease, but the scope was later expanded to include patients with a diagnosis of coronary artery disease, peripheral artery disease, or asthma. In addition, to be eligible, RCT participants were required to smoke ≥4 days per week, with at least 5 cigarettes smoked on the days that participants did smoke; be motivated to quit smoking; and possess a phone with SMS text messaging capabilities. A total of 121 participants were recruited into the pilot RCT.

RCT EMA Protocol

In the pilot RCT, combustible cigarette use and e-cigarette use, as well as smoking-related cravings, were measured as part of an EMA protocol, in which SMS text messaging served as a smoking diary. The SMS text messaging was intended for data collection only and not designed to serve as part of the intervention. After a baseline assessment, participants were asked to record their daily nicotine use for 12 weeks by responding to text message prompts that they received 4 times per day. The coverage design prompted participants to provide brief check-in reports via text message over the course of each day, wherein they were asked to report combustible cigarette and e-cigarette use based on their study arm (Figure 1). Responses to 1-item measures of cigarette craving and satisfaction were also collected from each report.

Figure 1. Sample of ecological momentary assessment texting prompts. CIG: cigarette; ECIG: e-cigarette.



Data Collection

Semistructured, in-depth telephone interviews, which lasted approximately 30 minutes, were conducted by research staff (OW and MV). Interviews were audio-recorded, transcribed, and imported into Dedoose software (SocioCultural Research Consultants LLC) for qualitative data analyses.

The interview guide covered topics that were designed for the following goal: gaining a deeper understanding of the participants' experiences, intervention satisfaction, attitudes toward e-cigarettes, and intentions to quit. The interviews were intended to assist with the further adaptation of the e-cigarette smoking intervention and behavioral counseling manual used in the RCT. The interview guide was developed based on the pilot RCT procedures to provide additional insights about the barriers and facilitators of e-cigarette use and how to refine the current approach to enhance program retention and outcomes. Interviews covered topics such as program aspects that the participants liked or disliked, features of the intervention that should be modified, participants' experiences with using e-cigarettes or NRT, intentions of using e-cigarettes after the intervention, and whether participants' health symptoms interfered with their ability to engage in the intervention. The participants were prompted to share their opinions on the EMA texting component of the trial but were not directly asked about the influence of the EMA on their behaviors. Participants were prompted to discuss the texting in the interview, as follows: "During the program, you answered questions over text on daily basis—What was that experience like for you?" This was followed by probes, including "How may texting have affected your overall experience with the program?" A copy of the interview script is available in Multimedia Appendix 1.

Data Analysis

Interview transcripts were coded by using procedures that were designed to ensure thoroughness and reliability. We used Dedoose software to manage the data and coded the data according to the principles of the framework for applied research [18], which consists of the following 5-stage process: familiarization, identifying themes, indexing, charting, and interpretation. Codes were primarily developed a priori based on intervention components and the quality improvement goals of this study. Additional codes were developed by reviewing a random sample of interviews and via discussion with the coding team. The general development of themes arose from the data, using the principles of grounded theory [19]. To enhance reliability, 2 researchers took part in the coding and analysis process for each interview. Prior to full coding, a random sample of interviews was double coded, and intercoder reliability was assessed based on percent agreement (range 79.5%-87.9%). Afterward, all disagreements were discussed as a group to improve concordance among coders. All interviews were then independently coded by 5 coders (GX, KO, RL, RW, and SR) who worked in various pair combinations; each pair met with the other coders and a coauthor (ERS) to resolve discrepancies.

When coding was completed, the quotations for each code were examined, summarized, and grouped together into themes.

Results

Participants

Interviews were performed with a total of 27 participants. Due to an audio malfunction, 1 interview was not included in the analysis. As such, 14 participants were in the e-cigarette study arm and 12 were in the NRT study arm. The average age of the participants included in the analysis was 57.1 (range 28-74) years; 54% (14/26) of participants identified as female, 46% (12/26) were White, 31% (8/26) were Black, 15% (4/26) were Hispanic, and 4% (1/26) were Asian. The majority (17/26, 65%) of participants had completed at least some college; 35% had a high school education or less. Around two-thirds (17/26, 65%) of participants had a diagnosis of chronic obstructive pulmonary disease, 15% (4/26) of participants were diagnosed with coronary artery disease or peripheral artery disease, and 19% (5/26) of participants were diagnosed with asthma.

Themes

Overview of Themes

Without being directly prompted, 18 of the 26 participants described EMA impacting their behaviors or emotions, and several themes indicating a potential, inadvertent influence of EMA on smoking behaviors emerged. The perceived impacts of EMA texting on smoking behaviors were polarized; some participants emphasized the positive impacts of the text messages on their efforts to reduce smoking, while others stressed the ways in which the texting negatively impacted their smoking reduction efforts. These contrasting experiences were captured by 2 major themes and their subthemes, reflecting the positive impacts on smoking behaviors, including increased awareness of smoking behaviors and a sense of accountability, and the negative impacts on emotions and smoking behaviors, including provoking a sense of guilt and triggering smoking behaviors (Table 1).

Table . Major themes and subthemes.

Themes and subthemes	Frequency, n
EMA[a] texting has a positive impact on smoking behaviors	16
EMA texting serves as a source of accountability	13
Anticipation of the next text message serves as a deterrent to impulsive smoking	6
Texting prompts increase awareness of smoking habits	16
Reminders of the goal to reduce cigarette smoking	11
Check-ins serve as markers of progress made toward quitting	5
Negative impact of EMA texting on emotions and smoking behaviors	7
Repeated text messages asking about smoking behaviors produce negative emotions	4
Text messages inquiring about cigarette use may have a triggering effect	5

[a]EMA: ecological momentary assessment.

Perceived Positive Impacts of EMA Texting Procedures

Overview of Positive Impacts

A major theme that arose was the perceived positive impacts of the EMA methods on efforts to reduce smoking, as many (n=16) participants perceived the SMS text messaging smoking diary as an important component of the tobacco treatment intervention and their experience during their efforts to reduce their cigarette smoking. Participants described the EMA text messages as helpful because "you could use [them] for yourself as a tool" (Participant E09), and while stating that "the text messages are a pain in the butt," a participant thought that "they were very useful.…A useful pain in the butt" (Participant E04). Within this overarching theme—the positive influence of EMA—four subthemes that highlighted the potential roles of EMA text messages emerged: EMA text messages (1) increase awareness of smoking habits, (2) serve as reminders of smoking goals, (3) mark progress made, and (4) provide a sense of accountability.

Texting Prompts Increase Participants' Awareness of Their Smoking Habits

Many (n=16) participants noted that the EMA text messages helped them with their smoking behaviors because the act of recording the number of cigarettes smoked increased their awareness of their smoking behaviors. This theme—increased smoking habit awareness—encompassed the following three layers: (1) awareness of the number of cigarettes smoked and smoking habits, (2) reminders of the goal to reduce cigarette smoking, and (3) markers of progress made.

The predictable and repeated EMA text message requests for participants to report the number of cigarettes smoked prompted reflection on their smoking habits. By engaging in the conscious effort of quantifying the number of cigarettes smoked, the participants heightened their self-awareness and gained a clearer

understanding of the frequency of their cigarette use. One participant remarked:

> *[The text message would say] "…have you smoked? When was the last time you smoked your last cigarette?" So, it helped me to be aware of how many cigarettes I was smoking per day.* [Participant N24]

With regard to the act of recording cigarette use, a participant noted:

> *…you're so aware with the…text messages…of just how often you smoke.…Because with the text, I was physically writing it and seeing it.* [Participant E27]

Reminders of the Goal to Reduce Smoking

For some participants (n=11), the EMA text messages also served as reminders of their goal to reduce or quit smoking and heightened their sense of purpose and determination. One participant said, "It [the text messaging] does remind you what you're supposed to be focused on" (Participant N20), and in this way, the messages served as frequent reminders of participants' intentions to change their smoking behaviors. The messages also invigorated their commitment to achieving these goals; one participant said:

> *It [the text messages] kept me going. It kept me wanting to quit, you know, and to keep doing it, to keep at the program.* [Participant N36]

The text messages also kept participants feeling involved:

> *…[questions] like, "how many cigarettes have you smoked?"…kind of keep you involved in it instead of letting it go on the way side. Like it would kind of keep reminding you that…this is what you're working on, you know?* [Participant N50]

Markers of Progress Made Toward Smoking Reduction

The EMA text messages served as markers of progress made toward reducing smoking (n=5). By regularly quantifying and reporting their smoking behaviors, participants saw tangible evidence and took note of the accomplishments resulting from their efforts. By tracking progress over time, participants observed patterns of improvement, which reinforced their motivation to continue cutting back on smoking. When describing why they found the text messages useful, one participant said:

> *…it's like a progress type thing. So, I enjoyed the texts.…It kind of gave me a reminder [of my progress] because as I went on, I had less and less craving.* [Participant N58]

EMA Texting Serves as a Source of Accountability for Progress Toward Reducing Cigarette Smoking

Many participants (n=13) believed that the EMA text messages had a positive effect on their sense of accountability in their efforts to reduce smoking. Knowing that they would receive inquiries about their smoking habits increased participants' mindfulness in reducing their smoking. One participant stated:

> *I loved it [the text messaging] because it kept me…accountable…because it kept asking the questions over and over again. In the beginning, it was like a little stressing because I was like, "Oh, my God, these messages, I don't want to deal with it." But, it kept me accountable. And it was good.* [Participant N36]

Similarly, another participant remarked:

> *I had to answer for all the cigarettes I smoked today and hold myself accountable. I thought that was ingenious.* [Participant N06]

In some instances (n=6), the text messages served as deterrents to impulsive smoking. One participant shared:

> *[There] were a couple of times when they [cigarettes] were right on hand…I'm upstairs, I'm getting ready to light and then boom [sic], oh, "did you smoke today? How many times did you smoke since we last communicated?"* [Participant N31]

Similarly, the anticipation of upcoming EMA messages served as a motivator for refraining from smoking or delaying the next cigarette. The participant went on to describe their morning routine:

> *…while you're trying to wake up and organize yourself, you pick up the cigarette…[but] you know you're going to get a text at 9 o'clock saying, "did you smoke?" right? So that notion pops in your head, so you don't smoke right away.* [Participant N31]

Having the knowledge that there was a regular time for reporting their smoking activities encouraged participants to make more deliberate choices regarding their smoking behaviors. One participant discussed how they used EMA check-ins to consciously reduce their cigarette consumption during the time leading up to the EMA prompt:

> *I knew at a certain time, I was going to get this text. So, when I went to the text, I wanted to have everything in line. I wanted it to be right. So therefore, I would only smoke four cigarettes because that was the allotted cigarettes that I was supposed to smoke at the time. During that time, I would only smoke three cigarettes because I had cut down to three during that period of time and I looked forward to doing it.* [Participant N04]

EMA Text Messages Can Negatively Impact Participants' Emotions and Smoking Behaviors

Overview of Negative Impacts

A second major theme that emerged from the data was the potential negative effects that EMA texting could have on participants. Although many participants reported experiencing positive effects of EMA on their smoking behaviors, some participants (n=7) reflected on the potential negative impacts of the EMA text messages. This theme—the negative effects of EMA—was further distilled into the following two subthemes: the potential roles of EMA in (1) producing negative emotions and (2) triggering cigarette cravings.

Repeated Text Messages Asking About Smoking Behaviors Produce Negative Emotions

Some participants (n=4) mentioned feeling "bad" when they had to admit to smoking or experiencing relapses via the text messages. However, some respondents admitted that the guilt experienced as a result of the text messages, while being a negative emotion, reinforced their determination and prompted them to make renewed efforts, with one participant stating that the text messages "helped me because when I wrote how…I smoked a cigarette…I kind of felt bad" (Participant N58). Moreover, other participants emphasized the negative emotions and guilt experienced when a spotlight was focused on their perceived failures. One participant described the experience by saying, "being able to tell about my progress, or lack thereof, I would have felt bad if I had a slip up" (Participant N21).

Text Messages Inquiring About Cigarette Use May Have a Triggering Effect

Several participants (n=5) expressed their desire to remove the texting component of the program due to its triggering effect on their smoking. Some participants reported that the text messages acted as triggers for cigarette use, as the text messages reminded them of smoking, thereby eliciting an urge to smoke. One participant said that the EMA "was a reminder, actually," and "…with the reminder came in the struggles" (Participant N20). Notably, another participant said:

> *…[the text messages] happened so often, and you knew they were coming, and they started to almost act like a trigger because you sometimes weren't even thinking about [smoking], but then they would ask you about cigarettes and suddenly you're thinking about it…they were more triggers to smoke than to prevent smoking.* [Participant N31]

Discussion

Principal Findings

This study indicates that smoking intervention participants perceive the collection of EMA smoking behavior data via SMS text messaging as a potential influence on their smoking behaviors. The themes developed from the analysis revealed that EMA, in the form of an SMS text messaging smoking diary, may be perceived as a source of accountability for smoking reduction but may also be a trigger for cigarette use among some people. The results of this study emphasize the need to examine the potential influence of EMA data collection techniques on participants' behaviors within smoking interventions, as well as in other behavioral research.

The perceived impacts of EMA on smoking behaviors are consistent with previously made observations that the act of receiving EMA prompts can increase behavioral awareness and act as a trigger for craving [6-8], in addition to altering participants' moods [2,12]. This suggests that EMA for data collection purposes has the potential to unintentionally create an assessment and intervention effects in itself. Although a lack of EMA impact on behavior has been reported in some studies [11,14,15], these studies may be limited by the choice of measures used. As seen in suicide research, EMA prompts have been observed to have an effect on some measures, such as mood, but a minimal effect on other measures, such as suicidal ideation [2]. Therefore, when designing a study, it is important for researchers to reflect on the various factors that may influence the behaviors of interest and consider the potential effect that EMA may have on these factors, in addition to the primary outcomes of interest. Due to its potential effect on participants, investigators should consider and discuss the potential for a behavioral influence to be introduced into a study through the use of EMA data collection.

There is a need for further investigation into the ways that and the degree to which EMA affects participants. Within the EMA literature, there is a general lack of discussion around the effects of EMA on participants' behaviors. When seeking to improve EMA methods, focus is often placed on participant retention and the validity of the data collection method [20-23], with little to no discussion on the potential behavioral impact of EMA. Indeed, when discussing strengths and limitations of EMA, a large portion of the EMA study literature discusses and reports measures of adherence to and reliability of EMA data collection [20-23], with few studies exploring the potential limitation of EMA in which the data collection itself may affect behaviors of interest [2,5-8,11,12,14,15]. A potential effect from EMA may influence the interpretation of the results; therefore, investigators ought to be encouraged to report considerations related to EMA when designing and publishing a study. Future research may benefit from randomizing a subset of participants to receive one EMA modality (eg, texting) while observing behaviors among all participants with another measurement modality (eg, Bluetooth e-cigarette monitor).

When the potential for EMA to influence study outcomes is identified, less obtrusive EMA methods could be considered, when available. The participants in this study expressed the omnipresent awareness and anticipation of the SMS text messaging–based EMA. This awareness altered participants' behaviors and resulted in negative emotions that likely would not have been emphasized had the EMA not been used or had been subtler. There are numerous types of EMA strategies used in smoking research [4]. Future intervention research studies could consider less frequent SMS text messaging or EMA data collection methods outside of SMS text messaging that may have a more minor impact on smoking behaviors, such as the use of biosensors [24], Bluetooth-enabled devices [25], or puff counters [26].

This study had a few limitations. First, the interview guide was not designed to investigate the impact of EMA on participants' smoking behaviors. Therefore, further details on the effects of EMA were not deeply explored, limiting the scope of this analysis. The unprompted nature of the participants' observations of behavioral impact, however, strengthens the conclusion that the SMS text messaging–based EMA had a meaningful impact on the trial participants. Second, the sample of interview participants was not randomized, and the interview was not required; rather, it was offered to all participants sequentially as an optional component. This potentially introduced selection bias, as those with stronger opinions on the program may have been more likely to participate. Third, as EMA data were collected as part of a smoking reduction trial,

it is difficult to completely disentangle the effects of the intervention on changes in behavior from the effects of EMA. Finally, the impact of EMA on behavior change was based on the self-reported perceptions of interview participants, and behavior changes were not directly observed. Therefore, this study cannot be used as conclusive evidence that the EMA had a significant impact on smoking behaviors, and further research is needed.

Conclusion

The collection of EMA smoking behavior data via SMS text messaging may influence the behaviors and perceptions of participants in smoking interventions. More research is needed to determine the magnitude of impact and mechanisms, to account for the potential effects of EMA on behavior change. Furthermore, a broader discussion of the behavioral influence introduced by the use of EMA may be warranted among the EMA research community.

Abstract

Background: As mobile health (mHealth) studies become increasingly productive owing to the advancements in wearable and mobile sensor technology, our ability to monitor and model human behavior will be constrained by participant receptivity. Many health constructs are dependent on subjective responses, and without such responses, researchers are left with little to no ground truth to accompany our ever-growing biobehavioral data. This issue can significantly impact the quality of a study, particularly for populations known to exhibit lower compliance rates. To address this challenge, researchers have proposed innovative approaches that use machine learning (ML) and sensor data to modify the timing and delivery of surveys. However, an overarching concern is the potential introduction of biases or unintended influences on participants' responses when implementing new survey delivery methods.

Objective: This study aims to demonstrate the potential impact of an ML-based ecological momentary assessment (EMA) delivery system (using receptivity as the predictor variable) on the participants' reported emotional state. We examine the factors that affect participants' receptivity to EMAs in a 10-day wearable and EMA–based emotional state–sensing mHealth study. We study the physiological relationships indicative of receptivity and affect while also analyzing the interaction between the 2 constructs.

Methods: We collected data from 45 healthy participants wearing 2 devices measuring electrodermal activity, accelerometer, electrocardiography, and skin temperature while answering 10 EMAs daily, containing questions about perceived mood. Owing to the nature of our constructs, we can only obtain ground truth measures for both affect and receptivity during responses. Therefore, we used unsupervised and supervised ML methods to infer affect when a participant did not respond. Our unsupervised method used *k*-means clustering to determine the relationship between physiology and receptivity and then inferred the emotional state during nonresponses. For the supervised learning method, we primarily used random forest and neural networks to predict the affect of unlabeled data points as well as receptivity.

Results: Our findings showed that using a receptivity model to trigger EMAs decreased the reported negative affect by >3 points or 0.29 SDs in our self-reported affect measure, scored between 13 and 91. The findings also showed a bimodal distribution of our predicted affect during nonresponses. This indicates that this system initiates EMAs more commonly during states of higher positive emotions.

Conclusions: Our results showed a clear relationship between affect and receptivity. This relationship can affect the efficacy of an mHealth study, particularly those that use an ML algorithm to trigger EMAs. Therefore, we propose that future work should focus on a smart trigger that promotes EMA receptivity without influencing affect during sampled time points.

Introduction

User Engagement in Mobile Health Systems

Mobile health (mHealth) technologies continue to grow within the health care sector and are imperative for precision medicine initiatives. mHealth can provide beneficial interactions between health care providers and patients outside clinical settings. An engaged and responsive user base in any mHealth system is vital for maximizing the knowledge that researchers and providers acquire. Mental health research mainly depends on active users because investigators rely on participant survey responses to establish ground truth. Researchers can only adequately interpret the relationships between physiology and psychological state with a population that is compliant with sensors and surveys. Evaluating a health construct is only possible with highly receptive participants in mHealth studies.

Here, we discuss 2 forms of interaction between participants and mHealth systems: ecological momentary assessments (EMAs) and just-in-time interventions (JITIs). EMAs gather in situ data from users in real time. EMAs are commonly used in mHealth studies, as they allow researchers to prompt participants regularly throughout the day [1]. In the case of mHealth studies focusing on psychological states, EMAs enable users to report their momentary symptoms or context in a natural environment, often using smartphones, because of their accessibility. JITI is a method that allows investigators to send interventions as needed. The just-in-time adaptive intervention (JITAI) uses incoming information (physiological, contextual, or psychological markers) as context to determine when an intervention is required [2]. Researchers have been working on enhancing the efficiency of these interactions. As mentioned previously, this effort is crucial because ineffective interactions in an mHealth study can have significant effects on outcomes. Failing to collect EMA responses may impede researchers' ability to identify real-world measures of health behaviors, and without participants receiving or engaging in JITIs, researchers may find it challenging to measure the efficacy of the intervention.

Improving EMA Receptivity

To enhance compliance with EMAs and JITIs, it is imperative to gain a comprehensive understanding of the factors that influence participant adherence. Ho and Intille [3] described 11 factors that influence a person's interruptability (willingness to follow through if notified or interrupted). These factors encompass contextual aspects, such as social engagement, ongoing activities, future schedule, and emotional state, as well as message-related attributes, including frequency, complexity, modality, and utility.

Currently, many researchers have reduced interruptability by altering message-related attributes, often involving strategies such as reducing the complexity or frequency of an EMA or increasing the incentives for a response [4,5]. Reducing the size of the instrument relieves some of the burden associated with answering an EMA [6]. This is done by excluding redundant questions or by choosing a less complex instrument. The Perceived Stress Scale [7] was initially a 14-item question set. However, after some statistical analysis, researchers found that a 10-item instrument was sufficient for measuring stress. Another factor affecting receptivity is the frequency at which users are sampled. In 2 separate reviews, researchers demonstrated conflicting findings regarding the effects of frequency on EMA compliance [8,9]. These conflicting results can be attributed to the author's focus on differing populations and the many other factors that play a role in EMA compliance. The third method for improving receptivity rates is to increase the incentives based on EMA compliance. However, this method can be costly and seen as exploitative, especially when dealing with susceptible populations.

An emerging method for improving receptivity rates is the use of machine learning (ML). This can be achieved by using wearable data to predict the likelihood of a response, which can help deliver EMAs that mitigate interruptability. Mishra et al [10] used ML models built from previously collected data to improve the receptivity of a JITAI by contacting users at points where they are more likely to be receptive. The study showed a difference of >38% in receptivity rates between an ML-based static model (using previously collected data) and a control model (using a set schedule) to distribute EMAs. Mishra et al [11] built a model for predicting the optimal time to send an EMA. Their results demonstrated that a model built from contextual cues such as activity, audio, conversation, and location could significantly outperform a baseline model (prediction based on the proportion of responded EMAs). Researchers have also shown that contextual cues, including location [12,13], personality traits [14,15], physical activity [14,16], and time of day [17], influence participants' willingness to respond to regular surveys. Together, these methods can predict and respond to the unobserved contextual aspects of an interruption, thus offering a more holistic approach to addressing participant engagement. However, a system that reacts to these contextual aspects may have unintentional effects on the response of the user. For instance, emotional state is an underlying factor that affects receptivity. A model designed to initiate EMAs when a participant is most likely to respond favors prompting users when experiencing positive emotions. Consequently, this approach could influence the reported emotional state during each prompt, potentially making it challenging to collect subjective responses during negative emotions. Understanding the influence of ML-based EMA triggers on these underlying receptivity factors allows us to incorporate additional variables into an algorithm. Integrating predicted affect into the decision-making of an ML-based EMA trigger will ensure that participants receive prompts across a broad spectrum of emotions.

Relationship Between Affect and EMA Receptivity

Clark and Watson [18] described how positive and negative affect (NA) can influence participation in activities of daily living. Their results show differences in the expected mean across many social activities, with reported positive affect (PA) having more significance in differentiating the 2 groups. Similarly, research has also demonstrated a negative relationship between students' emotional state and academic achievement [19,20]. Although none of these studies demonstrate the relationship between affect and EMA receptivity during mHealth studies, they all demonstrate the effect of emotional state on a participant's general ability to engage in normal activities of daily living.

Several authors have examined the effect of emotional state on EMA adherence by using the preceding response as a gauge of affect during instances of nonresponse. Murray et al [21] conducted a study (N=261) demonstrating that NA and stress reduce the chance of a response during the next prompt. Other researchers have expanded on this by examining various contextual cues within an EMA that precede instances of nonresponse. The authors found that variables such as medication use, activity, battery life, and being away from home negatively impacted the compliance of the following EMA [22,23]. This work contributes to understanding how affect can influence participants' response behavior but falls short of providing real-time explanations for the absence of responses. Alternatively, real-time explanations for receptivity can be derived through passive sensing and ML. Leveraging these explanations allows for delivering EMAs at moments of heightened receptivity, guided by current contextual and physiological factors.

Objectives and Hypothesis

This study aims to analyze the relationship between participant EMA receptivity and affect in a 10-day wearable and EMA–based affect-sensing study (N=45). We hypothesize that a relationship exists between EMA receptivity and affect in mental health–related mHealth studies. We can establish the relationship between emotions when participants respond. However, to investigate this connection during nonresponses, we need to infer affect when a participant fails to provide a response. Therefore, we implemented ML models for identifying receptive time points and predicting emotional states. This allowed us to determine whether there was a statistically significant difference in emotions between responses and nonresponses. If this relationship exists and the likelihood of a response is dependent on emotional state, it would bias the outcome of an ML-based EMA delivery mechanism.

Methods

Ethical Considerations

Ethics approval was granted by the *Sociaal-Maatschappelijke Etische Commissie* of Katholieke Universitei Leuven (G-2018 09 1339) [24]. Informed consents were obtained from the participants. All data was de-identified prior to analysis.

Data Collection

This study included 45 healthy adult participants from Leuven, Belgium [24]. The average age of the participants was 24.5 (SD 3) years and ranged from 19 to 35 years. In total, 84% (38/45) of the participants were female. The participants were recruited via flyers distributed to areas around Leuven.

The study lasted for 10 days. The participants wore a sensor suite (Figure 1), including a chest patch with 2 electrodes for gathering electrocardiography (ECG) at 256 Hz and a wristband for electrodermal activity (EDA) at 256 Hz, skin temperature at 1 Hz, and accelerometer at 32 Hz. Participants were allowed to remove the device while they slept and were asked to remove the devices while bathing or participating in rigorous activities. The sensors had a battery life that surpassed the duration of the study, and the data were recorded on the device on an SD card.

Figure 1. (A) Chest patch for gathering electrocardiogram and accelerometer and (B) wristband for gathering electrodermal activity, skin temperature, and accelerometer.

Participants were given a research phone, and 10 EMAs were sent to the participants daily at random time points between 15 and 90 minutes apart. EMAs were initiated via text messages, and the participants had a specific amount of time to respond to the survey attached to the text message before it closed. The EMAs contained a question set to assess mood [25] in 3 languages: English, Belgian, and French. In total, there were 13 questions, including 9 negative (worried, stressed, anxious, annoyed, down, restless, tense, under pressure, and ashamed) and 4 positive (relaxed, cheerful, confident, and in control) affect-related questions. The questions were prefaced with the phrase "At the moment, I feel...," followed by a rating scale for each emotion, ranging from 1 (not at all) to 7 (very much). The participants were given €0.5 (US $0.54) for each EMA they responded to.

EMA Analysis

Our EMA question set was scored by adding the numerical interpretation of the 9 negative responses to the inverse (1 is 7 and 7 is 1) of the positive questions. The range of possible scores was between 13 and 91, with higher scores indicating more negative emotions. Owing to the low variance in reported positive and NA, we used a composite score of both positive and NA.

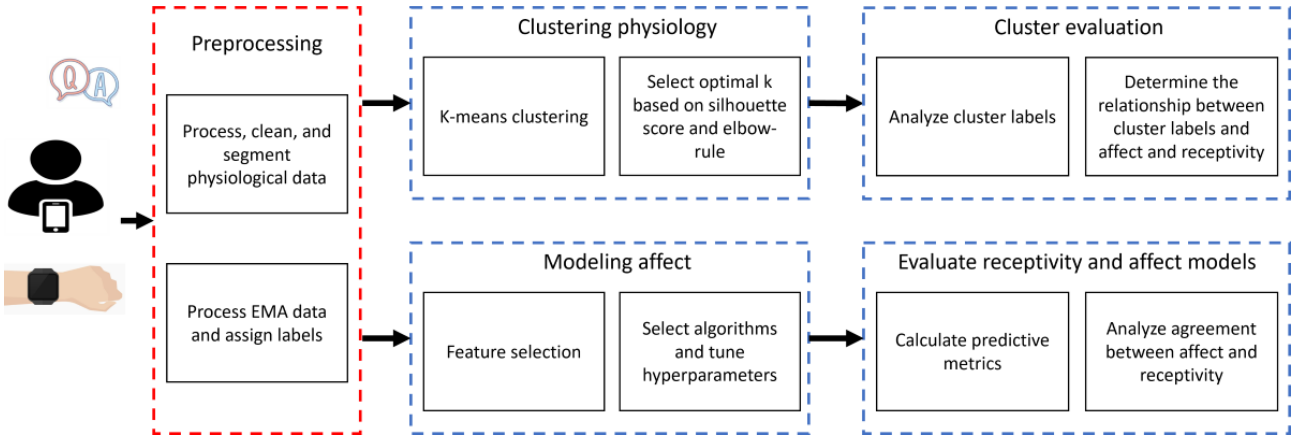
We also analyzed the participants' response time (time between the notification and onset of EMA) and the response rate to EMA. We then investigated the potential for loss of engagement over time, which may lead to reduced participant receptivity. The lack of engagement may impede our capacity to discern the underlying causes of nonresponsiveness, particularly when assessing the relationship between affect and receptivity.

