Abstract

Background: Physical activity (PA) plays a crucial role in health care, providing benefits in the prevention and management of many noncommunicable diseases. Wearable activity trackers (WATs) provide an opportunity to monitor and promote PA in various health care settings.

Objective: This study aimed to develop a consensus-based framework for the optimal use of WATs in health care.

Methods: A 4-round Delphi survey was conducted, involving a panel (n=58) of health care professionals, health service managers, and researchers. Round 1 used open-response questions to identify overarching themes. Rounds 2 and 3 used 9-point Likert scales to refine participants' opinions and establish consensus on key factors related to WAT use in health care, including metrics, device characteristics, clinical populations and settings, and software considerations. Round 3 also explored barriers and mitigating strategies to WAT use in clinical settings. Insights from Rounds 1-3 informed a draft checklist designed to guide a systematic approach to WAT adoption in health care. In Round 4, participants evaluated the draft checklist's clarity, utility, and appropriateness.

Results: Participation rates for rounds 1 to 4 were 76% (n=44), 74% (n=43), 74% (n=43), and 66% (n=38), respectively. The study found a strong interest in using WATs across diverse clinical populations and settings. Key metrics (step count, minutes of PA, and sedentary time), device characteristics (eg, easy to charge, comfortable, waterproof, simple data access, and easy to navigate and interpret data), and software characteristics (eg, remote and wireless data access, access to multiple patients' data) were identified. Various barriers to WAT adoption were highlighted, including device-related, patient-related, clinician-related, and system-level issues. The findings culminated in a 12-item draft checklist for using WATs in health care, with all 12 items endorsed for their utility, clarity, and appropriateness in Round 4.

Conclusions: This study underscores the potential of WATs in enhancing patient care across a broad spectrum of health care settings. While the benefits of WATs are evident, successful integration requires addressing several challenges, from technological developments to patient education and clinician training. Collaboration between WAT manufacturers, researchers, and health care professionals will be pivotal for implementing WATs in the health care sector.

Introduction

Background

Physical activity (PA) is critical in preventing and managing many noncommunicable diseases [1]. For chronic disease populations, PA can mitigate disease progression, improve physical function, and reduce the risk and burden of comorbid health conditions [2]. In the hospital setting, extremely low levels of patient PA are linked to poor outcomes, including functional decline, increased frailty and disability, and increased mortality risk [3-5]. Inactivity is also associated with higher rates of hospitalization [6-8], longer length of hospital stay [9,10], and increased risk of readmission [11,12]. Global guidelines recommend adults perform at least 150 minutes of moderate or 75 minutes of vigorous-intensity PA weekly, muscle strengthening exercise at least 2 days per week, and reduce sedentary behavior (SB) [2]. Yet just 1 in 5 adults globally meet these guidelines [13], resulting in a substantial global burden of physical inactivity, contributing to millions of premature deaths each year [1], and costing an estimated US $53.6 billion annually in health care costs and loss of productivity [14].

The need to address PA in the health care sector is clear. Indeed, organizations such as the World Health Organization [15] and the International Society for Physical Activity [16] have identified health care as a crucial setting for investment and implementation of strategies to promote PA. Health care professionals (HCPs) are strategically positioned to influence a wide range of people either living with or at risk of developing many diseases that could be alleviated or prevented through increased PA. Accordingly, PA has been endorsed as a "vital sign" that should be routinely assessed by HCPs to identify inactive individuals, prompt interventions targeted at increasing PA, and form a baseline for such interventions [17-19].

Wearable activity trackers (WATs) offer substantial potential for measuring and influencing patient PA. They have gained widespread acceptance among researchers, HCPs, and the general population. Consumer-oriented WATs, such as Fitbits, use accelerometers to measure PA, and have seen an uptick in popularity [20]. These consumer-oriented WATs may also incorporate additional sensors, like heart rate and blood oxygen saturation monitors, allowing users to track multiple health parameters via the device interface and associated smartphone applications. Compared with other methods of PA assessment, such as self-report questionnaires, WATs demonstrate superior validity, reliability, and reduced biases [21,22]. Furthermore, there is a substantial body of evidence demonstrating the effectiveness of WAT-based interventions for augmenting PA across diverse populations, with subsequent benefits like improved physical function, body composition, and blood pressure [23-25].

Despite considerable evidence demonstrating the opportunities and value of using WATs in health care settings, their routine use in health care has not yet been achieved. Nonetheless, HCPs and researchers are endeavoring to adopt WATs and are exhibiting optimism about their potential for PA measurement, informing exercise prescription and PA promotion, and fostering patient motivation and self-monitoring [26,27]. While smaller-scale efforts that have been made so far are encouraging and demonstrate interest from a spectrum of stakeholders, barriers to broader and routine use of WATs in health care persist. These barriers range from practical obstacles related to the WAT itself, such as battery life and wear issues, to clinician workload, software and data access limitations, lack of interdisciplinary support, and costs and resource concerns [26,28,29]. This highlights the need for standardized and coordinated approaches to WAT deployment in health care. A more systematic approach could facilitate the comparison and amalgamation of data across similar populations from disparate settings, circumvent recurring issues, and enhance the desired outcomes of using WATs in health care.

Objectives

This study aimed to establish a standardized and consensus-based framework for the quality use of WATs in health care settings. To do this, we sought to identify the most important metrics and device characteristics for health care–focused WAT use, identify suitable clinical populations and settings for WAT deployment, and explore stakeholders' perceptions of the most significant barriers to WAT adoption in health care, alongside potential solutions.

Methods

Study Design

A 4-round web-based Delphi study was conducted to meet the study aims between March 2021 and June 2022. This research adhered to the Conducting and Reporting of Delphi Studies (CREDES; Multimedia Appendix 1 [30]).

Ethical Considerations

This research was conducted in accordance with the Helsinki declaration of 1975, as revised in 2000. The University of South Australia's Human Research Ethics Committee granted ethical approval (approval number: 203069). Given the web-based survey design, opening the survey weblink and completing the survey were considered implied informed consent. Participants could elect to withdraw from this study if requested.

Participants and Recruitment

We recruited participants representing three stakeholder groups with experience or expertise on the topic: (1) HCPs, (2) researchers, (3) health service managers (eg, department officials or heads of services), or any combination thereof. Potential participants were identified through multiple channels: HCPs from a preceding study [26], professional associations and networks, participant referrals (ie, invitees were encouraged to share with relevant contacts), by searching for health service managers and officials from health networks (eg, government health departments), and international researchers with relevant expertise. Potential participants were emailed study information and invited to participate. A follow-up email was sent after 1 week to nonrespondents. We aimed to recruit 50 participants based on recommendations for Delphi studies with multiple stakeholder groups [31]. We anticipated similar representation from HCPs and researchers, with fewer health service managers (approximately 15% of the total sample) due to the limited

number of these positions. All participants who agreed were invited to complete all survey rounds, regardless of earlier rounds' completion.

Delphi Surveys

Four survey rounds were distributed via email (SurveyMonkey). Surveys were piloted by 5 people who were not participants (2 HCPs, 1 researcher, and 2 both HCP and researcher) to ensure clarity, timeliness, and appropriate topic exploration, with amendments made if required. Surveys took 15-25 minutes to complete, and participants had 3 weeks to complete each survey. Reminders were sent after 7 and 14 days. Results from each round were provided to participants within subsequent rounds, with summaries incorporated within the surveys for context.

Round 1

The Round 1 survey (Multimedia Appendix 2) aimed to generate items and identify broad themes on the topic. Round 1 collected data on participants' professional experience with WATs, and used 12 open-ended questions to explore perspectives on the following: clinical value of WATs, suitable clinical populations and settings, important metrics, important device characteristics, and barriers and enablers to use in health care settings. At the outset of the survey, we defined "wearable activity trackers" as "a wearable device for tracking activity-related metrics such as steps, sleep, energy expenditure (eg, calories), and in some cases, activity minutes." Open-response questions were analyzed thematically, categorized, and converted to items for the subsequent round.

Round 2

The Round 2 survey (Multimedia Appendix 3) used findings from Round 1 to refine opinions and establish consensus on 64 items across 4 sections and introduced a fifth section on software, based on its emergence as a significant topic in Round 1. The first 4 sections considered key metrics, essential WAT characteristics, and usefulness for various populations and settings. Participants rated their agreement with items on a 9-point Likert scale (eg, "it is critically important for the wearable to measure 'x'": 1=strongly disagree to 9=strongly agree), and were encouraged to provide comments on open-response questions in each section. One multiple-choice question determined participants' preferred wear site for WATs. The fifth section on software comprised multiple-choice, item rating, and open-response questions which were tailored for participants with direct WAT experience in health care.

Round 3

The Round 3 survey (Multimedia Appendix 4) comprised 3 sections and was designed using insights from earlier rounds. It sought to refine opinions and reach consensus on new items, rerate items that did not meet consensus in Round 2, and further explore barriers and potential strategies identified in Round 1. The first section required participants to rate 28 items on the same topics explored in Round 1 (6 rerating, 22 new). The second section explored software, requiring participants to rate 11 new items, and included an optional open-response question for additional comments. The third section explored barriers, and required participants to select 1 multiple-choice response for what they considered to be the most important barrier to using WATs in health care across 3 categories (patient, clinician and interdisciplinary team, and health care–system), and included open-response questions to provide suggestions for strategies to address the barriers. Barriers were explored in Round 3, given the length and item volume of the Round 2 survey.

Round 4

Between Rounds 3 and 4, three authors (KS, CM, and JA) drafted a 12-item checklist containing key elements for clinicians and service planners to consider when developing procedures for using WATs in health care settings (Multimedia Appendix 5 [26-28,32-47]). Results from Rounds 1-3 and the Consolidated Framework for Implementation Research (CFIR) [48] informed the constituents of the draft checklist. The CFIR provides a structure for approaching and evaluating intervention implementation and recognizes that to be effective, new innovations need to be adapted to "fit" the needs of a setting while retaining their "core" components. The draft checklist included "core" elements to consider when developing procedures for using WATs in different settings while allowing the user to adapt details based on their specific circumstances. Each item included prompts and explanations. During Round 4, participants evaluated the checklist items' clarity and usefulness and provided overall feedback.

Data Analysis

Response rates, participant characteristics, and responses on Likert scales and multiple-choice questions were analyzed using descriptive statistics (frequency of responses and percentages). Results were presented for each stakeholder type ("health system" and "research") and for the entire sample. Qualitative data from open-response questions were analyzed thematically and organized into emergent categories and themes, or converted to items for rating in subsequent rounds.

Consensus Agreement

Consensus was determined based on responses on 9-point Likert scales. Participants rated their agreement with statements regarding either the importance, appropriateness, or usefulness of items. Ratings were categorized as "not important/appropriate/useful" (1-3), "neutral" (4-6), and "critically important/appropriate/useful" (7-9) based on the 9-point GRADE methodology [49]. Items were scored as either:

- "Critically important/appropriate/useful": ≥75% of participants rating ≥7, and ≤15% of participants rating ≤3.
- "Somewhat important/appropriate/useful": 50%-74% rated an item ≥7
- "Not important" when <50% rated an item ≥7.

Item scores were grouped based on responses from different stakeholder groups: "healthcare" (HCPs and health-service officials) and "research" (researchers). Scores were summarized by group and for the entire sample. To establish consensus, we considered item scores from the 2 groups, and scores from the entire sample. Scores from each group were considered, as we were interested in different perspectives that the types of stakeholders may have, and if this influenced the overall rating of items.

Items reached consensus based on the following criteria:

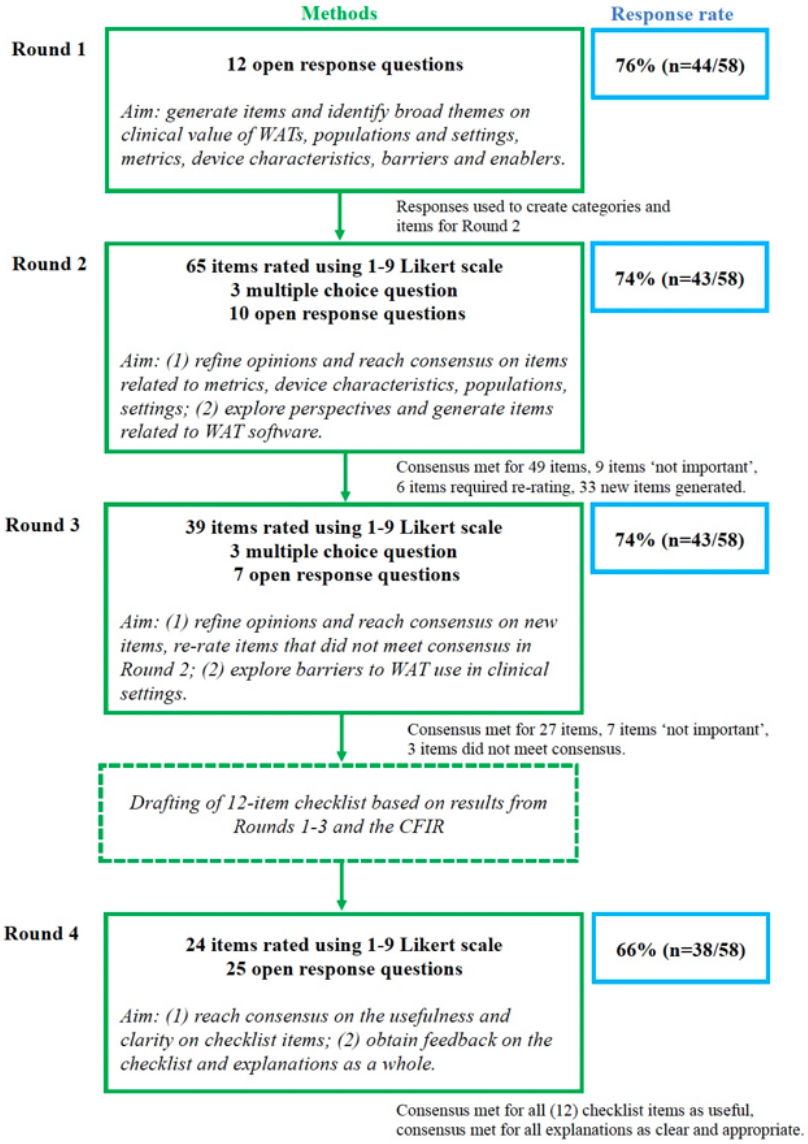
- "Critically important/appropriate/useful": when this was the score for both groups or for one group only and the overall score was "critically important/appropriate/useful."
- "Somewhat important/appropriate/useful" when this was the score for both groups or for one group and the overall rating was "somewhat important/appropriate/useful."
- "Consensus not met": the score from one group was either "critically important" or "somewhat important," and the score from the other group was "not important."
- "Not important" (omitted from exploration in subsequent rounds): when the rating from both groups was "not important."

Results

Participants

Of 82 potential participants who were directly invited to the study, 38 (46%) individuals expressed interest in participating. An additional 20 individuals contacted the research team after learning about the study via word of mouth, yielding a total sample of 58. Response rates for rounds 1 to 4 were 76% (n=44), 74% (n=43), 74% (n=43), and 66% (n=38) respectively, with 52 (90%) participants responding to at least 1 round, and 28 (48%) participants completing all 4 rounds. An overall summary of the structure of the Delphi rounds, item consensus, and response rates is shown in Figure 1.

Figure 1. Overview of Delphi process. WAT: wearable activity tracker; CFIR: Consolidated Framework for Implementation Research.



Round 1

Of the 44 participants who completed Round 1, 8 participants were health service managers, 24 participants were HCPs, and 17 participants were researchers (Table 1). All participants considered WATs to be useful in health care settings, predominantly for the purposes of monitoring patient activities (ie, PA, SB, and sleep), intervening in patient PA, and monitoring physiological parameters (ie, heart rate). Participants provided a wide variety of responses for suitable populations and settings (eg, people with metabolic conditions, rehabilitation, inpatient, and outpatient). Various PA and physiological metrics were suggested, with 26 discrete metrics identified. The most frequently reported metrics were daily step

count (n=27), daily PA minutes (n=20), and heart rate (n=19). A total of 28 device characteristics were reported as important for clinical settings, which were categorized under battery and charging (eg, long battery life), wear (eg, waterproof), device interface (eg, real-time feedback), data (eg, easy data access), and other (eg, affordable cost). Qualitative analysis suggested that the selection of metrics and characteristics would be influenced by the purpose of use, the population and setting, and patient factors such as goals and level of mobility. Numerous barriers and enablers to using WATs in health care settings were reported, which were grouped into 4 categories: device-related (eg, battery: short battery life), patient-related (eg, patient suitability: cognition and mobility), clinician-/multidisciplinary team-related (eg, time constraints and competing demands: setting up devices) and system-level (eg, lack of procedures and systems: distributing and managing devices). Enablers were generally the inverse of barriers (for instance, if short battery life was a barrier, long battery life was an enabler). A full summary of results from Round 1 is available in Multimedia Appendix 2.

Other	2 (5)

Round 2

Round 2 comprised five sections. The first 4 sections required item rating to indicate agreement with the importance of different metrics and characteristics of WATs for clinical use, and to indicate agreement with the appropriateness of using WATs with different clinical populations and settings.