EMA Receptivity and Affect Detection Models

Overview

In the following sections, we discuss the sequential methodology, which encompasses the collection of raw signal data, the subsequent data processing and feature extraction, and the design of ML models for inferring 2 constructs—receptivity and affect. This framework is shown in Figure 2.

Figure 2. Methodology used from the raw signals to our evaluation of the relationship between affect and receptivity. EMA: ecological momentary assessment.



We began by processing our 4 sets of time series data: skin temperature, ECG, EDA, and accelerometer. Once we processed the data, we segmented them and attached labels to each segment based on the conditions explained in the *EMA Receptivity Labels* section. Next, we built and tested multiple ML algorithms to infer EMA receptivity and affect and verified the results using several statistical techniques.

Preprocessing

Time Series Processing

We began by extracting all the data from the 4 time series data sets. Table 1 shows the features computed for the 4 sets of the data. We used IQR to process skin temperature to remove outliers. We used *biosppy* [26] for the ECG to process the data and extract the R peaks. *Biosppy* uses a bandpass filter with frequencies of 3 Hz and 45 Hz, a sampling rate of 256, and the Hamilton segmentation algorithm to extract R peaks. We then validated the R peaks using an algorithm by Hovsepian et al [27]; this algorithm uses the criterion beat difference based on the maximum expected difference for a beat and the minimal artifact difference. We then used heart rate variability analysis to extract heart rate and heart rate variability features such as number of pairs of successive normal-to-normal intervals that differ by more than 20 ms and root mean square of successive differences between normal heartbeats [28]. We also obtained some frequency- and geometric-based features. For EDA, we used the method proposed by Taylor et al [29] to process and extract the statistical and wavelet features. Finally, for accelerometer, we smoothed the signal by using a fourth-order 10-Hz low-pass Butterworth filter and obtaining an average, and then, we used a package from the study by Simon [30] to extract step features. The features we extracted and the information on how those features were calculated are shown in Table 1.

Table 1. Features from our 3 raw sources and definitions of the features that are less commonly used.

Signal	Features	Description	Prior work
ST[a]	Mean, median, mode, minimum, range, root mean square, zero cross, kurtosis, skew, and IQR (25th percentile and 75th percentile)	Zero cross here is based on the number of times ST crosses over the mean ST. Kurtosis measures the extremity of the data in the segment, and skew is the measure of asymmetry.	[31]
ECG[b]	Mean, median, mode, minimum, range, root mean square, zero cross, kurtosis, skew, IQR (25th percentile and 75th percentile), RMSSD[c], CVSD[d], CVNNI[e] SDNN[f], NNI50[g], NNI20[h], PNNI50[i], PNNI20[j], LF[k], VLF[l], HF[m], high/low-frequency ratio	Normal to Normal or RR[n] interval indicates time between heartbeats. NNI20 or NNI50 refers to the number of successive intervals that differ by more than 20 or 50 ms. "P" indicates the proportion of NNI20 or NNI50 in the segment. RMSSD is the root mean square of successive differences between heartbeats. CVNNI and CVSD are the coefficients of variation SDNN/mean and RMSSD/mean, respectively. Our frequency domain features are based on how much of the signal lies between 0.003 and 0.04 Hz (VLF), 0.04 and 0.15 Hz (LF), and 0.15 and 0.40 Hz (HF).	[32-35]
Electrodermal activity	*Wavelet:* maximum, mean, SD, median, and above zero (1-second and half-second wavelet); *raw*: amplitude, maximum, minimum, and mean; and *filtered*: amplitude, maximum, minimum, and average	A 1-second and a half-second window were used for wavelet features. Features were calculated for both the first and second derivatives of each window size.	[31,36-39]

[a]ST: skin temperature.

[b]ECG: electrocardiography.

[c]RMSSD: root mean square of successive differences between normal heartbeats.

[d]CVSD: coefficient of variation of differences between adjacent normal-to-normal intervals.

[e]CVNNI: coefficient of variation of the normal-to-normal intervals.

[f]SDNN: SD of the normal-to-normal intervals.

[g]NNI50: number of pairs of adjacent normal-to-normal intervals differing by more than 50 ms.

[h]NNI20: number of pairs of adjacent normal-to-normal intervals differing by more than 20 ms.

[i]PNNI50: percentage of pairs of adjacent normal-to-normal intervals differing by more than 50 ms.

[j]PNNI20: percentage of pairs of adjacent normal-to-normal intervals differing by more than 20 ms.

[k]LF: low frequency.

[l]VLF: very low frequency.

[m]HF: high frequency.

[n]RR: R-peak to R-peak.

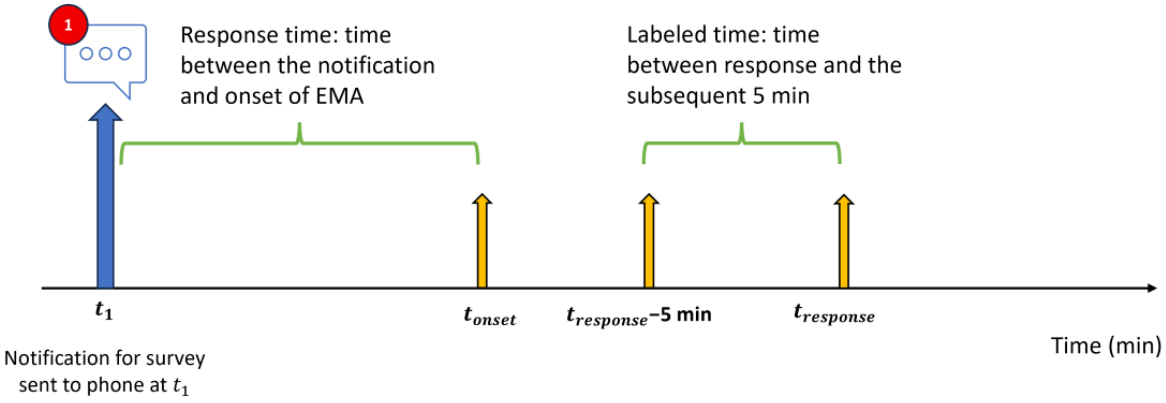
Segmentation

We segmented the data into 1-minute windows with a 30-second overlap. We then calculated the statistical features for each of the sensors, excluding steps. For each of these windows, we calculated historic features. To do so, we elongated each of the windows by 5, 30, and 60 minutes and then extracted the features with the extended window size (ie, for each 1-min window, we have not only the features from the 1 min but also the features going back to these 4 time frames).

EMA Receptivity Labels

Labels for receptivity were based on whether the user responded to the EMA and were assigned to segments based on whether it was within a specified time of the scheduled notification. By expanding the window of labeled data, we can increase the size of the labeled data set (pseudolabeling). However, as this window increases, so does the distance between some of our time points and the corresponding label. We tested windows that are 5, 30, 60, and 120 minutes long. For instance, for the 5-minute window, if an EMA was sent at midnight, the segments that fell between 11:55 AM and midnight would be labeled "responded" if they did respond and "no response" if they did not. We applied the same method for the affect labels (Figure 3). We ultimately chose 30-minute windows owing to the balance between the size of the training set and the labeled points being relatively close in terms of time to the actual response (or nonresponse).

Figure 3. Representation of our labeled segments for the 5-minute window. It also demonstrates how we calculate response time (time between notification [t1]) and the start of the ecological momentary assessment (EMA; tonset).



Affect Labels

Previous research on monitoring and tracking emotional states using wearables has commonly used binary or categorical affect measures to detect emotions [40]. These psychological instruments often feature well-defined categorical score representations, which make it easier to distinguish between emotions. The distribution of the reported composite affect scores made defining an adequate categorization of the labels difficult. Most participants reported positive emotional states, which complicated setting an appropriate cutoff. Setting the cutoff at a high value would result in an imbalanced set of labels, whereas selecting a lower value would create a balanced data set but lack logical consistency. For instance, choosing a cutoff of 26 to distinguish between positive and negative emotions would lead to a balanced data set. However, the range of possible responses was between 13 and 91, so a response would be considered negative even if the participant indicated relatively positive or neutral emotions.

In response to these challenges, we used recorded composite affect values as our class labels and designed our ML algorithms as a regression problem. Although this method of affect inference is less commonly found in the literature, it prevents the need for arbitrary data classification. Given that the data exhibited an inherent imbalance, with less frequent occurrences of negative emotional states, using regression may still affect our ability to predict these less common negative emotions.

Analysis of the Relationship Between Features and Receptivity and Affect

We examined the significance of each feature in terms of its ability to predict affect and receptivity. To do so, we conducted a repeated measures ANOVA test to assess how well each feature is related to the response class labels. In addition, we used a linear mixed model (LMM) to investigate the relationship between features and affect scores. We used an LMM because we worked with constant labels instead of converting the affect score into binary or categorical values, as done for receptivity. The dependent variable (affect score) was regressed on the fixed effect variable (features), while accounting for random effects (participant ID). These tests help identify any features or signals that may have significance in determining receptivity or affect.

Receptivity and Affect Model Design and Hyperparameter Tuning

We designed ML models to infer EMA receptivity and affect. A wide variety of ML algorithms are used in affect and receptivity prediction including random forest (RF) [31,32,39], support vector machine [33,34,39], logistic regression, *k*-nearest neighbors [30], neural network (NN; long short-term memory, recurrent NN, convolutional NN, etc) [31,39], and naive Bayes [39,41]. On the basis of our sensor data, initial tests, and drawing inspiration from previous studies, especially those by Mishra et al [10,11]. We selected (1) RF for predicting emotional state and receptivity, (2) an NN for predicting emotional state, and (3) a baseline model. This baseline model serves as a benchmark for evaluating whether our models outperform random chance, whereas the NN algorithm was introduced as a possible improvement on existing model implementations. Unlike the research mentioned previously, we used physiological data rather than contextual data. These signals are sampled at higher frequencies compared with contextual data and allow the extraction of more fine-grained features, making NNs more feasible. We designed personalized models to infer the receptivity and effect of EMA.

To optimize our personalized model, we selected hyperparameters using the grid search method for each participant, explicitly using the *GridSearchCV* method defined in *scikit-learn*. This method uses an exhaustive search method (ie, testing each user-defined parameter permutation). The hyperparameters tested included the number of estimators, maximum depth of the estimator, minimum number of samples per leaf, minimum number of samples for split, and maximum number of features that can be used for the split. Using training and validation sets, we selected the parameters and then applied the optimal model to our test set. The optimal set of hyperparameters differed for each participant, although the most common optimal hyperparameters chosen included 60 estimators, maximum depth=3, minimum sample leaf=2, minimum sample split=2, and maximum features=square root of the number of features.

Our NN model was structured to use 3 densely connected layers using a rectified linear unit activation function at each layer. The output dimension of each layer was 256, 128, and 64, and the output layer was a densely connected layer with 2 output

dimensions. The reasoning for an output layer of 2 is to define a CI for our regression model.

The baseline model was built by predicting random output based on the distribution of the class labels in the training set (ie, if 10/100, 10% of the labels were nonresponses and 90/100, 90% were responses, the model would predict nonresponses 10/100, 10% of the time). We can determine the expected outputs for this model; our true positive rate should be equal to *Pr(response in the training set)* × *Pr(response in the test set)*. The more evenly the class labels are distributed, the worse the performance of the model. For the affect regression models, we used a normal sampling method with the mean and SD based on the training set class labels.

As there are more labeled responses compared with nonresponses, we considered this imbalance in the receptivity prediction model, weighting the classes based on the distribution in our training set. All models were built using the Python packages *scikit-learn* [42] or *Tensorflow* [43].

Model Uncertainty

To determine the relationship between affect and receptivity, we must use predictions to infer the emotional state of our participants during nonresponses. As affect is a complex and difficult-to-predict construct, we need a method for filtering our predictions based on some level of confidence. Therefore, we introduced a method for calculating uncertainty for regression using an NN.

Determining a confidence value for a regression model is difficult compared with a binary or categorical model. We can use a custom loss function in our NN to estimate epistemic and aleatoric uncertainty for our regression model, where epistemic uncertainty is based on our ability to predict our class labels with the available data (affected by lack of knowledge or data), and the aleatoric uncertainty is affected by randomness, which is unknown or unmeasured in the model [44].

Our affect prediction model outputs are 2D rather than a single predicted output. The first output is the predicted affect, $\mu(x)$, and the second output, $\ln(\sigma(x))$, is the predicted variance (the log allows us to take the exponent to ensure a positive value for σ). Both μ and σ are functions of our training set x.

The loss function L is shown in the equation (custom loss function for measuring model uncertainty) and is derived from the mean square error (MSE) calculation and the maximum likelihood of a normal Gaussian distribution [45]. The numerator of this equation is identical to the MSE loss function, where $\mu(x)$ is the predicted output of our model. Unlike the MSE loss function, we continuously update not only our predicted output μ but also the predicted variance σ. The σ output of our model is based on error; the sigma value increases to account for higher error and decreases to account for lower error. This σ value can be used as an uncertainty or error metric. Although it is still a predicted value, it should align with how confident the model is in the $\sigma(x)$ output. The σ value plays a crucial role in assessing the confidence of our affect predictions, given that we use predicted affect to infer emotional states during nonresponses. Consequently, to illustrate the relationship between the predicted sigma value and model uncertainty, we performed a mixed effect model analysis using affect scores and the predicted sigma values and tested whether greater uncertainty will occur in emotional states that are less frequently represented and when the testing error is larger. As uncertainty is a measure of the model's confidence in its predictions, we can reasonably assume that predictions associated with larger testing errors would correspond to higher levels of uncertainty.

Model Evaluation

For cross-validation, we used a personalized random train-test split cross-validation method. We randomly split the data into training and testing sets using the response label (whether they responded to the EMA or not) to stratify the split. Responses and nonresponses can encompass multiple segments; by grouping them together, we avoid splitting up segments from a single response or nonresponse. As our response labels are unbalanced, we want to ensure that our training, validation, and test sets have a relatively even number of responses and nonresponses. For the purpose of fairness, we excluded 3 participants who had a single nonresponse from our receptivity results.

We first normalized the training and test sets independently of one another based on the participant. In total, we obtained approximately 230 features from the sensor signals. We reduced our feature set using principal component analysis. Our implemented principal component analysis was set such that the number of produced components explained 99% of the variance (48 features). This method was used for each model, excluding the RF model, in which the original normalized data were used as the input.

Analysis of the Relationship Between Affect and Receptivity

Overview

We conducted two different analyses to understand the relationship between affect and receptivity better:

1. To infer emotional state during nonresponses, we clustered the physiological data and then examined the makeup of the clusters. By doing so, we can assume the emotional state of different clusters and unlabeled data points.
2. For EMAs the participants did not respond to, we used the affect prediction model described in the previous section to infer the emotional state at the time of a nonresponse. With these newly predicted affect scores, we can analyze the differences in the emotional state during a response and nonresponse.

Cluster Evaluation

We used the most significant features (based on correlation) when predicting receptivity for our clustering analysis. To determine the optimal clustering method, we tested several clustering methods, including hierarchical and *k*-means clustering, with a maximum number of iterations of 300. We then calculated the silhouette score across all clusters using receptivity as our ground truth and selected our best-performing set of hyperparameters. On the basis of the cluster distribution,

we analyzed the difference in the perceived emotional state of the participants. We calculated the average NA, PA, and receptivity rates in the clusters for each participant and then characterized the clusters based on receptivity rates (high receptive and low receptive clusters). Next, using repeated measure ANOVA, we demonstrated the statistical difference between affect and the clusters. Given that the clusters were created from physiological data, we know that the data points within each cluster are physiologically similar; therefore, we inferred that they would also exhibit similar psychological states. This allowed us to assign affect scores to nonresponsive data points within each cluster based on the labeled data points within that cluster. Unlike affect prediction, we used the raw NA and PA values in our evaluation as the clustering was performed independently of affect scores; therefore, the lack of variance in responses did not affect the output of the clustering. These results gave us a sense of participants' perceived emotional state during nonresponses. We also investigated differences in receptivity in 2 clusters using the chi-square test.

Analysis of the Receptivity and Affect Relationship

Ideally, we would show the interaction between affect and receptivity using the data collected. However, because nonresponses do not have a corresponding affect score, we designed and implemented our models for receptivity and emotional state.

After generating predictions for our test data set, we assessed the agreement (using Cohen κ) and correlation (using the point biserial method) between receptivity and predicted affect, leveraging true labels at time points when affect measures were reported. A high level of agreement or correlation would suggest a strong relationship between these 2 constructs, thereby highlighting the potential influence each construct would have on an ML algorithm to predict the other construct. We then examined the disparities between the predicted affect during nonresponses and the reported affect during responses. By doing so, we can establish the extent to which emotional state influences receptivity. Substantial disparities in affect between responses and nonresponses suggest that participants' emotional states impact their receptivity. Consequently, a model designed to predict receptivity would indirectly include emotional state as a determinant of a participant's receptiveness. However, it is essential to acknowledge that some of these variations could be attributed to model error. As a result, we also compared the predicted and reported affects during responses to investigate the significance of the model error. We then calculated and visualized the cumulative distribution of these 3 sets of values to illustrate the influence of affect on receptivity and the associated model error.

Finally, we investigated the potential effects that an ML-based receptivity algorithm would have on reported affect, influencing the outcome of the study. On the basis of our receptivity model, we can estimate the difference in the reported perceived emotional state between our true findings and predicted affect during time points that would initiate an EMA.

Results

In the following sections, we discuss the results of our study, particularly the methods of evaluation that were discussed in the previous section.

EMA Analysis: Affect and Receptivity

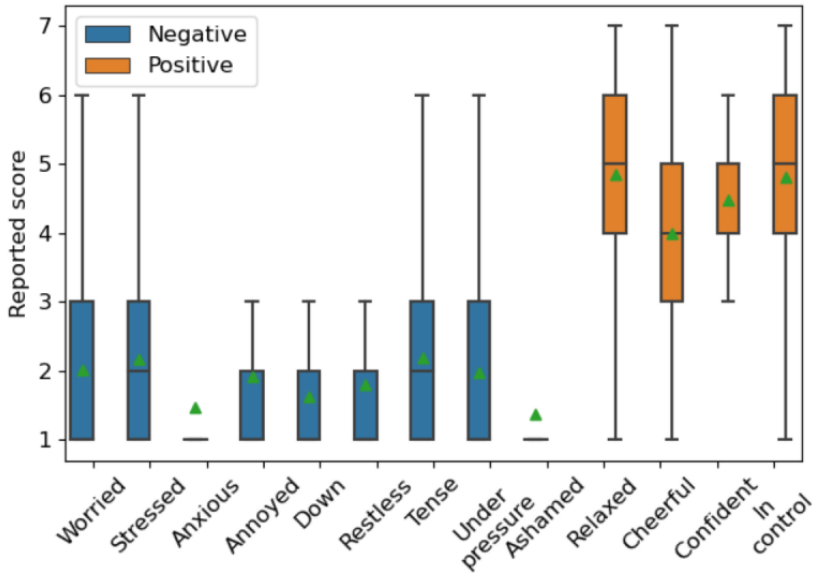
The distribution of EMA responses is shown in Figure 4. Although participants rarely indicated high negative emotions, this trend is evident in Figure 5, illustrating a box plot of composite scores for each participant. Participants' average and median reported affect were <26, meaning that, on average, the participant responded to each question with a relatively low score of 2 (on a scale between 1 and 7, where 1 indicates high positive emotion and 7 shows high negative emotion). We also investigated participants' emotional states as the study advanced and observed minimal to no variations based on their duration of enrollment or time of day.

On average, participants responded with a 4.5 for PA questions and a 1.8 for NA questions. This disparity in affect intensity was consistent with previous research [23]. There was a slight difference in the reported affect between male and female participants. On average, female participants responded with a 1.9 (SD 1.08) for the NA questions and 4.5 (SD 1.3) for the PA questions, whereas male participants responded with a 1.8 (SD 0.9) for the NA questions and 4.7 (SD 1.0) for the PA questions.

Of the 3885 notifications sent to the 45 participants, there were 3066 (78.92%) responses. As the study persisted, there was little to no drop-off in receptivity rates over time. This finding helped confirm that loss of engagement was not a contributing factor to receptivity. Most studies have stated that the quality receptivity rate is at 80%. The range of response time (time between notification and initiation of the EMA; Figure 3) was between 0.5 seconds and 306 seconds. Participants responded to the notification on average in 20.9 seconds and had a median response time of 8.7 seconds. There were no responses after 306 seconds of a notification. The reason for this fast response time is that participants were allowed 90 seconds to begin the survey, after which the survey would no longer be accessible (we had a few responses after the 90-second restriction owing to software or design issues). This restriction makes it challenging to relate response times to participant affect, as has been done by other researchers.

We found that none of the mood responses were strongly correlated with the time to respond. Across each question, we did not obtain a correlation coefficient >0.03 (all correlations indicated significant confidence; $P<.05$). This low correlation coefficient indicates that the participant's mood had little to do with how long it took the participant to initiate the EMA. Although considering the limit we put on the response time, this relationship might be difficult to assume.

Figure 4. Question set: includes the 13 questions used to measure affect with their mean, SD, and correlation to the final affect score. For each question, participants were asked to rate the degree they were experiencing each emotion. These 13 questions can be split into positive affect (orange) and negative affect (blue).



Analysis of Features

The features that we found to be the most significantly related to receptivity were ECG low frequency (1 min, momentary: $F_{2,54}$=6.7; P<.001) and very low–frequency features (1 min, momentary: $F_{2,54}$=4.7; P=.02 and 60 min: $F_{2,54}$=4.1; P<.001); EDA mean ($F_{2,54}$=10.2; P<.001) and median ($F_{2,54}$=15.4; P<.001); number of pairs of adjacent NN intervals differing by more than 20 ms in the 5 and 60 minute windows; percentage of pairs of adjacent NN intervals differing by more than 50 ms in the 30 minute window ($F_{2,54}$=11.2; P<.001); and maximum ($F_{2,54}$=6.3; P<.001), minimum ($F_{2,54}$=3.6; P=.009), and absolute maximum ($F_{2,54}$=6.6; P=.002) of the first and second derivatives for EDA. These results show that ECG and EDA-related features were best at differentiating between responses and nonresponses compared with features derived from accelerometer and skin temperature.

When running the LMMs to determine the relationship between features and emotional state, we found a nonsignificant relationship between affect scores and steps or sleep features. However, heart rate was significant when predicting emotional state, particularly negative emotion. This LMM showed a significant positive relationship between heart rate and affect (β=.007; P<.04). This underscores the significance of heart rate as a predictor of emotional state, although it does not necessarily imply that steps and sleep features lack importance in this context.

Receptivity and Affect Models

After processing, cleaning, and filtering out segments with confounding values, we obtained 1368 responses with usable physiological data. As our class labels were expanded to include segments 30 minutes before the point of response (pseudo labeling), we ended up with 13,477 data points for determining affect and 17,254 data points for predicting response.

Model Performance

Table 2 shows the results of our receptivity (binary) and affect (regression) models. On the basis of these results, there was little difference between the RF and NN models, although we used the NN models to demonstrate the relationship between affect and receptivity in the following section.

Table 2. Model results for predicting receptivity (binary) and affect (regression).

Model	Accuracy, mean (SD)	Precision, mean (SD)	Recall, mean (SD)	F_1-score, mean (SD)	Root mean square error (SD)
Baseline	0.73 (0.001)	0.83 (0.002)	0.84 (0.002)	0.83 (0.002)	11.1 (4.3)
Neural network	0.84 (0.19)	0.82 (0.006)	0.85 (0.10)	0.86 (0.20)	7.3 (2.7)
Random forest	0.83 (0.11)	0.82 (0.15)	0.94 (0.10)	0.87 (0.12)	7.5 (3.1)

Analyzing Uncertainty in the Affect Model

Figure 6A shows the relationship between the calculated sigma value (uncertainty) and the reported affect scores. Uncertainty should follow a pattern where class labels that are more represented in the training set should have lower uncertainty. Conversely, values that are less represented in the data set should have larger uncertainty. As can be seen, Figure 6A σ values are smaller when the reported emotional state is more positive. As shown in Figure 5, most respondents indicated relatively low composite scores, with a few participants reporting an affect score >40. We also observed a statistically significant relationship between sigma and affect scores, as shown in Figure 6A, using a mixed effect model. In this model, we accounted

for the random effect associated with participants, as indicated by the mixed linear model results (intercept: 7.090; P<.001 and affect score: 0.002; P=.046).

Figure 6B shows the relationship between σ and the testing error; in particular, σ values were larger when the model was further from the ground truth. This relationship shows that our σ value is an accurate representation of model uncertainty. On the basis of Figure 6, we can say that the σ value we calculated is related in some way to uncertainty. Figure 6B shows that most responses indicating an affect score of <39 had a σ of <6. Therefore, we chose 6 as the cutoff for uncertainty. This cutoff filters out many of the predictions that are more likely to have higher errors because we cannot look at errors during nonresponses, as we have no affect label.

Figure 5. Box plot of perceived emotional state, minimum is 13 (negative) and maximum is 91 (positive). The average perceived emotional state is 26.42, denoted by the blue horizontal line.

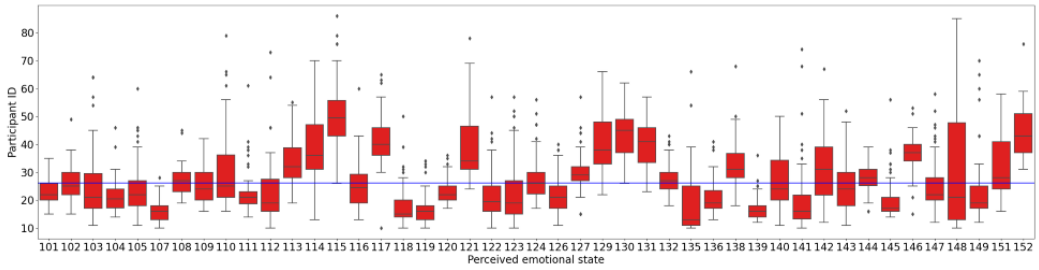


Figure 6. Box plot showing the σ value for (A) true labels and (B) predicted error.

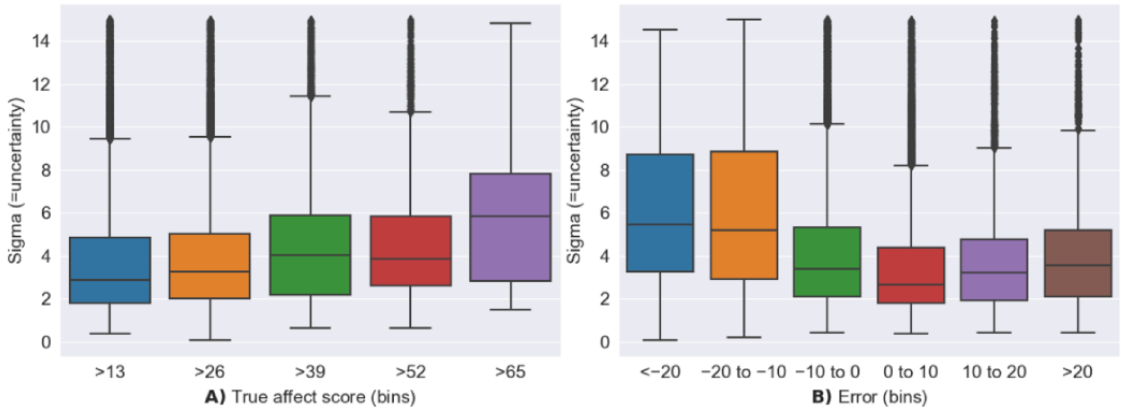


Receptivity and Affect Analyses

Cluster Analysis

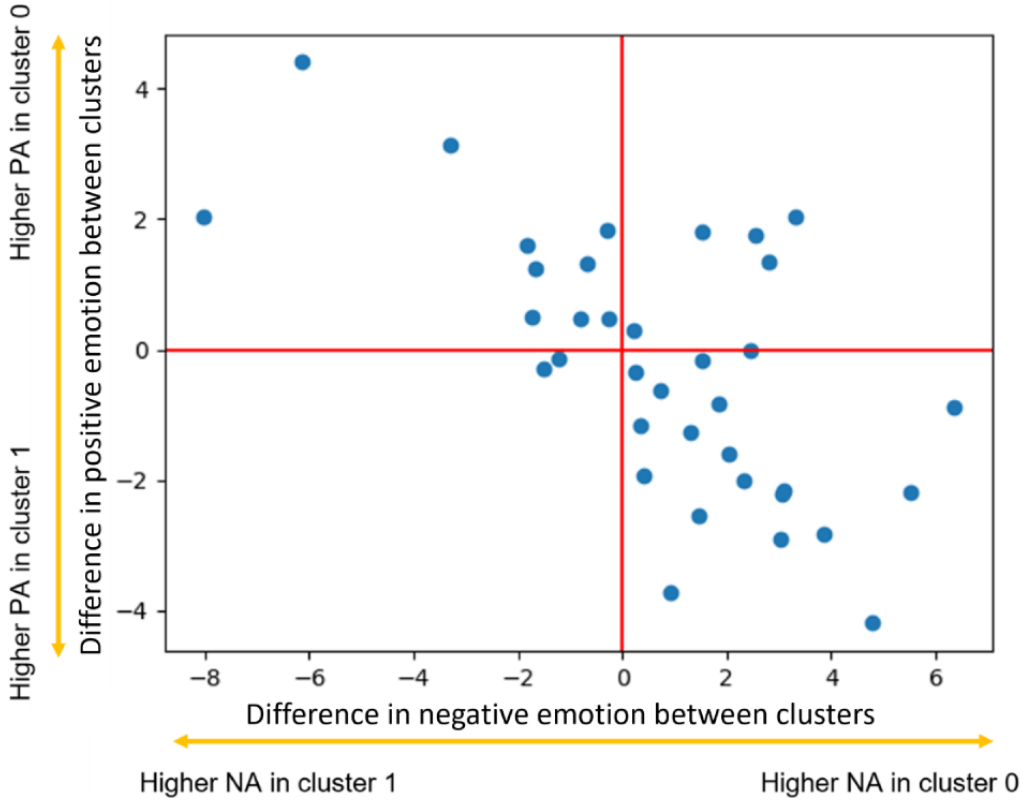
On the basis of the "elbow rule" of silhouette scores, we chose *k*-means as our clustering method with 2 clusters. We found that the distribution of receptivity was somewhat different between clusters. Cluster 0 contained a higher density of responses, with just <15% nonresponses, whereas cluster 1 had a higher density of nonresponses of just >21%. We first analyzed the overall affect scores in the 2 clusters, where we found the average reported affect score in cluster 1 to be >3 points higher than the average reported affect in cluster 0 (repeated measure ANOVA, F_2=23.16; P<.001). The receptivity rates and average reported affect scores for the 2 clusters are shown in Table 3. We also found that the distribution of receptivity was different between the 2 clusters using the chi-square test of independence (χ^2_2=898.8; P<.001). These results indicate distinctions between response and affect across the cluster labels. Considering that the cluster with a higher density of nonresponses (cluster 1) also had a higher average affect score (higher scores indicate more intense negative emotions or lower positive emotions), we can assume that there was a relationship between EMA receptivity and reported affect.

Figure 7 shows a scatter plot of the difference in perceived PA between the 2 clusters and the difference in perceived NA between the 2 clusters for each participant. The results show that participants' perceived emotion was more negative regarding lower PA and higher NA in cluster 1 compared with their perceived emotional state in cluster 0. As stated earlier, cluster 1 contains a higher percentage of nonresponses compared with cluster 0, indicating that cluster 1 is a better representation of a nonresponse. Therefore, it appears that there is a relationship between negative perceived emotional state and receptivity. Using the cluster labels as groups, we calculated the F test statistic using an ANOVA test for each feature. The features that separated the 2 clusters were mostly calculated from the ECG signal, including the minimum heart rate, low or very low frequency, mean heart rate, coefficient of variation of the NN intervals, coefficient of variation of differences between adjacent NN intervals, high frequency, and maximum heart rate (in order of F_1-score). Features obtained from the EDA, accelerometer, and body temperature did not return significant P values when calculating the F test statistic.

Table 3. Receptivity rates and average reported affect scores in each cluster.

Cluster number	Receptivity rate	Reported affect score, mean (SD)
Cluster 0	0.85	24.3 (4.7)
Cluster 1	0.78	27.3 (4.9)

Figure 7. Each point represents a participant, where the x-axis denotes the difference between average negative affect (NA) of cluster 0 and 1, whereas the y-axis represents the difference between average positive affect (PA) of clusters 0 and 1.



Relationship and Analysis Between Receptivity and Affect

Figure 8 shows the cumulative distribution of reported affect scores for responses and predicted affect scores for responses and nonresponses. On the basis of this figure, there is a clear difference between the predicted affect during nonresponses and our true affect scores. Although this could be a model error, we also predicted affect scores during these responses and found that our model consistently predicted lower affect values (higher PA).

There was a fair amount of agreement between our affect and our binary response model, with a Cohen κ score of 0.33 and a correlation of 0.44. When our model predicted a response, 77.42% (22,761/29,399) of the segments were during times when the affect model predicted PA. Only 69.72% (7760/11,131) of the predicted nonresponses reported PA. This indicates that the predicted response is negatively related to affect (ie, responses are associated with PA, whereas nonresponses are associated with NA). The reason determining the relationship between our constructs is important is because this bias can, and as we show, affect the overall outcome of a study. For instance, the average predicted affect score for times that we predicted as low likelihood for a response was a full 1.5 (SD 1.35) or 2.01 points higher than the average predicted affect for points predicted to be of high likelihood for a response. When observing only the segments where we misclassified a response (ie, we had a true affect, but the response was misclassified as a nonresponse), we found that the average affect score dipped slightly from 26.1 (predicted nonresponse) to 25 (predicted response). This difference in affect between responses and nonresponses is evidence that our receptivity model is indirectly based on affect. The SD of the affect score also decreased from 11.1 (true labels) to 9.8 (true affect and predicted response) during responses.

The average predicted affect score for a nonresponse was 30.9 (SD 11.2), and the average affect score for a response was 29.3 (SD 10.7; true) and 27.7 (SD 8.9; predicted). The predicted affect scores during nonresponses were higher than the reported and predicted affect scores during responses. Given that our average testing error was −1.6, we could also assume that the predicted affect during these nonresponses could be more negative than the true predictions. The distribution of these scores is shown in Figure 9. In Figure 9, all 3 groups' affect scores peaked at around 20 to 25; this is probably owing to the large number of reported affect scores in this range. However, nonresponses had a second peak at an affect score of 40. This bimodal distribution could indicate that our affect distribution

during nonresponse was affected by ≥2 factors. Some nonresponses may not be affected by their affect but perhaps by their daily life activities (seeing a movie, spending time with family, showering, etc). In contrast, the second peak indicates that NA is related to nonresponses.

Figure 8. Cumulative distribution of predicted and actual affect scores for responses and nonresponses.

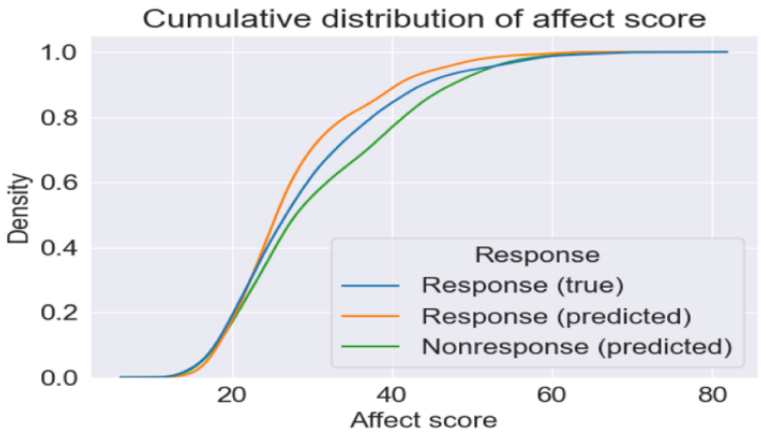


Figure 9. Distribution of predicted and true affect scores for responses and nonresponses. Density is specific to the response and nonresponse.

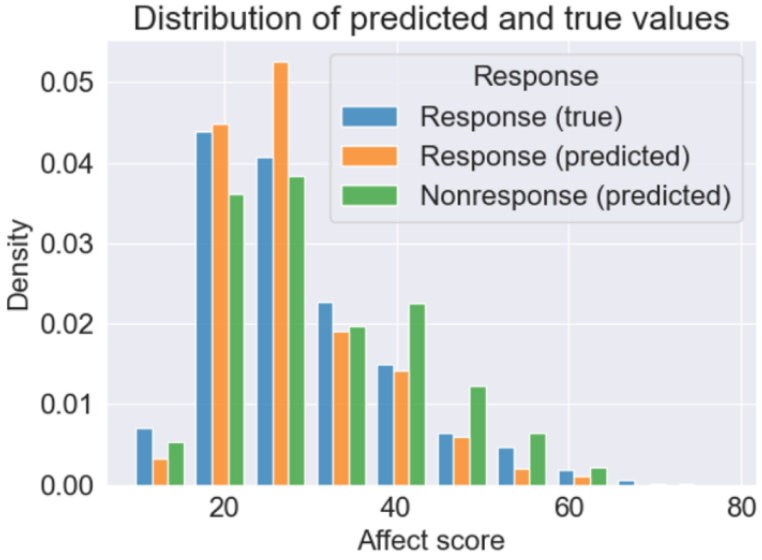

Discussion

In this section, we discuss the outcome of our study, particularly the relationship between emotional state and receptivity, what that means, how it affects our results, and how we might implement a receptivity model that removes this bias. We also mention the limitations of this study.

Principal Findings

This study aimed to understand how ML models used to improve participant receptivity can affect the outcome of a study. Although we focus on emotional state in this study, we feel as if there are many health constructs and outcomes that can be affected by these receptivity models. Improving receptivity is not a new concept, but in the realm of mHealth, it is an emerging problem. The factors influencing study adherence have been analyzed and discussed in depth in previous research. One such scope is in medication adherence. Researchers have found many factors that influence medication adherence, from social, therapeutic, patient-related, and disease-related factors [46]. However, few have examined the momentary factors that affect adherence to medication or a health construct, and few have had the ability to do so without wearable sensors and momentary assessments.

Our findings using supervised learning and clustering indicate a clear relationship between emotional state and user receptivity. The clustering method demonstrated clear differences in affect between a highly receptive cluster and a less receptive cluster. The results of supervised learning demonstrate that users experience more negative emotions during nonreceptive time points. Although our results showed promise for a model dedicated to predicting response, we also showed the biases inherent in such a model. Ideally, we would want a receptivity model that is completely independent of emotion. Otherwise, we are influencing the participant's responses.

Our results demonstrate that an mHealth study implementing a receptivity trigger based purely on the likelihood of responding (a model that triggers EMAs and JITIs using predicted receptivity) will bias the participant's response. In this case, the model would initiate an EMA or JITI during times of more positive emotions, thereby decreasing the overall affect score

for the EMA and possibly sending the JITI during times when the intended construct was not being met. As our ability to predict binary affect is limited with this data set, we believe that using the affect regression and ground truth labels for responses will return the most realistic representation of affect during nonresponses.

Comparison With Prior Work

Our findings are consistent with those of the previous studies. Many prompt-level studies [21-23] found a relationship between nonresponses and higher levels of NA in previous prompts. Although these results can provide insight into what makes a participant less compliant with EMAs, they do not offer a reasonable method for using this information in real-time decision-making. Using ML, wearable sensors, and contextual cues allows researchers to predict noncompliance components and distribute EMAs accordingly.

Consistently, our models either surpassed or achieved equivalent performance compared with previous research efforts. We achieved F_1-scores ranging from 0.83 to 0.87 when predicting receptivity. In contrast, Künzler et al [14] reported F_1-scores of approximately 0.4 while relying solely on contextual features. It is important to note that these results are not directly comparable, as contextual data lack the granularity of the data collected in our study.

Regarding affect prediction, our results present a unique challenge for comparison because we used regression in our predictions, unlike most researchers who typically use binary or categorical labels for emotion recognition. We chose not to convert our ground truth data into binary or categorical labels because of the inherent ambiguity in setting the thresholds and the limited variance in user responses. The effectiveness of affect prediction can vary significantly depending on the specific construct of interest and the sensors and signals available. Schmidt et al [40] conducted a review and reported an emotion recognition accuracy ranging from 40% to 95% using wearable sensors and signals. In terms of regression analysis, Tuarob et al [47] achieved nearly identical root MSE scores (PA=7.37; NA=7.40) when forecasting positive and NA scores from Positive and Negative Affect Scale using RF regression and previously collected questionnaire data.

Limitations

In this section, we address the limitations of our study, which can be categorized as limitations in our population, study design, data collection, and affect prediction models.

The major concern of our study population is that our results may be specific to this cohort. The study population was very receptive, even with 10 EMAs sent daily. This could be difficult for other researchers to implement, as the frequency and complexity of the EMA are fairly burdensome. Although we believe that the relationship between affect and receptivity would extend to other studies, it is important to note that our population was relatively small (N=45), predominately young (age 24.5 y), and had a higher representation of female participants (38/45, 84%). Consequently, our results may be specific to our cohort and EMA question set, but previous studies analyzing medication adherence and prompt-level relationships between EMAs and nonresponses indicate that the effect of emotional state on receptivity is common across multiple populations [21-23]. Further research is needed to explore the extent of this relationship between different emotional states and receptivity across multiple populations.

One limitation of the study design is that we cannot examine how loss of engagement over time affects the relationship between emotional state and receptivity. There was little to no drop-off in receptivity rates as our study progressed. This may have been because of the relatively short time frame in which the participants were enrolled. As a result, it is difficult to explore the effect emotional state would have on EMAs in the latter part of a study when participants can be more fatigued and less engaged. In future work, we intend to study a population for an extended period to analyze how emotional state affects participant response rates later in the study. Ideally, this will allow us to see the rate at which responses decay, the causes, and how we might combat it. Furthermore, we believe that a measure of this decay in engagement could be included in our ML-based decision-making for delivering EMAs that mitigate study fatigue, similar to how we would use model uncertainty to diversify emotional response.

Another potential study design limitation is that the app and research phone were shared with participants. Carrying 2 phones, especially one dedicated solely to responding to EMAs, can be burdensome for participants. In addition, the app designed for EMA distribution requires further usability evaluation. In future work, we aim to develop an app that can seamlessly integrate into users' devices and assess its ease of use.

The data gathered in this study were limited to physiological features and user-defined responses. Although the physiological features make up a large portion of what researchers consider important for predicting psychological constructs, the data set lacks sampling contextual data. Certain contextual information is imperative for recognizing emotions and improving EMA response rates that cannot be obtained using physiology, such as social context. The social context can help infer the participant's emotional state and willingness to respond to an EMA or JITAI.

Similarly, by incorporating more psychological and environmental cues (personality traits, working hours, etc), we can better understand what to expect from our participants regarding receptivity and affect before the start of the study. Using these prestudy measurements, we could assess the type of participants enrolled. Specifically, what will be their needs regarding receiving and responding to EMAs. This will help us develop and personalize our ML models for affect and receptivity.

The last significant limitation of our study is the use of predicted affect labels in determining the relationship between emotional state and receptivity. We can never collect reported affect during nonresponses for this or any data set. We attempt to reduce this limitation by using uncertainty to filter out less-confident predictions. Nevertheless, the predicted affect is only as good as our models. The only way to overcome this limitation is to improve the affect models. Although some may argue that the quality of our models needs to be more robust to claim a

relationship between affect and receptivity, the effects of emotional state on engagement in social and daily life activities are well documented and consistent with our conclusion.

Conclusions

This paper presents the possibilities for bias in ML models to trigger surveys and interventions for participants in mHealth studies. Our results show a clear relationship between emotional state and user EMA receptivity. By designing an mHealth study using a "trigger" to improve participant response, it is imperative to consider some biases that may arise, in this case, affect. Participants were more likely to respond to an EMA during positive emotional states. If we distribute those EMAs to times when they are more likely to respond, we would further be biasing our participants' recorded emotional state. Although this may not be a significant problem for less responsive populations, for the general population, this could change researchers' perception of the participant's perceived emotional state. In this study, we did not examine other constructs that might be a factor of receptivity because affect is the focal point of this study. For this objective, we are collecting both subjective and physiological data. Although this may be broad, it can be applied to any construct, particularly the intended construct of an mHealth study.

The pitfall of any mHealth study, particularly those involving psychological concepts, is the dependency on subjective user responses. The sampling rate of subjective responses will always be less than that of the physiological sensors and even some contextual cues. As our feature set became increasingly comprehensive, our labeled data remained relatively sparse. Considering that our proposed trigger considers factors beyond receptivity, it would likely have lower receptivity rates compared with triggers solely based on receptivity. However, the importance of even a minimal increase in a user's adherence or engagement in a study can drastically improve researchers' understanding of the health construct.

The models discussed in this paper have mostly proposed single-objective optimization functions that try to optimize based on whether the model considers that a user will respond to an EMA. In future work, we will propose a multiobjective optimization function for triggering EMAs and JITAIs based on the likelihood of responding and an active-learning measurement of the health construct. This multiobjective function would base the timing of the EMAs on 2 separate objectives: receptivity and model uncertainty. By initiating EMAs or JITAIs based on these 2 objectives, we can obtain an expected response that is more diverse in terms of affect. We hope that the work presented in this paper can be used to further enhance communication and the ability to gain knowledge from participants.

Conflicts of Interest

AS has received travel reimbursement or honorarium payments from Leuven Mindgate, American Epilepsy Society, the Institute of Electrical and Electronics Engineers, and Apple. AS has also received research support from Microsoft, Sony Corporation, NEC Corporation, Pola Chemicals, and Meta and consulting fees from Gideon Health and Suntory Global Innovation Center. Abstract

Background: The relationships between alcohol marketing exposure, alcohol use, and purchase have been widely studied. However, prospective studies examining the causal relationships in real-world settings using mobile health tools are limited.

Objective: We used ecological momentary assessment (EMA) to examine both the within-person– and between-person–level effects of alcohol marketing exposure on any alcohol use, amount of alcohol use, any alcohol purchase, and frequency of alcohol purchase among university students.

Methods: From January to June 2020, we conducted a prospective cohort study via EMA among university students in Hong Kong who reported current drinking. Over 14 consecutive days, each participant completed 5 fixed-interval, signal-contingent EMAs daily via a smartphone app. Each EMA asked about the number and types of alcohol marketing exposures, the amount and types of alcohol used, and whether any alcohol was purchased, all within the past 3 hours. We used 2-part models, including multilevel logistic regressions and multilevel gamma regressions, to examine if the number of alcohol marketing exposure was associated with subsequent alcohol use and alcohol purchase.

Results: A total of 49 students participated, with 33% (16/49) being male. The mean age was 22.6 (SD 2.6) years. They completed 2360 EMAs (completion rate: 2360/3430, 68.8%). Participants reported exposure to alcohol marketing in 5.9% (140/2360), alcohol use in 6.1% (145/2360), and alcohol purchase in 2.4% (56/2360) of all the EMAs. At the between-person level, exposure to more alcohol marketing predicted a higher likelihood of alcohol use (adjusted odd ratio [AOR]=3.51, 95% CI 1.29-9.54) and a higher likelihood of alcohol purchase (AOR=4.59, 95% CI 1.46-14.49) the following day. Exposure to more alcohol marketing did not increase the amount of alcohol use or frequency of alcohol purchases the following day in participants who used or purchased alcohol. At the within-person level, exposure to more alcohol marketing was not associated with a higher likelihood of alcohol use, amount of alcohol use, higher likelihood of alcohol purchase, or frequency of alcohol purchases the following day (all P_s>.05). Each additional exposure to alcohol marketing within 1 week predicted an increase of 0.85 alcoholic drinks consumed in the following week (adjusted B=0.85, 95% CI 0.09-1.61). On days of reporting alcohol use, the 3 measures for alcohol marketing receptivity were not associated with more alcohol use or purchase (all P_s>.05).

Conclusions: By using EMA, we provided the first evidence for the effect of alcohol marketing exposure on initiating alcohol use and purchase in current-drinking university students. Our findings provide evidence of the regulation of alcohol marketing for the reduction of alcohol use and purchase among young adults.

alcohol marketing; drinking; ecological momentary assessment; health behaviors; young adults; mobile phone

Introduction

Alcohol use is a leading risk factor for premature death and disability worldwide and has no safe level of consumption [1]. Among individuals aged 15-29 years, alcohol use is the single biggest risk factor for violence and death due to external causes and plays a major role in mental health problems such as depression and anxiety [2]. According to the social-ecological model, the associated factors of alcohol use are nested in 5 levels—individual, interpersonal, organizational, community, and policy [3]. Alcohol marketing is a major community- and policy-level factor through advertising, promotion, sponsorships, and point-of-sale display in retail [4].

The relationship between alcohol marketing and drinking behaviors has been extensively studied, particularly in Western countries. Alcohol marketing influences drinking behaviors through short-term effects [5], where repeated exposure increases familiarity and leads to more consumption and purchases, and long-term effects, where marketing normalizes alcohol use by increasing perceived social approval and emphasizing positive consequences [6]. Two systematic reviews, including 25 cross-sectional and longitudinal studies, consistently indicated a positive association between alcohol marketing exposure and intentions to drink, as well as binge or hazardous drinking [7,8]. These studies also found dose-response relationships between marketing exposure and the initiation and frequency of drinking [7,8]. However, these studies may underestimate the true impact of alcohol marketing as they often focus on advertising, neglecting other forms of promotion. Another systematic review extended the analysis to various forms of alcohol marketing, including advertising on mixed media, points of sales, and so forth, and these were positively associated with frequency and quantity of alcohol use [9]. However, using self-reported marketing exposure in the previous week or month had a large recall bias. Also, cross-sectional studies failed to establish causality. The alcohol industry argues that marketing regulations are ineffective, claiming insufficient evidence that marketing influences behavior and asserting that it only affects brand selection and market share [10].

To better understand the causal relationship between alcohol marketing and drinking behavior, several randomized controlled trials (RCTs) have been conducted [11-17]. A meta-analysis of 7 RCTs in young adults found that exposure to alcohol marketing within a 1- to 90-minute timeframe led to a small but significant increase in alcohol use (effect size: 0.20, 95% CI 0.05-0.34) [18]. However, these RCTs, which were all laboratory based with low ecological validity, often failed to account for prior exposure to alcohol marketing and involved only television marketing. This highlights the need for studies that accurately measure alcohol marketing exposure and drinking behavior in real time and explore the prospective associations between marketing exposure and drinking behavior in real-world settings.

Ecological momentary assessment (EMA) is a repeated real-time data collection method in the natural environment and allows the modeling of temporal dynamics [19]. EMA facilitates monitoring of behavioral processes in their natural context, which can minimize recall bias [20] and avoid reverse causality [21]. Our searches on PubMed and Web of Science up to July 2023, using relevant keywords of “ecological momentary assessment,” “alcohol marketing,” “alcohol advertisement,” “drinking,” “alcohol consumption,” and “alcohol use,” found only 2 studies that used EMA to assess the association between alcohol marketing exposure and normalization of alcohol use in adolescents [22,23]. One study found that more alcohol marketing exposure was associated with higher perceived social approval and popularity of alcohol use [22]. Another study found that higher adolescent perceptions of social approval and popularity of alcohol use were associated with more receptivity toward marketing exposures [23]. We found no other EMA-based studies examining the effect of alcohol marketing directly on alcohol use and purchase in adolescents and young adults.

Hong Kong has a low alcohol consumption compared to most Western countries and Asian countries such as Japan (8.0 L per capita), with a per capita consumption of 2.9 L [24,25]. A recent study found that about 30% of Hong Kong adults drank alcohol in the past 12 months [26], and Hong Kong drinkers consume 9.7 L per capita, nearly two-thirds of the per capita consumption in Japanese drinkers (14.1 L) [24]. The Hong Kong government eliminated the tax on beer and wine in 2008, which coincided with an increase in both the frequency of alcohol consumption among ever-drinkers and the prevalence of new drinkers [27,28]. This policy, combined with the high accessibility of alcohol due to no restrictions on the time and place of alcohol sales, as well as the high density of alcohol outlets, has led to an increase in alcohol consumption in the recent decade. The prevalence of past 30-day alcohol use in Hong Kong students aged 19 years and older increased from 24.2% in 2008 [29] to 33.8% in 2020 [30]. Young adults aged 18-35 years have the highest proportion of binge drinking and alcohol abuse compared to older age groups and are at high risk of various alcohol-related harms [26-28,31]. Alcohol use is also significantly associated with substance use among young adults [32,33]. A recent cross-sectional study among young adults in Hong Kong found that 71.6% were exposed to traditional marketing and 53% to social media marketing, with exposure positively associated with past-month alcohol consumption [34]. Despite this, Hong Kong imposes minimal restrictions on alcohol marketing. The only policy is a ban on alcohol advertisement on domestic free television from 4 PM to 8:30 PM [35]. Thus, Hong Kong young adults are frequently exposed to alcohol marketing in both offline and internet-based channels [36,37].

Given the extensive alcohol marketing and the surge in drinking among young adults, we aimed to examine the association between alcohol marketing and drinking behaviors to inform

effective public health interventions. We used EMA to examine the effects of alcohol marketing exposure on drinking behaviors among university students. We hypothesized that first, more exposure to alcohol marketing in a day would predict any alcohol use, any alcohol purchase, increased alcohol use, and more frequent alcohol purchases the following day. This association was examined at both the within-person and between-person levels to account for intra- and interindividual variability in responses to marketing exposure, respectively. Second, more exposure to alcohol marketing in the first week would predict any alcohol use, any alcohol purchase, increased alcohol use, and more frequent alcohol purchases the following week. Finally, positive alcohol marketing receptivity would predict more alcohol use and a higher frequency of alcohol purchases the following day.

Methods

Study Design

This prospective study included 49 university students who participated in a 2-arm RCT (allocation ratio 1:1) to examine the discrepancy in reporting alcohol marketing exposure between EMA and conventional retrospective survey. The participants in the intervention group who completed 2 weeks of EMAs were included in this analysis.

Procedures

We recruited participants from January to June 2020 via mass emails with a link to an internet-based anonymous survey of all undergraduate and postgraduate students in the University of Hong Kong (HKU). Potential participants interested in this project can complete the internet-based enrollment form by clicking the provided link in the mass emails. The enrollment form included questions to screen the eligibility. Students who were (1) Hong Kong residents, (2) aged 18 to 35 years, (3) enrolled in an undergraduate or postgraduate program, (4) had a smartphone with internet access, (5) drank any alcohol in the past 30 days, (6) able to read and write Chinese, and (7) stayed in Hong Kong throughout the study were eligible. A research assistant contacted the eligible participants; provided a brief overview of the study via telephone; and scheduled a face-to-face enrollment session with them in the HKU campus to obtain written consent, conduct the baseline survey, and install the EMA app on their smartphones.

EMA Operation

Participants allocated to the intervention group were instructed to install and set up a free EMA app on their smartphones during the enrollment session. This setup included imputing a personal identification number (the last 5 digits of their phone number) and specifying the date and time they wanted to receive the first EMA. The app "HKU alcohol study" (HKU, Hong Kong Special Administrative Region of the People's Republic of China) was developed specifically for this study. The app featured automated notifications, a customizable scheduling system, and intuitive data entry interfaces allowing participants to select options without manual text input. Alcohol marketing exposure is typically discrete. Hence, fixed-interval and signal-contingent prompts can reliably capture all exposures and behaviors, enabling comprehensive data collection on the cumulative effects of these exposures on drinking behaviors [38]. Additionally, signal-contingent EMAs are the predominant method for prompting in EMA studies, with over 77% (81/105) of EMA studies using this approach [39], as it mitigates the underreporting of alcohol events often observed in event-contingent EMAs [40]. Participants were required to complete 5 fixed-interval, signal-contingent [41] EMAs each day for 14 consecutive days, with a fixed time interval of 3 hours between each EMA. The app notified participants with a pop-up message, reminding them to use the app and complete the EMA within 5 minutes of receiving the prompt. If they did not respond, 2 additional prompts would be sent within the next 10 minutes. If they still did not respond, the corresponding EMA episode would be treated as nonresponse. The completed EMA data were immediately uploaded to the HKU server.

All participants were awarded HK $100 (US $1=HK $7.8) shopping vouchers after completing the baseline and follow-up questionnaires. Additionally, participants who completed 3 EMAs within each day would be rewarded with a HK $15 shopping voucher. An additional HK $10 shopping voucher was further provided to participants who completed all 5 EMAs within each day.