The consensus was reached for 26/64 items as being “critically important” (metrics: 2/14, device characteristics: 8/19), or “highly appropriate” (populations: 6/10, settings and purposes: 10/21), and 23/64 items as being “somewhat important” (metrics: 2/14, device characteristics: 8/19), or “somewhat appropriate” (populations: 3/10, settings and purposes: 10/21; Tables 2 and 3). Nine items reached an outcome of “not important.” Six items did not reach consensus and were rerated in the following round. Interestingly, despite step count being the most frequently reported useful metric in Round 1, 74% of participants overall rated it as “critically important” in Round 2, leading to an overall score of “somewhat important” (<75% of participants rating ≥7). Given its frequent mention and relevance in research [23,50], the team decided this item warranted rerating in the next round. Most participants (72%) considered the wrist to be the most appropriate wear site, with 18 participants providing open-response comments on the wear site. Comments mostly related to wear site affecting the validity and reliability of data, as well as patient engagement and preferences, with themes identified that wear site should consider both the purpose of using WATs (ie, is patient engagement the priority), and the patient context (ie, walking speed; Multimedia Appendix 3).

Table 2. Device-related items that reached consensus in Rounds 2 and 3.

Item	Percentage agreement (≥7 on 9-point Likert scale)	
	Round 2 (n=43)	Round 3 (n=43)
Metrics		
Critically important (≥75% rated ≥7) ≥7		
Daily minutes of PA[a]	95	N/A[b]
Daily minutes of SB[c]	81	N/A
Daily step count	74	86
Somewhat important (50%-74% rated ≥7)		
Intensity of PA (heart rate zones)	56	N/A
Details of PA intensities (eg, light/moderate/vigorous)	__[d]	74
All daily activities (physical activity, sedentary time, sleep)	58	N/A
Sit to stand transitions	—	58
Position of SB (eg, sitting/standing/lying down)	—	56
Heart rate	44[e]	58[e]
On versus off body time (wear time)	—	60
Characteristics		
Critically important (≥75% rated ≥7)		
Easy to charge	95	N/A
Comfortable to wear day and night	93	N/A
Water resistant	81	N/A
Easy to clean and disinfect	81	N/A
Simple data syncing process	98	N/A
Simple data download or export process	91	N/A
Store at least 5 days of data without syncing or downloading	88	N/A
Easy to navigate and set up	93	N/A
Provide data that is easy to interpret	—	88
Wrist-worn is most appropriate for patient acceptability and compliance	MCQ[f]	77
Adaptable wear site for different populations and individuals (eg, those with walking frames)	—	84
Somewhat important (50%-74% rated ≥7)		
Battery that lasts at least 2 days on a single charge	74	N/A
Battery that lasts at least 5 days on a single charge	63	N/A
Quick to charge (eg, reach full charge in 1 hour)	70	N/A
Measure steps in slow ambulators	72	N/A
Ability to set personalized goals	63	N/A
Simple data interface (eg, interpret key data at a glance)	74	N/A
Real-time feedback is provided on the interface	67	N/A
Data can be accessed remotely by clinician	56	N/A
Aesthetically pleasing	51[e]	50
Ability to set specific reminders	—	56
Ability to select between different metrics for viewing	—	70
Ability to wear at different bodily locations	49[e]	63

Item	Percentage agreement (≥7 on 9-point Likert scale)	
	Round 2 (n=43)	Round 3 (n=43)

Section 5 focused on the software aspects of using WATs in health care settings. Participants with direct experience were specifically asked to rate their satisfaction with the existing WAT software they had used in health care settings. Of the 32 respondents to this item, most (59%) rated their software experience as neutral or dissatisfied. Twenty-nine participants described the software they had used and how they thought software could be improved to better meet the needs of health care settings. The majority reported using proprietary software linked to the device or reading outputs from the device interface, and some either invested in third-party software or developed their own. Those who described difficulties generally reported that software was difficult to use, time-consuming, and expensive (eg, logging in and out of separate accounts to view data on consumer WATs, or needing to purchase specialized software to download data). Participants provided numerous suggestions regarding the requirements of WAT software to meet the needs of health care settings, which were converted into items for consensus rating in Round 3. A full summary of results for Round 2 is available in Multimedia Appendix 3.

Round 3

Round 3 comprised 3 sections. The first section covered metrics, device characteristics, populations, and settings and purposes, and focused on rating new items and rerating items that did not meet consensus in Round 2. The second section focused on software, and involved rating items generated from Round 2 to identify "ideal" software features. The third section focused on barriers to WAT use in health care.

Consensus was reached for 11/39 items as being "critically important" (metrics: 1/13, device characteristics: 3/11, software: 7/11), and 16/39 items as being "somewhat important" (metrics: 3/13, device characteristics: 4/11, software: 4/11) or "somewhat appropriate" (patient populations: 3/3, settings and purposes: 1/1; Tables 2-4). Four items did not meet consensus (metrics: 2/13, device characteristics: 2/11). Seven items reached an outcome of "not important."

Table 4. Ideal software items that reached consensus in Round 3 (n=43).

Item	Percentage agreement (≥7 on 9-point Likert scale)
Critically important (≥75% rated ≥7)	
Present relevant data at varying levels of simplicity	93
Centralized access of patient data	84
Access to multiple patients' data simultaneously	79
Wireless data upload or export	93
Batch data downloads	84
Access to raw data sets	77
Ability to conduct separate or additional analyses to those provided by the device	79
Somewhat important (50%-74% rated ≥7)	
Capacity to input self-report data (eg, RPE[a], pain, and fatigue VAS[b])	53
Provide useful and relevant data on the wearable interface (eg, without further analysis needed)	70
Capacity to download and access data sets instantly	72
Automatically present data in different formats (eg, graphs, tables, summary scores without having to edit or analyze data sets)	65

[a]RPE: rate of perceived exertion.

[b]VAS: visual analog scale.

The barriers section of the survey asked participants to identify the most significant obstacles to WAT use in health care across 3 categories: patient-related, clinician– and interdisciplinary team–related, and health care system. Results were presented by group (health care and research participants) and overall. No single patient-related barrier dominated, but there were nuances between health care and research participants (Multimedia Appendix 4). Most health care participants (37%) considered "clinical unsuitability" to be the most important, and most research participants (37%) considered "patient reluctance" to be the most important. Participants from both groups considered "time constraints and competing demands" to be the most important clinician-related barrier (overall: 51%, health system: 53%, research: 50%), and "lack of funding and resources" to be the most important health care system–related barrier (overall: 58%, health system: 63%, research: 54%). Participants provided strategies to address these barriers, with the top 5 strategy categories, in order of frequency, being: clinician information and support (19 mentions); standardized approach (17 mentions), broader involvement of teams or families and caregivers (15 mentions), top-down support (14 mentions), and patient education and support and improved funding and resourcing (13 mentions each). A full summary of results for Round 3 is available in Multimedia Appendix 4.

Round 4

A draft 12-item user checklist was developed based on insights from Rounds 1-3 and guided by the CFIR. This checklist was designed to assist HCPs and health service managers in planning to implement WATs across various health care settings. During Round 4, participants were presented with the draft checklist with the goal of gauging consensus on the usefulness of individual items and assessing the clarity and appropriateness of explanations. There was clear support for individual items and explanations, with every item on the checklist reaching consensus as being "very useful," and all explanations reached consensus as being "very clear and appropriate" (Multimedia Appendix 5 [26-28,32-47]). Fourteen participants provided comments on the checklist as a whole, which was predominantly positive feedback. A few comments related to the presentation of the final product, shortcomings, and the clarity or amount of information. Twenty-three participants provided feedback on individual items and explanations, which was mostly general comments related to the content of items (eg, suggestions to provide more detail and citations regarding the accuracy and validity of devices in different contexts). Other common responses included suggestions for additional information, suggestions to condense information, specific suggestions on wording or formatting, and feedback on the clarity of wording. All comments for individual items and the expanded checklist including elaboration statements for each of the 12 items are provided in Multimedia Appendix 5 [26-28,32-47].

Discussion

Principal Results

This Delphi study brought together HCPs, health service managers, and researchers to gather expert opinions regarding the application of WATs in health care settings. Findings revealed that participants believed that WATs offer utility for monitoring and improving patient PA in a wide variety of clinical populations and health care settings. The study identified various metrics and device characteristics as critical, with the specific choice of metrics being contingent on the clinical context and patient factors. Software was acknowledged as a vital element, with most participants being unsatisfied with the currently available software. Key barriers to WAT adoption in health care were recognized in relation to patients, clinicians, and health care system categories, with time constraints and resource limitations being major obstacles. To overcome these, participants suggested strategies such as clinician support, standardized approaches, and improved funding. The study culminated in the development of a 12-item checklist to assist HCPs and service planners in successfully integrating WATs within various health care settings.

Potential for Widespread Adoption of WATs in Health Care

Our findings highlight widespread interest in using WATs in a very wide range of clinical populations, settings, and purposes. Various clinical groups were identified as suitable for WAT applications, across different health care contexts. This multifaceted application of WATs is corroborated by existing literature, with previous studies using WATs with post-surgical patients and acutely ill patients in hospitals for daily step count monitoring to predict hospital readmission and length of stay [10,11], as well as using WATs in various community-dwelling chronic disease populations [24,51,52] and various hospitalized populations [25] for promoting patient PA. Together, these findings highlight the versatility of using WATs in health care settings and their promising role in advancing patient care.

Toward More Systematic Integration of WATs in Health Care

This study identified a desire for more standardization in WAT use in health care, yet with such a range of different potential applications for WATs, a universal approach seems unfeasible. Nevertheless, there was consensus on essential components for diverse WAT applications. Out of 45 important elements identified, 21 were classified as "critically important," encompassing 3 metrics, 11 device characteristics, and 7 software characteristics. Furthermore, an additional 24 elements were classified as "somewhat important." Recognizing these pivotal components can steer HCPs and potential users to select devices and software that meets their clinical needs. These elements were incorporated into the user-oriented Wearable Activity Tracker Checklist for Health care (WATCH) developed from this study, which is presented in the companion article [53]. Given that the barriers this study identified were similar to those described in international studies [28,29], it seems likely that the core elements we identified will be relevant for applications in different locations.

Strengths and Limitations

This study is the first to use an expert consensus approach to advance the use of WATs in health care settings. It adhered to rigorous Delphi methodology, including defining consensus, having clear criteria for accepting, rerating, and omitting items,

defining the number of rounds to be performed a priori and piloting surveys before sending them to participants [54]. The average response rate of 73% was another strength of this study, given the large number of items and larger size of the panel, both of which have been associated with lower response rates for Delphi studies [55].

This study has several limitations that warrant consideration. First, a limitation of the Delphi methodology is that it uses a limited sample of participants to represent various stakeholder groups of interest. It is possible that the participants in this Delphi study may not represent the broader population of HCPs, health service managers, and researchers with expertise and experience in the application of WATs in health care. While participants in this Delphi study represented various professions and had diverse experiences with WATs in different populations and settings, the sample was predominantly Australian. This may limit the generalizability of our findings to other contexts, as digital technology and data landscapes vary significantly across countries. These variations can influence the accessibility, usability, and integration of wearable technologies and associated software in health care practices. For instance, differences in regulatory environments, data privacy laws, and technological infrastructure can impact the deployment and effectiveness of WATs. Therefore, HCPs from different jurisdictions may hold different attitudes and perspectives. A further limitation of the Delphi methodology is that, as a consensus-driven approach, it can potentially overlook important opinions or knowledge if they are not widely held by the sample [31]. In this study, some metrics were considered more important than others for clinical use. However, the combination of multiple metrics (and metrics considered “less important”) should not be overlooked in gaining other important insights from WAT data. For example, heart rate data can be used to determine if devices are being worn by patients. This Delphi study did not involve patients, who are also end users of WATs, thereby lacking their perspectives. Patients will be an important stakeholder group in future research as the integration of WATs in health care becomes more widespread. Finally, as WAT technology continues to advance rapidly, the considerations and factors explored in this study may require updating.

Implications

Our study identified various barriers to the use of WATs in health care that will need to be addressed to support widespread implementation. First, patient-related barriers included clinical unsuitability for certain conditions, and patient reluctance, often rooted in apprehension or lack of understanding. Addressing this will require comprehensive patient education and selecting WATs suitable for specific patient needs. Additionally, clinician-related barriers like time constraints necessitate streamlining of WAT integration processes. Incorporating training programs for HCPs is likely to enhance their competency in efficiently using WATs. At the system level, financial constraints and lack of resources appear to be significant obstacles. Strategically advocating for funding, possibly through demonstrating the long-term cost benefits of WATs in patient care, may be instrumental to addressing this. Lastly, interoperability and data integration into electronic health records will be pivotal in the future for clinicians to effectively access and interpret data. The study also reveals a substantial gap between the ideal and actual capabilities of currently available WAT devices and software in health care settings. Current options fall short in areas deemed critical by participants, particularly in software features, wearability, and data accuracy. This highlights an urgent call for the innovation of WAT technology and software tailored specifically for health care applications. Such innovations may include the integration of behavior change and gamification techniques (eg, goal-setting, feedback loops, rewards, and nudges) into devices to foster use and engagement, potentially leading to increased effectiveness of PA promotion efforts. A collaborative approach between WAT manufacturers, researchers, and HCPs will be imperative to develop solutions that not only address the practical necessities of health care settings but also rigorously uphold data privacy standards required for handling patient information.

Conclusions

This Delphi study offers valuable insights into the prospects and challenges of integrating WATs in health care settings for PA promotion. The collective perspectives of HCPs, health service managers, and researchers underscore the broad potential of WATs across diverse clinical scenarios. Yet, for WATs to be fully effective in patient care, several hurdles must be addressed, ranging from patient education to technological advancements specific to the health care sector. The evolving nature of WAT technology will necessitate continuous collaboration and re-evaluation. As the health care landscape seeks more personalized and data-driven approaches, the integration of WATs presents a promising avenue to enhance PA promotion and patient outcomes, optimize clinical processes, and elevate the overall quality of health care delivery.

Acknowledgments

This project received no specific funding. KS was supported by the Australian Government Research Training Program domestic stipend as a postgraduate student at the University of South Australia. CM is funded by a Medical Research Future Fund Investigator Grant (GNT1193862). The authors thank all of the participants who were involved in this study for sharing their time, expertise, and experiences. The authors also thank those who shared this study among their networks, helping us to identify participants who were involved with this study.

Authors' Contributions

KS, JA, and CM conceived and designed the study. All authors contributed to recruitment and the development of the study protocol and survey instruments. KS, EMH, MS, JA, and CM carried out data analysis. KS, JA, and CM contributed to the checklist draft. KS drafted the full manuscript and all authors reviewed the drafts and approved the final submission.

Abstract

Background: Longitudinal monitoring of vital signs provides a method for identifying changes to general health in an individual, particularly in older adults. The nocturnal sleep period provides a convenient opportunity to assess vital signs. Contactless technologies that can be embedded into the bedroom environment are unintrusive and burdenless and have the potential to enable seamless monitoring of vital signs. To realize this potential, these technologies need to be evaluated against gold standard measures and in relevant populations.

Objective: We aimed to evaluate the accuracy of heart rate and breathing rate measurements of 3 contactless technologies (2 undermattress trackers, Withings Sleep Analyzer [WSA] and Emfit QS [Emfit]; and a bedside radar, Somnofy) in a sleep laboratory environment and assess their potential to capture vital signs in a real-world setting.

Methods: Data were collected from 35 community-dwelling older adults aged between 65 and 83 (mean 70.8, SD 4.9) years (men: n=21, 60%) during a 1-night clinical polysomnography (PSG) test in a sleep laboratory, preceded by 7 to 14 days of data collection at home. Several of the participants (20/35, 57%) had health conditions, including type 2 diabetes, hypertension, obesity, and arthritis, and 49% (17) had moderate to severe sleep apnea, while 29% (n=10) had periodic leg movement disorder. The undermattress trackers provided estimates of both heart rate and breathing rate, while the bedside radar provided only the breathing rate. The accuracy of the heart rate and breathing rate estimated by the devices was compared with PSG electrocardiogram-derived heart rate (beats per minute) and respiratory inductance plethysmography thorax-derived breathing rate (cycles per minute), respectively. We also evaluated breathing disturbance indexes of snoring and the apnea-hypopnea index, available from the WSA.

Results: All 3 contactless technologies provided acceptable accuracy in estimating heart rate (mean absolute error <2.12 beats per minute and mean absolute percentage error <5%) and breathing rate (mean absolute error ≤1.6 cycles per minute and mean absolute percentage error <12%) at 1-minute resolution. All 3 contactless technologies were able to capture changes in heart rate and breathing rate across the sleep period. The WSA snoring and breathing disturbance estimates were also accurate compared with PSG estimates (WSA snore: r^2=0.76; P<.001; WSA apnea-hypopnea index: r^2=0.59; P<.001).

Conclusions: Contactless technologies offer an unintrusive alternative to conventional wearable technologies for reliable monitoring of heart rate, breathing rate, and sleep apnea in community-dwelling older adults at scale. They enable the assessment of night-to-night variation in these vital signs, which may allow the identification of acute changes in health, and longitudinal monitoring, which may provide insight into health trajectories.

Introduction

Background

Vital signs measured in clinical practice include heart rate, breathing rate, blood pressure, and body temperature. These serve as objective measurements of normal physiological functions and play a fundamental role in the assessment of health [1,2]. With aging, there is an increased incidence of functional limitations and chronic conditions, including hypertension, coronary heart disease, stroke, type 2 diabetes, and sleep apnea. More than 65% of adults aged ≥65 years report multimorbidity. The presence of uncontrolled comorbidities reduces the quality of life; leads to loss of independence; and increases the incidence of falls, hospitalization, and mortality [3-6].