Ethical Considerations

Ethical approval was obtained from the institutional review board of the University of Hong Kong/Hong Kong Authority Hong Kong West Cluster (UW-19-155). All participants were informed that the collected data will be kept strictly confidential and used solely for research purposes. All data were deidentified and no personal information was disclosed in this paper. Participants' contact information was securely stored on the server located in HKU, encrypted with a password accessible only to the principal investigator and authorized research staff. Participants could be rewarded up to HK $450 for shopping vouchers in total as compensation.

Measures

Alcohol Marketing Exposure

In each EMA, participants reported any exposure to alcohol marketing in the past 3 hours, except for the first episode, which enquired the exposure "since the last survey" (yes or no). Alcohol marketing includes all forms of promotional material or activities for alcoholic products; alcohol brands; or the culture of alcohol consumption such as beer festivals, wine fairs, and media of new alcoholic beverages or bars. If they reported exposure, they were asked about the number of exposures (an exposure could be counted multiple times if the same marketing was seen in various places) and the sources of exposure (including restaurants, YouTube, apps, social media, web banners, bus stations, metro stations, ads on public transport, point-of-sale at retail stores, television, newspapers, magazines, radios, and others). The number of exposures to alcohol marketing was aggregated daily, bi-daily, weekly, and 2 weeks for each participant.

Marketing Receptivity Toward Alcohol Marketing

For each reported exposure to alcohol marketing, participants rated their receptivity toward the marketing content using 3 items: "I like the alcohol marketing," "I think the alcohol marketing was innovative," and "I think the alcohol marketing was attractive" (1=strongly disagree and 5=strongly agree). For participants who reported exposure to alcohol marketing once a day, the daily marketing receptivity score for each item was the score rated by the participant for that single exposure. For participants with multiple exposures in a day, the daily score for each receptivity item was calculated by averaging the scores for all exposures on that day. These average scores were recorded as a binary variable (1 to 3: disagree and >3: agree). The "number of positive receptivity" was calculated by summing the binary variables for attractiveness, innovation, and likeability, resulting in a score from 0 to 3, indicating the number of these items the participant agreed with. Indicating "agree" to any item of marketing receptivity was treated as "any positive alcohol marketing receptivity" (yes or no) for that day.

Alcohol Use

In each EMA, participants reported any alcohol use in the past 3 hours, except for the first episode, which enquired about alcohol use "since the last survey" (yes or no). If they responded to alcohol use, they were asked the type of alcohol (including beer, alcopops, wine, spirits, cocktails, rice wine, Chinese spirits, Japanese sake, and others) and the number of drinks consumed. One drink is equivalent to one 330-mL bottle of beer or alcopops, one 125-mL glass of wine, one 22-mL shot of spirits or cocktails, one 180-mL glass of rice wine, or one 20-mL glass of Chinese spirits or Japanese sake. The number of drinks was aggregated daily, bi-daily, weekly, and 2 weeks for each participant. Participants who consumed at least 1 drink for the time periods (1) within the past day, (2) within the past 2 days, and (3) within the past week were classified as having had alcohol (yes or no) use for those time periods.

Alcohol Purchase

In each EMA episode, participants reported any purchase of alcohol in the past 3 hours, except for the first episode, which enquired about alcohol purchase "since the last survey" (yes or no). We did not ask about the quantity or frequency of alcohol purchased within each EMA episode. If they responded "yes," it was treated as 1 instance of an alcohol purchase. The frequency of alcohol purchase was then aggregated daily, bi-daily, weekly, and 2 weeks for each participant. Participants who purchased alcohol at least once for the time periods (1) within the past day, (2) within the past 2 days, and (3) within the past week were classified as having purchased alcohol (yes or no) for those time periods.

Baseline Characteristics

Sex, age, study program, smoking status, age of initiating alcohol use, age of purchasing alcohol for the first time, and Alcohol Use Disorder Identification Test (AUDIT) were assessed at baseline. AUDIT is a 10-item scale (0 to 7=low-risk, 8 to 15=increasing risk, 16 to 19=harmful risk, and ≥20=probable dependence) [42,43]. AUDIT has been validated in Chinese [44]; the Cronbach α was 0.79 in this study.

Statistical Analyses

Baseline demographic variables, smoking status, age of initiating alcohol use, age of purchasing alcohol for the first time, and AUDIT were described using percentage or mean as appropriate.

To test the first hypothesis, we used a 2-part modeling approach to address the zero-inflated and right skewed alcohol use and purchase data. First, we used multilevel logistic regressions with a random intercept to assess the prospective association between daily alcohol marketing exposure and the following day's outcomes of (1) any alcohol use and (2) any alcohol purchase. Second, for days with reported alcohol use or purchase, multilevel gamma regression models assessed the association between daily alcohol marketing exposure and the following day's outcomes of (1) amount of alcohol used and (2) frequency of alcohol purchase. Analyses included within-person and between-person effects, with predictor variables centered using the *xtcenter* command in Stata (StataCorp).

To test the second hypothesis, we used multivariable logistic and linear regressions to assess the effect of alcohol marketing exposure in the first week on the following week's outcomes. Logistic regression assessed the association between alcohol marketing exposure with any alcohol use and any alcohol purchase, while linear regression assessed the association between alcohol marketing exposure with amount of alcohol use and frequency of purchases. Since participants were assessed for only 2 weeks, multilevel regression was not applied.

To test the third hypothesis, we used 2-part modeling approaches. First, multilevel logistic regressions were used to assess the association between alcohol marketing receptivity in a day (binary responses in the 3 separate items of receptivity and a total number of positive receptivity) and the following day's outcomes. Second, for days with reported alcohol use or purchase, multilevel gamma regression models were used to assess the association between alcohol marketing receptivity in a day (binary responses in the 3 separate items of receptivity and a total number of positive receptivity) with the following day's amount of alcohol used and frequency of purchases. Sex, age, and AUDIT were adjusted for in all regressions as younger male drinkers were more likely to be exposed to alcohol marketing and drink more alcohol [45,46].

Three sensitivity analyses with the same 4 outcomes were used to supplement our result interpretation. First, in line with prior findings suggesting the effect of marketing exposure might fade out within 1.5 days [47], we performed a sensitivity analysis to evaluate the impact of a 2-day cumulative exposure on the outcomes on the subsequent day. Second, we used multivariable logistic and linear regressions to assess the cross-sectional association between alcohol marketing exposure and the 4 outcomes over 2 weeks. Third, regarding the prospective associations between alcohol marketing receptivity with alcohol use and purchase, we conducted 2 additional analyses treating the 3 separate items of alcohol marketing receptivity as continuous variables and EMAs with no marketing exposure as 0 or 3. All analyses were done using Stata (version 16.0).

Results

Sample Description

This study enrolled 51 participants in the EMA group. A total of 2 participants were unable to complete the 2-week EMAs due to failure to install the EMA app and receive prompts; hence, EMA data from 49 participants were analyzed. Table 1 shows that 33% (16/49) of participants were male. The mean age was 22.6 (SD 2.6) years. About 74% (36/49) had a bachelor's degree and 18% (9/49) were current smokers. The mean age of initiating alcohol use and mean age of purchasing alcohol for the first time were 16 (SD 3.3) and 18.2 (SD 1.1) years, respectively. The mean AUDIT score was 5.8 (SD 4.5).

Table 1. Demographic characteristics, drinking behavior and EMA[a] completion rate of participants (N=49).

Characteristics	Values
Age (years), mean (SD)	22.6 (2.6)
Male, n (%)	16 (33)
Study program, n (%)	
Bachelor's	36 (74)
Master's or above	13 (27)
Age of initiating alcohol use (years), mean (SD)	16.0 (3.3)
Age of purchasing alcohol for the first time (years), mean (SD)	18.2 (1.1)
Smoking in the past 30 days	9 (18)
AUDIT[b], mean (SD)	5.8 (4.5)
Low-risk drinking (1-7), n (%)	36 (74)
Increasing risk (8-15), n (%)	10 (20)
Harmful risk (16-19), n (%)	2 (4)
Probable dependence (≥20), n (%)	1 (2)
EMA completion rate, n (%)	
Below 50%	7 (14)
50%-74.9%	19 (39)
75% or above	23 (47)

[a]EMA: ecological momentary assessment.

[b]AUDIT: Alcohol Use Disorders Identification Test. Total score ranged from 0 to 40, higher scores indicating higher level of alcohol dependence.

EMA Completion Rate and Description

A total of 49 participants completed 2360 EMAs upon the 3430 prompts from the app (completion rate: 2360/3430, 68.8%). Table 2 shows that 37 (76%) of the 49 participants reported 173 exposures to alcohol marketing from various sources—restaurants (52/173, 30.1%), internet (49/173, 28.3%), public transportation (25/173, 14.5%), point-of-sale retail locations (19/173, 11%), television (14/173, 8.1%), and other places (14/173, 8.1%). On average, each participant reported 4.7 (SD 3.7) times of exposure to alcohol marketing within the 2-week EMA period. Among all alcohol marketing exposures, 38.2% (66/173) were rated as being liked, 32.9% (57/173) as innovative, and 35.2% (61/173) as attractive.

Table 2. Description of EMA[a] data for alcohol marketing exposure, alcohol use, and alcohol purchase.

Variables	Values
Total episodes of exposure to alcohol marketing, n	140
Sources of alcohol marketing exposure (n= 173), n (%)	
Restaurant	52 (30.1)
Internet (YouTube, app, social media, web banners, etc)	49 (28.3)
Transportation (bus stations, metro stations, ads on public transport, etc)	25 (14.5)
Point-of-sale at retail stores	19 (11.0)
Television	14 (8.1)
Others (newspapers, magazines, radios, etc)	14 (8.1)
Marketing receptivity toward alcohol marketing in those exposure (n=173), n (%)	
I agree that I liked the alcohol marketing	66 (38.2)
I agree that the alcohol marketing is innovative	57 (32.9)
I agree that the alcohol marketing is attractive	61 (35.2)
Total episodes of alcohol use, n	145
Type of alcohol use (n=145), n (%)	
Beer	51 (35.2)
Wine	37 (25.5)
Alcopops	22 (15.2)
Cocktails	14 (9.7)
Spirits	14 (9.7)
Japanese sake	12 (8.3)
Total episodes of alcohol purchase, n	56

[a]EMA: ecological momentary assessment.

Table 2 also shows that 39 (80%) participants reported 145 episodes of alcohol use including beer (51/145, 35.2%), wine (37/145, 25.5%), alcopops (22/145, 15.2%), cocktails (14/145, 9.7%), spirits (14/145, 9.7%), and Japanese sake (12/145, 8.3%). On average, each participant reported 3.7 (SD 3.0) episodes of alcohol use and consumed 7.5 (SD 12.1) drinks within the 2-week EMA period. A total of 26 (53%) participants reported 56 episodes of purchasing alcohol within the 2-week EMA period.

Association of Alcohol Marketing Exposure With Alcohol Use and Purchase

Table 3 shows that at the between-person level, exposure to more alcohol marketing predicted a higher likelihood of alcohol use (adjusted odd ratio [AOR]=3.51, 95% CI 1.29-9.54; *P*=.01) and a higher likelihood of alcohol purchase the following day (AOR=4.59, 95% CI 1.46-14.49; *P*=.01). At the within-person level, exposure to more alcohol marketing was not associated with the likelihood of alcohol use, amount of alcohol use, the likelihood of alcohol purchase, or frequency of alcohol purchase the following day (all P_s>.05). The results at both the between-person and within-person levels remained robust in the 2-day cumulative exposure models.

Table 3. Prospective associations of alcohol marketing exposure with alcohol use and alcohol purchase on the following day (N=49).

Predictors	Outcomes			
	Any alcohol use or purchase the following day		Amount of alcohol use or purchase the following day	
	Adjusted OR[a] per exposure (95% CI)	*P* value	Adjusted exp (B) (95% CI)	*P* value

[a]OR: odds ratio.

[b]The exposure is the number of alcohol marketing exposures within a day. The outcomes are any alcohol use the following day and the amount of alcohol use the following day.

[c]Multilevel logistic regression adjusted for sex, age, and baseline AUDIT (Alcohol Use Disorder Identification Test; number of observations=562).

[d]Multilevel gamma regression adjusted for sex, age, and baseline AUDIT, exclude daily alcohol use=0 (number of observations=97).

[e]The exposure is the number of alcohol marketing exposures over the past 2 days. The outcomes are any alcohol use on the subsequent day after the 2-day cumulative exposure and the amount of alcohol use on the subsequent day after the 2-day cumulative exposure.

[f]Multilevel logistic regression adjusted for sex, age, and baseline AUDIT (number of observations=532).

[g]Multilevel gamma regression adjusted for sex, age, and baseline AUDIT, exclude daily alcohol use=0 (number of observations=90).

[h]The exposure is the number of alcohol marketing exposures within a day. The outcomes are any alcohol purchase the following day and the frequency of alcohol purchases the following day.

[i]Multilevel logistic regression adjusted for sex, age, and baseline AUDIT (number of observations=562).

[j]Multilevel gamma regression adjusted for sex, age, and baseline AUDIT, exclude daily alcohol purchase=0 (number of observations=45).

[k]The exposure is the number of alcohol marketing exposures over the past 2 days. The outcomes are any alcohol purchase on the subsequent day after the 2-day cumulative exposure and the frequency of alcohol purchases on the subsequent day after the 2-day cumulative exposure.

[l]Multilevel logistic regression adjusted for sex, age, and baseline AUDIT (number of observations=532).

[m]Multilevel gamma regression adjusted for sex, age, and baseline AUDIT, exclude daily alcohol purchase=0 (number of observations=42).

Within the 2-week EMA period, 12 participants reported 0 exposure to alcohol marketing. A total of 10 participants reported no alcohol use. A total of 23 participants reported no alcohol purchase. Summing up the 3 key indicators, we identified 4 participants who did not report any exposure to alcohol marketing, alcohol use, and alcohol purchase. Therefore, we excluded these participants and ran the 2-part models of examining the prospective associations between alcohol marketing exposure with alcohol use and alcohol purchase. The results (Multimedia Appendix 1) were still consistent with Table 3.

Table 4 shows each additional exposure to alcohol marketing within 1 week predicted an increase of 0.85 alcoholic drinks consumed in the following week (adjusted B=0.85; *P*=.03). Although each additional exposure to alcohol marketing over a week was marginally associated with increased likelihood of alcohol use (AOR=1.62; *P*=.054), it was not significantly associated with likelihood of purchasing alcohol or frequency of alcohol purchases (both P_s>.05, see Table 4) in the following week. Multimedia Appendix 2 shows that exposure to more marketing exposure over 2 weeks was associated with a larger amount of alcohol use (adjusted B=0.90; *P*=.02) and more frequent alcohol purchases (adjusted B=0.14; *P*=.01).

Table 4. Prospective associations of alcohol marketing exposure with alcohol use and alcohol purchase in the following week (N=49).

Predictors	Outcomes							
	Any alcohol use the following week[a]		Amount of alcohol use the following week[b]		Any alcohol purchase the following week[a]		Frequency of alcohol purchases the following week[b]	
	Adjusted OR[c] per exposure (95% CI)	*P* value	Adjusted B per exposure (95% CI)	*P* value	Adjusted OR per exposure (95% CI)	*P* value	Adjusted B per exposure (95% CI)	*P* value

Association of Alcohol Marketing Receptivity With Alcohol Use and Purchase

Table 5 shows that on days of liking alcohol marketing, when perceiving the marketing as innovative or attractive, they were more likely to use and purchase alcohol the following day compared to days where they reported no marketing exposure, but the results were not significant (all P_s>.05). On days of reporting alcohol use, the 3 measures for alcohol marketing receptivity were not associated with more alcohol use or purchase (all P_s>.05). Our sensitivity analysis by treating alcohol marketing receptivity as a continuous variable showed similar results as the main analysis (Multimedia Appendix 3).

Table 5. Prospective association of alcohol marketing receptivity with alcohol use and alcohol purchase on the following day (N=49).

Predictors	Any alcohol use the following day[a]			Amount of alcohol use the following day[b]		Any alcohol purchase the following day[c]			Frequency of alcohol purchases the following day[d]

Discussion

Principal Findings

Our findings provide the first evidence that increased exposure to alcohol marketing within a single day or 2 days predicted higher likelihoods of alcohol use and purchase the following days, implying the direct effect of marketing on alcohol use and purchases. Alcohol marketing exposure in a week predicted a larger amount of alcohol use the following week, implying the accumulative effect of marketing on consumption level. Sensitivity analyses by excluding 4 participants with 0 reports of the key indicators supported the robustness of the results.

Our finding is the first to support that increased exposure to alcohol marketing was associated with a higher likelihood of alcohol use within the following day and subsequent day after 2-day cumulative exposure. This extends the evidence from previous experimental RCTs [11-17], which lacked ecological validity and only examined the immediate effects 30 minutes after the exposure. Such a direct effect is consistent with the "mere exposure effect" [5], whereby drinkers might be stimulated to initiate drinking due to greater familiarity with alcohol products due to more recent exposure to marketing. Therefore, to reduce the likelihood of alcohol use in young adults, alcohol control policies in reducing the exposure to alcohol marketing and avoiding the glamorization of drinking behavior should be implemented.

Exposure to alcohol marketing might stimulate alcohol use, but our findings showed that the exposure did not significantly increase the amount of alcohol use on the following day. We showed that 74% (36/49) of our participants have low AUDIT scores; hence, most were light drinkers and nondaily drinkers, and the marketing effect on alcohol consumption in 1 day may be small. However, we found a positive effect of weekly alcohol marketing exposure and amount of alcohol use the following week (adjusted B=0.85). Thus, the effect of accumulative alcohol marketing exposures on the amount of alcohol use assessed in the week was more detectable in this group with low alcohol consumption.

The lack of significant association between daily variations in alcohol marketing exposure and the amount of alcohol use can be attributed to the low variability in individual exposure to alcohol marketing, with only 5.9% (140/2360) of EMA episodes reporting such exposure. This limited variability in individual exposure levels results in insufficient statistical power to detect significant within-person effects. Besides, this study was conducted with the onset of the COVID-19 pandemic in Hong Kong. During this period, the government implemented numerous restrictive policies such as bar closures and dining restrictions. These restrictions likely reduced participants' opportunities to encounter varying levels of alcohol marketing exposure, thus reducing the detectable within-person effects.

We found a positive effect of alcohol marketing exposure within a day on alcohol purchase the following day, but not on the frequency of alcohol purchase. The null association between alcohol marketing exposure in a day and the frequency of alcohol purchase the following day can be attributed to several factors. First, our EMAs did not ask for and analyze the quantity of alcohol purchased. Karaoke bars and pubs in Hong Kong often target students with discounted party packages and fixed-price "all-you-can-drink" nights, promoting larger 1-time purchases. Second, university students often consume alcohol obtained from others in social settings. A recent study has shown that students living in residence halls are twice as likely to have binge drinking compared to those living with family [48]. Third, financial constraints may limit university students' ability to purchase alcohol frequently within a short period. Besides, our cross-sectional analysis (Multimedia Appendix 2) found that exposure to more alcohol marketing over a 2-week EMA period was associated with a higher frequency of alcohol purchases during the same period, which supported the long-term effect of alcohol marketing on purchases. Finally, reverse causation of the alcohol purchase and exposure to alcohol marketing was likely to happen.

Contrasting with previous studies that alcohol marketing receptivity might increase the frequency and amount of alcohol use [49,50], our analysis did not show sufficient evidence to support similar results at day-level. The discrepancy may be attributed to only a small number of participants who were exposed to alcohol marketing being eligible to respond to receptivity questions. In the 2360 completed EMA episodes, only 173 episodes of exposure to alcohol marketing and the corresponding marketing receptivity were assessed. It might limit the statistical power to confirm the association between marketing receptivity and alcohol use from both the main and sensitivity analyses. Further studies with a larger sample size to examine the effect of alcohol marketing receptivity and alcohol use and purchase are warranted.

Our study had a few limitations. First, the overall completion rate of EMA was about 68.8% (2360/3430), which was generally lower than previous EMA studies, which was about 76.4% on average (4 to 5 prompts per day) [51]. Future EMA studies may use a combination of event-contingent and signal-contingent prompts to capture more alcohol marketing exposure, thereby increasing the completion rate [52]. Second, the study sample was not a representative sample of all university students or young adults. Third, due to the time constraint in each EMA, we did not assess the type, quantity, and venue of alcohol purchases. Furthermore, the small sample size is unable to assess the association between different sources of alcohol marketing exposure and drinking behaviors. Our power analysis estimated the power of the between-person effect of daily marketing exposure on the likelihood of alcohol use in our study was about 22.5% (95% CI 19.9%-25.1%). Future studies with larger, more representative samples are warranted to evaluate the effects of various types of marketing exposure on drinking behavior.

Conclusions

In conclusion, by using EMA, our study showed the direct effect of alcohol marketing exposure on initiating alcohol use and alcohol purchase in current-drinking university students in a real-world environment, refuting the claim by the alcohol industry that the marketing is only for brand promotion. Our findings provide evidence of regulating alcohol marketing for the reduction of alcohol use and purchase in young adults.

Acknowledgments

The authors are grateful to all the project coordinators, including Titan Mak and Bonnie Wu, for their effort to recruit participants and administrative duties. This study was supported by the Seed Fund for Basic Research of the University of Hong Kong (201711159257). The funder has no roles in study design, collection, management, analysis, and interpretation of data.

Data Availability

The data sets analyzed during this study are not publicly available due to privacy and ethical restrictions but are available from the corresponding author on reasonable request

Authors' Contributions

YTDC obtained funding for, conceptualized, and administered this study. MJZ and YTDC contributed to the methodology. MJZ conducted the formal analysis and investigation and wrote the original draft. All authors contributed to reviewing and editing the paper. All authors have approved the final paper.

Conflicts of Interest

None declared.

Abstract

Background: Adolescence is a period characterized by an increased susceptibility to developing risky alcohol consumption habits. This susceptibility can be influenced by social and situational factors encountered in daily life, which, in conjunction with emotions and thoughts, contribute to behavioral patterns related to alcohol use even in the early stages of alcohol experimentation, when initial experiences with alcohol are formed, and regular consumption is still evolving.

Objective: This study aimed to examine the association between detailed behavioral and movement patterns, along with emotional and cognitive factors, and the early onset of alcohol use in the everyday lives of adolescents.

Methods: A total of 65 healthy adolescents (33 male, twenty-nine 14-year-olds, and thirty-six 16-year-olds) underwent mobile-based ecological momentary assessments on alcohol (once a day at 9 AM, assessing alcohol use the day before), positive and negative affect, craving, rumination, and social context (6 prompts/day at 9 AM, 11 AM, 2 PM, 4 PM, 6 PM and 8 PM), type of day (weekdays or weekends, with weekend including Fridays, Saturdays, and Sundays), and using geospatial measures (specifically roaming entropy and number and type of trigger points for alcohol use met) over 14 days. After adjusting for a compliance rate of at least 50%, 52 participants (26 male and twenty-four 14-year-olds) were included in the analyses.

Results: Generalized linear multilevel models revealed that higher positive affect (b=0.685, P=.007), higher rumination (b=0.586, P=.02), and a larger movement radius (roaming entropy) (b=8.126, P=.02) were positively associated with alcohol use on the same day. However, social context (b=–0.076, P=.90), negative affect (b=–0.077, P=.80), or potential trigger points (all P>.05) did not show significant associations. Alcohol use varied depending on the type of day, with more alcohol use on weekends (b=1.082, P<.001) and age (t_{50}=–2.910, P=.005), with 16-year-olds (mean 1.61, SD 1.66) reporting more days of alcohol consumption than 14-year-olds (mean 0.548, SD 0.72).

Conclusions: Our findings support previously identified factors as significant contributors to very early and low levels of alcohol consumption through fine-grained analysis of daily behaviors. These factors include positive affect, rumination, weekend days,

and age. In addition, we emphasize that exploratory environmental movement behavior (roaming entropy) is also significantly associated with adolescent alcohol use, highlighting its importance as an additional factor.

Introduction

Adolescence (spanning from ages 10 to 19 years, according to the World Health Organization [1]) represents a sensitive period characterized by rapid developmental transitions across biological, neurophysiological, psychological, and social domains [2]. These changes are important for the development of healthy behaviors in daily life [3] but can, inversely, also pose a risk for the development of unhealthy behavioral patterns. Such behaviors include the use of alcohol, which is usually initiated in midadolescence (ages 14 to 17 years) [4,5] and peaks in late adolescence around the age of 21 years [6-9]. Alcohol represents the most commonly used and abused substance during adolescence (eg, in Germany [10]) while also accounting for the most pervasive and devastating effects on life quality, general well-being, and neurodevelopmental processes [11-14]. Understanding the factors influencing very early adolescent alcohol use is crucial, as earlier initiation of alcohol consumption during this period is associated with heightened alcohol use in late adolescence and an elevated risk of developing alcohol use disorder in young adulthood [15,16]. Furthermore, alcohol use during adolescence can adversely affect structural and functional neural development [14,17], as well as various aspects of adolescent health and well-being [18,19], particularly when it involves risky behaviors such as binge drinking [13]. Therefore, elucidating the determinants of very early adolescent alcohol use, when potentially harmful patterns may be emerging for the first time, is paramount.

A Theoretical Approach: The Incentive Sensitization Theory

Previous frameworks stem from findings on inter-individual differences in neurophysiological, genetic, personality, social, and environmental factors and their interaction in contribution to adolescent alcohol use [20-23]. The Incentive Sensitization Theory (IST) [24] proposes alcohol as a potentially rewarding stimulus that is liked at first (ie, its use is positively reinforced), for instance, due to its positive impact on mood and evolves into a so-called wanting in the course of addiction development, where its use is negatively reinforced for instance through the amelioration of negative mood states or craving [24]. Greater incentive salience is assigned to alcohol-related cues (eg, the favorite bar or the favorite alcoholic drink), which results in greater attention to these cues compared with other rewarding cues or conditions [25]. Importantly, these cues can then trigger the urge to drink alcohol [26]. Especially adolescents show hyperreactive responses to alcohol-related rewarding cues [7,27]. This model represents a theoretical approach to explaining how alcohol use transitions from early use to habitual use over time. However, specifically in the very early periods of alcohol use, that is, the onset and first experiences, information on these processes is rather scarce. Recently, through advanced methodologies, it is becoming possible to receive much more fine-grained information at the intraindividual level and in daily life to explain when and why adolescents consume alcohol.

Daily Life Experiences Influence Alcohol Use in Adolescence

Methods to map daily life experiences, trajectories, and movements in daily life are increasingly available. These encompass ecological momentary assessments (EMAs) and GPS tracking (geospatial measures), enabling the concurrent investigation of interindividual mechanisms identified as risk factors for alcohol use (eg, IST) alongside behavioral patterns. These patterns include movements within the daily environment and exposure to specific environmental triggers (eg, nightclubs, youth gatherings, or social contexts such as being in close proximity to peers). This combination is an important addition to traditional diary methods as a resource for gaining information on individuals' health status over time. Due to the potential to capture momentary states multiple times throughout the day, EMA methodology allows to obtain a high-resolution representation of self-reports, including emotions and thoughts as well as daily behavior and information on contexts, including social situations. Its intuitive usability further ensures greater attractiveness and, consequently, increased compliance and ecological validity compared with retrospective assessments as well as paper and pencil applications [28,29]. This also becomes significant in the realm of health research, as it provides more sensitive data regarding critical daily triggers for symptoms. Consequently, it aids in deciding on the most adaptive interventions. Previous studies using EMA have demonstrated that in adolescent and young adult alcohol users, contextual factors [30], such as the presence of peers or being in specific locations like bars or restaurants [31], along with mood-related factors, including heightened negative affect [32-34], are highly influential in initiating alcohol use. In addition, smartphone technology allows us to assess geospatial movement patterns as proxies for exploratory behaviors and environmental context factors in which specific behaviors occur (ie, alcohol-associated trigger points) and combine this with information gathered from using EMA. This provides the possibility to investigate and identify triggers with not only respect to individual feelings or thoughts but also specific contexts, including information on where (eg, private or public environments) or when (eg, time of the day, day in the week) adolescents consume alcohol [35]. These triggers can also encompass specific situational cues that are associated with alcohol use [36-38]. This information can be gained through exploratory movement patterns, which are estimated, for example, through roaming entropy, an index of "the variability in an individuals' physical location over the course of a day" [39]. Even in the early period of alcohol use,

these data could be beneficial to explore how potential trigger points develop over time. In terms of alcohol use, geospatial measures have successfully been used in app-based alcohol use disorder treatment in adults by sending alerts if patients are near alcohol-related trigger points that are risky places for lapse, relapse, or craving [40-43]. Furthermore, studies have demonstrated that neighborhood disadvantages are associated with increased substance use among adolescents [44], and adolescents tend to consume alcohol in proximity to locations where it is available for purchase [45]. However, environmental exploratory movement patterns, such as roaming entropy, have not been considered in these studies. Thus, together with EMA data, geospatial measures might allow additional insight into adolescent drinking behavior and driving factors and can add to our understanding of transitions from nonrisky to risky alcohol use, and thus inform the development of early prevention approaches, for example, in the form of ecological momentary interventions (EMI). Therefore, this study aimed to delineate the influence of daily variability in affect, craving, rumination, and presence of others (social context), together with exposure to potential environmental alcohol triggers and the characterization of environmental movement patterns on early adolescent daily alcohol use.

Methods

Sample

Participants were included in the study if they were either 14 or 16 years old at the time of enrollment, aiming to capture early drinking patterns typically initiated around the age of 14 years, and the period when alcohol consumption becomes more frequent and prevalent, around age 16 years [4]. This approach facilitated a better understanding and comparison of these developmental stages. In addition, participants had to be fluent German speakers, right-handed, safe to perform magnetic resonance imaging tasks (eg, no metal in the body or claustrophobia), and without any present history of psychiatric or somatic disorders [46]. Out of 72 recruited participants, 70 participants (twenty-nine 14-year-olds, thirty-six 16-year-olds, 49% female) underwent the entire assessment battery. This included a series of questionnaires (eg, sociodemographic information of participants and their parents, general alcohol consumption, stress, mindfulness, experience with meditation techniques, emotion regulation, personality, quality of life, and rumination), behavioral tasks, neuropsychological tasks in an magnetic resonance imaging scanner, and EMA. Participants received a reimbursement of €50 (approximately US $58) for their participation in the entire study. For the present purpose, only the EMA was of interest, and 65 participants underwent the entire EMA assessment.

Instruments

Daily Life Experiences and Geospatial Measures

Daily life experiences were assessed by an EMA. The implementation of the EMA was done by movisensXS (movisens GmbH) [47], which allows the integration of relevant items and additional information like geospatial measures. Within the EMA assessment, participants were asked to carry along a study phone (Nokia 5 with Android version 7.1.1 Nougat) over 14 days [48]. This period was selected due to the relatively low frequency of drinking behavior observed in a healthy sample of adolescents, aiming to increase the variance in drinking occasions. A total of 6 prompts per day were presented on fixed time points (at 9 AM, 11 AM, 2 PM, 4 PM, 6 PM, and 8 PM) with 2 reminders at 5-minute intervals [48]. We thus asked participants to answer a total of 43 items regarding affect, event appraisal, craving, social context, self-esteem, and rumination within a 15-minute time window. Answering one prompt took about 2 minutes. For the current purpose, we concentrated on affect (5 items for positive affect, 5 items for negative affect, eg, “Right now I feel scared”; response scale: 1=“not at all” to 7=“very much” [49], based on Positive and Negative Affect Schedule [50]), craving (6 items, eg, “Drinking would make things seem perfect”; response scale: 1=“I totally agree” to 7=“I totally disagree,” based on ACQ [51]), social context (1 item: “Are you currently alone?” [Yes/no]) and rumination (4 items, eg, “The moment before the beep, I thought about my feelings,” reversed, response scale: 1=“I totally agree” to 7=“I totally disagree,” similar to [52]). We did not include event appraisal or self-esteem in our study. This is based on assumptions that event appraisal for good and bad experiences is reflected in positive and negative affect [53] and that fluctuations in self-esteem are rather discussed in relation to depression [54]. For positive affect, negative affect, craving, and rumination, a mean score was and for social context, a sum score was calculated for each day within each participant, with higher scores indicating higher expression of each construct (for social context, higher scores indicating more time spent alone within a day). In order to increase compliance with EMA measurements, we offered participants an additional monetary incentive (cinema voucher) if they responded to 90% or more of the EMA prompts. As compliance is central to the quality of EMA data [55], only subjects with a compliance rate of 50% or more were included in the data analyses [55], leaving a sample of 52 participants (twenty-four 14-year-olds and 26 female).

In addition to the psychometric instruments of the EMA, we gathered the GPS location of each participant on a per-minute basis, allowing us to build detailed daily movement patterns. While GPS was not linked directly to individual EMA assessments, places, or drinking events, it still enables a characterization of daily activity of and environmental influences on the participants. In addition, participants provided information on places they visited frequently during the EMA assessment (what or who was visited and where was the place or address).

Alcohol Use

Our main alcohol outcome was assessed within the EMA once a day, within the 9 AM prompt. Participants were asked about their alcohol use the day before (1 item: “Did you drink alcohol yesterday?” [Yes/No]). This method was used to capture every occurrence of alcohol use the day before, since the last prompt of EMA reached participants at 8 PM, and it is conceivable that participants used alcohol even after this time point [56]. If participants missed the 9 AM prompt, we coded alcohol use for the day before as missing data. In addition, as a control, we

included the sum score (range 0 to 40) of the 10-item self-report Alcohol Use Disorder Identification Test (AUDIT) [57] to check whether general alcohol use is generally associated with daily alcohol patterns.

Data Analysis

Geospatial Measures Preprocessing

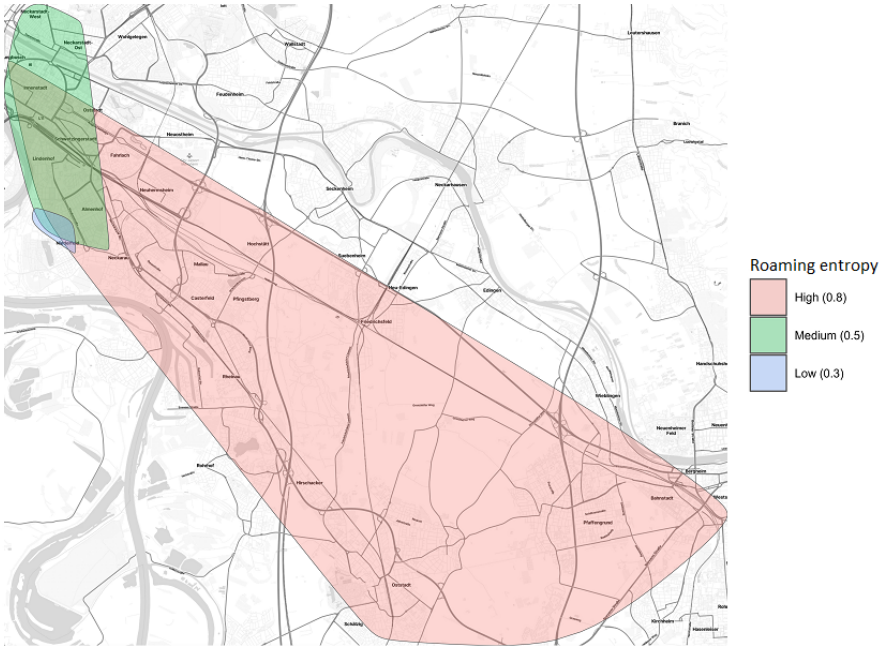
To use geospatial measures in our model, we preprocessed GPS information. In particular, we calculated 2 measures based on individual trajectories: Roaming Entropy as a marker of environmental exploratory movement and the contact with potential alcohol trigger points, that is, locations where alcohol use might be especially salient. All analyses were done using R (R Foundation of Statistical Computing) [58].

Roaming entropy (RE) is an information-theoretic measure used to quantify the variability of a movement trajectory. Specifically, it calculates the entropy of a trajectory based on unique places visited [55]. Places are defined as distinct latitude-longitude-pairs, rounded to the fourth decimal place [39,59], providing an accuracy of approximately 11 m around the participant, which corresponds to the size of a small house or street section.

For each participant and each day separately, Roaming Entropy was calculated using the following formula:

Here, p_i is the probability (estimated by the relative within-day frequency) that the participant is at location i, while n is the total number of unique locations visited during that day. RE can take values from zero to one, with zero meaning a participant did not move at all during the day and one meaning that every place visited was unique [39]. Figure 1 shows exemplary movement patterns with high, medium, and low RE.

Figure 1. Abstract examples of 3 participants categorized by their roaming entropy within this study, depicting high (red), medium (green), and low (blue) levels. While roaming entropy primarily quantifies movement variability rather than area, it frequently aligns with larger areas covered.



Please note, the map tiles are by Stamen Design, under CC BY 4.0. Data by OpenStreetMap, under ODbL.

To calculate the contact of each participant with trigger points (TPs), we had to use additional data sources to add semantic meaning to locations. We used geolocalized information from "OpenStreetMap" (OpenStreetMap Stiftung) [60] and the "Kulturatlas Mannheim" (Stadt Mannheim) [61] to identify bars, clubs, parks, and other potential places of interest. These places were selected based on insights from previous research indicating that adolescents typically consume alcohol in places where it is legally permissible in Germany (such as private homes, friends' homes, bars, or restaurants for 16-year-olds for specific alcoholic beverages) and that alcohol consumption among adolescents often occurs in social settings (such as clubs, meeting spots, etc). In addition, we used information provided by participants regarding their frequently visited places during the assessment period to distinguish between places of residence, study, or social interactions, such as meeting with peers.

Using these data sources, we defined categories of potential TPs. To the best of our knowledge, there is currently no standardized framework for classifying potential TPs for adolescent alcohol use based on geospatial features. Therefore, we had to create the categories by considering the available tagged locations in the data and the information provided by participants. We defined categories of TPs related to distinct social situations likely associated with alcohol use in adolescents. The five defined categories were "nightlife," "culture," "leisure," "peers," and "meeting spots," with most of these categories standardized across the entire sample (all locations grouped under each category can be found in Table S1 in Multimedia Appendix 1). Figure 2 shows a view of the city of Mannheim, Germany, with all places categorized

accordingly. Please note, the map tiles are by Stamen Design, under CC BY 4.0. Data by OpenStreetMap, under ODbL.

For each subject, we tracked how often, during one day, they would get in contact with each of the TP categories. Contact was defined by physical closeness (within 15 m) with places belonging to a category. Based only on GPS trajectories, without further detailed information on the locality and participant's direction of view, any measurement of closeness can only be a rough estimate. In this context, the radius of 15 m was chosen as a reasonable tradeoff between accuracy and precision. Small changes in the radius did not affect our model's results. Continuous contact (eg, many minutes or hours at the same location) was not accumulated over time but rather counted as one contact. It was possible to be in contact with multiple types of TPs at the same time.

Figure 2. Trigger point categories within city of Mannheim, Germany.

Effects of Daily Life Experiences and Geospatial Information on Daily Alcohol Use

For a comprehensive examination of daily alcohol use in relation to daily life experiences and geospatial information, we used binomial generalized multilevel models with logit link function. These models are used to conduct logistic regression analyses of alcohol use as a binary outcome for each day and subject. For this purpose, the alcohol item, which was assessed on the following day, was shifted to the day before, and thus, the alcohol use of the respective day was related to the corresponding life experiences of that day. Alcohol use was predicted then by daily life experiences as independent variables assessed by EMA: positive affect (PA), negative affect (NA), craving, rumination, and social context. In addition, we used the geospatial measures TPs and RE of each day as independent variables, as well as a binary classification of assessment day into weekday (Monday, Tuesday, Wednesday, and Thursday) or day of weekend (Friday, Saturday, and Sunday) and personal level variables age and sex. To account for intraindividual correlation, we used a generalized linear multilevel model approach with a fixed slope and a random intercept for each participant, with participant as random effect and independent variables (PA, NA, craving, rumination, social context, TP, RE, weekday, age, and sex) as fixed effects.

Not all participants responded to every EMA prompt on each day. Requiring participants to answer all prompts to be included in the analyses is an open discussion in the EMA research, as it would always result in a significant reduction of the sample size [55]. Similarly, in our study, requiring participants to answer all 6 prompts would significantly reduce the sample size, making it too stringent as a cutoff criterion. Conversely, setting a cutoff too low could potentially introduce bias control challenges, particularly if nonresponse is related to drinking behavior. Therefore, we calculated a model that strikes a balance between the number of answered prompts (here, 4 prompts per day) and the number of participants, including all participants in the analysis. This approach aligns with previous work [55]. In addition, we calculated 5 additional models with varying levels of prompt completion (1 prompt/day, 2 prompts/day, 3 prompts/day, 5 prompts/day, and 6 prompts/day) to assess the stability of the results and the impact of participant compliance (more details in Figure S1 in Multimedia Appendix 1). For our main model, we evaluate the overall significance by comparing the marginal or null-model (model with only random effects) deviance to the conditional model (model containing random and fixed effects) deviance by chi-square tests. The significance of random effects is tested using the Wald test.

All analyses were done with R [58] using the lme4 package [62] and a significance threshold of $P<.05$. To check for overall effects of sex, age, and the COVID-19 pandemic restrictions, we used *t* tests for independent measures to compare the overall reported days of alcohol use within the 14-day assessment period. Since the data acquisition period coincided with the COVID-19 pandemic in Germany [63], we decided to check for these potential differences in our sample. We also evaluated

the correlation of the AUDIT sum score in the sample with the number of drinking days during the EMA assessment and tested whether compliance rate had an influence on all assessed variables with *t* tests.

Ethical Considerations

Within our subproject of the IMAC-Mind consortium [64], participants were recruited through advertisements in schools in Mannheim, Germany, through social media, and with the help of the local registration office of Mannheim. Both participants and their primary caretaker gave written informed consent before study participation. The ethics committee of Medical Faculty Mannheim, Heidelberg University, approved the study (2007-024-N-MA).

Results

General Sample Information

There was no significant difference in alcohol use between participants doing the EMA under COVID-19 restrictions compared with participants doing the EMA before COVID-19 occurred (t_{50}=–0.372, *P*=.71), and no significant differences in alcohol use due to sex (t_{50}=0.199, *P*=.85). However, there was a significant effect for age (t_{50}=–2.910, *P*=.005), with 16-year-olds (mean 1.61, SD 1.66) reporting significantly more alcohol drinking days than 14-year-olds (mean 0.548, SD 0.72). We noted a significant positive correlation (*r*=0.49, 95% CI 0.26 to 0.68; *P*<.001) between reported alcohol days within the EMA and AUDIT sum score. Additionally, there was a significant sex difference in rumination (t_{50}=–2.513, *P*=.02), with males having lower scores (mean 1.56, SD 0.513) than females (mean 2.08, SD 0.907) and a significant difference between participants doing the EMA under COVID-19 restrictions compared with participants doing EMA before COVID-19 occurred in negative affect (t_{50}=–2.091, *P*=.04) with participants doing EMA before COVID-19 having lower scores (mean 0.89, SD 0.67) than participants doing EMA under COVID-19 restrictions (mean 1.26, SD 0.55) and social context (t_{50}=2.027, *P*=.048) with participants doing EMA before COVID-19 having higher scores (mean 0.549, SD 0.215) than participants doing EMA under COVID-19 restrictions (mean 0.438, SD 0.162). All other variables were comparable between males and females and between 14- and 16-year-olds (all *P*>.05; more details in Table 1 and Table 2, and Figure S2 in Multimedia Appendix 1). Furthermore, no significant differences were observed in any of the variables between participants who did not meet the inclusion criteria of compliance (>50%) and those who did meet these criteria (all *P*>.05).

Effect of Daily Life Experiences and Geospatial Measures on Daily Alcohol Use

An overview of the model statistics can be found in Table 3. The model comprises a total of 587 observation days, which is the sum of the days on which participants completed at least 4 prompts per day. There is high variability between participants, with a range of 4 days included in the model for the participant with the fewest days and 14 days for the participant with the most days (mean observation days per participant: 11.29, SD 3.15). Comparing the deviance of the conditional or full model (with fixed and random effects) to the marginal or null model (containing only fixed effects), we see an overall significant difference. The pseudo R^2 of the generalized linear mixed models for both conditional and marginal models show weak to moderate fit. While some predictors remained stable, there was variability across models with different amounts of prompts included (Table S2 in Multimedia Appendix 1 shows detailed results of models with 1, 2, 3, 5, or 6 prompts included). In the model analyzing 4 prompts per day (more details in Table 3), predictors of alcohol use were positive affect (b=0.685, P=.007), rumination (b=0.586, P=.02), weekend day (b=1.082, P<.001), and RE (b=8.126, P=.02). All other predictors did not reach significance in this model.

Discussion

Interpretation of Results

The aim of this study was to examine the influence of daily life experiences, such as affect, craving, rumination, and social context, together with the exposure to potential environmental alcohol triggers (TP) and environmental movement patterns (RE) in contributing to daily alcohol use in healthy adolescents in the very early period of alcohol experience. Our exploratory results show that daily variations in positive affect, rumination, and RE can predict drinking behavior in healthy 14- and 16-year-old adolescents. We identified core concepts that might represent a pattern associated with a higher risk for the development of risky alcohol use.

Interestingly, positive affect (not negative affect) was significantly positively associated with alcohol use on that day in our sample, with robust effects across varying levels of compliance rates (more details in Table S2 in Multimedia Appendix 1). From previous research concerning affective states on alcohol use (stress reactivity theory [5]), it would be expected that alcohol use would follow negative affect, representing a coping strategy to deal with unwanted and aversive emotions [65,66]. In contrast, our results indicate that during early alcohol use, with a low level of frequency, that is, seldom use, adolescents use alcohol when experiencing positive emotions during the day, suggesting it might be used to enhance positive emotions. This is in line with previous work on alcohol-drinking motives in adolescents [18,67]. In addition, adolescents often underestimate the risks of alcohol use and have positive attitudes toward alcohol [68]. However, it is important to note that our data does not allow for the derivation of directionality between positive affect and alcohol use. This limitation stems from the retrospective assessment of alcohol use in this study, conducted without further situational or contextual information. It is plausible that either affect may change as a result of alcohol use, or that situational features prompt both positive affect and alcohol use (eg, a celebratory event, more details in Table S3 in Multimedia Appendix 1), or that adolescents experiencing positive emotions are more likely socialize and thus consume alcohol with peers. Future studies could address this by adopting a more detailed assessment of alcohol use, including information on when, where, and in what context alcohol was consumed, or by using event-related sampling schemes to specifically collect data when alcohol is used.

Furthermore, another central factor in association with alcohol use was rumination, with higher rumination being associated with a higher probability of alcohol use on that day. This association was rather weak compared with the other predictors, and rumination ratings were generally low, but the results are still robust across differing compliance thresholds (more details in Table S2 in Multimedia Appendix 1). Thus, our data suggests that already in early, as of yet non-hazardous alcohol-using adolescents, rumination is a factor that contributes to momentary alcohol use. As we outlined above, we cannot infer directionality from our data. However, it can be speculated that even at early use, alcohol might be used to relieve negative thoughts, posing a risk factor for the development of risky drinking patterns. This is in accordance with a body of work investigating rumination as a predisposing factor of alcohol use in patients with alcohol use disorder [69] and also in adult [70] and adolescent [71,72] regular drinkers. Furthermore, our results on rumination and positive affect might be cautiously interpreted in regard to the IST [72], representing the rather prominent “liking” mechanism of early alcohol use (experiencing positive affect) [73,74] and a risk potential already at early stages for a “wanting” mechanisms (relieving rumination), which might later generalize from momentary to more stable patterns, as more habitual alcohol use develops.

Our results regarding environmental exploratory movement patterns, such as RE and potential alcohol trigger points (TPs), suggest that, unlike individuals with alcohol use disorder or heavy drinkers [31,42], adolescents in the earlier stages of alcohol use may not yet have established stable environmental cues or locations that consistently trigger alcohol use, neither on weekdays nor on weekends (more details in Table S4 in Multimedia Appendix 1). Furthermore, places potentially associated with alcohol use were visited similarly during both weekdays and weekends (more details in Figure S3 in Multimedia Appendix 1). However, it is important to consider that we used a “standardized” categorization of trigger points across the entire sample. Future studies could benefit from assessing more personalized potential trigger points for adolescents by directly asking them where they typically consume alcohol and associating these locations with EMA-based information such as affect or rumination.

Nonetheless, our results suggest that these TPs might indeed be developing, as indicated by higher RE. RE emerged as a consistently robust predictor of alcohol use across various models (more details in Table S2 in Multimedia Appendix 1). It could be speculated that this association is driven by the fact that RE may lead to increased exposure to potential alcohol contexts, such as alcohol advertisements, bars, drinking opportunities, or social contexts. However, there may be other factors contributing to this relationship. For instance, higher RE could be linked to the motivation to drink, such as prosocial

drinking motives [67,75], or it could reflect a decrease in daily structure and reduced parental supervision [76,77] or a lack of scheduled activities [78-80], such as regular participation in sports clubs. In addition, it is possible that RE varies substantially within individuals from day to day due to planned behaviors related to alcohol consumption on drinking days compared to nondrinking days [81]. Exploring the relationship between RE and these factors influencing alcohol use warrants further investigation in future studies, potentially using event-related sampling schemes to align movement patterns with alcohol use patterns. In addition, in order to learn more about the development of alcohol use disorders, it would be beneficial to examine whether a similar association with alcohol use remains in adolescents with alcohol use disorders.

Finally, our results indicate that alcohol use also seems to be dependent on adolescents' age and day of the week. These findings corroborate previous work showing alcohol use increases with age [82] and that adolescents mainly use alcohol on weekends [83,84] when there are usually no obligations to be fulfilled, but there is instead leisure time to spend with peers. Importantly, our results showing adolescents drink more on weekend days might reflect a particular behavioral pattern of adolescence that can change over time (less drinking, but also during the week) or become more pronounced (development towards alcohol addiction).

Our results have implications for prevention approaches, which should sensitize adolescents to alcohol use and its consequences and risks at an early stage before alcohol use manifests in hazardous or risky patterns. At this stage, adolescents might be less aware of the risks concerning alcohol, such as a gradual beginning that might cascade into problematic alcohol use [85]. A relevant concept of prevention might be mindfulness, which has already been successfully used in alcohol addiction treatment [86,87]. However, our results on trait attention regulation, as a relevant part of mindfulness [88], do not show a relevant influence on daily alcohol use (more details in Table S5 in Multimedia Appendix 1). It can be assumed that both mindfulness and attention regulation might be situation-dependent (eg, someone is stressed or in a hurry vs relaxed) and thus may also have a situation-dependent influence on alcohol use.

Limitations

Several limitations of this study should be noted. First, we assessed alcohol use only once a day in the morning, inquiring about alcohol use on the previous day. Consequently, we cannot infer the directionality underlying our findings nor establish any causal relationship. In addition, we are unable to link specific alcohol use episodes to momentary ratings or motives (EMA), social contexts, event appraisal, fluctuations in self-esteem, environmental locations (geospatial information), or the amount of alcohol consumed, which would provide additional crucial information for understanding the occurrence of alcohol-related harm [89]. Future studies could benefit from using participant-initiated assessments (event-related sampling), such as when drinking episodes commence or when participants report a specific context or emotional state [31]. This would provide insights into how the appraisal of occurring events and daily fluctuations in self-esteem contribute to and interact with emotional states and environmental exploratory movement behaviors during certain alcohol consumption occasions. This, in turn, would offer a comprehensive understanding of additional factors that contribute to the initiation of alcohol use in adolescents on a daily basis and help to investigate potential comorbidities with alcohol use behaviors, such as depression, where self-esteem is discussed as a potential critical factor as well [54]. This could also help in further examining alcohol-related coping strategies and their interaction with individual factors.

Second, our study partially coincided with the COVID-19 pandemic in Germany [63], so the generalizability of our results is limited due to COVID-19 restrictions regarding environmental and social factors [90]. Nevertheless, we identify factors influencing alcohol use even under these extremely restricted circumstances. Thus, our results might be underestimated compared with times when access to alcohol and peer communities is easier.

Furthermore, we lacked information on the socioeconomic status of participants and their families. We attempted to estimate this based on the type of school attended by the adolescents (more details in Table S6 in Multimedia Appendix 1), but future studies may benefit from directly inquiring about socioeconomic status, such as family income, as this factor may also influence adolescents' drinking behavior [91]. In addition, geospatial information like GPS shows a certain inaccuracy, especially in a dense urban environment like Mannheim, which leads to ambiguity as to what a participant is currently seeing or interacting with. This is exacerbated by the reliance on publicly available crowdsourced data sources, which correctness and relevance are not guaranteed, especially in view of temporal gaps between the EMA study and the data processing or temporal development within the assessment phase.

Future Directions

Our results provide a first indication of how emotional and other alcohol-related factors might be related to adolescent activity profiles, that is, RE, to predict very early adolescent alcohol use. However, some of the questions raised remain unanswered. Additional EMA studies are warranted to validate the associations identified herein, including within other, more diverse (adolescent) populations, and to assess whether completing an EMA could potentially influence subsequent behavior, such as through postassessment questionnaires [92]. Once these findings are corroborated, low-threshold smartphone or app-based EMIs or ecological momentary prevention approaches could be derived from them. These interventions may assist adolescents in the early stages of alcohol use and potentially prevent the progression to risky or even abusive alcohol consumption during this vulnerable phase by bolstering resilience factors, such as psychoeducation or mindfulness [93].

Geospatial data might contribute to our understanding of developing risky alcohol use in addition to the aforementioned trigger points; in fact, internal contexts (ie, emotional trigger states) might be identified by linking emotional experience or changes in emotional states with geolocation (construction of emomaps [94]). This might be an important step for future

research and would enable a link between environmental causes and behavior, such as alcohol use [95]. Building such emotional maps could be achieved by combining GPS positioning with EMA assessment as in our study, thereby enabling the exploration of the interaction of different alcohol theories with the real-life experiences of participants.

Furthermore, we observed reduced effects in certain variables when applying a stricter threshold for EMA participation, possibly due to fewer observations (more details in Table S2 in Multimedia Appendix 1). Future approaches could potentially enhance participant compliance by offering incentives, a common challenge in EMA studies [48,96], such as reducing the number of prompts per day. Our model comparison indicates that, with a fixed time-based sampling method, an optimal balance for prompts per day exists, ensuring adequate momentary data collection for statistical analysis and comparison. Study designs could be further strengthened by using a longitudinal design and a more age-diverse sample so that the effects on alcohol development could be observed over the period of adolescence.

Conclusion

Through the use of an EMA and geospatial approach, we identified daily life positive affect, rumination, weekend days, and environmental exploratory movement behaviors, as indicated by roaming entropy, as prominent factors associated with very early adolescent drinking behavior during the initial stages of drinking pattern development. Specifically, exploring such movement patterns could serve as an important avenue for future research, offering insights into the development of trigger points from early alcohol use to potentially hazardous use or use disorders.

While environmental factors may not yet play a significant role in the early stages of alcohol use, they are recognized as critical mechanisms in later stages of alcohol use. This understanding can inform the development of future research and may be used in prevention approaches during the early stage of alcohol use.

Acknowledgments

This study is supported by the Federal Ministry of Education and Research Germany (BMBF 01GL1745B, subproject 2), the Deutsche Forschungsgemeinschaft (FL 156/44-1, NE 1383/15-1 and BA 2088/7-1, CoviDrug).

With the public-funded research project IMAC-Mind: Improving Mental Health and Reducing Addiction in Childhood and Adolescence through Mindfulness: Mechanisms, Prevention and Treatment (2017-2023), the Federal Ministry of Education and Research contributes to improving the prevention and treatment of children and adolescents with substance use disorders and associated mental disorders. The project coordination is realized by the German Center of Addiction Research in Childhood and Adolescence at the University Medical Center Hamburg–Eppendorf. The consortium comprises seven projects in Germany. The Principal investigators are Rainer Thomasius (Coordinator, University Medical Center Hamburg–Eppendorf), Tobias Banaschewski and Herta Flor (both Central Institute for Mental Health, Mannheim), Johannes Kornhuber (Friedrich-Alexander-Universität Erlangen–Nürnberg), Michael Klein (Catholic University of Applied Sciences, Cologne), Olaf Reis (University Medicine of Rostock), Tanja Legenbauer (Ruhr-University Bochum), and Antonia Zapf (University Medical Center Hamburg–Eppendorf). Further members of the consortium are Nicolas Arnaud, Austermann Maria, Christiane Baldus, Anne Daubmann, Léa Josette Laurenz, Sabrina Kunze, Sophie Luise Schiller, and Michael Supplieth (University Medical Center Hamburg–Eppendorf), Frauke Nees, Karl Gottfried, Stella Guldner, Sabina Millenet, and Maren Prignitz (Central Institute for Mental Health, Mannheim), Bernd Lenz, Peter Fasching, Matthias Beckmann, Hartmut Heinrich, Verena Nadine Buchholz, Anna Eichler, Lothar Häberle, Christiane Mühle, Patrick Stelzl, and Bernhard Volz (Friedrich-Alexander-University Erlangen–Nürnberg), Katharina Ise and Diana Moesgen (Catholic University of Applied Sciences, Cologne), Lucie Waedel (University Medicine of Rostock), and Martin Holtmann, Regina Herdering, Carina Maria Huhn, and Laura Mokros (Ruhr-University Bochum). For more information, please visit our home page [64].