Standardized, continuous vital signs monitoring systems, when implemented for at-home monitoring and care of older adults, including people living with dementia, can serve as an important tool for early identification of changes in health, improve care in older people, and reduce the burden on the health care system [7-10]. Commercially available wearable devices (wearables) and contactless technologies (nearables) are increasingly used for home monitoring and have the potential to enable remote health monitoring and promote independent living [11-18]. These technologies offer secure digital infrastructure that allows reliable and seamless transfer of collected data to cloud servers and can facilitate long-term remote monitoring opportunities for health care.

Wearables are widely used for continuous, at-home monitoring of heart rate, and some have been evaluated in-laboratory settings, predominantly in younger age groups [17-25]. Although several wearables have been shown to be acceptable for older adults, lower technology adoption rate; user comfort trade-off; and burden of maintenance (eg, removal during some daily activities such as showers, periodic recharging, and mobile app use) may make them unsuitable for long-term use in people with cognitive impairment due to their associated behavioral and psychological symptoms [23,26].

Contactless technologies can be embedded in the living environment such as under the bed mattress (undermattress devices or bed sensors) or on the bedside table (eg, bedside radars) and allow contactless monitoring when the user is in bed [27]. They are powered by the mains and securely stream the collected data wirelessly. They use several contactless sensing modalities to measure a composite signal (ballistographic signal) containing movements resulting from breathing and cardiac activity to extract vital signs (heart rate and breathing rate) information. The bedside radars use the Doppler radar technique, while the undermattress devices use several technologies, such as electromechanical films and pneumatic sensors [27,28]. Due to their inconspicuous nature and low maintenance, they do not pose any of the burdens imposed by wearables and are an ideal tool for continuous monitoring of vital signs, behavioral information, and sleep in community-dwelling older adult populations with long-term conditions and in people living with dementia [13,14,29,30].

Objective

To realize the potential of contactless technologies for monitoring vital signs such as heart rate and breathing rate in the community, the validity of their measurements needs to be evaluated in relevant populations. While the validity of the heart rate and breathing rate estimates collected from a few contactless technologies has been evaluated in younger populations, to the best of our knowledge, there are no vital signs evaluation studies in older adults (aged >65 years) although these devices have been implemented in longitudinal studies [13,29,31-33]. Here, we evaluated the validity of heart rate and breathing rate measurements collected from 3 contactless technologies (a bedside radar and 2 undermattress devices) against polysomnography (PSG) electrocardiogram (ECG)-derived heart rate and respiratory inductance plethysmography thorax (RIP thorax)-derived breathing rate in a laboratory setting. Throughout this paper, we have used the term vital signs to denote heart rate or breathing rate and vice versa. The evaluation addresses aspects of overnight average estimates; the ability to capture overnight trends; variability in heart rate and breathing rate; and accuracy at different sleep stages and time resolutions (60-, 10-, and 1-minute intervals) of estimates. We also discuss the data collection reliability in a home environment and summary estimates of breathing disturbance from the devices. To enhance the relevance of this study, we applied liberal inclusion and exclusion criteria for the participant selection, such that several participants had comorbidities that were representative of the general older population.

Methods

Cohort Characteristics

The study data were collected at home for a period of 7 to 14 days, followed by an overnight laboratory session (with full PSG) at the Surrey Sleep Research Centre in 2 cohorts (cohort 1: n=18, from January to March 2020; cohort 2: n=17, from June to November 2021). The participant group consisted of 35 individuals (men: n=21, 60%) aged between 65 and 83 (mean 70.8 SD 4.9) years. The participants were identified and recruited through the Surrey Clinical Research Facility. All participants attended an in-person screening visit, during which a range of assessments were completed. These included medical history (self-reported), the Pittsburgh Sleep Quality Index, the International Consultation on Incontinence

Questionnaire-Urinary Incontinence, intermediate activities of daily living questionnaire, and the Epworth Sleepiness Scale. The vital signs (heart rate, breathing rate, blood pressure, and temperature) were also collected and reviewed to determine inclusion in the study. To ensure the ecological validity of the collected data in this population, participants with stable comorbidities such as hypertension, type 2 diabetes, arthritis, and so on, were included in the study if their comorbidity and concomitant medications were stable and were not considered to pose a safety risk. Eligible participants had to be able to independently perform activities of daily life, as assessed by the intermediate activities of daily living questionnaire, and comply with study procedures. Participants were provided with detailed information about the study and provided written informed consent before any study procedures were performed. A detailed description of the inclusion and exclusion criteria can be found in our previous publications, in which we evaluated the ability of these technologies to estimate sleep timing in the home environment and sleep stages as defined by PSG [34,35].

Ethical Considerations

The study received a favorable opinion from the University of Surrey Ethics Committee (UEC-2019-065-FHMS) and was conducted in line with the Declaration of Helsinki and the principles of Good Clinical Practice. Potential participants were given detailed information about the study protocol, and they provided written informed consent before any study procedures were performed. Complete details of the study, along with the data management, privacy, and confidentiality measures, are discussed in the protocol [36].

Study Protocol

The undermattress devices (Withings Sleep Analyzer [WSA]; Withings] and Emfit QS; Emfit Ltd) were deployed both in the laboratory and at home, while the bedside radar (Somnofy; VitalThings) was only used in the laboratory. The participants also used an actigraphy device (Actiwatch Spectrum [AWS]; Philips Respironics) and maintained a consensus sleep diary at home [37]. During the home deployment period, the contactless technologies did not require any manual intervention or maintenance by the participants, and the data was transmitted automatically via Wi-Fi. To ensure the anonymity of the data, no personally identifiable participant information was added to the device applications, and a portable Wi-Fi router was used for data transfer. The contactless devices remained active and collected data continuously for the entire period of the study. The participants wore AWS on their nondominant hands throughout the study period, removing them briefly in scenarios that could lead to the device becoming wet. AWS data have been reported elsewhere [34].

After the home data collection period, 1 overnight full clinical PSG recording was conducted, which included an extended time in bed of 10 hours. On average, the participants slept 385.97 (SD 65.67) minutes in the sleep laboratory as measured via PSG and 405.96 (SD 84.00) minutes as measured via consensus sleep diary at home [34,35]. The WSA was used in both cohort 1 and cohort 2, while the Somnofy and Emfit were deployed only in cohort 2. The data from the contactless technologies were collected simultaneously along with PSG in the laboratory and with AWS and sleep diary at home. Empatica E4 (Empatica Srl), a wrist-worn device that collects activity and photoplethysmography, was also deployed during the laboratory session, and our evaluation of this device is reported elsewhere [26]. All devices and PSG data were collected for the entire 10-hour in-bed period in the laboratory. A detailed description of the study protocol is given in the protocol [36].

The Reference Vital Signs Data

During the in-laboratory session, PSG data were collected using the SomnoHD system (SOMNOmedics GmbH). The collected data included electroencephalography (256 Hz; F3-M2, C3-M2, O1-M2, F4-M1, C4-M1, and O2-M1); ECG (modified lead II subclavicular electrode placement; 256 Hz); RIP thorax and abdomen (128 Hz); photoplethysmography (128 Hz); electromyography (256 Hz, both submental and limb); and electrooculography (256 Hz; E2-M1 and E1-M2). In addition, data on the snore sensor (256 Hz) and airflow via nasal cannula and flow thermistor (128 Hz) were also collected. Sleep was scored at 30-second intervals in the Domino software environment as per American Academy of Sleep Medicine (AASM) guidelines by 2 independent scorers (a registered polysomnographic technologist and a trained scorer), and a consensus hypnogram was generated [38]. The sleep hypnogram contains 5 stages: rapid eye movement (REM), stage 1 of non-REM sleep (N1), stage 2 of non-REM sleep (N2), stage 3 of non-REM sleep (N3), and wake. The apnea-hypopnea index (AHI; number of apnea/hypopnea events per hour) and period limb movement index (PLMI; number of period limb movement events per hour) were determined by the Registered Polysomnographic Technologist using scoring rules recommended by AASM. An apnea was scored when there was a ≥90% drop in airflow lasting for at least 10 seconds, while a hypopnea was scored using the 3% drop in oxygen saturation and an arousal in the electroencephalogram criteria. The severity of apnea was determined using the following thresholds as per AASM guidelines: AHI score of <5 (normal), 5 to <15 (mild apnea), 15 to <30 (moderate apnea), and ≥30 (severe). A periodic limb movement event was scored when at least 4 consecutive limb movements occurred, each separated from the preceding limb movement by at least 5 seconds but not more than 90 seconds apart. PLMI of >15 seconds is used as the cutoff for the presence of periodic limb movement disorder [39,40]. In addition, participants with cardiac arrhythmia were identified using the arrhythmia index generated by the Domino software and verified by visual inspection of the record.

The PSG data were exported as standard EDF+ files along with recording markers and the consensus hypnogram. The ECG from the PSG was used for the extraction of the heart rate reference data, while the RIP thorax was used as the breathing rate reference data. For one of the participants in whom RIP thorax was unavailable, RIP abdomen was used to create the breathing rate reference data. MATLAB 2021b was used for all data analyses reported. The RR intervals used for the computation of the heart rate were derived from the ECG using the PhysioNet cardiovascular signal toolbox and a well-evaluated beat detection toolbox [41,42]. This beat-to-beat information was used to estimate reference heart rate (beats per minute [bpm]) at 30-second intervals, which is the same as the

PSG hypnogram. For extracting the breathing rate (cycles per minute [cpm]) from the RIP thorax signal at 30-second intervals, the RRest package was used [43,44].

Contactless Technologies: Data Overview

The WSA and Somnofy data (json format) were downloaded using the respective manufacturer's application programming interface, while the Emfit data (CSV format) were downloaded from the manufacturer's web interface. All the compared contactless technologies (WSA, Emfit, and Somnofy) provided breathing rate data, while only the undermattress devices (WSA and Emfit) provided heart rate data.

The devices provided vital signs (heart rate and breathing rate) data and sleep hypnograms at different resolutions (WSA: 60 seconds; Emfit and Somnofy: 30 seconds). The WSA and Somnofy heart rate and breathing rate estimations were available at 60 and 30-second resolutions (same as the respective device hypnogram resolution), while the Emfit estimated heart rate at a 4-second resolution. These 4-second estimates were averaged to generate estimates at 30-second intervals to match the Emfit sleep label intervals. To allow data analysis relative to local time, daylight savings correction was applied to the Coordinated Universal Time timeseries generated by the devices. The sleep hypnograms generated by the devices contain 4 stages: deep sleep (DS=N3), light sleep (LS=N2/N1), REM, and wake.

Apart from heart rate and breathing rate, Emfit generates continuous heart rate variability and activity measures, while Somnofy provides the estimates of movement and environmental variables such as ambient light, sound, temperature, pressure, humidity, and indoor air quality, which were out of scope for this evaluation and are not discussed here.

Both at home and in the laboratory, all devices were connected to the same network, and the devices used the manufacturer's time synchronization protocol such as network time protocol to timestamp the data. Although this ensured that the devices were synchronized to local time, we performed another synchronization step to allow an accurate comparison of the data between the devices. The device vital signs measures were aligned to the PSG reference vital signs estimates via cross-correlation between the device and PSG vital signs and hypnograms, and the lag (within a 5-minute window) that provided the best alignment of both the vital signs data and hypnograms was then applied. The WSA data were converted from 60- to 30-second intervals by upsampling. Epochs in the PSG and device hypnograms that were scored as artifacts or no presence were excluded from the assessment.

Vital Signs Assessment

Overview

The evaluation of the epoch-by-epoch heart rate and breathing rate data collected by the contactless technologies was performed against reference estimates derived from PSG ECG and RIP thorax. The accuracy and reliability of the heart rate and breathing rate estimates were performed at different levels of time resolution to determine use cases in which the contactless technologies can be used. These include accuracy assessment of overnight average estimates; ability to capture overnight trends; variability in vital signs; and accuracy in different sleep stages and at different time resolutions (60-, 10-, and 1-minute intervals) of estimates. All laboratory data analyses were performed over the total recording period of the PSG. At all temporal resolutions of comparisons, only complete or valid pairs of estimates were used.

Performance Measures

To assess the accuracy of the vital signs estimates (heart and breathing rates), mean absolute error (MAE) and mean absolute percentage error (MAPE) were used as the primary metrics. MAE and MAPE are used to measure the error in the estimate between the device and the PSG reference vital signs. Bland-Altman metrics such as minimum detectable change (MDC), bias, and limits of agreement (LoA) were also computed to provide an overview of the agreement of the estimates and to allow comparison with the evaluations reported in the literature [45,46]. All the measures are reported with 95% CIs. MDC is the smallest change in the estimate that can be detected by the device that exceeds the measurement error. It is equal to half the agreement width [47],

$$MDC = (LoA_{\text{Upper bound}} - LoA_{\text{Lower bound}}) / 2 \quad \textbf{(1)}$$

We used intraclass correlation (ICC) with 2-way random effects to measure the reliability of measurement and standardized absolute difference, a directionless Cohen *d*, described by Guruswamy Ravindran et al [35] and Haghayegh et al [47], for measuring the dispersion in the bias. All ICC values (range 0-1) were estimated with α of .05; ranges used for interpretation were as follows: ICC<0.5 (poor), ICC=0.5 to 0.75 (moderate), and ICC>0.75 (good reliability). Apart from the above metrics, the coefficient of determination (r^2, a measure of how close the measured estimates are to the reference, computed using simple linear regression) was also used for the concordance analysis. For estimating the significance of differences between vital signs during different sleep stages, devices, and time courses, we used ANOVA followed by linear mixed effects models with the different groups (devices, sleep stages, and time) as fixed effects (with interactions) and participant as a random effect. MATLAB 2021b was used for all statistical analyses.

Acceptable Agreement for Heart Rate

The satisfactory level of agreement between the PSG reference heart rate and the device-determined heart rate was set to an error of 10% or +5 or –5 bpm as recommended by the Association for the Advancement of Medical Instrumentation [42,48].

Acceptable Agreement for Breathing Rate

For breathing rate, to the best of our knowledge, no device-specific satisfactory level of agreement is discussed in the literature. Hence, the agreement in breathing rate estimates between human observers is used to set the acceptable level for our evaluation. We set the permissible level of error in breathing rate estimation to be +4 or –4 cpm, as reported by Lim et al [49].

Breathing Disturbance Estimates

Apart from epoch-by-epoch heart rate and breathing rate, WSA also provides a "snoring" signal, which is a binary variable

depicting snore presence detected by the device. In addition, the WSA also provides the summary estimates of snoring duration (WSA snore), breathing disturbance intensity (WSA breathing disorder index [BDI]), and AHI (WSA AHI). The Emfit and Somnofy devices do not generate breathing disturbance measures. Only complete or valid pairs of estimates were used to analyze the summary measures. For WSA BDI and AHI estimates, we explored the relationship between them and the concordance of these WSA estimates to the PSG AHI in the laboratory.

For the WSA snore estimates, we explored the concordance of the all-night snore duration estimated by the PSG snore sensor (ie, PSG snore microphone placed on the side of the neck) and the WSA. The PSG snore sensor data were scored by the Somnomedics Domino software using 30 dB as the snore amplitude threshold and a minimum snore duration of 300 ms. We further explored the differences in the snore intensity as measured by the PSG snore sensor for the epochs determined to contain snore events by the WSA, followed by an exploration of the distribution of the snore events during the different sleep stages.

Results

Characteristics of the Study Population

Of the 35 participants, more than half of the participants (n=20, 57%) reported comorbidities, including type 2 diabetes, obesity, arthritis, and hypertension, with concomitant medication. In this study population, the mean heart rate was 62.2 (SD 8.9) bpm (men: n=21, 60%; mean 60.6, SD 9.3 bpm; women: n=14; 64.4, SD 7.8 bpm), and mean breathing rate was 14.7, SD 2.9 cpm (men: 14.6, SD 2.9 cpm; women: 14.7, SD 3.0 cpm), as assessed from the overnight laboratory PSG. The average BMI of the participants was 27.0 (SD 4.8) kg/m^2, with 17% (n=6, BMI >30) being obese. The mean systolic and diastolic blood pressures measured during screening were 148.7 (SD 16.2) mmHg and 87.0 (SD 9.6) mmHg, respectively. During the clinical PSG, it emerged that 95% (n=33) of the participants in the study had some degree of apnea. Of the participants with apnea, 8 (23%) had severe (AHI>30), 9 (26%) had moderate (AHI=15 to <30), and 16 (46%) had mild apnea (AHI=5 to <15). A total of 10 (29%) participants had PLMI>15, which is similar to the prevalence of periodic limb movement syndrome in community-dwelling older adults [50,51]. Some form of cardiac arrhythmia was found in 51% (n=18) of the participants, with 29% (n=10) of them also having severe or moderate apnea. A detailed description of the population characteristics can be found in the study by Ravindran et al [34].

Overview of Vital Signs Data

Example Case

An example of vital sign data collected by WSA for 14 days at home followed by 1 day in the laboratory is shown in Figure 1. The participant had moderate apnea with an AHI of 24.1 events/hour, as determined by the clinical PSG during the laboratory visit (day 0). The raster plot (Figure 1A) shows heart rate, sleep-wake stage, and breathing rate as estimated by the WSA. The vital sign data were available when the participant was in bed at night and during daytime in-bed periods, which were also reported as naps by the participant. The days –14 to –1 depict the data collected at home, while day 0 depicts data collected in the sleep laboratory. The darker, purple-colored regions denote sleep, while the lighter regions denote wake as identified by the WSA. The gray areas represent out-of-bed periods (ie, periods during which the device did not record data). The first day of data from the WSA at home were lost. This participant had irregular nocturnal bed timing, with an average time in bed during the nocturnal period of 10 hours 8 minutes at home. Mean nocturnal heart rate and breathing rate varied across nights. The WSA AHI showed night-to-night variability (Figure 1B), and the WSA AHI during the laboratory visit was 25 events/hour, which was close to the PSG AHI value. The heart rate showed a trend across the nocturnal sleep period, with a higher heart rate at the beginning of the nocturnal sleep period and a lower heart rate just before the end of the sleep period.