This study also received funding from the European Union. Complementary funding was received by UK Research and Innovation (UKRI) under the UK government's Horizon Europe funding guarantee (10041392 and 10038599). Views and opinions expressed are, however, those of the authors only and do not necessarily reflect those of the European Union, the European Health and Digital Executive Agency (HADEA), or UKRI. Neither the European Union, HADEA, nor UKRI can be held responsible for them.

Data Availability

The anonymized datasets generated during and/or analyzed during this study are available from the corresponding author on reasonable request.

Conflicts of Interest

None declared.

Multimedia Appendix 1

An Ecological Momentary Assessment Approach of Environmental Triggers in the Role of Daily Affect, Rumination, and Movement Patterns in Early Alcohol Use Among Healthy Adolescents: Exploratory Study - Supplement.

Abstract

Background: Conventional daytime monitoring in a single day may be influenced by factors such as motion artifacts and emotions, and continuous monitoring of nighttime heart rate variability (HRV) and respiration to assist in chronic obstructive pulmonary disease (COPD) diagnosis has not been reported yet.

Objective: The aim of this study was to explore and compare the effects of continuously monitored HRV, heart rate (HR), and respiration during night sleep on the remote diagnosis of COPD.

Methods: We recruited patients with different severities of COPD and healthy controls between January 2021 and November 2022. Vital signs such as HRV, HR, and respiration were recorded using noncontact bed sensors from 10 PM to 8 AM of the following day, and the recordings of each patient lasted for at least 30 days. We obtained statistical means of HRV, HR, and respiration over time periods of 7, 14, and 30 days by continuous monitoring. Additionally, the effects that the statistical means of HRV, HR, and respiration had on COPD diagnosis were evaluated at different times of recordings.

Results: In this study, 146 individuals were enrolled: 37 patients with COPD in the case group and 109 participants in the control group. The median number of continuous night-sleep monitoring days per person was 56.5 (IQR 32.0-113.0) days. Using the features regarding the statistical means of HRV, HR, and respiration over 1, 7, 14, and 30 days, binary logistic regression classification of COPD yielded an accuracy, Youden index, and area under the receiver operating characteristic curve of 0.958, 0.904, and 0.989, respectively. The classification performance for COPD diagnosis was directionally proportional to the monitoring duration of vital signs at night. The importance of the features for diagnosis was determined by the statistical means of respiration, HRV, and HR, which followed the order of respiration > HRV > HR. Specifically, the statistical means of the duration of respiration rate faster than 21 times/min (RRF), high frequency band power of 0.15-0.40 Hz (HF), and respiration rate (RR) were identified as the top 3 most significant features for classification, corresponding to cutoff values of 0.1 minute, 1316.3 nU, and 16.3 times/min, respectively.

Conclusions: Continuous monitoring of nocturnal vital signs has significant potential for the remote diagnosis of COPD. As the duration of night-sleep monitoring increased from 1 to 30 days, the statistical means of HRV, HR, and respiration showed a better reflection of an individual's health condition compared to monitoring the vital signs in a single day or night, and better was the classification performance for COPD diagnosis. Further, the statistical means of RRF, HF, and RR are crucial features for diagnosing COPD, demonstrating the importance of monitoring HRV and respiration during night sleep.

Introduction

Chronic obstructive pulmonary disease (COPD) is a prevalent chronic respiratory disease characterized by persistent airflow restriction, with main symptoms including chronic cough, expectoration, and dyspnea that may not be apparent in the early stages of the disease [1]. In recent years, there has been an increasing trend in the prevalence rate of COPD, and large numbers of cases and deaths have been reported. A cross-sectional study conducted in 2007 among 20,245 adults from 7 provinces in China revealed a COPD prevalence rate of 8.2% among individuals older than 40 years [1]. In 2018, data from 2 large epidemiological surveys in China revealed a prevalence rate of ~13.6% among individuals older than 40 years [2,3]. According to the 2019 Global Burden of Disease Study, the global mortality due to COPD reached 3.3 million individuals, with China alone accounting for over 1 million deaths, representing approximately one-third of the total [4]. Due to dyspnea and other symptoms, the daily activities and exercise ability of patients with COPD are greatly limited, which not only seriously affects their quality of life but also imposes a substantial economic burden on the families and society [5,6].

According to the guidelines for the diagnosis and treatment of COPD in China, the current clinical diagnosis methods of COPD primarily include the pulmonary function test, chest imaging examination, pulse oxygen saturation monitoring, arterial blood gas analysis, electrocardiogram, and echocardiography. Among these methods, the pulmonary function test is the gold standard for diagnosing COPD by assessing the degree of airflow limitation and evaluating disease severity. If the ratio of the forced expiratory volume in the first one second to the forced vital capacity of the lungs is less than 70% after inhalation of the bronchodilator, one will be considered to have persistent airflow limitation and can be further diagnosed in conjunction with the clinical symptoms, signs, and history of exposure to risk factors [7].

Patients with COPD commonly exhibit autonomic nervous dysfunction, and the heart rate variability (HRV) serves as a valuable indicator for assessing autonomic nervous function by reflecting the tension and balance between the sympathetic and parasympathetic nerves [8]. Previous studies [9,10] have compared the resting heart rate (HR) and respiratory rate (RR) monitored during daytime between patients with COPD and healthy individuals, and the results suggested that HR and RR can be used as critical indicators for the auxiliary diagnosis of COPD.

In recent years, the rapid development of sensing technology has facilitated the employment of wearable devices for vital signs monitoring [11]. Pioneer studies have demonstrated that the vital signs (including HRV, HR, and respiration) monitored using wearable sensors are identical to those recorded by medical devices [12]. Thus, wearable sensors–aided continuous monitoring is applicable to patients with chronic disease at home [13,14]. Long-term continuous monitoring with wearable sensors during night sleep can effectively record the vital signs of patients [15,16]. Specifically, Bellos et al [17] utilized wearable devices and external devices from the CHRONIOUS platform system to record vital signs such as blood pressure and blood glucose levels and other short-term information of 30 patients with COPD. A mixed classifier was utilized after performing data fusion to classify the severity of COPD among patients, and it yielded an accuracy of 94%. The principal component analysis–based classification using the daytime-recorded vital signs, including HR, respiration, and blood pressure from 8 healthy individuals and 47 patients with COPD, was examined to assess the severity of COPD, and this yielded an accuracy of 88% [18]. In addition to using HR and respiration, Rahman et al [19] considered 30-minute recorded daytime HRV as a feature by using smartwatches to aid in the diagnosis of COPD, yielding a classification accuracy around 80%. By analogy, with daytime-recorded HRV and HR by using wearable devices, Tiwari et al [20] attempted to predict the acute exacerbation of COPD and verified the feasibility of remote sensing–based early warning. The aforementioned studies were based on wearable device–based vital signs recording during daytime in a single day. However, wearable devices have limitations for recording vital signs during night sleep. In addition, studies on diagnosis of COPD based on long-term monitored vital signs (over weeks or even months) have not been reported yet.

Based on the above concerns, we propose to explore the potential of long-term monitored vital signs (including HR, HRV, and respiration) during night sleep to assist in the remote diagnosis of COPD. To the best of our knowledge, this is the first prospective study based on the continuous monitoring of nocturnal vital signs for the remote diagnosis of COPD. Specifically, the HR, HRV, and respiration in patients with COPD and healthy individuals were recorded with bed sensors from 10 PM to 8 AM on the forthcoming day, and the continuous monitoring of each patient lasted no less than 30 days. With the continuously monitored vital signs, the statistical means of HR, HRV, and respiration over the time periods of 7, 14, and 30 days were extracted as features for the diagnosis of COPD.

Methods

Study Sites and Participants

A prospective observational study was conducted to recruit case and control individuals from January 2021 to November 2022. The case group comprised of patients with confirmed COPD, while the control group consisted of individuals without any definite diagnosis, and both these groups were recruited from the Guangdong Provincial Technology Research Center of COPD Rehabilitation, the Third Affiliated Hospital of Sun Yat-sen University. Specifically, the case group was derived from the outpatient, emergency, and inpatient departments of this hospital, and the control group consisted of individuals recruited by the Guangdong Provincial Technology Research Center of COPD Rehabilitation. Pulmonary function examination was performed either at or prior to the enrollment of the case group. According to the 2022 Global Initiative for Chronic Obstructive Lung Disease (GOLD) diagnostic criteria, if the ratio of the forced expiratory volume in the first one second to the forced vital capacity of the lungs is less than 70% after inhalation of the bronchodilator, one will be considered to have persistent airflow limitation [21]. This is the gold standard for COPD diagnosis and the only inclusion criterion for case groups. The exclusion criteria for the case and control groups were as follows:

1. Participants younger than 45 years
2. Individuals exhibiting poor compliance, dropouts, or loss to follow-up, including those in coma, in shock, with multiple organ failure, or with a history of epilepsy or any other condition that hinders continued participation in the monitoring study; also excluded were individuals who did not utilize monitoring equipment and those with missing lung function indicators
3. Patients with a history of severe lung diseases such as lung cancer, tuberculosis, severe pulmonary heart disease, and any other malignant tumor disease; individuals with severe cardiovascular diseases, including myocardial infarction, heart failure, arrhythmia, hypertension, and coronary heart disease, and patients with diabetes
4. Individuals with irregular schedules.

Ethics Approval

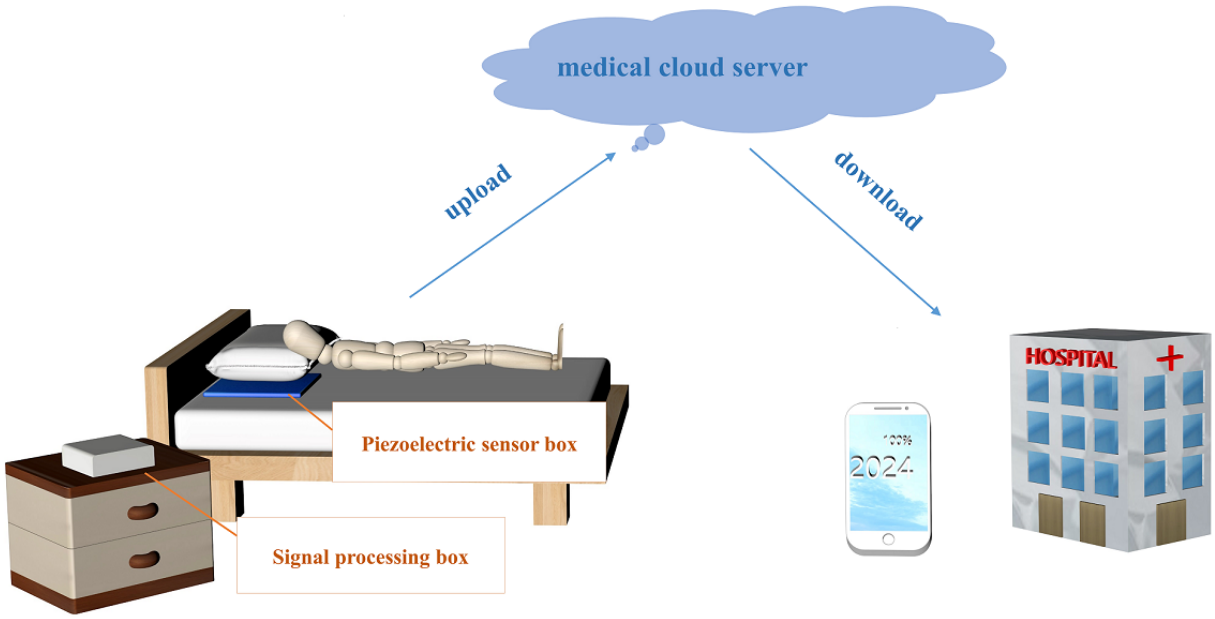
This study obtained the written informed consent from all participants, and the study protocol was reviewed by the medical ethics committee of the Third Affiliated Hospital of Sun Yat-sen University (approval [2021]02-019-01).

Data Collection and Processing

We obtained the pertinent data of individuals in the case group through the hospital information management system, including demographic characteristics, disease history, pulmonary function test data, and acute exacerbations. We also recorded the demographic characteristics and the disease history of participants in the control group. Piezoelectric sensor–based HR and respiratory recorders (model: WSM-LN-03, medical device; China Food and Drug Administration; 20182071130) were distributed to the participants and placed under the pillow to continuously record the HR, respiration, and HRV during night sleep from 10 PM to 8 AM the next day. Prior to the examination, all participants passed the standardized training on how to use the vital sign monitoring device. The recorded vital signs were manually uploaded to the medical cloud server for further data analysis. The architecture of the proposed study is shown in Figure 1. Due to the long duration of the experiment, there may be cases of inevitable data loss. Therefore, specific exclusion criteria with regarding to the data on the medical cloud server were as follows:

1. Number of artifact motions during night sleep ≥600
2. Sleep duration less than 5 hours or longer than 9 hours
3. Data loss in 1 night sleep ≥1 hour
4. Outliers such as HR or RR is 0
5. Data obtained 7 days before and during cases of acute exacerbation of COPD

Figure 1. Architecture of the proposed study.



Principle of Device and Feature Description

The distributed vital signs monitoring device was deployed under the pillow. With piezoelectric sensors, the analogy signals representing cardiac and respiratory activities are recorded with a sampling frequency of 1 kHz. Specifically designed filter banks can detect the heartbeat interval and respiration per minute during night sleep, and the averaged HR (beat/min) and respiration (times/min) of a whole night can be obtained [22-24]. In addition, by taking advantage of the heartbeat interval, both time and frequency domain HRV parameters can be calculated, as illustrated in Table 1 [25]. Specifically, HRV contains 7 times/frequency domain features, including standard deviation of heartbeat interval (SDNN), total power of heartbeat interval (TP), low frequency of TP (LF), high frequency of TP (HF), low frequency/high frequency (LF/HF), very low frequency of TP (VLF), and ultralow frequency of TP (ULF). The features of respiration also contain the cumulative duration of RR faster than 21 times/min (RRF).

Table 1. Feature descriptions of heart rate variability, heart rate, and respiration.

Category, abbreviation of feature	Definition
Heart rate variability [25]	
SDNN	Standard deviation of heartbeat interval
TP	Total spectral power of heartbeat interval
LF	Low frequency band power of 0.04-0.15 Hz
HF	High frequency band power of 0.15-0.40 Hz
ULF	Ultralow frequency band power of <0.0033 Hz
VLF	Very low frequency band power of 0.0033-0.04 Hz
LF/HF	Ratio of low frequency band power over high frequency band power
Heart rate	
HR	Heart rate mode during night sleep (beats/min)
Respiration	
RR	Respiratory rate mode during night sleep (times/min)
RRF (min)	Cumulative duration of respiratory rate faster than 21 times/min

Since the bed sensors continuously monitor during night, HRV, HR, and respiration can be continuously monitored over weeks without affecting the lifestyle of the recruited patients. Considering that the features of HRV, HR, and respiration obtained in a single night sleep monitoring could be influenced by the daytime emotions and health status of the patients, we propose to use the statistical average of the continuously monitored features (HRV, HR, and respiration) over weeks instead of that recorded in a single day for further analysis. Numerically, the statistical average of the features HRV, HR, and respiration over t consecutive days are calculated by the following method. We first calculated the sum of the values of HRV, HR, and respiration for t consecutive days; then subtracted the maximum and minimum values in the values of HRV, HR, and respiration for t consecutive days; and then obtained the statistical means by dividing by t–2. In this study, we set t=1, 7, 14, and 30 days as the cutoff observation time for analysis.

Sample Size Estimation

The purpose of this study was to evaluate the diagnostic value of continuous HRV and respiration monitoring in patients with COPD and control groups by using pulmonary function examination as the diagnostic gold standard. We expected continuous HRV and respiration monitoring to diagnose COPD with sensitivity of 90%, tolerance error of 10% of sensitivity, specificity of 90%, tolerance error of 10% of specificity, and the test criteria α=.01. The sample size for patients with COPD and control groups was set at 1:2, and the dropout rate was set as 10%. Finally, we used PASS 11.0 software (NCSS Statistical Software) to calculate the sample size, and we found that there should be at least 37 patients with COPD and 74 controls, for a total of 111 participants.

Statistical Analysis

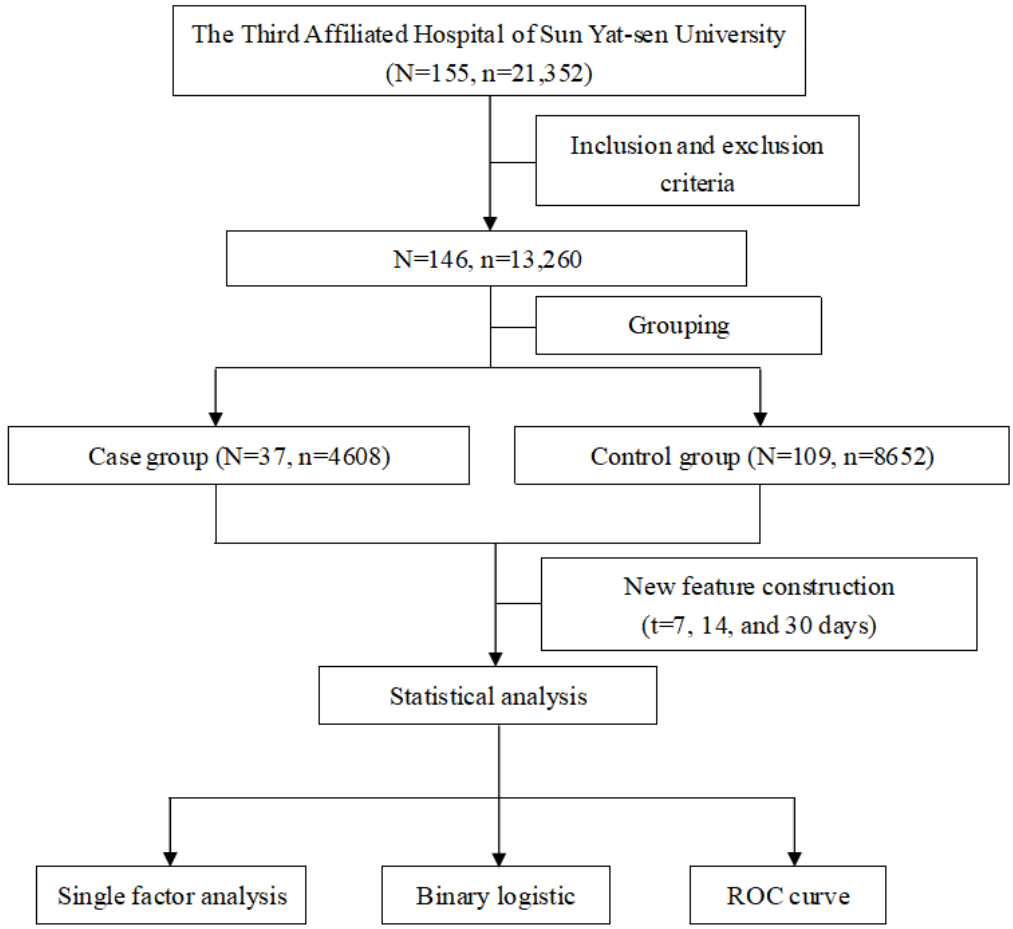
Statistical analysis was conducted using SPSS software (version 20.0; IBM Corp). The main statistical methods included descriptive analysis, χ^2 test, nonparametric test, binary logistic regression, and receiver operating characteristic (ROC) curves. For statistical description, counting data were described by frequency and rate, and metrological data were described by median and quartile. For statistical tests, the χ^2 test was employed to compare the 2 groups in terms of the counting data, with the χ^2 value serving as the test statistic. The metrological data were analyzed using a nonparametric test, specifically the Mann-Whitney U test. The z score was employed as the test statistic. In the multifactor analysis, the classical binary logistic regression was applied for classification, and the ROC curve was used to evaluate the diagnosis of each variable. The determination of the cutoff values relied on the maximum Youden index as the tangent point. The test criterion was set as α=.05, and P<.05 was considered statistically significant. The classification cutoff point was set as 0.5.

Data Cleaning and Analysis Flowchart

The experimental process of this study is shown in Figure 2. We recruited 155 participants corresponding to a total number

of 21,352 night-sleep monitored samples (person-time) of patients with COPD and healthy participants in the Third Affiliated Hospital of Sun Yat-sen University, in accordance with the abovementioned inclusion criteria for the population. After data cleaning based on the abovementioned exclusion criteria, 146 patients corresponding to a final number of 13,260 samples (person-time) were included, corresponding to case and control groups of 4608 and 8652 samples, respectively. Subsequently, the statistically averaged features of long-term HRV, HR, and respiration over the observation time of 7, 14, and 30 days were constructed for further analysis.

Figure 2. Flowchart of data cleaning and analysis. N: number of participants; n: number of person-times; ROC: receiver operating characteristic; t: cutoff observation time.



Results

Baseline Characteristics

A total of 146 individuals who met the inclusion and exclusion criteria were enrolled in this study, comprising 37 cases and 109 controls. There were 12 mild to moderate cases and 25 severe cases. The overall compliance rate among the participants was 0.73 (IQR 0.50-0.86), with no statistically significant difference between the 2 groups (z score=–1.5; P=.15). Moreover, the average number of continuous night-sleep monitoring days per person was found to be 56.5 (IQR 32.0-113.0) days, showing no significant difference between the 2 groups again (z score=0.5; P=.65). Therefore, compliance and monitoring duration between the 2 groups were comparable. Significant differences were observed between the 2 groups in terms of age, gender, and BMI (P<.001). Specifically, the case group exhibited a higher proportion of older individuals, males, and those with low BMI in comparison to the control group (as depicted in Table 2).

Table 2. Overall baseline characteristics of the total population.

Variables	Total (N=146)	Control group (n=109)	Case group (n=37)	*z* score/χ^2 (*df*)	*P* value
Compliance rate, median (IQR)	0.73 (0.50-0.86)	0.76 (0.53-0.86)	0.65 (0.43-0.83)	–1.5	.15
Monitoring per person, median (IQR)	56.5 (32.0-113.0)	56.0 (34.0-107.0)	78.0 (25.0-164.0)	0.5	.65
Age (years), median (IQR)	59.0 (52.0-68.0)	55.0 (51.0-63.0)	73.0 (66.0-77.0)	7.0	<.001
Sex, n (%)				21.8 (1)	<.001
Male	70 (47.9)	40 (36.7)	30 (81.1)		
Female	76 (52.1)	69 (63.3)	7 (18.9)		
BMI (kg/m^2), n (%)				18.9 (2)	<.001
<18.5	8 (5.5)	2 (1.8)	6 (16.2)		
18.5-24	95 (65)	67 (61.5)	28 (75.7)		
≥24	43 (29.5)	40 (36.7)	3 (8.1)		

Statistical Comparisons of the Features Between Case and Control Groups

This study consists of 13,260 samples (person-time), corresponding to 8652 in the control group and 4608 in the case group. During the monitoring period of 7, 14, and 30 days, there was a total of 12,396, 11,422, and 9404 person-times recorded, respectively. In 4 cutoffs of the observation time of 1, 7, 14, and 30 days, the distributions of HRV, HR, and respiration features, that is, SDNN, TP, LF, HF, VLF, ULF, HR, RR, and RRF, averaged over different timescales were of significant statistical difference, as shown in Tables S1-S4 of Multimedia Appendix 1. Specifically, the values of all the averaged features in the different timescales in the case group were significantly higher than those of the control group (P<.001). Interestingly, no significant difference was observed in the distribution of the features LF/HF between the 2 groups (P>.05). Consequently, when performing a binary logistic regression analysis, all features of LF/HF averaged over different timescales (t= 1, 7, 14, and 30 days), that is, LF/HF_1, LF/HF_7, LF/HF_{14}, and LF/HF_{30} were excluded, while the rest 36 features were included.

Classification Performance of Multidimensional Vital Sign Features

HRV, HR, and respiratory features at different timescales are represented by features and timescales, where timescales are in subscripts. The overall classification accuracy of HRV, HR, and respiration at 1, 7, 14, and 30 days achieved a high level of 0.958, with an impressive Youden index of 0.904 and an excellent area under the ROC curve (AUC) of 0.989 (as presented in Table 3 and Figure 3A).

We combined the vital signs features based on 4 different timescales (t= 1, 7, 14, and 30 days) and subsequently classified the participants into case and control groups. Figure 4 demonstrates that the classification performance of HRV, HR, and respiration improved as the monitoring duration increased, with HRV, HR, and respiration at 30 days exhibiting superior performance (accuracy 0.956, Youden index 0.899, AUC 0.989). Specifically, the ranking of the performance was presented as follows: HRV, HR, and respiration in 30 days > HRV, HR, and respiration in 14 days > HRV, HR, and respiration in 7 days > HRV, HR, and respiration in 1 day.

We combined them again based on the vital signs category and subsequently classified those participants into the case and control groups. Figure 4 demonstrates an improving trend in the classification efficacy of respiration, HRV, and HR, surpassing that of single-day monitoring. On the one hand, when evaluating the classification effect using accuracy and Youden index, we observed an improvement in the classification effect of HRV with the increasing duration of monitoring, where HRV_{30} demonstrated the highest performance (accuracy 0.866, Youden index 0.717). Similarly, as the monitoring duration increased, respiration also exhibited enhanced performance, with respiration at 30 days achieving the best results (accuracy 0.913, Youden index 0.792). However, there was minimal variation in the classification performance of HR across different timescales, maintaining an accuracy rate of approximately 0.67 and a Youden index of around 0.15. On the other hand, AUC was utilized to be evaluated. The findings demonstrated that all AUC values exceeded 0.5 and exhibited statistical significance. Notably, the classification performance of HRV improved with longer monitoring duration, specifically presented as HRV_{30} > HRV_{14} > HRV_7 > HRV_1. Similarly, the performance of respiration gradually tended to increase with extended monitoring duration, indicated by respiration over 30 days/respiration over 14 days > respiration over 14 days/respiration over 7 days > respiration over 1 day. However, there were no statistically significant differences between respiration over 14 days and respiration over 7 days or between respiration over 14 days and respiration over 30 days. Furthermore, the performance of HR also progressively enhanced with prolonged monitoring time ($HR_{30}/HR_{14}/HR_7$ > HR_1). Nevertheless, there were no statistically significant differences among HR_7, HR_{14}, and HR_{30}, as shown in Table 3.

Table 3 and Figures 3B-3E demonstrate that the classification performance, as evaluated by the accuracy, Youden index, and AUC, consistently showed respiration > HRV > HR over a single timescale. This consistent pattern was observed over all 4 timescales. In addition, the sensitivity of HR remained consistently low over the 4 timescales, ranging from

approximately 0.2 to 0.3, indicating a high potential for missed diagnoses rate (1–sensitivity) of up to 0.7-0.8. Specifically, the sensitivity of HR_1 was 0.177, with a corresponding missed diagnosis rate of 0.823. These findings highlight that only using HR features for the diagnosis of patients with COPD may lead to a significant increase in missed diagnosis rates exceeding 80%.

Table 3. The model evaluation index for the diagnosis of chronic obstructive pulmonary disease by using a combination of multidimensional features.

Features (time=1, 7, 14, 30 days)	Accuracy	Sensitivity	Specificity	Youden index	Area under the curve (95% CI)	*P* value
(HRV[a], HR[b], respiration) in 1, 7, 14, and 30 days	0.958	0.924	0.980	0.904	0.989 (0.987-0.991)	<.001
(HRV, HR, respiration) in 1 day	0.915	0.813	0.970	0.783	0.959 (0.955-0.963)	<.001

Respiration in 14 days	0.907	0.789	0.975	0.764	0.937 (0.932-0.943)	<.001
Respiration in 30 days	0.913	0.819	0.973	0.792	0.944 (0.939-0.950)	<.001

[a]HRV: heart rate variability.

[b]HR: heart rate.

Figure 3. Receiver operating characteristic curve of multidimensional features based on 4 timescales (1, 7, 14, and 30 days; shown in subscripts in the graph). HR: heart rate; HRV: heart rate variability.