Figure 2 shows the contactless technology–derived vital sign data collected alongside PSG reference data during the laboratory visit for the participant depicted in Figure 1. The PSG heart rate and breathing rate both show changes as the hypnogram shows transitions between different stages of sleep, with higher variability during wake and REM sleep and lower variability during non-REM sleep. The differences in the data resolution (WSA: 60 seconds; Emfit and Somnofy: 30 seconds) between the contactless technologies can be seen from the plots. The WSA vital signs estimates provided by the device are rounded to the nearest integers, leading to more discretized vital sign data. The trends in the heart rate and breathing rate data recorded by the PSG and the contactless technologies are more similar during the sleep periods compared with the wake periods. The Somnofy had a number of missing estimates of breathing rate during many of the wake epochs determined by the device, and these missing vital sign epochs also coincided with periods of higher activity, as detected by a wrist-worn activity device (Empatica E4). Snoring, as detected by the WSA, followed a pattern that closely followed the snoring signal detected by PSG, with some disagreement in the detection of the snoring event (Figure 2).

Figure 1. Vital signs from a male participant aged 65 to 70 years collected at home and in the laboratory. (A) Raster plot showing the heart rate (bpm), and breathing rate (cpm) as detected by the Withings Sleep Analyzer along with device-detected sleep (or) wake period and sleep diary information. (B) Estimates of mean heart rate, mean breathing rate, and apnea-hypopnea index (AHI; depicted as circles adjacent to the time courses) were made during the night as determined by the device.

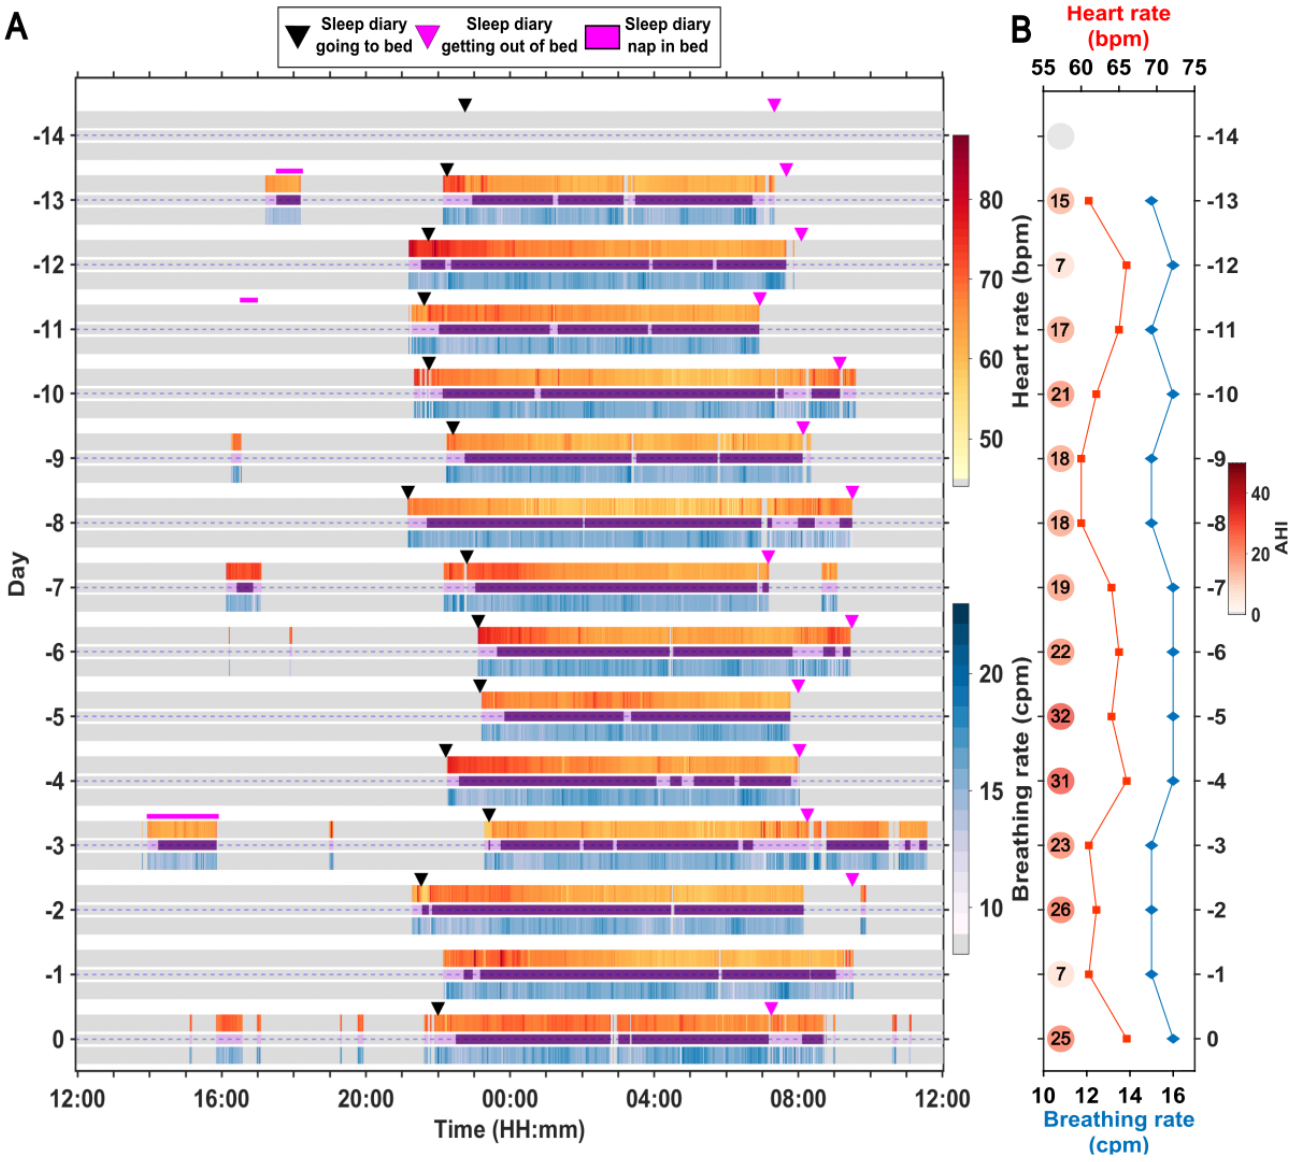

Figure 2. Vital sign data simultaneously collected from 3 contactless technologies and polysomnography (PSG) in the laboratory for the male participant described in Figure 1. The PSG consensus hypnogram (top) is depicted at the top followed by the heart rate (red), and breathing rate (blue) from PSG and contactless devices, and activity data in arbitrary units are from the Empatica E4 device. The gray regions in all the plots correspond to the lights-off period. A: artifact; bpm: beats per minute; cpm: cycles per minute; N1: stage 1 of nonrapid eye movement (non-REM) sleep; N2: stage 2 of non-REM sleep; N3: stage 3 of non-REM sleep; R: REM sleep; W: wake; WSA: Withings Sleep Analyzer.

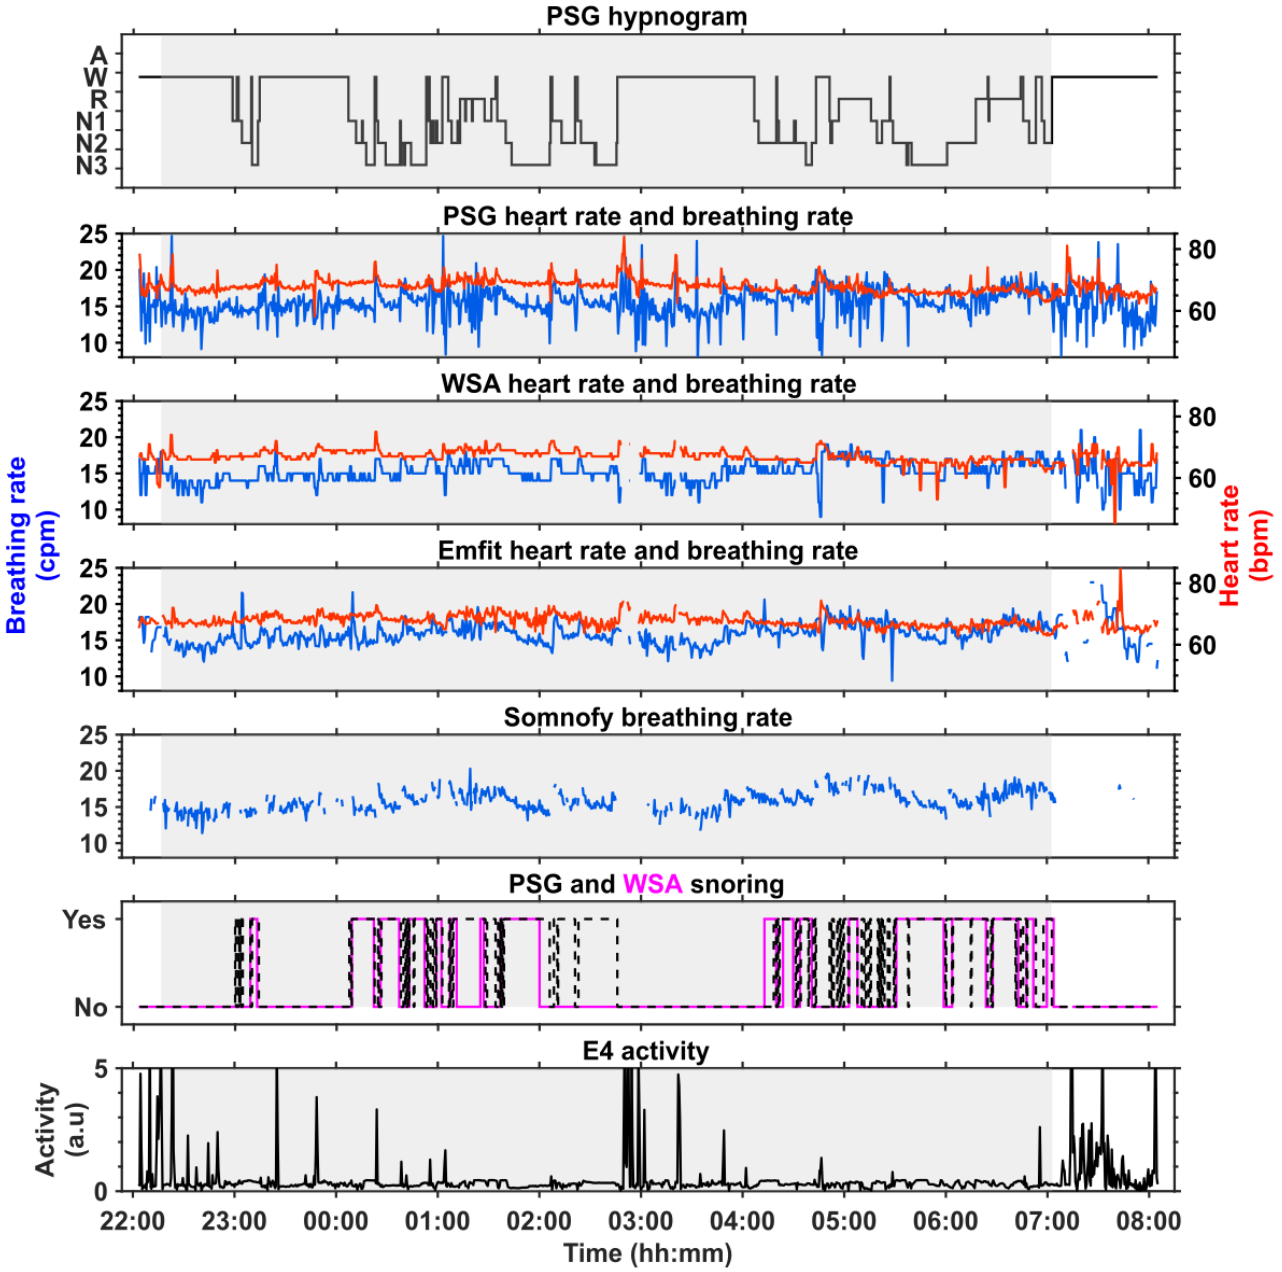

Summary of Collected Data

In the laboratory study, all 35 PSGs (ground truth or reference data, cohort 1: n=18, 51%; cohort 2: n=17, 49%) were available. The total number of nights of data collected in the laboratory for each of the 3 contactless technologies were 35 for WSA, 16 for Emfit, and 17 for Somnofy. One night of data was lost due to a device malfunction for Emfit. At home, a total of 401 days of data were collected across the 35 participants, with 321 days of data available for WSA (cohort 1: n=10, 56%; cohort 2: n=17, 100%) and 228 days of data available for Emfit (cohort 2: n=17, 100%). At home, for WSA, portions of data from 8 participants were lost in cohort 1 due to deployment errors and Wi-Fi dropouts, with a data loss of 3.3% (11/332 days lost). For Emfit, the data loss was 4.2% (10/238 days lost).

In the laboratory, the range of the heart rate estimated (minimum to maximum) by the contactless technologies was 40 to 90 bpm for WSA and 40 to 135 bpm for Emfit, whereas for breathing rate, the ranges were 8 to 35 cpm for WSA, 6 to 30 cpm for Emfit, and 6 to 30 cpm for Somnofy. The undermattress device–generated vital sign (both heart rate and breathing rate) data for 100% of the in-bed periods. Somnofy bedside radar, by contrast, generated breathing rate data less continuously, resulting in data unavailability at 32.21% (54.41/169.14 hours) of the in-bed period (in-laboratory). Most of these missed breathing rate epochs were found to be in the Somnofy-predicted

wake state (the total percentage of breathing rate epochs unavailable per label was follows: wake=34.35/54.41 hours, 62.39%, REM=6.96/54.41 hours, 12.73%; LS=12.19/54.41 hours, 23.1%, and DS=0.91/54.41 hours, 1.78%).

All-Night Vital Signs

The concordance between the nightly average heart rate and breathing rate estimates of the contactless technologies against PSG are shown in Figure 3 and Table 1. The WSA (MAPE 3.28%; ICC=0.87) had a lower level of agreement compared with Emfit (MAPE 1.83%; ICC=0.96), and this was due to an outlier participant with severe arrhythmia (see the outlier in Figure 3). When the outlier was removed WSA (WSA*: MAPE 1.87%; ICC=1.0) had an agreement with the PSG that was similar to that of Emfit. The MDC was higher for Emfit (3.25 bpm) compared with WSA* (1.17 bpm), which can be seen from the higher dispersion in the Emfit estimates (Figure 2A). For the breathing rate, Somnofy (MAPE 4.64%; ICC=0.82) had a high agreement, followed by WSA (MAPE 6.29%; ICC=0.78) and Emfit (MAPE 5.46%; ICC=0.76). The MDC follows the agreement results, with Somnofy (1.98 cpm) having a somewhat lower value compared with WSA (2.08 cpm) and Emfit (2.21 cpm).

Figure 3. Association between vital signs estimated by 3 contactless devices and estimates from polysomnography (PSG) averaged across the night while sleeping in the sleep laboratory. (A) Heart rate (beats per minute [bpm]); (B) breathing rate (cycles per minute [cpm]). The error bars represent the SD of the estimate within participants. The PSG heart rate and breathing rate are derived from electrocardiogram (ECG) and respiratory inductance plethysmography thorax (RIP thorax), respectively. The number of participants (ie, nights) available for the devices are Withings Sleep Analyzer (WSA; n=34), Emfit (n=16), and Somnofy (n=17).