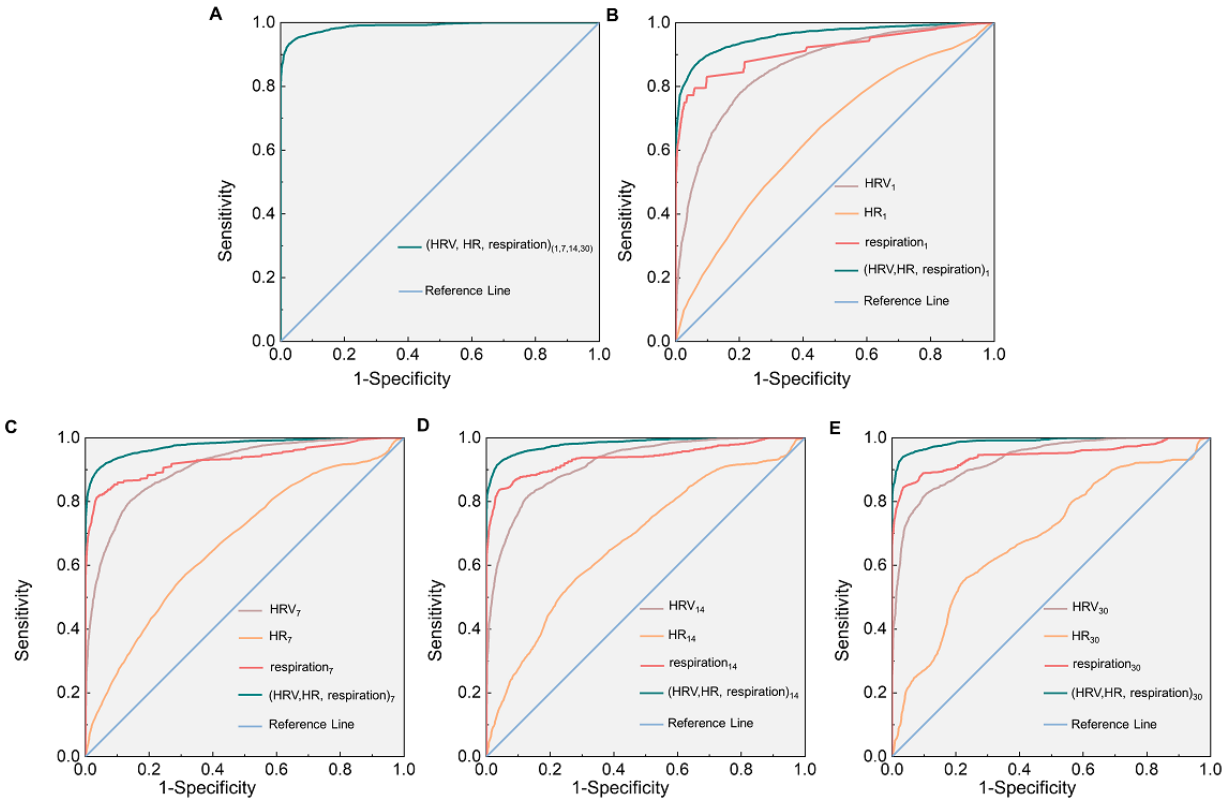

Figure 4. Relationship between area under the curve and monitoring duration of multidimensional statistical features. AUC: area under the curve; HR: heart rate; HRV: heart rate variability; t: time.

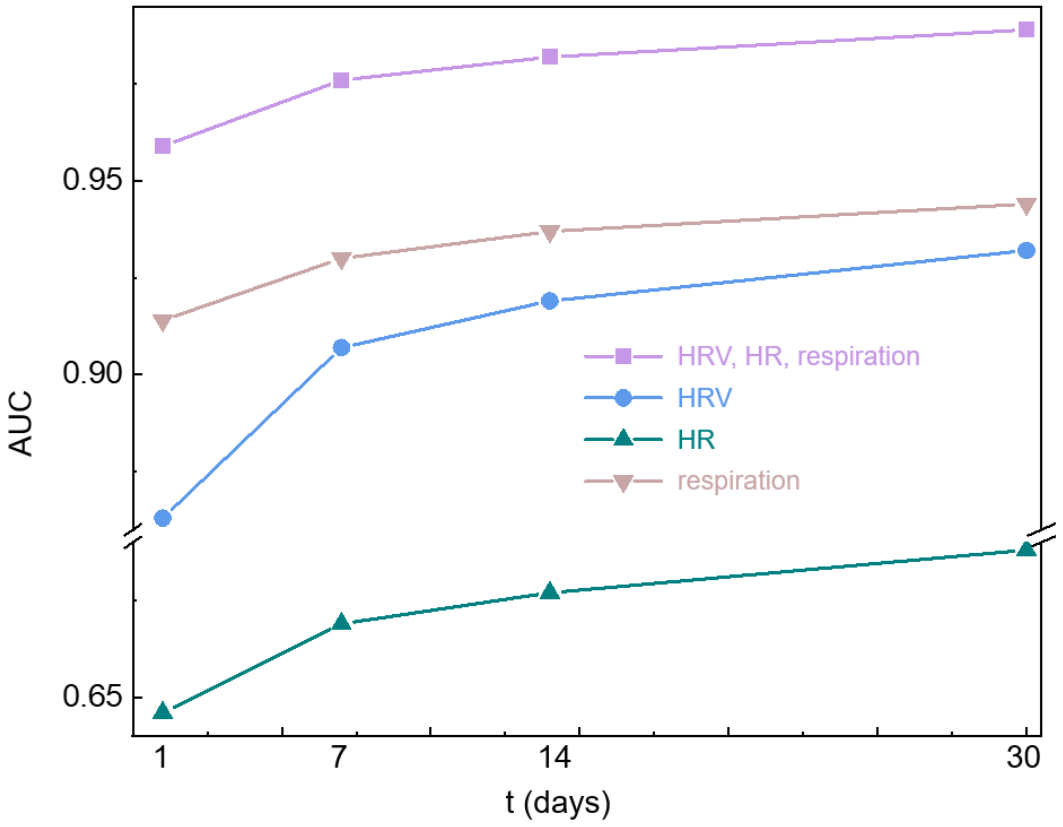

Classification Performance of Single Features for 7 Days Long-Term Monitoring

The results shown in Figure 4 indicate that the classification performance using the 7-day monitored features (HRV, HR, respiration; AUC=0.976) is already comparable to that of the 30-day monitored features (HRV, HR, respiration; AUC=0.989). Therefore, considering that the performance of monitoring longer than 7 days tends to saturate, while increasing the monitoring time leads to an increase in the dropout rate, we recommend continuous monitoring for 7 days during daily home life, which can already provide valuable assistance in the auxiliary diagnosis of COPD.

We classified the case and control groups by a single measured vital sign feature during the 7-day long-term monitoring period. As shown in Table 4, the results revealed that the HF_7 exhibited the most effective classification performance (accuracy 0.830, Youden index 0.602), followed by TP_7 (accuracy 0.792, Youden index 0.474) among the 6 features (HRV) evaluated by the accuracy and Youden index. Among the features set (HRV, HR, respiration)$_7$, RRF_7 demonstrated the best performance (accuracy 0.898, Youden index 0.733), followed by HF_7, while HR_7 showed the poorest performance (accuracy 0.674, Youden index 0.147). Furthermore, both HR_7 and ULF_7 exhibited very low sensitivity with the missed diagnosis rate exceeding 70%, indicating that using HR_7 or ULF_7 for classification and prediction could lead to higher chances of missed diagnosis.

Additionally, AUC was used to evaluate the effect of the features on the classification performance. As depicted in Figure 5, the AUCs of all 7-day time-scale monitored features were greater than 0.5 and demonstrated statistical significance (P<.001). The highest AUC value was observed for RRF_7 at 0.955. The order of the classification effects was as follows: $RRF_7 > HF_7 > RR_7 > LF_7/TP_7 > SDNN_7 > VLF_7 > ULF_7/HR_7$. Notably, there were no statistically significant differences between LF_7 and TP_7, ULF_7, and HR_7.

Table 4. Model evaluation index of the single statistical average of features based on 7 days monitoring.

Features (time=7 days)	Accuracy	Sensitivity	Specificity	Youden index	Area under the curve (95% CI)	*P* value
SDNN[a]	0.745	0.465	0.899	0.364	0.768 (0.759-0.777)	<.001
TP[b]	0.792	0.549	0.925	0.474	0.832 (0.825-0.840)	<.001
LF[c]	0.788	0.555	0.917	0.472	0.829 (0.821-0.837)	<.001

RR[h]	0.830	0.651	0.927	0.578	0.869 (0.862-0.876)	<.001
RRF[i]	0.898	0.759	0.974	0.733	0.955 (0.950-0.959)	<.001

[a]SDNN: standard deviation of heartbeat interval.

[b]TP: total spectral power of heartbeat interval.

[c]LF: low frequency band power of 0.04-0.15 Hz.

[d]HF: high frequency band power of 0.15-0.40 Hz.

[e]VLF: very low frequency band power of 0.0033-0.04 Hz.

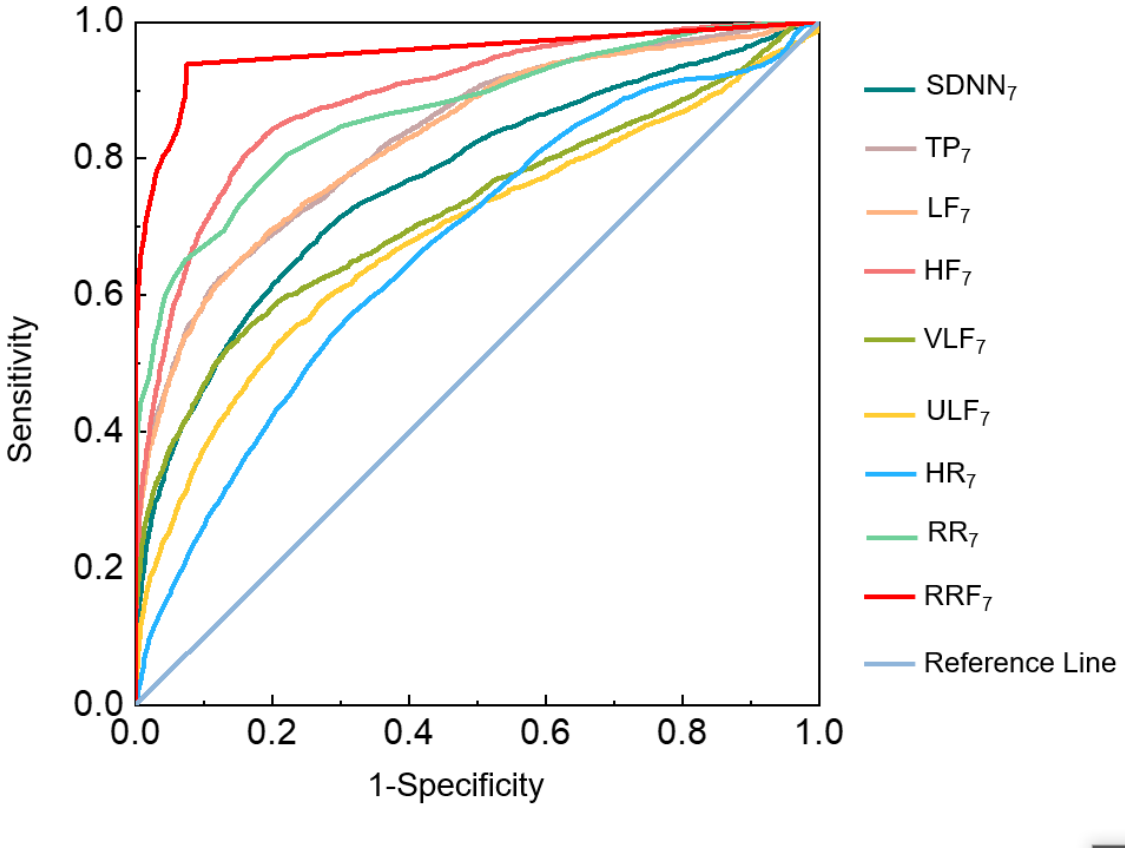
[f]ULF: ultralow frequency band power of <0.0033 Hz.

[g]HR: heart rate.

[h]RR: respiratory rate.

[i]RRF: respiratory rate faster than 21 times/min.

Figure 5. Receiver operating characteristic curve of single statistical average of features based on 7 days monitoring. HF: high frequency band power of 0.15-0.40 Hz; HR: heart rate; LF: low frequency band power of 0.04-0.15 Hz; RR: respiratory rate; RRF: respiratory rate faster than 21 times/min; SDNN: standard deviation of heartbeat interval; TP: total power of heartbeat interval; ULF: ultralow frequency band power of <0.0033 Hz; VLF: very low frequency band power of 0.0033-0.04 Hz.



Cutoff Values

Considering that the classification performance of HF_7, RR_7, and RRF_7 was superior to that of other features, which reflected the potential values of such features for the diagnosis of COPD, we further analyzed the cutoff values based on the maximum Youden index for HF_7, RR_7, and RRF_7. This serves as a reference for auxiliary diagnosis in patients with COPD. The determined cutoff value for HF_7 was 1316.30 nU, which corresponded to sensitivity and specificity values of 0.836 and 0.810, respectively. The cutoff value for RR_7 was 16.3 times/min, accompanied by sensitivity and specificity values of 0.783 and 0.803, respectively. As for RRF_7, the designated cutoff value was set at 0.1 minute with corresponding sensitivity and specificity values of 0.938 and 0.925, respectively. Samples exceeding these respective cutoff values would be assigned to the case group, while the others would be assigned to the control group (as illustrated in Table 5).

Table 5. Cutoff values of statistical average of respiration rate faster than 21 times/min, high frequency band power of 0.15-0.40 Hz in heart rate variability, and respiration rate.

Features (time=7 days)	Cutoff point	Sensitivity	Specificity	Youden index
High frequency band power of 0.15-0.40 Hz	1316.30	0.836	0.810	0.646
Respiratory rate	16.30	0.783	0.803	0.585
Respiratory rate faster than 21 times/min	0.10	0.938	0.925	0.864

Discussion

Principal Findings

The primary purpose of this study was to explore the feasibility of bed sensor–aided continuous night-sleep monitoring of vital signs (HRV, HR, and respiration) to assist in the remote diagnosis of COPD. Our findings show that continuous night-sleep monitoring has significant potential in the diagnosis of COPD, and the statistical means of RRF, HF, and RR are the crucial features. By extracting statistical features from the continuously recorded HRV, HR, and respiration over 7, 14, and 30 days, the classification performance of the vital signs for COPD diagnosis was evaluated and compared in different timescales, and the cutoff values of the most important features were obtained as a reference point for in-home diagnosis of COPD. Our prospective cohort experimental analysis verified

that the classification performance of the diagnosis of COPD increases directionally proportional to the monitoring duration of vital signs recording. This outcome is expected due to the influence of various factors such as environment, daytime emotions, and activities on the recorded vital signs during a single night sleep [26,27]. Comparatively, by increasing the statistical timescale with regard to feature extraction, the derived statistical features can reflect the status of individual health more accurately [28,29]. Under the tradeoff between the performance of diagnosis and the feasibility of continuous monitoring, it is recommended that a 7-day daily home-based continuous monitoring is sufficient to assist in the diagnosis of COPD.

According to previous research, the resting HR and respiration of patients with COPD are higher than those of healthy individuals. However, there is still a lack of literature support regarding the comparison of the correlation between these indicators and patients with COPD [30]. In this study, we discovered that long-term monitored features such as RR, HF, and RRF were more significant for diagnosing COPD than HR alone. Using either RR or HF as features, the classification performance accuracy already exceeded 80%. Furthermore, when utilizing RRF for classification, the accuracy reached 90%. In comparison, if HR was used for classification purposes only, the accuracy dropped to 67%, with a missed diagnosis rate exceeding 70%.

The resting RR for healthy individuals ranges from 12 to 20 beats per minute [31]. However, our findings showed that RR exceeded 16 beats per minute, which can be viewed as an important feature for the diagnosis of COPD. This finding is expected since patients with COPD are more prone to experiencing rapid breathing [32]. The cutoff value for RRF in this study was determined as 0.1 minute, indicating that any presence of rapid breathing during night sleep significantly increases the probability of a COPD diagnosis. The corresponding sensitivity and specificity values reach up to 94% and 93%, respectively.

Patients with COPD exhibit abnormal autonomic nervous function and reduced HRV [33,34]. Studies have demonstrated a decrease in sympathetic regulation among stable patients with COPD, suggesting a potential shift toward parasympathetic regulation [35]. By contrast, our findings show that patients with COPD exhibit an elevated HRV compared to healthy controls. The possible reasons are 2-fold. On the one hand, the HRV indicators of patients with COPD were increased due to cardiac compensation since all patients with severe cardiovascular diseases were excluded in this study. This phenomenon was also validated by a pioneer study [36]. On the other hand, as pointed out by [37], parasympathetic regulation is more active in patients with acute exacerbation of COPD compared to those with stable COPD. In this study, although the events of acute exacerbation in the case group were excluded before analysis, potential labelling errors of the acute exacerbation cases existed, since the recording of periodic follow-up might have been incomplete due to out-of-hospital visits or recall bias, and small amount of monitoring data during acute exacerbations were included, which could account for the observed increase in HRV among patients with COPD.

LF reflects the regulation of the sympathetic nerve, HF reflects the activity of the parasympathetic nerve, and LF/HF reflects the relative activity of the sympathetic nerve and the parasympathetic nerve, that is, the balance between the sympathetic nerve and the parasympathetic nerve [36]. The results of our study showed that there was no statistically significant differences in the LF/HF characteristics between the case group and the control group, which indicated that in patients with COPD, the LF and HF both increased, thus resulting in the relatively constant LF/HF indices. This is also consistent with previous studies, which demonstrated no significant difference between the LF/HF of patients with COPD and the control groups [37].

Strengths and Limitations

This study is the first prospective observational study based on continuous vital signs monitoring during night sleep to assist in-home diagnosis of COPD. With the help of noncontact sensors placed under the mattress, we performed continuous night sleep monitoring for individuals with COPD and healthy individuals over weeks and employed the statistical means of the monitored HR, respiration, and HRV at different timescales as features instead of the short-term measurement in a single day. Comparatively, the proposed long-term monitoring could reduce the uncertainty and inaccuracy caused by various interference factors present in short-term monitoring sessions and thereby improve the performance of the auxiliary diagnosis of COPD.

This study has some limitations. The majority of the individuals in the case group were patients with COPD recruited from the hospital. Due to the characteristics of COPD, the proportion of old and lean men in the case group was higher, while individuals in the control group were normal primarily. Statistical comparisons revealed uneven distributions regarding age, sex, and BMI at baseline between the 2 groups, potentially introducing a selection bias. To address this issue, we accounted for these factors during data analysis by adjusting them prior to analysis. Consequently, we observed an improvement in the classification performance while observing minor impacts on the comparison of the classification effects for different features among our patients.

Conclusions

In this paper, we report the utilization of bed sensors for continuous recording of vital signs, including HR, respiration, and HRV during nighttime, thereby aiming to provide auxiliary diagnosis for COPD. Compared to single-time and single-day measurement, the long-term statistical features derived from continuous vital signs recordings demonstrate superior performance in the diagnosis of COPD. Moreover, the longer the timescale used for constructing the statistical features, the better is the classification performance for COPD diagnosis. Feature importance analysis showed that the statistical features of respiration and HRV contributed significantly more than the HR features in the COPD diagnosis. Specifically, RR, RRF, and HF exhibited the highest contribution to COPD diagnosis and hold important reference for home-assisted diagnosis of COPD. Additionally, this study determines the cutoff values for important features, which can provide a reference range for

clinical COPD diagnosis. In principle, this design may also be applicable to other cardiovascular diseases such as heart failure, but the important features for disease diagnosis may be different.

Abstract

Background: Wearables that measure vital parameters can be potential tools for monitoring patients at home during cancer treatment. One type of wearable is a smart T-shirt with embedded sensors. Initially, smart T-shirts were designed to aid athletes in their performance analyses. Recently however, researchers have been investigating the use of smart T-shirts as supportive tools in health care. In general, the knowledge on the use of wearables for symptom monitoring during cancer treatment is limited, and consensus and awareness about compliance or adherence are lacking.

Objectives: The aim of this study was to evaluate adherence to and experiences with using a smart T-shirt for the home monitoring of biometric sensor data among adolescent and young adult patients undergoing cancer treatment during a 2-week period.

Methods: This study was a prospective, single-cohort, mixed methods feasibility study. The inclusion criteria were patients aged 18 to 39 years and those who were receiving treatment at Copenhagen University Hospital - Rigshospitalet, Denmark. Consenting patients were asked to wear the Chronolife smart T-shirt for a period of 2 weeks. The smart T-shirt had multiple sensors and electrodes, which engendered the following six measurements: electrocardiogram (ECG) measurements, thoracic respiration, abdominal respiration, thoracic impedance, physical activity (steps), and skin temperature. The primary end point was adherence, which was defined as a wear time of >8 hours per day. The patient experience was investigated via individual, semistructured telephone interviews and a paper questionnaire.

Results: A total of 10 patients were included. The number of days with wear times of >8 hours during the study period (14 d) varied from 0 to 6 (mean 2 d). Further, 3 patients had a mean wear time of >8 hours during each of their days with data registration. The number of days with any data registration ranged from 0 to 10 (mean 6.4 d). The thematic analysis of interviews pointed to the following three main themes: (1) the smart T-shirt is cool but does not fit patients with cancer, (2) the technology limits the use of the smart T-shirt, and (3) the monitoring of data increases the feeling of safety. Results from the questionnaire showed that the patients generally had confidence in the device.

Conclusions: Although the primary end point was not reached, the patients' experiences with using the smart T-shirt resulted in the knowledge that patients acknowledged the need for new technologies that improve supportive cancer care. The patients were positive when asked to wear the smart T-shirt. However, technical and practical challenges in using the device resulted in low adherence. Although wearables might have potential for home monitoring, the present technology is immature for clinical use.

Introduction

Patients with cancer can be exposed to several treatments (eg, surgery, radiation, chemotherapy, and hormone therapy), individually or in combination, depending on their disease and stage. Cancer treatment is known to cause acute side effects [1-3]. The degree of symptoms and side effects depends on the type of cancer, the treatment modality, and the pre-existing comorbidity [1,4,5]. During oncological treatment, the patients may need acute hospitalization due to side effects, while in other cases, side effects are related to poor treatment compliance and reduced quality of life (QoL) [6].

Several studies have emphasized that patients and health care professionals can assess and perceive symptoms and side effects differently [7,8]. This is exemplified by the fact that health care professionals tend to underestimate patients' symptoms [9]. The development of side effects and symptoms often results in a deterioration of the patient's health condition, affecting the patient's QoL [10,11]. This applies especially to adolescents and young adults (AYAs) with cancer [12].

There is an increased focus on home monitoring to help patients manage their symptoms and side effects. Patient-generated health data can provide health care professionals with valuable information. One type of patient-generated health data is biometric sensor data, which are typically collected by wearables [13-15]. A wearable device is a noninvasive wireless sensor that monitors and collects health parameters [13,16]. A newer type of wearable is a smart T-shirt with biometric sensors embedded in the fabric. Wearables allow health professionals to monitor an increased number of health parameters on various biometric data points.

The data collected from wearables are predicted to be exact and comparable to data collected from conventional medical measuring devices [17-19]. These new technologies allow for the more extensive passive monitoring of patients in their home environment and may minimize the burden resulting from hospital visits [6,16,20-23]. In addition, wearables ensure exact information without recall and reporting bias, which hopefully results in better cancer treatment [20,24-26]. However, studies that investigate the use of wearables in an oncological setting are limited [24,27-29]. Furthermore, it has been stated that there is a lack of consensus and awareness about compliance with or adherence to wearables. These are essential parts of using and comparing collected biometric sensor data [30].

Many existing and new technologies are not developed or evaluated based on users' perspectives and sometimes do not adequately meet the needs of their target groups [31-33]. The AYA patient group frequently uses new technologies, such as wearables [34]. AYAs thus have unique and beneficial knowledge, which is why patients' involvement in the study design and in feasibility assessment can be extremely useful [35].

The aim of this study was to evaluate feasibility based on adherence to and experiences with using a smart T-shirt for the remote monitoring of biometric sensor data among AYA patients undergoing cancer treatment during a 2-week test period.

Methods

Ethical Considerations

This study was an investigator-driven partnership between the Department of Oncology, Rigshospitalet, and Chronolife and was registered at ClinicalTrials.gov (trial number: NCT05235594). This study conformed to the General Data Protection Regulation guidelines and was registered at the Capital Region of Denmark (registration number: P-2021-357). The trial was approved by the local division for IT and Medico Technology in the Capital Region of Denmark and was a collaboration between the Department of Oncology, Rigshospitalet; the Department of Innovation, Rigshospitalet; and the Telemedical Knowledge Center, Capital Region of Denmark. Approval from the National Committee on Health Research Ethics was not required for this trial in the Danish context when this study was conducted. Informed consent was obtained from all patients involved in this study. The patients received verbal and written information. Written informed consent was required, and patients were informed that it was possible to withdraw from this study at any time during the study period. No financial compensation was provided.

Study Design

The OncoSmartShirt study was a prospective, single-cohort, mixed methods study that investigated the feasibility of using the Chronolife smart T-shirt (Keesense) during cancer treatment. This smart T-shirt was designed with multiple fully embedded sensors and electrodes, which engendered 6 different measurement flows continuously [25]. Before this study was conducted, the project was presented to a group of AYAs with cancer at a social meeting with the "Kræftværket" cancer network group. The participants provided the researchers with their inputs and perspectives on the study design to make it relevant and feasible. The acceptance and comfort of wearing the Chronolife smart T-shirt throughout the day (8 h/d) for 2 weeks (14 d) were investigated among all enrolled patients.

The inclusion criteria were young patients with cancer aged 18 to 39 years (defined as *AYAs*) and those who were receiving antineoplastic treatment at the Department of Oncology and Department of Haematology of the Centre for Cancer and Organ Diseases, Copenhagen University Hospital - Rigshospitalet, Copenhagen, Denmark. Other inclusion criteria were having the ability to read and speak Danish and having no serious cognitive deficits. There were no requirements regarding specific cancer diagnoses, and both patients in curative care and patients in palliative care could be included. Inclusion in this study did not interfere with the planned oncological treatment.

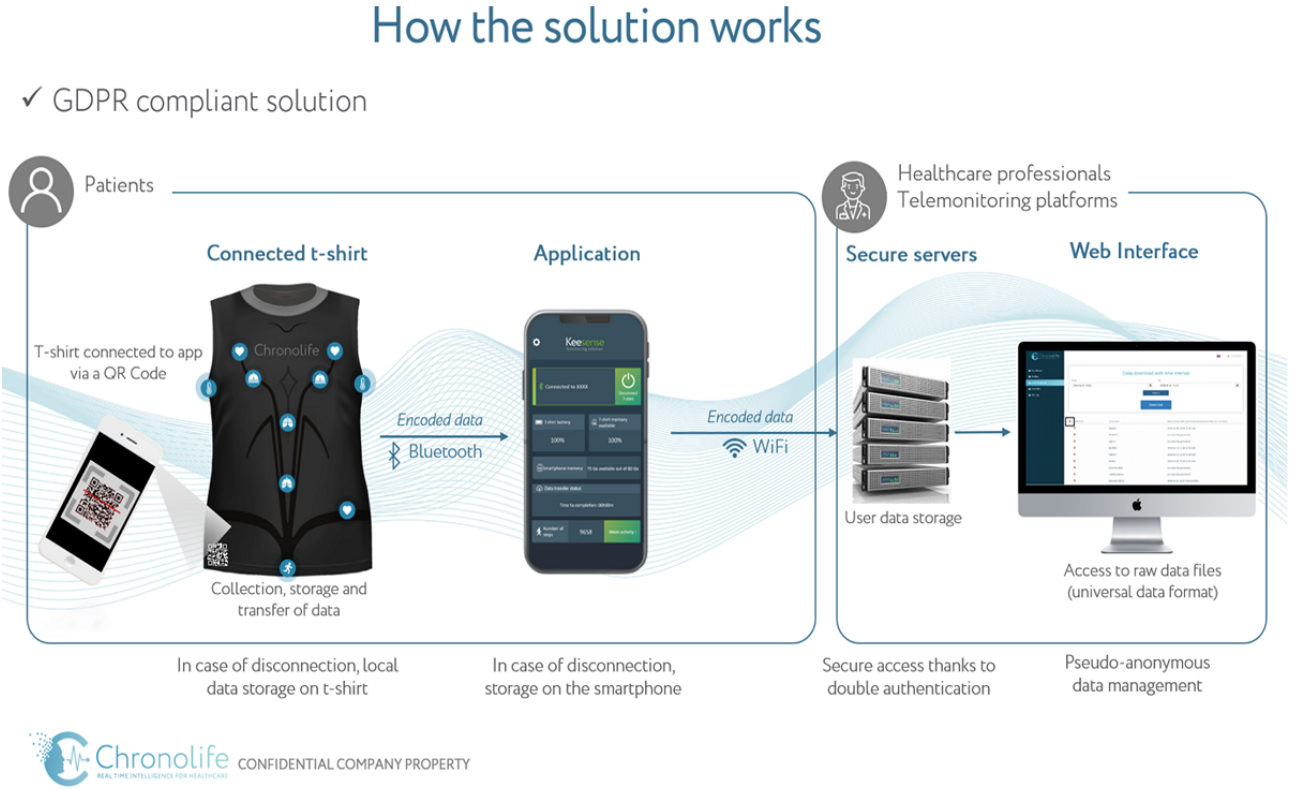
Further details on the OncoSmartShirt study can be reviewed in the previously published protocol article [36]. This paper reports results from 10 patients with cancer aged under 39 years (defined as *AYAs*). The decision to have a sample size of 10 AYA patients was influenced by the feasibility study design, which does not require a formal power calculation but aligns with the sample sizes used for similar studies in the literature [36]. In the previously published protocol, the plan was to also include 10 patients with cancer older than 65 years (defined as *elderly*). However, due to the results from the AYA cohort, the

research group omitted the inclusion of the second cohort of older patients.