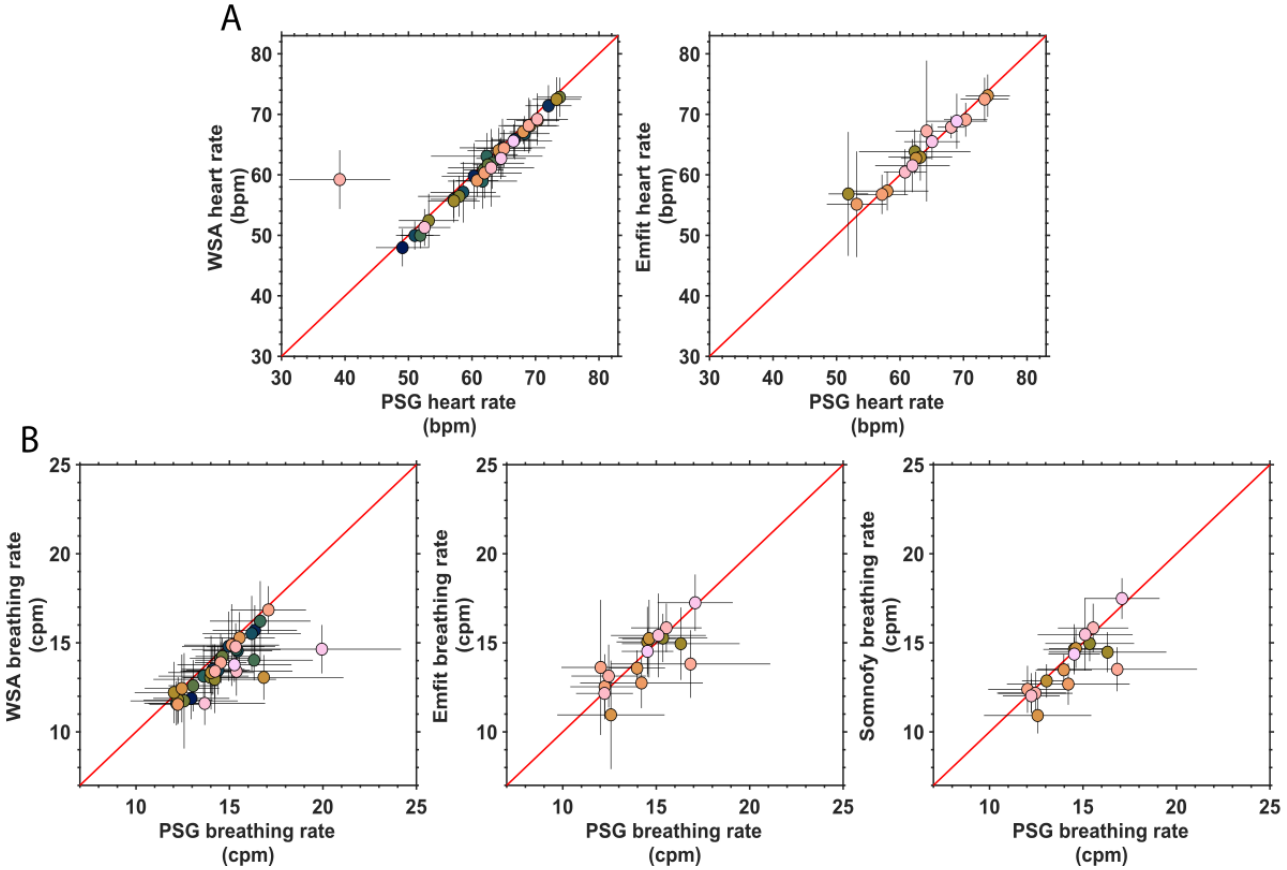

Table 1. All-night average of vital signs and their agreement metrics[a].

[a]Metrics of agreement for overall heart rate of the devices against the electrocardiogram (ECG) estimates (included in the PSG). The number of participants contributing to each of these devices was as follows: WSA (n=35), WSA* (n=34), Emfit (n=16), and Somnofy (n=17).

[b]PSG: polysomnography.

[c]Bias is the difference in measurement between the device and PSG ECG.

[d]LoA: limits of agreement.

[e]MDC: minimum detectable changes; smallest detectable change independent of measurement error (half of Bland-Altman agreement width).

[f]MAE: mean absolute error.

[g]SAD: standardized absolute difference; directionless version of Cohen *d*.

[h]MAPE: mean absolute percentage error.

[i]ICC: intraclass correlation coefficient with 2-way random effects; measure of measurement reliability.

[j]WSA: Withings Sleep Analyzer.

[k]WSA* depicts the outlier-removed WSA data.

Vitals Signs During Different Vigilance States

We investigated the agreement of the vital signs estimated by the contactless technologies to the PSG reference during the different vigilance states of the consensus PSG hypnogram. The distribution of the vital signs for the different vigilance states is provided in Figure S1 in Multimedia Appendix 1. The heart rate and breathing rate estimates of both the PSG and contactless devices were not normally distributed (via the Kolmogorov-Smirnov test). The difference between the mean heart rate estimated by the devices and PSG was <2.5 bpm across all sleep stages. The difference between the mean breathing rate estimated by the devices and the PSG was <1.5 cpm across all sleep stages. Overall, the concordance between the estimates of both heart and breathing rate provided by the contactless technologies and PSG was good across all vigilance states (Figure S2 and Tables S1 and S2 in Multimedia Appendix 1).

Time Course of Vital Signs During Sleep

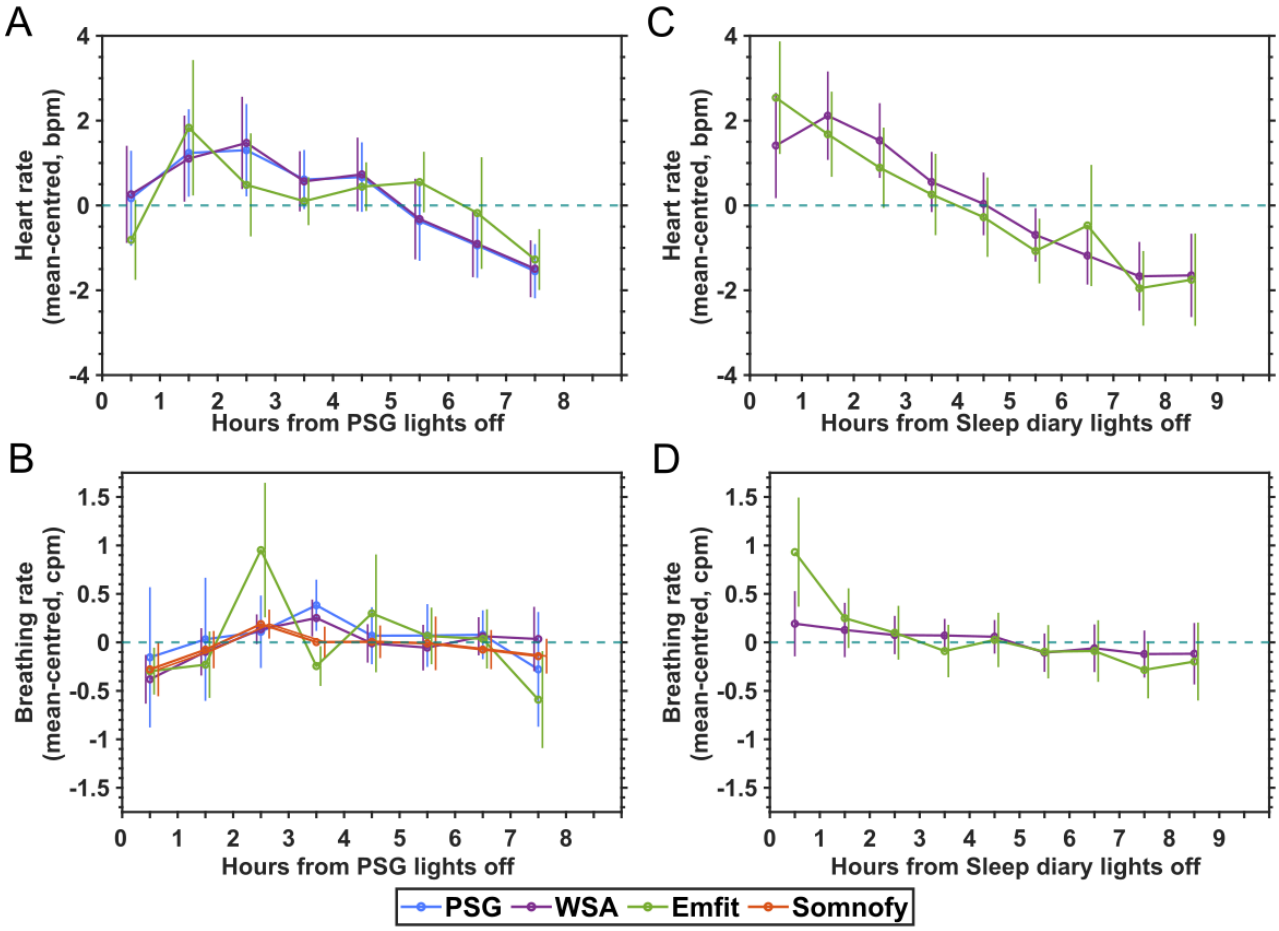
Figure 4A shows the time course of the heart rate and breathing rate estimated by the contactless devices and PSG over the PSG lights-off period in the laboratory. Figure 4B shows these time courses for the sleep diary–defined lights-off periods recorded at home (Figure 4B). The vital sign data were mean centered and averaged over the epochs during which participants were asleep as detected by the PSG hypnogram for the laboratory data and as detected by the sleep scoring algorithms of the devices for the at-home data. The data are plotted per hour starting from the onset of the lights-off period. The error bars represent the SD of the estimate and are shifted along the x-axis to improve visibility.

Both in the laboratory and at home, the heart rate started close to or above the mean, gradually decreased over the night, and reached the nightly minimum in the second part of the sleep period before a slight increase at the end of the sleep period. The similarity between the contactless technology and PSG heart rate hourly time series in the laboratory was determined using MAPE. The WSA (MAPE 14.42%) closely follows the PSG, while the Emfit (MAPE 144.34%) is less similar.

The breathing rate trends at home were similar to that of the heart rate, starting above the overnight mean and gradually decreasing to a lower value closer to the end of the night. In the laboratory, the breathing rate hourly estimates were fluctuating and did not show any clear trend. Both the WSA (MAPE 129.95%) and Somnofy (MAPE 130.01%) had the highest

similarity with the PSG, while the Emfit had the lowest similarity (MAPE 295.76%).

Figure 4. Time course of vital signs during sleep in the laboratory (A and B) and at home (C and D). The number of participants available for each of the devices (measured in nights) in the laboratory (polysomnography [PSG]: n=35, 35 nights; Withings Sleep Analyzer [WSA]: n=34, 34 nights; Emfit: n=16, 16 nights; and Somnofy: n=17, 17 nights) and at home (WSA: n=27, 295 nights; Emfit: n=17, 213 nights). bpm: beats per minute; cpm: cycles per minute.



Effect of Temporal Resolution on the Vital Signs Accuracy

To examine the effect of the length of the time period over which the vital signs are computed, we averaged the heart rate and breathing rate estimates over 60 minutes, 10 minutes, and 1 minute and computed the agreement with the corresponding PSG reference estimates (Tables 2 and 3). We examined the cumulative distribution function (CDF) of the MAE at these resolutions to better characterize the estimation error. The CDFs are depicted in Figure 5, while more detailed scatter plots and associated agreement measures are provided in Figure S3 and Tables S2 and S3 in Multimedia Appendix 1.

For all devices and both heart and breathing rates, the CDFs become steeper with increasing duration of the time window over which these variables are computed. For both heart rate and breathing rate, the agreement (measured by ICC) with the PSG reference estimates increased with decreasing temporal resolution (Figure S3 in Multimedia Appendix 1). On closer inspection of the CDFs, we find that for the heart rate estimates, the error at the 90th percentile is lower for WSA than for Emfit for the 1-minute and 60-minute estimations (overall error<4 bpm). For the Emfit, the median (50th percentile) error of the heart rate estimates became smaller with increasing duration of the time window, but the WSA median error was always close to 1. For the breathing rate, at all 3 resolutions, 50% of the estimates had an error of <1 cpm. When we inspected the 90th percentile error of breathing rate estimates at 1 minute, we found that Somnofy had the lowest error (2.56 cpm), followed by WSA (3.46 cpm) and Emfit (4.26 cpm). This trend was seen for lower resolutions as well. At the 50th percentile, we see the effect of discrete breathing rate output from WSA on the 50th percentile error, where the error of the other 2 devices falls below 0.5, while the WSA error does not. A detailed discussion of the effects of temporal resolution on the agreement between the device and PSG vital sign estimate is provided in Multimedia Appendix 1.

Table 2. Effect of temporal resolution on reliability of estimates of heart rate[a].

Heart rate resolution	Device, mean (SD)	PSG[b], mean (SD)	Bias[c] (SD; 95% CI)	LoA[d] (lower bound), (95% CI)	LoA (upper bound), (95% CI)	MDC[e]	MAE[f] (95% CI)	SAD[g] (95% CI)	MAPE[h] (95% CI)	ICC[i] (95% CI)

[a]Metrics of agreement for overall heart rate estimates from the devices against PSG electrocardiogram (ECG) estimates (beats per minute) at various temporal resolutions.

[b]PSG: polysomnography.

[c]Bias is the difference in measurement between the device and PSG ECG (device–PSG ECG).

[d]LoA: limits of agreement.

[e]MDC: minimum detectable changes; smallest detectable change independent of measurement error (half of Bland-Altman agreement width).

[f]MAE: mean absolute error.

[g]SAD: standardized absolute difference; a directionless version of Cohen *d*.

[h]MAPE: mean absolute percentage error.

[i]ICC: intraclass correlation coefficient; with two-way random effects (measures of measurement reliability).

[j]WSA: Withings sleep analyzer.

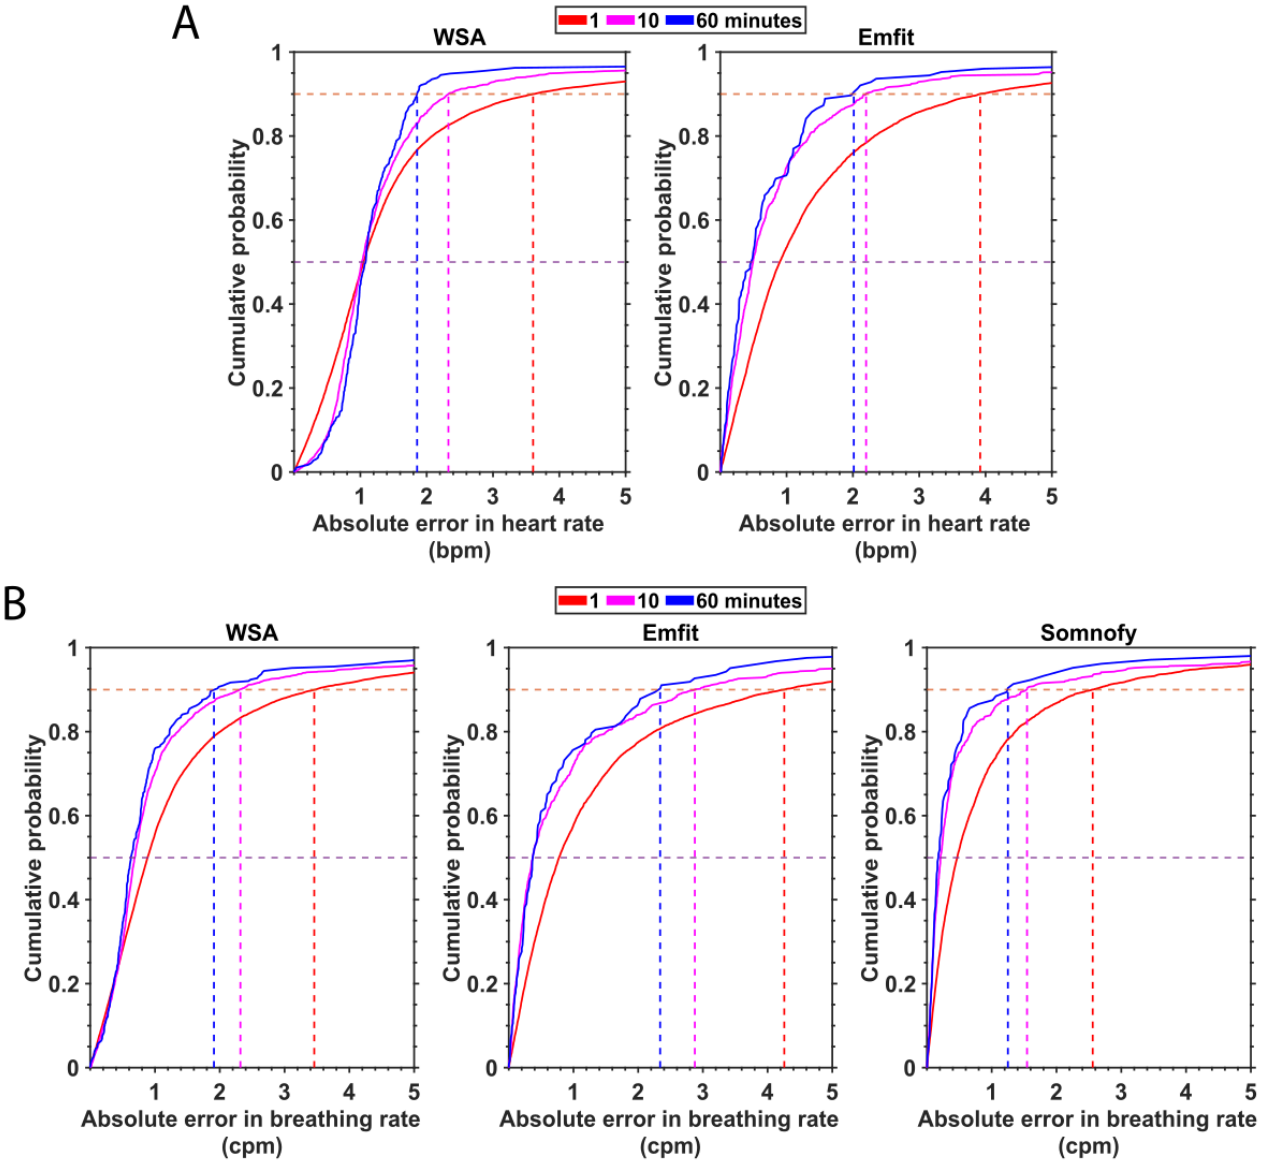
Figure 5. Effect of time window over which vital signs are estimated on device measurement error; (A) heart rate (beats per minute [bpm]) and (B) breathing rate (cycles per minute [cpm]). The cumulative density function of the absolute error is represented for each of the devices for the window lengths 1, 10, and 60 minutes. The median (50th percentile) and the 90th percentile are represented by horizontal lines. PSG: polysomnography; WSA: Withings Sleep Analyzer.



Estimating Breathing Disturbances During Sleep

WSA Snore

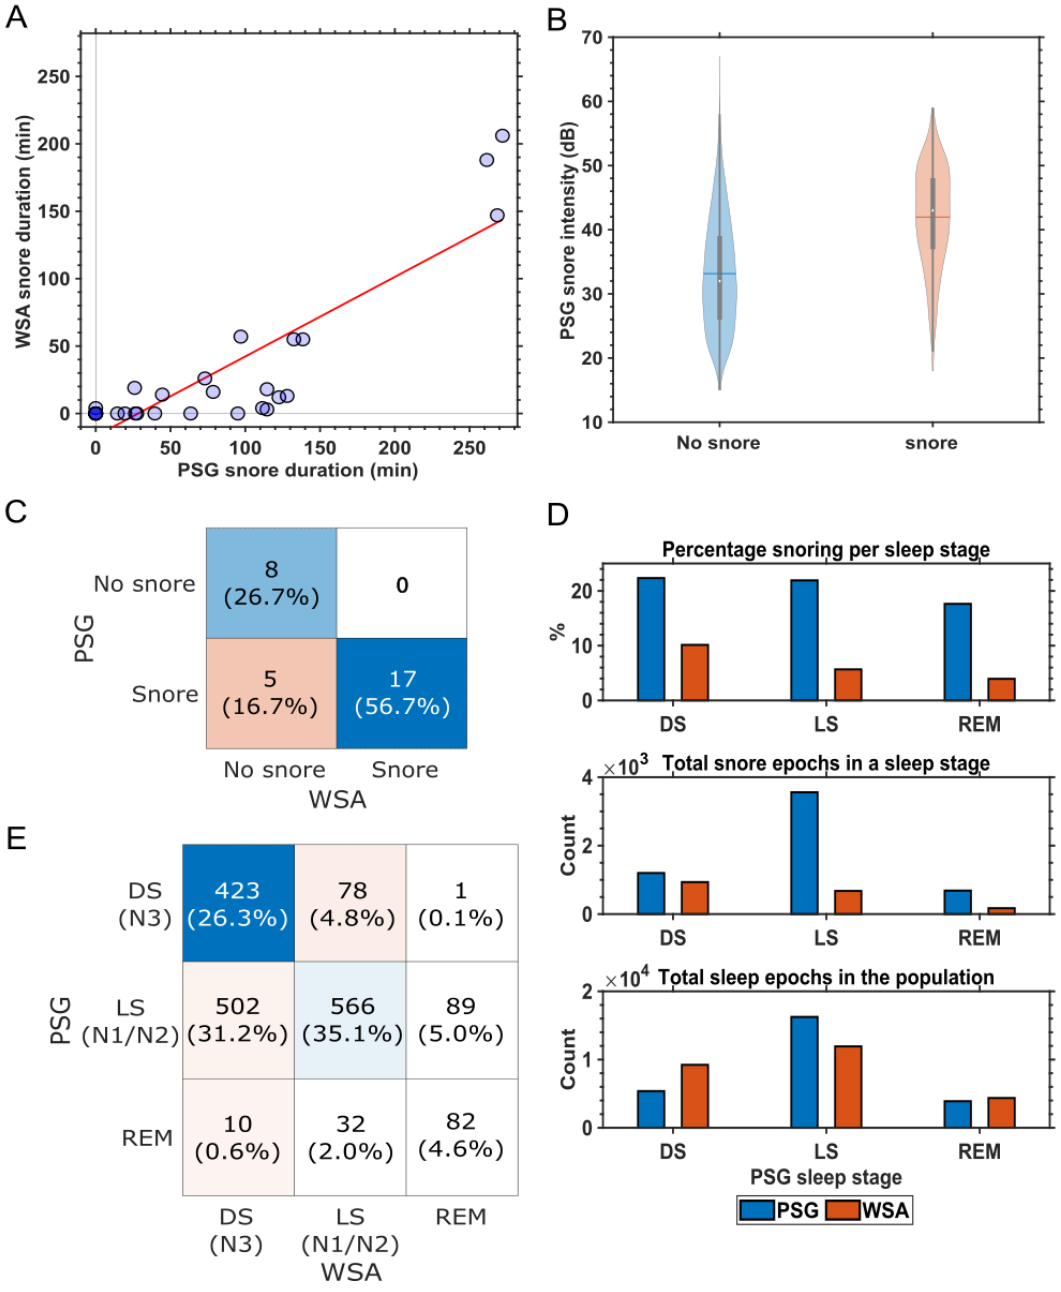
The results of the WSA snore analysis and an example of the overnight time course of the snore data are depicted Figure 6, as well as in Figure S6 in Multimedia Appendix 1. Out of the 35 participants, snore data from both PSG and WSA were available for 30 (86%) participants (PSG snore sensor data were not available for 2 participants, and WSA snore data were unavailable for 3 participants). Of the remaining 30 participants, it was determined from PSG snore sensor data that 8 (27%) participants did not have any form of snoring, whereas 22 (73%) participants snored. The WSA incorrectly determined that 5 (23%) of these 22 participants had no snoring, leading to a moderate performance with a Matthews correlation coefficient of 0.69 (Figure 6C).

PSG determined that the 22 snorers had a nightly snoring duration ranging between 10 and 270 minutes (Figure 6A). The concordance between the snore duration estimates from the WSA and PSG was high (r^2=0.76; P<.001; n=30). When the snoring intensity determined by the PSG snore sensor was grouped based on the WSA snore labels (Figure 6B), we found that, on average, the intensity of the PSG-detected snore events that were not detected by WSA was lower than the intensity of the snore events detected by both PSG and WSA, but there was a considerable overlap between the distributions.

Overall, the snore events were underestimated by the WSA compared with PSG. The distribution of the snoring events as determined by the PSG snore sensor showed that snoring was present across all sleep states, with >20% of all non-REM epochs having snore events, while for REM epochs, this was 17.48% (Figure 6D). By contrast, when the distribution of snore events automatically identified by WSA was analyzed, the

WSA-determined snore events were high during LS and DS and low during REM (Figure 6E). The corresponding confusion matrix between the PSG consensus sleep stage and Withings sleep stage prediction during WSA-identified snore events is depicted in Figure 6E, which shows that the WSA does not score wake when snore events are detected. WSA also scored more snore epochs as DS, followed by LS and REM sleep.

Figure 6. Withings Sleep Analyzer (WSA) snore analysis. (A) Concordance of polysomnography (PSG)-assessed snore duration and WSA snore (n=30). The linear fit is depicted by the red line. (B) Snore intensity as detected by the PSG snore sensor during WSA predicted snore and no snore. (C) Confusion matrix for participants identified as snorers or nonsnorers (n=30). (D) Distribution of snore events across PSG-derived sleep stages for both PSG and WSA. (E) Confusion matrix of epoch-to-epoch (EBE) concordance between PSG and WSA during WSA snore events (total WSA snore epochs: 1611). bpm: beats per minute; cpm: cycles per minute; DS: deep sleep; LS: light sleep; REM: rapid eye movement.



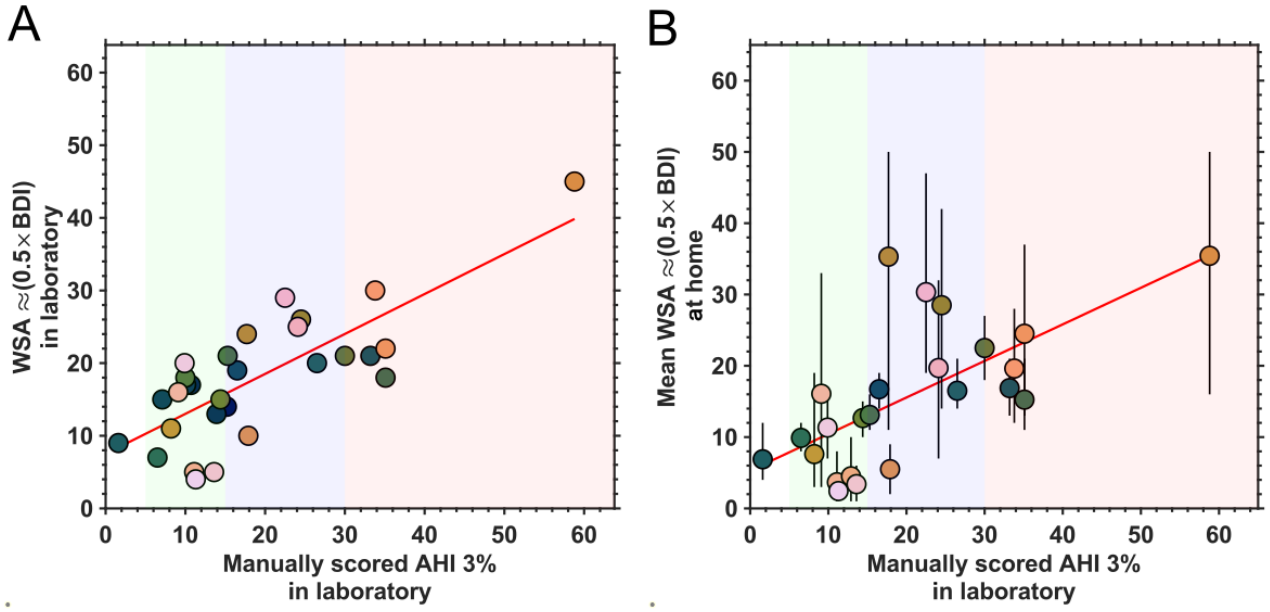
WSA AHI

The WSA summary measures relevant to breathing disorders are the BDI and AHI. WSA BDI data were available for 29 participants in the laboratory and for 24 participants at home (a total of 222 nights available). Both WSA AHI and BDI were available for only 64 nights across 7 participants at home. Upon inspection of potential correlations between the WSA AHI and WSA BDI, we found that the WSA BDI was double the value of WSA AHI (WSA BDI=(2.006×WSA AHI)–0.133; r^2=.999; P<.001; n=64; Figure S7 in Multimedia Appendix 1). On the basis of this inference, we used half BDI as the proxy for WSA AHI for the remainder of the analysis.

We found a high correlation between the WSA AHI and PSG AHI in the laboratory (r^2=0.59; P<.001; n=29; Figure 7A). The MAE was 6.49 (95% CI 4.89-8.10) events per hour. We further explored the relationship between the PSG AHI in the laboratory

and the mean WSA AHI at home (Figure 7B). We found that there was a moderate level of correlation between the 2 (r^2=0.44; P<.001; n=24). There was also a high level of agreement between the WSA AHI 1 night before the laboratory and both in-laboratory WSA AHI (r^2=0.74; P<.001; n=15) and PSG AHI (r^2=0.59; P<.001; n=16). We have depicted the WSA AHI (half WSA BDI) for the 24 participants' data available at home as a heat map showing the night-to-night variability and missing values in Figure S8 in Multimedia Appendix 1.

Figure 7. Relationship between polysomnography (PSG)-based apnea-hypopnea index (AHI) and Withings Sleep Analyzer (WSA) breathing disorder index (BDI). (A) In laboratory (n=35) and (B) at home (n=29). The linear fit is depicted by the red line. AHI reference ranges are as follows: 0 to 4 (no apnea), 5 to 14 (mild; shown in green), 15 to 29 (moderate; shown in blue), and ≥30 (severe; shown in red). For the WSA AHI estimates at home, each data point depicts the mean per participant, and the vertical bars depict the minimum and maximum values.



Discussion

Principal Findings

In this study, we provide an evaluation of 3 contactless technologies for monitoring heart rate, breathing rate, and breathing disturbances during sleep in older men and women. Overall, the contactless technologies provided heart rate (WSA and Emfit) and breathing rate estimates (all 3 devices) with acceptable agreement compared with standard reference estimates from PSG ECG and RIP thorax. We also found that these devices can be used for detecting respiratory events, including apnea and snoring, in this population of older men and women with stable comorbidities.

We were able to successfully collect data at home with limited (<5%) data loss. The data loss was primarily due to Wi-Fi dropouts, where the device spontaneously lost connection to the Wi-Fi network. Overall, this demonstrates the ability of these contactless devices to reliably collect continuous vital sign data remotely in the community with little oversight and maintenance.

The devices also captured the time course of vital signs during sleep, in good agreement with the PSG, with relatively small differences in performance between the devices. The heart rate estimate range of both WSA and Emfit was narrower than the Association for the Advancement of Medical Instrumentation–recommended minimum allowable range of 30 to 200 bpm, with WSA having a more limited range compared with Emfit [48]. WSA performed somewhat better than Emfit at capturing heart rate trends, while Somnofy performed the best in terms of breathing rate, followed by WSA and Emfit. The decline of heart rate during the sleep period is in accordance with previous studies, although the upswing in heart rate at the end of the sleep period, which has been observed in younger participants [52], was not very clear in the data collected by any of the methods in this study. This may be because, here, we studied older participants with comorbidities including sleep apnea.

The contactless technologies provided estimates of heart rate and breathing, which, when averaged across the night, were in very good agreement with the PSG estimates. Outliers in both the breathing rate and heart rate agreement plots were found to originate from participants with severe breathing disturbances or significant abnormal cardiac rhythm. The overall agreement between contactless technology–derived estimates and the estimates derived from PSG becomes poorer when the time period over which the estimate is computed becomes shorter. This is not surprising, but it puts limitations on the use cases in which these devices can be applied. Improvement in the estimates from WSA with reducing temporal resolution was limited by the discretized or rounded output of vital signs from the WSA, with 50% of the estimates having a minimum error of 1 bpm.

At 1-minute resolution, the undermattress devices had an acceptable accuracy with an MAE of <2.12 bpm and an MAPE of <5% for heart rate estimates, which is lower than the errors reported in the literature for wearable technologies during daily activities and for many contactless technologies during sleep

[24,27]. The breathing rate estimates at 1-minute resolution were acceptable across all 3 devices with an MAE of ≤ 1.6-cpm and an MAPE of >12% and were comparable to other contactless technologies in previous evaluations in young participants [27]. The accuracy of both the vital signs estimates was higher during sleep than in the wake period primarily due to reduced body movements. Somnofy, the best-performing device in estimating breathing rate, was also the best-performing device in our evaluation of sleep stage classification performance [35].

Although in our evaluation of older participants, all the compared contactless devices provided acceptable performance, this performance was poorer than what was previously reported in studies (Emfit and Somnofy) in a younger population. In the evaluation conducted by Ranta et al [32] in a population of 34 participants with a median age of 32 years, the Emfit had an MAE of 1.34 bpm for heart rate and an MAE of 0.59 cpm for breathing rate. In contrast, in the evaluation conducted by Toften et al [31], Somnofy had an MAE of 0.18 cpm in a population of 37 participants with a mean age of 32.6 years. Although the vital sign estimates from WSA have been used in large-scale studies, there is no existing evaluation of the WSA-estimated vital signs in the literature to the best of our knowledge [53,54].

The higher accuracy of Somnofy in estimating breathing rate compared with the undermattress devices can be attributed to the device not estimating breathing rate when the signal quality is affected by body movements. Although this leads to some loss of data, this also leads to better accuracy, highlighting the need for a signal quality index associated with the device-generated vital signs estimates.

Finally, our evaluation revealed that the WSA snore and BDI estimates were accurate, and the performance of the WSA AHI in terms of MAE in our study (MAE 6.49 events per hour; n=29) was better than the results reported by Edouard et al [55] (MAE 9.5 events per hour; N=118; mean age 49.3 years). The variability of WSA AHI across nights, as seen in Figure S8 in Multimedia Appendix 1, highlights the ability of contactless monitoring devices like WSA to capture fluctuations in obstructive sleep apnea and their potential to play a crucial role in understanding changes in daytime function, comorbid conditions, and personalized management.

To the best of our knowledge, WSA snore has not been previously evaluated in other studies. The breathing disturbance detection has been performed using Emfit raw ballistography data in the literature, but these algorithms are not open source or available directly from the manufacturer and hence not used in our analysis [56,57]. The availability of these breathing disturbance estimates, along with the acceptable agreement of the vital sign measures generated by the contactless technologies, demonstrates their immediate potential usefulness in population-wide deployment for home monitoring and care [58].

Limitations

One of the limitations of the work is that the data synchronization of the PSG reference data and the device data is based on the best alignment of the vital signs data and hypnogram, which is not ideal. Second, the algorithms used by the different devices in deriving the ballistography signal and heart rate and breathing rate information are hidden due to their proprietary nature, and hence the interpretability of several observations made in this study such as the bounded nature of the output vital signs, outliers, and unavailability of data is limited. Due to a lack of detailed documentation on the snore-detection approach used by WSA, the minimum intensity of the snoring that is detected as a snoring event by WSA is unclear. Finally, out of the compared contactless devices, the Somnofy radar does not provide heart rate estimates, which is a limitation.

Conclusions

With their ability to reliably collect heart rate, breathing rate, and breathing disturbance data longitudinally and at scale, contactless technologies have the potential to be a powerful tool for unintrusive remote vital signs monitoring in community-dwelling older adults and people living with dementia. Applications range from early detection of abnormalities and deterioration of health to monitoring the impact of interventions to improve health (eg, treatment of sleep apnea). This is particularly valuable for patients using prescribed medications for long-term conditions, as it may indicate the need for dosage adjustments or even discontinuation (eg, bradycardia in patients on cholinesterase inhibitors). Together, these applications could improve overall home care. They also allow for investigation into the night-to-night variation in sleep and vital signs and how this variation is associated with health outcomes and daytime function. Such approaches have already shown that night-to-night variation in sleep apnea is associated with uncontrolled hypertension [58] and that night-to-night variation in sleep continuity is associated with day-to-day variation in symptoms in people living with Alzheimer disease [59].