Device

The device in this study consisted of the following four units: a washable smart T-shirt from Chronolife; a companion smartphone app; a secure, accredited data hosting server; and a web interface (Figure 1) [37]. The Chronolife smart T-shirt was designed for everyday use. It had electrical sensors embedded, allowing for the detection of the following six physiological parameters: electrocardiogram (ECG) measurements (beats/min), thoracic respiration (respirations/min), abdominal respiration (respirations/min), thoracic impedance (kΩ), physical activity (steps), and skin temperature (°C) [37]. A rechargeable battery powered the sensors. Additionally, a memory card that stores data and a Bluetooth interface that transmits data were fully integrated into the smart T-shirt and sealed in water-resistant coatings. The smart T-shirt was commercialized and Conformité Européenne–marked for the consumer market.

Figure 1. Framework for the OncoSmartShirt study (previously published figure from our protocol article [36]). GDPR: General Data Protection Regulation.



The smart T-shirt connected to the smartphone app via a QR code located on the smart T-shirt. Bluetooth Low Energy transmitted collected health data to the connected smartphone app designed for storage. The app transmitted data to a data hosting server that stored and provided data for a web interface, which was used for analysis and algorithm training [37].

The devices—the smart T-shirt and connected smartphone—were supplied by the hospital and returned after study termination. For data safety reasons, the patients could not use their own smartphones. Each smart T-shirt was produced based on individual patients' size measurements. No biometric data on health parameters collected by the smart T-shirt were sent to health care professionals during this study. The patients could contact a study assistant if they experienced technical difficulties, but this was not a requirement.

Patient Feedback

Immediately after the intervention period, qualitative individual telephone interviews were performed with the participants, allowing them to elaborate on their experiences with using the smart T-shirt. A semistructured interview guide was used. The interview guide was developed by SH based on research in the field [38,39] and consisted of questions about the pros and cons of using the smart T-shirt, material and appearance, identity and social stigma, behavioral changes, and ethics [36]. The interviews were performed by SH, who did not have prior knowledge about the participants and vice visa.

Patients were also asked to complete a quantitative paper questionnaire (handed out by a study assistant) concerning their experiences with wearing the smart T-shirt. The questionnaire consisted of 21 items, of which 14 were statements; patients could use a 5-point scale to indicate whether they agreed or disagreed with the statements. The remaining items consisted of free-text questions and items for gathering data on patients' estimates of wear time. The patients were asked to complete the questionnaire once. The questionnaire was prepared by Chronolife.

Variables

The primary end point was to assess the feasibility of using the Chronolife smart T-shirt based on adherence, which was defined as the number of included patients who used the smart T-shirt

(wear time) at least 8 hours per day during the 2-week period. The wear times were obtained from the processed data provided by Chronolife. Wear time was not self-reported. Secondary end points were patient feedback, which was obtained as described in the *Patient Feedback* section, and technical feasibility in a Danish health care system, including data quality. Explorative end points were changes in the health parameters monitored.

Data Analysis

Chronolife conducted the analysis of the collected health data. Qualitative data from the telephone interviews were transcribed and analyzed thematically, according to Braun and Clarke's [40] approach. Text coding involved reading and rereading the transcriptions to identify and categorize concepts across data. Concepts relevant to the research question were highlighted using colored marks in the transcriptions and then sorted into themes. One researcher did the coding (SH), which was discussed thoroughly with a senior researcher (HP) until a consensus was reached.

Results

Baseline Demographics and Characteristics

The recruitment of patients for the project was organized by using a Facebook post (Meta Platforms Inc; May 2021) about the project, which was posted in a closed group for young patients with cancer. The patients thus contacted the research groups if they wanted to participate in the project. A total of 10 patients (female: n=5; male: n=5) aged 22 to 30 (median 27, IQR 24.5-29.5) years were included during the inclusion period (March to June 2022). The types of cancer were leukemia (n=3), lymphoma (n=2), breast cancer (n=2), central nervous system cancer (n=1), testis cancer (n=1), and malignant melanoma (n=1).

Feasibility and Data Quality

As shown in Table 1, the number of days with wear times of >8 hours during the study period varied from 0 to 6 (mean 2 d). Only 3 patients had a mean wear time of >8 hours during each of their days with data registration. The number of days with any data registration varied from 0 to 10 (mean 6.4 d). No one managed to wear the smart T-shirt 8 hours per day for 14 days straight. Further, 4 patients had no data registrations at all. For 3 of these patients, the connection between the smart T-shirt and the smartphone app was unsuccessful because of technical issues or malfunctions, and for the last patient, the connection was successful, but the patient did not use the smart T-shirt due to disease-related issues.

Table . Wear time data for the smart T-shirt.

	Number of sessions[a]	Number of days with data registration	Number of days with a wear time of >8 h	Maximum wear time per session (h)	Wear time per day (h), mean[b]	Total wear time (h)	Data quality (%), mean[b]
Patient 1	20	10	6	19.1	10.4	110.4	63
Patient 2	—[c]	—	—	—	—	—	—
Patient 3	—	—	—	—	—	—	—
Patient 4	0	0	0	0	0	0	—
Patient 5	—	—	—	—	—	—	—
Patient 6	2	2	0	0.08	0.065	0.13	92
Patient 7	15	9	4	14.4	8	76	90
Patient 8	12	10	2	20	4.2	34	87
Patient 9	16	9	3	14.4	10.4	93.8	65
Patient 10	5	5	1	8.6	4.1	20.4	63

[a]The number of sessions is the total number of times the smart T-shirt was worn.

[b]SDs were not available from Chronolife.

[c]Not available.

The heart rate was calculated based on an ECG segment that was considered reliable by the manufacturer's data cleaning algorithm. The data quality was defined as the following ratio: the length of the session with heart rate values available divided by the total length of the session. The mean data quality for patients from whom data were collected varied from 63% to 92% (mean 77%). In this study, the data quality value was based on the quality of the heart rate values. The data quality can vary with multiple factors. The most important factor was the fit of the smart T-shirt; if the smart T-shirt was too large, the electrodes for the ECG would not have optimal contact with the skin, which would cause noise and artifacts in the collected data.

As variable compliance and data quality were noted, the analysis of the collected health data has been omitted due to the risk of the misinterpretation of the results.

Feedback From Patients

Interviews

Overview of Thematic Analysis

The thematic analysis was based on telephone interviews. The interviews lasted between 8 and 21 (mean 12) minutes. The thematic analysis pointed to the following three main themes: (1) the smart T-shirt is cool but does not fit patients with cancer, (2) the technology limits the use of the smart T-shirt, and (3) the monitoring of data increases the feeling of safety.

Theme 1: The Smart T-Shirt Is Cool but Does Not Fit Patients With Cancer

The smart T-shirt was described as "soft," and some participants did not even notice wearing it. All participants agreed that the smart T-shirt had a nice design, which they did not associate with anything patient-like. The term "cool" reflects the look of the smart T-shirt rather than the sensation experienced while wearing it. There were different opinions about how the body's temperature was affected by the smart T-shirt. A few participants got extremely hot and could not bear to wear it for a long time, and this worsened when these participants were physically active. However, others thought it felt cool in terms of body temperature. The smart T-shirt was closed with a zipper at the side. Most participants had a hard time zipping it by themselves. Some described the smart T-shirt as a bit too long, and several were bothered by the transverse bands on the smart T-shirt that contained the measuring equipment, which was not elastic like the rest of the smart T-shirt. For the sake of measurements, the smart T-shirt was designed to fit very tightly, which was a problem for several participants who had undergone surgery or were experiencing medical side effects. Moreover, the women could not wear a bra under the smart T-shirt. The consequence of all of these challenges was that it was too difficult for the participants to wear the smart T-shirt as prescribed.

Theme 2: The Technology Limits the Use of the Smart T-Shirt

The participants generally had challenges with getting the technology in the smart T-shirt and smartphone to work. Several participants described problems with charging the smart T-shirt. The smartphone's connection to Wi-Fi was associated with some problems. Additionally, 1 participant noted that the app stopped working one night when his smartphone made automatic updates. In general, the participants requested the smart T-shirt to connect to their own smartphones, so that they did not have to carry 2 smartphones simultaneously. The technical challenges were experienced as barriers to wearing the smart T-shirt. One of the participants explained that as a patient with cancer, they had very little energy to overcome everyday things (eg, technology that does not work).

Theme 3: The Monitoring of Data Increases the Feeling of Safety

All participants described the smart T-shirt as a useful and important invention that met their need for safety when being released from the hospital and not being monitored by health professionals anymore. Most participants believed that the smart T-shirt could be used optimally if the health professionals could track their health parameters from the hospital and then contact them if something looked abnormal (eg, in cases of changes in heart rate or breathing). One of the participants expressed that the monitoring was like "bringing the hospital home" because it provided him with the same feeling of safety as when they were hospitalized. Another explained that he felt less ill when he was at home and that the smart T-shirt could play a key role in getting home under safe conditions. However, there was also a participant who explained that constant monitoring from the hospital would require the patients to be introduced to their tracking data, so that they would know what was normal and what was not. Some participants explained that being released from the hospital could be very concerning, especially because of their increased focus on their body and whether it behaved differently. In general, the participants strongly desired to follow bodily signs during cancer treatment. One participant believed that it would have been more motivating to use the smart T-shirt if he could follow and view the collected data on the smartphone.

Quantitative Questionnaire

Of the 10 patients, 8 responded to the quantitative questionnaire, providing 165 out of 210 (item response rate: 78.6%) possible answers. The patients' answers to the 14 statements in the questionnaire are illustrated in Table 2. The answers were very different among the patients, but in general, the patients had confidence in the product and believed that their physician could use the collected health data. In addition, several patients were concerned about whether the smart T-shirt worked correctly and whether it would limit their daily activities.

Table . The patients' responses to the questionnaire concerning their experiences with the smart T-shirt (Keesense). The questionnaire was prepared by the smart T-shirt manufacturer (Chronolife).

Questionnaire statements	Patients' responses, n					Total responses, N
	1 (strongly disagree)	2 (disagree)	3 (neutral)	4 (agree)	5 (strongly agree)	
"Before starting the project, I had no fears regarding the medical device - the smart t-shirt and the phone"	0	0	0	1	7	8
"I think using this device will help my doctors monitor my condition more closely"	0	0	0	4	4	8
"I am afraid that using the Keesense medical device may affect my daily activities"	1	4	1	1	1	8
"I think using the Keesense medical device can help me be more active"	0	4	3	0	1	8
"I am concerned about a possible malfunction of the Keesense medical device"	3	2	1	2	0	8
"After being shown and taught how to use the Keesense medical device, I was confident that I could then use it"	0	0	1	4	3	8
"I think the smart t-shirt was easy to use"	0	1	2	4	1	8
"I felt comfortable with the use of the Keesense medical device"	0	3	1	3	1	8

Discussion

Principal Findings

The OncoSmartShirt study was a feasibility study that tested a smart T-shirt for the home monitoring of AYA patients with cancer from a public health care hospital in Denmark. To investigate adherence, we had predefined a preferred wear time of 8 hours daily for 2 weeks [36]. Unfortunately, none of the included patients achieved this. This finding is similar to the results from a comparable study conducted by Höllander-Mieritz et al [41] that investigated adherence to a smartwatch during radiotherapy among patients with head and neck cancer. Specific literature reviews show that it is possible to achieve high adherence to wearable technology in an oncology setting [30,42]. In general however, there is a tendency for compliance to decrease as the length of the study period increases. In addition, the exact desired wear time per day is not specified in several studies. This can contribute to the fact that it can be difficult to compare adherence across different studies.

We included qualitative and quantitative data in this study, and even though the wear time target was not met, this feasibility study resulted in knowledge about patients' experiences with the smart T-shirt and why the patients did not use the smart T-shirt in the predetermined time. In the qualitative interviews, we identified a discrepancy between the need for the smart T-shirt and the design of the smart T-shirt. The T-shirt met the patient's needs in terms of monitoring their health, but at the same time, it was not designed for patients with cancer experiencing treatment-induced side effects, such as gastrointestinal problems, increased body heat, and scars.

Another explanation for the lack of compliance is the technical challenges that some of the participants encountered. Prior to the completion of this study, we assumed that the group of AYAs would have greater technical ability and thus experience fewer technical problems when compared to older patients with cancer [43]. Based on the questionnaire, it appeared that most participants were confident with the technology and could use the smart T-shirt and the smartphone. However, in reality, 3 participants never connected their smart T-shirts to the smartphone app correctly, and several others experienced technical issues. In addition, it emerged from the interviews that patients with cancer do not have the energy to deal with technical problems associated with, for example, a smart T-shirt.

Responses to the questionnaire varied widely among participants and spanned the entire scale. Nevertheless, it is important to emphasize that the smart T-shirt manufacturer (Chronolife) prepared the questionnaire, which probably increased the risk of a ceiling effect among the answers [44].

To our knowledge, no studies have investigated the use of a smart T-shirt in an oncology setting, but there have been a few studies in the field of cardiology that primarily investigated if the monitoring of ECGs via a smart T-shirt can replace Holter monitoring [17,18,45]. In general, compliance is better in cardiology studies, but unlike the participants in the OncoSmartShirt study, the participants in those aforementioned cardiology studies were healthy and were not undergoing treatment. Thus, healthy participants in cardiology studies probably do not have the same challenges and annoyances as those among AYA patients with cancer [17,18]. Further, because of the low adherence and the patient experiences identified in patient interviews and the quantitative questionnaire, the research group excluded the preplanned group of older patients from this study. We believed that compared to the AYA patients included in this study, older participants would have experienced the same amount of issues (if not more) with the smart T-shirt and the setup with an extra phone. Therefore, we did not find it ethical to proceed with their inclusion in this study. However, we believe that age would not be an issue with a less demanding technical setup.

This study highlights the importance of investigating practical and technical feasibility. Practical feasibility refers to the specific wearable chosen, including the design, comfort, number of connected devices, and need for charging and maintenance. The smart T-shirt was not comfortable for our patient population. The patients had to have an extra phone to secure the setup and ensure safe data transfer. Both the smart T-shirt and the phone required charging, and the smart T-shirt also needed to be washed, which added to the patients' tasks. Technical feasibility refers to the setup for securing the data transfer, data quality, and reliable data. In this study, the data were safely transferred, but the data quality fluctuated.

For future studies investigating wearables, we suggest that the device be simple, comfortable, and minimally disturbing for the patient. The technical setup must also be simple; a possibility could be using the bring-your-own-device study design if the data can be securely transferred and if the data quality is sufficient. However, caution is advised for conducting bring-your-own-device studies in research due to the potential

imbalance [46]. We also recommend having a technical backup team that patients can contact and providing resources for electronic health education to patients and health care professionals. Finally, studies must assist in determining the potential uses of the data collected.

Although wearables might have the potential to be used in selected patient groups who need monitoring for a period of time, it is essential that the wearables can be worn and accepted by the patients and that the technical setup is as convenient as possible.

Conclusion

The OncoSmartShirt study was a feasibility study that investigated the use of a Chronolife smart T-shirt for the home monitoring of vital parameters among AYA patients with cancer during treatment. This study showed that AYA patients with cancer could not wear a smart T-shirt 8 hours per day for 2 weeks. However, this study revealed new and important perspectives and knowledge, which, among other things, pointed to why it can be challenging to achieve high compliance in this type of study. Furthermore, this study, as well as the patients, emphasized that wearables have potential. However, this area requires more research to develop the proper setup with minimal effort on the part of patients. Hopefully, in the long term, wearables can help improve the QoL for patients with cancer.

Abstract

User engagement with remote blood pressure monitoring during pregnancy is critical to optimize the associated benefits of blood pressure control and early detection of hypertensive disorders of pregnancy. In our study population of pregnant individuals, we found that *connected* blood pressure cuffs, which automatically sync measures to a monitoring platform or health record, increase engagement (2.13 [95% CI 1.36 - 3.35] times more measures per day) with remote blood pressure monitoring compared to *unconnected* cuffs that require manual entry of measures.

(JMIR Mhealth Uhealth 2024;12:e55617) doi:10.2196/55617

Introduction

Hypertensive disorders of pregnancy affect 5% - 10% of pregnancies and increase the risk of adverse pregnancy and postpartum outcomes [1,2]. Typically, management of these disorders involves blood pressure (BP) monitoring and initiation of antihypertensive therapy. Remote BP monitoring (RBPM) enables at-home BP monitoring to inform clinical decision-making in a timely manner [2-4]. Previous studies have shown that RBPM facilitates earlier detection of elevated BP and reduces prenatal hospitalizations and clinic visits [2,3]. Despite studies establishing feasibility and patient acceptability of RBPM [4-9], best practices for integrating RBPM within prenatal care have not yet been established. One open question is whether connected BP cuffs, which automatically sync measures to a health record, improve data quality and frequency over standard BP cuffs, which require users to manually enter measures [3-8]. The goal of this study was to compare user engagement with RBPM between *connected* and *unconnected* BP devices among users of a pregnancy care platform.

Methods

Study Population

The study population consisted of pregnant individuals enrolled in Delfina Care [10], a comprehensive pregnancy care platform, at a community practice in Texas, USA, between January and July 2023. Initially, these users were provided with unconnected BP devices at their provider's discretion, with a recommendation to record 2 BP measures a day per internal expert clinical consensus. Connected devices were introduced in April 2023 as part of a quality improvement initiative. Differences in user experiences between the connected and unconnected device groups are further described in Multimedia Appendix 1.

The outcome of interest was user engagement, defined as the number of daily BP measures taken, and as a binary indicator of completing the daily recommended BP measures (ie, 2 distinct BP measures per day). Analogous engagement outcomes at the weekly level were also reported. To avoid inflated differences due to repeated measures from connected device users, we considered multiple entries within 1 hour as a single measurement (Multimedia Appendix 2). The exposure of interest was receiving a connected versus unconnected device. Clinical

and demographic characteristics were collated from user-reported questionnaire data and electronic health records.

Statistical Analysis

Poisson and logistic regressions were fit for the daily number of BP measures and ≥2 daily BP measures, respectively. Both models controlled for relevant confounders (ie, age, parity, weeks since enrollment, primary clinic, and preferred language) and included a random effect for users across enrollment days.

Ethical Considerations

The study team received an institutional review board exemption waiver of HIPAA (Health Insurance Portability and Accountability Act) authorization on August 22, 2022, from WIRB-Copernicus Group (WCG) Institutional Review Board (protocol number 202208 - 001).

Results

During the study period, 164 users with BP cuffs were enrolled in the Delfina Care platform. Restricting to those with covariate data, the analytic sample consisted of 163 users (97 unconnected device users and 66 connected device users). Users with connected devices had more mean BP measure entries per day (0.51 vs 0.32) and a higher proportion completed the recommended ≥2 daily BP measures (12% vs 7%) compared to users with unconnected devices (Table 1). At the weekly level, the mean entries per week (3.37 vs 2.07) and the proportion of users who completed the recommended ≥1 weekly BP measure (63% vs 47%) were higher for connected users than for unconnected device users (Table 1).

Adjusting for confounders, users with connected devices had 2.13 (95% CI 1.36 - 3.35) times more measures per day and 5.62 (95% CI 2.28 - 13.83) times the odds of meeting the recommendation of ≥2 daily BP measures than unconnected device users (Table 2).

Table . Study population characteristics.

Characteristics	Overall (n=163)	Unconnected device users (n=97)	Connected device users (n=66)	*P* value
Age in years, mean (SD)	28.73 (6.02)	28.71 (5.61)	28.76 (6.61)	.96
Language, n (%)				.32
English	139 (85.3)	80 (82.5)	59 (89.4)	
Spanish	24 (14.7)	17 (17.5)	7 (10.6)	
Parity, mean (SD)	1.37 (1.44)	1.36 (1.32)	1.38 (1.60)	.99
Primary clinic, n (%)				.07
A	35 (21.5)	20 (20.6)	15 (22.7)	
B	71 (43.6)	49 (50.5)	22 (33.3)	
C	57 (35.0)	28 (28.9)	29 (43.9)	
User engagement[a], mean (SD)				
Weekly entries	2.59 (3.02)	2.07 (2.78)	3.37 (3.20)	.007
Daily entries	0.40 (0.46)	0.32 (0.42)	0.51 (0.49)	.008
Proportion ≥1 weekly entries	0.53 (0.35)	0.47 (0.35)	0.63 (0.33)	.003
Proportion ≥2 daily entries	0.09 (0.17)	0.07 (0.15)	0.12 (0.19)	.048

[a]User engagement metrics were first averaged within a user and then averaged across users for each device type and overall.

Table . Effect estimates and 95% CIs by outcome model.

	Number of BP measures per day		Completed ≥2 BP measures per day	
Predictors	Incidence rate ratio	95% CI	Odds ratio	95% CI
Connected versus unconnected device	2.13	1.36 - 3.35	5.62	2.28 - 13.83
Age (years)	1.06	1.02 - 1.11	1.11	1.03 - 1.20
Weeks since enrollment	0.97	0.97 - 0.98	1.00	0.98 - 1.01
English vs Spanish language	1.25	0.66 - 2.35	0.72	0.22 - 2.38
Parity (number of live births)	0.88	0.74 - 1.05	0.79	0.57 - 1.10
Clinic B vs A	1.44	0.79 - 2.61	4.18	1.25 - 14.03
Clinic C vs A	1.54	0.83 - 2.86	4.06	1.16 - 14.20

Discussion

We observed user engagement with RBPM was significantly higher among those with connected devices than those with unconnected devices. Previous studies among pregnant individuals have shown that the recommended frequency of BP measures ranges from several times daily to once weekly [4,7,8,11]. In our cohort, the proportion of users meeting the twice-daily recommendation was low, but the majority of users completed the once-weekly entry at least, and connected device users still had higher utilization than unconnected device users (63% vs 47%; *P*=.003). Compared to in-clinic BP measures, all users had a higher average number of weekly readings than the in-clinic average (2.59 vs 0.50 BP readings/week). Our study corroborated the feasibility of at-home RBPM during pregnancy and highlights the potential advantages of device connectivity on user engagement.

Limitations

Our findings are limited by the lack of true randomization to device types, which we addressed by controlling for potential confounders. We also addressed potential time-related confounding via a sensitivity analysis with no change in findings (Multimedia Appendix 2).

Conclusion

This study highlights how connected BP devices can improve patient engagement to RBPM during the prenatal period. Other aspects of RBPM, such as recommended frequency and patient education, should be further investigated to ensure users are able to successfully engage with monitoring technologies.

Abstract

The increasing interest in the potential applications of generative artificial intelligence (AI) models like ChatGPT in health care has prompted numerous studies to explore its performance in various medical contexts. However, evaluating ChatGPT poses unique challenges due to the inherent randomness in its responses. Unlike traditional AI models, ChatGPT generates different responses for the same input, making it imperative to assess its stability through repetition. This commentary highlights the importance of including repetition in the evaluation of ChatGPT to ensure the reliability of conclusions drawn from its performance. Similar to biological experiments, which often require multiple repetitions for validity, we argue that assessing generative AI models like ChatGPT demands a similar approach. Failure to acknowledge the impact of repetition can lead to biased conclusions and undermine the credibility of research findings. We urge researchers to incorporate appropriate repetition in their studies from the outset and transparently report their methods to enhance the robustness and reproducibility of findings in this rapidly evolving field.

KEYWORDS

large language model; generative AI; ChatGPT; artificial intelligence; health care

Since OpenAI released ChatGPT-3.5, there has been a growing interest within the medical community regarding the prospective applications of this general pretrained model in health care [1-7]. Using ChatGPT as a search keyword in the PubMed database, the results show that 2075 papers discussing ChatGPT were published in 2023. As the leading journal in the field of digital medicine, JMIR Publications Inc published a total of 115 papers related to ChatGPT in the year 2023. It should be noted that this is a quick and simple search that may not comprehensively capture all relevant articles, but it provides a general reflection of the growing interest and research on ChatGPT in the medical field. For example, Gilson et al [8] explored the performance of ChatGPT on the United States Medical Licensing Examination (USMLE) step 1 and step 2 exams, discovering that ChatGPT's performance exceeded the passing score for third-year medical students in step 1. More studies are exploring

ChatGPT's performance on other medical exams, such as the Japanese and German Medical Licensing Examinations [9,10], the Otolaryngology-Head and Neck Surgery Certification Examinations [11], and the UK Standardized Admission Tests [12]. Beyond examinations, many articles have discussed the potential applications of ChatGPT in medicine from various perspectives. Shao et al [13] examined the suitability of using ChatGPT for perioperative patient education in thoracic surgery within English and Chinese contexts. Cheng et al [14] investigated whether ChatGPT could be used to generate summaries for medical research, and Hsu et al [15] evaluated whether ChatGPT could correctly answer basic medication consultation questions. However, we would like to point out that as a relatively new technology, there are some differences in evaluating the potential application of generative artificial intelligence (AI) like ChatGPT in health care that require additional attention from researchers.

The most significant difference affecting the evaluation of ChatGPT compared to traditional AI models known to people is the randomness inherent in the responses generated by ChatGPT. Common perception holds that for a given input, an AI model should produce the same output consistently each time. However, for natural language models like ChatGPT, this is not the case. ChatGPT generates a response by predicting the next most likely word, followed by each subsequent word. The process of generating responses involves a certain degree of randomness. If you access ChatGPT using the application programming interface, you can also control the degree of randomness in the generated responses with the temperature parameter. Even with the same input, the responses provided by ChatGPT will not be the same, and sometimes may even be completely contradictory. Therefore, when evaluating ChatGPT's performance, it is necessary to generate multiple responses to the same input and assess these responses collectively to explore ChatGPT's performance accurately; otherwise, there is a high likelihood of drawing biased conclusions. For example, as one of the earliest studies published, Sarraju et al [4] asked the same question three times and assessed whether the three responses given by ChatGPT to the same question were consistent. As OpenAI made the ChatGPT application programming interface accessible, it became feasible to ask the same question many more times. In a recent study investigating whether ChatGPT's peer-review conclusions are influenced by the reputation of the author's institution, von Wedel et al [16] conducted 250 repeated experiments for each question to mitigate the effects of ChatGPT's randomness. However, not all researchers have recognized this aspect. For instance, in a study where ChatGPT was asked to answer the American Heart Association Basic Life Support and Advanced Cardiovascular Life Support exams, they found that ChatGPT could not pass either examination [17]. However, that study only asked the question once without repeating, which means that the randomness of ChatGPT could have had an impact on the experiment, affecting the reliability of the conclusions. In another improved study, researchers acknowledged the impact of ChatGPT's randomness, asking each question three times. Compared to earlier results, ChatGPT's performance in this study significantly improved, and it could pass the Basic Life Support exam [18], further underscoring the importance of repetitions. Therefore, it is inappropriate to evaluate ChatGPT's performance based on a single response if one aims to draw rigorous, scientifically meaningful conclusions. Just as biological experiments typically require three repetitions for validity, without repetition, it becomes challenging to determine whether the observed phenomenon is an inherent characteristic of the model or merely a random occurrence. Additionally, for models intended for clinical practice applications, whether for patient education, diagnosis, or support in clinical documentation writing, we hope that ChatGPT can always provide correct and harmless responses. Repetition also allows us to evaluate the model's stability and further assess its application value. However, we noticed that many recent manuscripts we reviewed were not aware of this, thus affecting the reliability of the conclusions.

Therefore, in research on the application of generative AI like ChatGPT in health care, appropriate repetition should be included to comprehensively evaluate the model's performance by assessing the stability of the model in the task set by the author. This should be considered from the beginning of the research. Since models like ChatGPT will continue to be upgraded, if the authors only realize the need for repetition when revising the manuscript, there will be a considerable time gap between the authors' supplementary analysis and the original analysis. The model has likely been upgraded during this period, introducing new uncertainties into the research. Alternatively, the authors need to completely redo the analysis from scratch during the manuscript revision process, wasting time and effort. Therefore, we hope that future researchers will recognize the necessity of repeated experiments from the start and report in the manuscript how the repetition was carried out in the study [19].