Acknowledgments

This work was supported by the UK Dementia Research Institute (award number UKDRI-7005) through UK DRI Ltd, principally funded by the UK Medical Research Council, and additional funding partner includes Alzheimer's Society. The authors thank the staff members of the Clinical Research Facility for their help with data collection and the members of Care Research & Technology for helpful discussions.

Data Availability

The data sets generated during and analyzed during this study are available from the coauthor CdM on reasonable request.

Authors' Contributions

KKGR conducted the data exploration and analysis and prepared the manuscript. DJD conceived the study and contributed to the writing of the manuscript. CdM, GA, HH, and VR contributed to the design of the study and were responsible for participant recruitment and screening, and study conduct. The devices were setup and data sets were downloaded and curated by DL, KKGR, GA, CdM, and VR. All the authors contributed to the data collection and finalization of the manuscript.

Conflicts of Interest

The authors declare no competing nonfinancial interests but the following competing financial interests: the Withings and Emfit devices used in this study were purchased from the manufacturers without any price reductions. The Somnofy devices used in the study were provided by Vital Things, Norway, at no cost. The manufacturers of these devices were not involved in the design and conduct of this study, the analysis and interpretation of the data, or the preparation of the manuscript.

Abstract

Background: Technological advances allow for recording and sharing health-related data in a patient-centric way using smartphones and wearables. Secure sharing of such patient-generated data with physicians would enable close management of individual health trajectories, monitoring of risk factors, and asynchronous feedback. However, most remote patient monitoring (RPM) systems currently available are not fully integrated into hospital IT systems or lack a patient-centric design.

Objective: The objective of this study was to conceptualize and implement a user-friendly, reusable, interoperable, and secure RPM system incorporating asynchronous feedback mechanisms using a broadly available consumer wearable (Apple Watch). In addition, this study sought to evaluate factors influencing patient acceptance of such systems.

Methods: The RPM system requirements were established through focus group sessions. Subsequently, a system concept was designed and implemented using an iterative approach ensuring technical feasibility from the beginning. To assess clinical feasibility, the system was used as part of the activeDCM prospective randomized interventional study focusing on dilated cardiomyopathy. Each patient used the system for at least 12 months. The System Usability Scale was used to measure usability from a subjective patient perspective. In addition, an evaluation was conducted on the objective wearable interaction frequency as well as the completeness of transmitted data classified into sensor-based health data (SHD) and patient-reported outcome measures (PROMs). Descriptive statistics using box plots and bootstrapped multiple linear regression with 95% CIs were used for evaluation analyzing the influence of age, sex, device experience, and intervention group membership.

Results: The RPM system comprised 4 interoperable components: patient devices, a data server, a data viewer, and a notification service. The system was evaluated with 95 consecutive patients with dilated cardiomyopathy (28/95, 29% female; mean age 50, SD 12 y) who completed the activeDCM study protocol. The system's app achieved a mean System Usability Scale score of 78 (SD 17), which was most influenced by device experience. In total, 87% (83/95) of the patients could integrate the use of the app well or very well into their daily routine, and 71% (67/95) saw a benefit of the RPM system for management of their health condition. On average, patients interacted with the wearable on 61% (SD 26%) of days enrolled in the study. SHD were available

on average for 78% (SD 23%) of days, and PROM data were available on 64% (SD 27%) of weeks enrolled in the study. Wearable interaction frequency, SHD, and PROM completeness were most influenced by intervention group membership.

Conclusions: Our results mark a first step toward integrating RPM systems based on a consumer wearable device for primary patient input into standardized clinical workflows. They can serve as a blueprint for creating a user-friendly, reusable, interoperable, and secure RPM system that can be integrated into patients' daily routines.

Introduction

Background

With constant advancements in digitalization, wearable devices such as smartwatches, fitness trackers, or chest straps are becoming an integral part of everyday life. These devices facilitate continuous recording and monitoring of patient-generated data, such as sensor-based health data (SHD) and electronic patient-reported outcome measures (PROMs). If these data were efficiently shared with physicians, they could gain a more comprehensive view of a patient's lifestyle and longitudinal insights into a patient's health trajectory [1]. Although most wearables are designed for the consumer market and are not primarily intended as medical devices, initial clinical trials have shown that the quality of patient-generated data from wearable consumer devices is sufficiently high to answer medical questions [2-4]. In addition, selected wearable consumer devices have been approved for various diagnostic purposes by authorities such as the US Food and Drug Administration. Especially for physical activity and cardiovascular monitoring, the development of wearables with accurate sensors is well advanced (eg, for step count as well as heart rate and electrocardiogram [ECG] measurements).

Patients show willingness to share their self-generated data with physicians, anticipating that the integration of wearables into their health care journey positively enhances their health [5]. Consequently, this holds potential for both patients and physicians to engage in collaborative health management. This can include monitoring the patient's health status; managing risk factors; and facilitating asynchronous feedback to support effective self-management, especially in the case of chronic conditions [6]. In addition, it has the potential of reducing the frequency of needed physician consultations; improving quality of life; and, ultimately, reducing long-term treatment costs [7-10].

To exploit this potential, suitable IT systems following a patient-centric design must be available. In the literature, these systems are often referred to as *telehealth*, *telemedicine*, *eHealth*, *mHealth*, or *remote patient monitoring* (RPM) systems; the terminology is used interchangeably and inconsistently [11,12]. RPM systems must be able to process and transfer large amounts of data in an automated manner and should facilitate the integration of wearable devices into a patient's everyday life as well as into standardized primary care and clinical research workflows. Methods for realizing such integrations are still immature due to numerous challenges in areas including patient digital literacy, data overload, interoperability, data privacy, data protection, and information security [13-16]. Overall, high usability and, consequently, high acceptance of RPM systems among patients during their treatment process is needed a priori. In addition, wearables are mostly used by healthy individuals as lifestyle devices [17] or for early disease detection in younger adults, such as in the Apple Heart Study [18] or the Fitbit Heart Study [19].

Objectives

In its position papers on wearable-based detection of arrhythmias [20] and eCardiology [21], the German Cardiac Society and other international organizations emphasize the benefits of wearables and RPM systems for primary care and clinical research, including the treatment of heart failure. This chronic disease has a high worldwide prevalence, with an estimate of up to 64 million individuals affected. In high-income countries, it is assumed that 1% to 2% of the adult population has heart failure [22]. These patients usually have multiple contact with health care providers each year; the rehospitalization rates can approach 30% within 90 days of discharge [23]. RPM systems have been shown to detect early health deterioration of patients with chronic heart failure, triggering therapeutic interventions that could reduce rehospitalizations. Overall, approximately 30% to 40% of patients with heart failure have nonischemic cardiomyopathy, such as dilated cardiomyopathy (DCM) [24]. Patients with DCM face physical and quality of life limitations and are often young. In the past, they have been discouraged from physical activity [25]. However, exercise has, in principle, been shown to positively impact morbidity, quality of life, and patients' psychological state, which in turn enhances their physical well-being [26-28]. Sports-related complications, such as ventricular arrhythmias, can counteract the positive effects. Therefore, the activeDCM study [29] investigated the impact of an individualized exercise program in patients with DCM. In this paper, we introduce the RPM system used in activeDCM, detailing its conceptualization, implementation, and evaluation. The objective of this study was to create a user-friendly, reusable, interoperable, and secure RPM system incorporating asynchronous feedback mechanisms using a broadly available consumer wearable device for primary patient input. In addition, this study sought to evaluate factors influencing patient acceptance of the developed RPM system.

Methods

Study Design

activeDCM was designed as a prospective, randomized, interventional case-control study and is described by Sedaghat-Hamedani et al [29]. The primary outcome measure of activeDCM was defined as the change in maximum oxygen uptake, whereas the secondary outcome measures focused on changes in quality of life and behavioral lifestyle. The inclusion criteria for patients were age between 18 and 75 years and diagnosis of nonischemic DCM (left ventricular ejection fraction of ≤50% and New York Heart Association Classification of I-III). The exclusion criteria were acute myocarditis or Takotsubo syndrome; known or suspected ischemic heart disease; known syndromic DCM; history of syncope, cardiac arrest, sustained ventricular tachycardia, or cardiac decompensation within the previous 3 months; contraindications for exercise testing or training; and pregnancy or breastfeeding in women. Patients were identified during initial presentations or routine examinations at the outpatient center for cardiomyopathies at Heidelberg University Hospital and were screened against the inclusion and exclusion criteria by a physician familiar with the study. Participation in the study lasted at least 12 months for each patient. On the day of enrollment, patients were randomly assigned to one of three study arms: (1) intervention group with an individualized exercise program and feedback messages (IG+), (2) intervention group with an individualized exercise program but without feedback messages (IG–), and (3) control group (CG).

Requirements

Using the focus group methodology [30], the following requirements for a patient-centric RPM system were systematically delineated through collaborative sessions involving cardiologists (n=3), mobile health experts (n=2), and potential users (n=2) affiliated with Heidelberg University Hospital, Germany.

The functional requirements were as follows:

1. Patients should use a wearable as primary input device. They should be equipped with a wearable by the study team and not use their own device.
2. Patients should be able to record and transmit patient-generated data (ie, the SHD steps, active burned energy, heart rate, and ECG as well as the PROMs of a study-specific, weekly 7-part questionnaire and an optional exercise diary) in near real time to the study center.
3. Physicians should be able to send personalized feedback messages to patients with motivational content about the individualized exercise program.
4. Physicians should be able to review the substantial volume of transmitted patient-generated data in a streamlined format.

The nonfunctional requirements were as follows:

1. The RPM system should prioritize usability, thereby minimizing barriers to integrating the wearable into patients' daily routines as many patients are older and a prestudy showed little penetration of wearable devices in this cohort (data not shown).
2. The RPM system should be based on medical IT standards for interoperability.
3. The RPM system should meet the regulatory requirements for data privacy and data protection as well as provide state-of-the-art information security.
4. The RPM system should be usable beyond the activeDCM study.

Concept and Implementation

On the basis of the identified requirements, a concept of an RPM system with asynchronous feedback mechanisms was designed and subsequently implemented using an iterative approach. In each iteration, a new module of patient-generated data or for feedback messages was added to the system. Throughout the implementation process, a test environment was available, allowing for the immediate testing of each newly added module. This facilitated short feedback cycles with test participants and physicians from the activeDCM study and ensured the technical feasibility of a patient-centric RPM system.

The final concept, as well as the implementation, consisted of 4 main components: patient devices, data server, data viewer, and notification service (see the Results section). The patient devices used in this study included an iPhone (SE generation 1 or newer) and an Apple Watch (Series 4 or newer, generously provided by Apple Inc). A study-specific wearable and smartphone app was implemented using the Swift programming language (version 5.1; Apple Inc) [31] for the operating systems of both devices (ie, iOS version 14 and watchOS version 7). The extraction of the SHD (steps, active burned energy, heart rate, and ECG) was based on the Core Motion [32] and HealthKit [33] frameworks for iOS and watchOS development. The PROMs (study-specific, weekly questionnaire and optional exercise diary) were recorded by means of a self-designed user interface using Apple's UIKit [34] framework. The transfer of data from the Apple Watch to the iPhone and vice versa was based on the iOS and watchOS Watch Connectivity protocol [35]. The data storage on the iPhone was based on the Realm database (version 5.5; MongoDB Inc) [36].

The implementation of the data server as well as the transmission of the patient-generated data was based on the standardized application programming interface (API) and the standardized data model of Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR) version R4 [37], as well as the Logical Observation Identifiers Names and Codes (LOINC) [38] and the Unified Medical Language System (UMLS) [39] (see the Data Model section) in the Java programming language (version 11; Oracle Corporation) [40] using the HAPI library (version 5.2) [41]. The database technology used was PostgreSQL (version 12; PostgreSQL Global Development Group) [42].

The physician data viewer component was implemented as a mobile-first TypeScript (version 4.1; Microsoft Corp) [43] web application using the vue.js framework (version 2) [44] and the chart.js library (version 2) [45]. The notification service was provided by the device manufacturer (ie, Apple Inc). Local on-device and remote push notifications for the patient devices

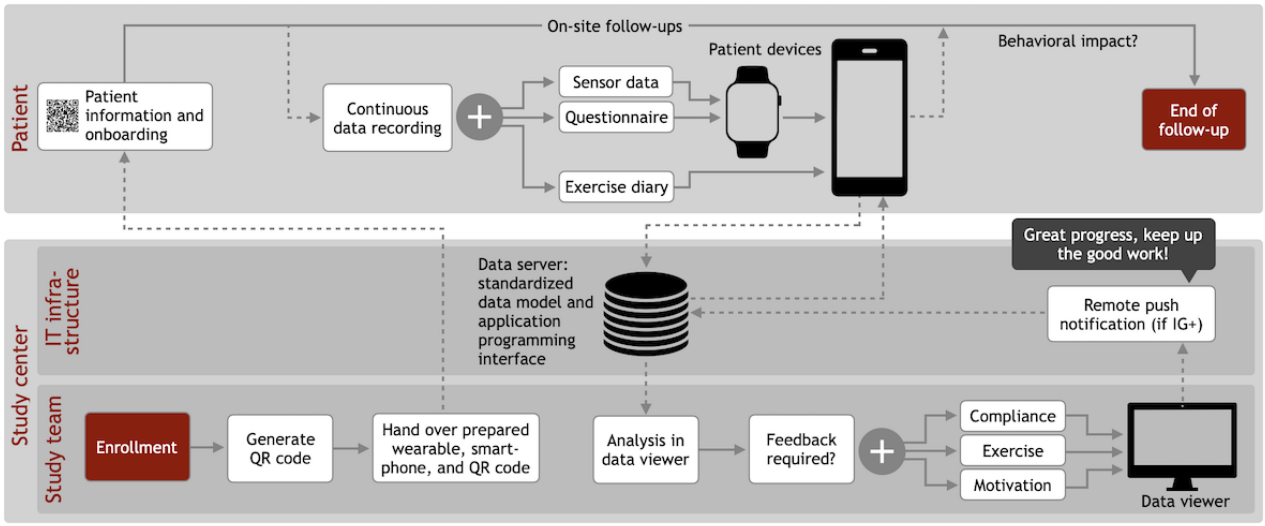
were implemented using the User Notifications [46] framework for iOS and watchOS development.

The aforementioned version numbers correspond to the ones at the beginning of the implementation process and were regularly updated during the use of the RPM system if new applicable versions were released or APIs changed. These updates did not change any functionality or user interfaces of any component.

Procedure

To ensure both technical and clinical feasibility, the RPM system was used in the activeDCM study following a procedure that was developed in addition to the requirements as part of the focus group sessions. The procedure is illustrated in Figure 1. On the day of enrollment, patients were randomized to 1 of the 3 study arms and provided with a configured device bundle consisting of a consumer wearable (Apple Watch Series 4 or newer) and a smartphone (iPhone SE generation 1 or newer) on which the corresponding app of the RPM system was preinstalled. Patients were not provided with a mobile data volume contract for the devices; instead, they were required to set up a Wi-Fi connection at their home. After a thorough patient educational session regarding the study and the RPM system covering instructions on use of the wearable and smartphone, including the RPM-specific app and how to launch a workout session with resultant increased frequency of activity measures, patients signed the written informed consent form. After that, they were onboarded to the app by scanning a patient-specific QR code using the smartphone's camera. From this point forward, the required SHD were continuously recorded by the wearable. The synchronization of the recorded data with the study center was confirmed by patients through a short daily interaction with the wearable. In addition, patients were asked to answer 1 randomly selected question daily from the study-specific, weekly 7-part PROM questionnaire [47], requiring a second daily interaction. To remind patients of these 2 mandatory interactions with the wearable, they were alerted daily at 11 AM and 5 PM with local on-device push notifications sent directly by the wearable app. An interaction with the smartphone was not mandatory but could take place to keep an optional PROM exercise diary, which was synchronized with the study center as well. Each patient was part of the activeDCM study over a period of at least 12 months. Patients were allowed to withdraw at any time from the study. During participation in the study, patient-generated data were collected and transmitted from the wearable via the smartphone to the study center, which in turn provided feedback messages to the patients in the corresponding intervention group (IG+). Feedback messages containing motivational content about the individualized exercise program were sent by a physician using the study center's data viewer approximately every 7 to 10 days using remote push notifications.

Figure 1. Use of the remote patient monitoring (RPM) system in the activeDCM study. After onboarding, patients are equipped with devices whose RPM system app is activated by scanning a patient-specific QR code. Patient-generated data are then continuously recorded and transmitted to the study center until the end of follow-up. Physicians analyze the data and send feedback messages to the patients' devices if appropriate. IG+: intervention group with feedback messages.



Evaluation

The evaluation of the RPM system was conducted in 2 parts. First, to assess patients' subjective perspectives on the RPM system, a 2-part evaluation questionnaire was used to address the following two end points: (1) the first part of the evaluation questionnaire asked about experience (no: without previous device experience [Exp–], yes: with previous device experience [Exp+]) using Apple devices (iPhone or Apple Watch) before participating in the activeDCM study and used a German version [48] of the standardized System Usability Scale (SUS) [49] to assess user-friendliness, and (2) the second part contained 5 self-designed questions to assess patients' attitudes toward the use of an RPM system for disease management.

Both parts of the evaluation questionnaire—the SUS and self-designed questions—used a 5-point ordinal Likert scale with each item ranging from *strongly disagree* to *strongly agree*. An SUS value of >68 was considered user-friendly [50]. The evaluation questionnaire was administered to each patient at completion of the activeDCM study protocol after at least 12 months and can be found in Multimedia Appendix 1.

Second, to assess patients' objective use of the wearable and the interaction with the study-specific wearable and smartphone app, three additional end points were evaluated: (3) to assess *wearable interaction frequency*, the number of days with at least one wearable interaction (either SHD transmission or answering a PROM questionnaire item) was compared with the total number of days that a patient was enrolled in the study; (4) *SHD completeness* was assessed by comparing the days with available SHD on the data server with the total number of days that a patient was enrolled in the study; and (5) finally, to assess *PROM completeness*, the number of completed and available PROM questionnaires on the data server was compared to the total number of PROM questionnaires expected to be completed during the study period (1 per week).

The statistical analysis of all 5 end points was conducted using descriptive statistics incorporating box plots. Continuous variables were described using mean and SD, and categorial variables were described using absolute and relative frequencies. Assessment of differences in the patient demographics of the evaluation groups was performed using the Kruskal-Wallis test [51] for continuous variables. For categorical variables, the Pearson chi-square test [52] was used.

As the number of days for which each patient participated in the activeDCM study varied, we calculated relative values for end points 3, 4, and 5 for each patient. We then described these relative values using mean and SD and used them for further statistical analysis. For comprehensiveness, we reported the ratio of mean absolute values in days and weeks across all patients for end points 3, 4, and 5 as well. However, the mean of the relative values offers a more detailed understanding of the differences between patients and produces more accurate results than the ratio of mean absolute values. It is important to note that these 2 measures are not mathematically equivalent.

Furthermore, bias-corrected and accelerated bootstrapped multiple linear regression [53] was performed to investigate evaluation group differences in the SUS, patient wearable interaction frequency, and SHD or PROM completeness. Thus, the outcome (dependent) variables were the SUS score, patient wearable interaction frequency, and SHD or PROM completeness after activeDCM study protocol completion. As independent variables, age in years at activeDCM study protocol completion, sex, device experience (no: Exp–, yes: Exp+), and study arm membership (CG, IG–, IG+) were chosen before the analysis. The analysis involved 10,000 bootstrap resampling distributions applying a CI of 95%. CIs not including 0 were considered as significant (P<.05). The analysis was conducted using Python (version 3.10; Python Software Foundation) [54] using the packages *scipy.stats.kruskal* (version 1.11.1) [55], *scipy.stats.chi2_contingency* (version 1.11.1) [56], *scipy.stats.bootstrap* (version 1.11.1) [57], and *statsmodels.regression.linear_model.OLS* (version 0.14.0) [58].

Due to the exploratory characteristics of this study, the analysis is intended for hypothesis generation only; thus, P values were not adjusted for multiplicity, and P<.05 was regarded as significant.

Ethical Considerations

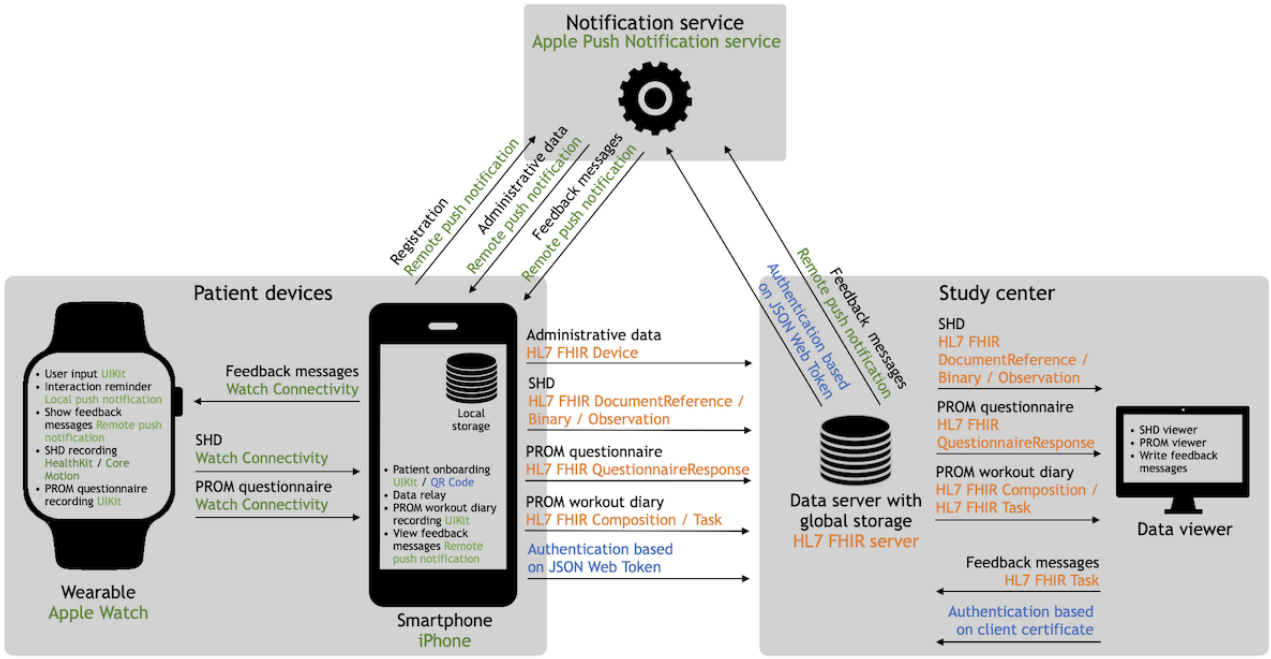
The activeDCM study, as well as its RPM system concept, its implementation, and its evaluation method, received ethics approval from Heidelberg University's research ethics committee (reference numbers S-740/2018 and S-740/2021). The study is registered on ClinicalTrials.gov (NCT04359238). It adheres to the principles of the Declaration of Helsinki and good clinical practice guidelines. Participation in the activeDCM study was voluntary and patients received no compensation. An Apple Watch (Series 4 or newer) and an iPhone (SE generation 1 or newer) were provided during participation in the activeDCM study. After study completion these devices had to be returned to the study team. A written informed consent form was signed by each patient participating in the study. In addition, the RPM system's data protection concept and its security mechanisms were audited by the data protection officer of Heidelberg University Hospital. No deficiencies were identified regarding data privacy, data protection, and information security.

Results

Concept

On the basis of the identified requirements, a concept of a patient-centric RPM system with asynchronous feedback mechanisms was designed. It consisted of 4 interoperable components: patient devices (ie, a smartphone and a connected consumer wearable device, both having a corresponding RPM system app installed), a data server, a data viewer, and a notification service. A graphical representation of the concept and its implementation can be found in Figure 2 summarizing the key features and functionalities of the individual components. In this concept, the smartphone was used for patient onboarding and as a data relay with local storage for data transmission to the data server, which was located at the study center. The wearable was intended to be the patient's primary input device. It was used to record SHD as well as collect PROMs to transmit these patient-generated data to the data server, relayed via the smartphone. In addition, the wearable was supposed to remind patients about necessary interactions and display personalized feedback messages, which were received from the notification service and forwarded by the smartphone. The data server was responsible for global storage of patient-generated data and feedback messages in a standard-compliant, interoperable manner. In addition, it made patient-generated data available to the data viewer. The data viewer, operated at the study center, allowed physicians to analyze patient-generated data and send personalized feedback messages to the data server. These feedback messages were stored on the data server and transmitted to the notification service. The notification service was responsible for identifying the smartphone that would receive the forwarded feedback messages. For the notification service to uniquely identify a smartphone, the latter must undergo an initial registration process during patient onboarding. At the end of this process, administrative data were generated and forwarded from the smartphone to the data server. The data server used the administrative data to identify the smartphone when forwarding feedback messages to the notification service.

Figure 2. Architecture of the remote patient monitoring system with asynchronous feedback mechanisms describing the 4 main components and their interaction. Black writing shows the initial concept, and colored writing shows concepts realized subsequently as part of the implementation. The services, frameworks, and protocols of the Apple ecosystem are shown in green; the standardized data model based on Health Level Seven (HL7) Fast Healthcare Interoperability Resources (FHIR) are shown in orange; and the authentication mechanisms are shown in blue. PROM: patient-reported outcome measure; SHD: sensor-based health data.



Implementation

Overview

The described concept was subsequently implemented for the activeDCM study. For patient devices, an iPhone (SE generation 1 or newer) was used as the smartphone, and an Apple Watch (Series 4 or newer) was used as the wearable for which a study-specific app was implemented. Selected screenshots of the Apple Watch app can be found in Figure 3. The onboarding of a patient to the RPM system was based on scanning a patient-specific QR code on the iPhone's app. After that, SHD recording started immediately on the Apple Watch. Security mechanisms permitting data access and extraction from HealthKit exclusively if the device was unlocked forced the extraction of SHD on the Apple Watch app, which must be unlocked during interaction. Each type of SHD and PROM was implemented in its own module so that each module could be activated and deactivated independently of one another. To remind patients to answer the daily question of the PROM questionnaire and transfer patient-generated data to the study center, local on-device notifications were implemented directly as part of the Apple Watch app.

Figure 3. Screenshots of the Apple Watch app. (A) and (B) show the daily notification to remind patients about answering 1 question of the 7-part weekly patient-reported outcome measure (PROM) questionnaire. (C) and (D) show the user interface to enter 1 of 2 different answer types for the PROM questionnaire—(C) allows for entering a star rating between 1 and 4, and (D) allows for entering a Boolean answer using yes or no. (E) shows the user interface during the transmission of the patient-generated data to the study center.

Transmission of patient-generated data from the Apple Watch to the iPhone was executed using background processes triggered by interactions with the Apple Watch on-device notifications. Transmission errors between Apple Watch and iPhone were displayed to the patient in the user interface, cached, and retried on the next transmission. Once the patient-generated data had been transmitted to the iPhone, they were forwarded again through background processes to the data

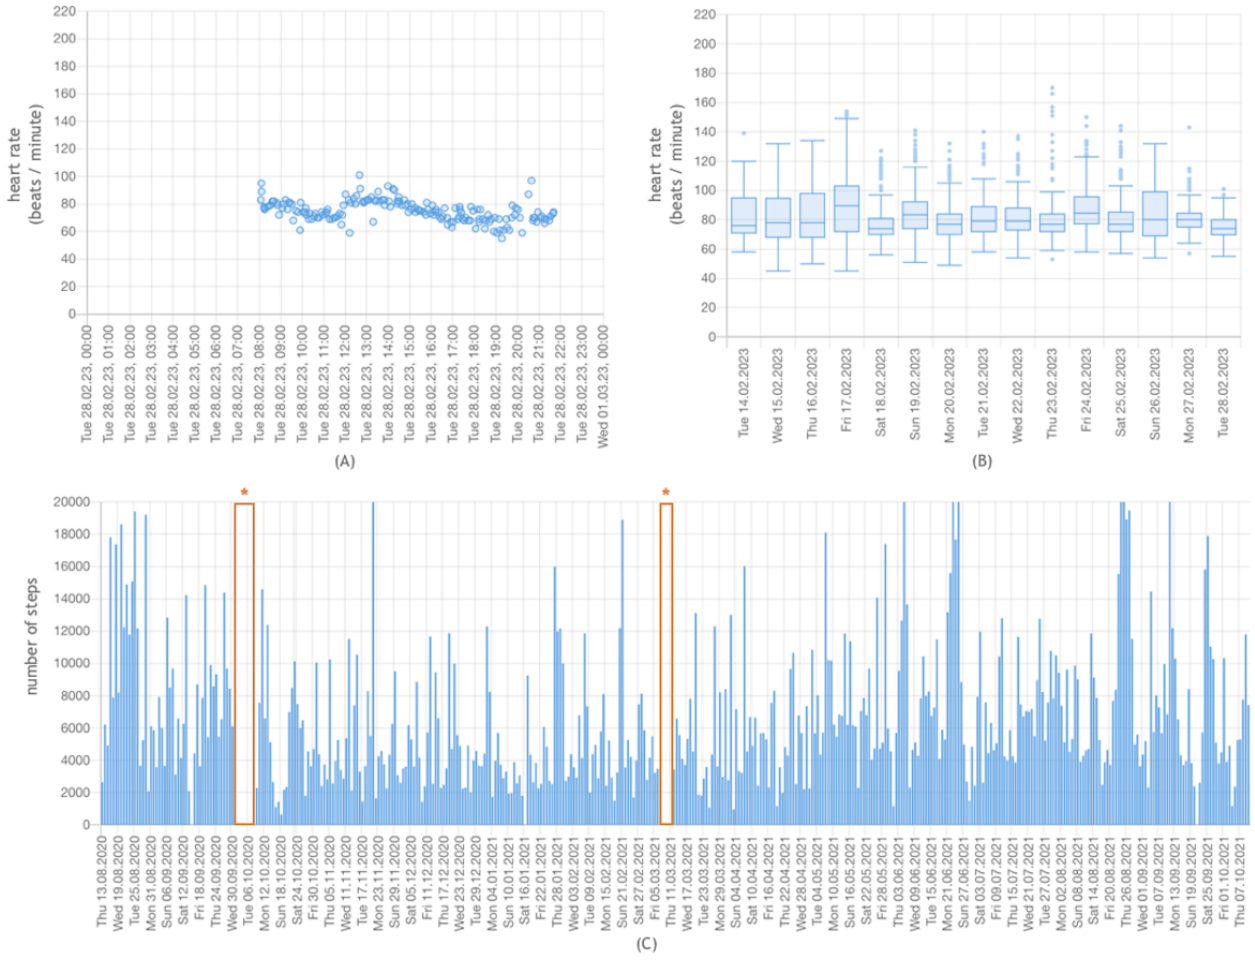
server without any user interaction. This meant that no patient interaction with the iPhone was necessary. It could remain plugged into a power supply socket for the duration of the study and did not have to be carried around. Data transmissions used the standardized HL7 FHIR API provided by the data server. Each data transmission from the iPhone to the data server was recorded with an audit message, which could be viewed by a patient on the user interface of the iPhone app. If a transmission error occurred, the patient-generated data were temporarily stored in an encrypted local database, and the transmission was retried during the next scheduled data transfer to the data server.

The data server provided global storage of patient-generated data and feedback messages using standardized HL7 FHIR R4 resources as a data model. In addition, it executed algorithms periodically to check the date and time of the last data transmission of each patient. If >5 days had passed since a patient's last data transmission, an automated feedback message was sent to the patient's devices with a request to synchronize data.

The data viewer retrieved patient-generated data via the HL7 FHIR API and displayed them through a self-designed user interface. Data transmitted by a patient could be viewed at several levels of granularity (ie, data for a single day, data for 2 weeks, data for 1 month, or all recorded and transmitted data since study enrollment). Depending on the data type, they were presented using different visualization formats: (1) bar plots illustrated various granularities of active burned energy and step data, (2) scatter plots were used for daily heart rate views, and (3) box plots were used for 2 weekly and all-data heart rate views.

If all the data of a patient since study enrollment were displayed, the visualization was zoomable so that a closer look at areas of interest was possible. Selected screenshots of the data viewer user interface can be found in Figure 4. A screencast showing the functionality of the data viewer (with a German user interface) can be found in Multimedia Appendix 2.

Figure 4. Screenshots of the data viewer application for 1 patient; (A) shows the recorded and transmitted heart rate data of a single day as a scatter plot; (B) shows the recorded and transmitted heart rate data over 2 weeks as daily box plots; (C) shows the recorded and transmitted step counts for all days included in the study as a zoomable bar plot, where asterisks indicate days without any recordings or transmissions, for example, because the wearable was not worn.



To receive remote push notifications from the study center, the patient's iPhone registered itself with Apple Push Notification service (APNs) directly after onboarding. APNs provided a device-specific identifier, which was forwarded by the iPhone app to the data server of the study center as administrative data. On the basis of the device identifier, the data server could forward a feedback message received from the data viewer to the APNs server after the message was transformed from the

standardized HL7 FHIR format to the APNs-required proprietary format. The device identifier then enabled the APNs server to forward the feedback message as a remote push notification to the patient's devices. Each feedback message was recorded, in addition to an audit message on the iPhone, and could be viewed by a patient in the app's user interface.

Data Model

The data model was based on standardized HL7 FHIR R4 resources to establish syntactic interoperability. A patient was identified by a *Patient* resource containing the patient's study pseudonym. The *Device* resource stored the device-specific identifier provided by APNs, which was needed to send and retrieve feedback messages via remote push notifications and linked to the *Patient* resource. Feedback messages were modeled using the *Task* resource, which contained information such as title, message, category, and recipient, which was a reference to the *Patient* resource. The SHD steps, active burned energy, and heart rate were modeled using the *Observation* resource. For steps and active burned energy, the recorded data were summarized in 1-hour intervals. For heart rate, 25 consecutive measurements were listed and transferred in 1 *Observation* resource to reduce network calls. The *DocumentReference* resource was used to store metadata related to ECG data, such as recording date, classification, and average heart rate. In addition, it referenced a *Binary* resource to transport the actual ECG recording (512 Hz; 30 seconds) as millivolt values in a CSV file. The PROM questionnaire was based on the *Questionnaire* resource, which contained the questions to be answered weekly, and the *QuestionnaireResponse* resource, which stored a patient's completed questionnaire. The exercise diary was based on the *Composition* resource, which stored the date of a completed workout and was linked to several *Task* resources containing information about the executed strength and endurance exercises during the workout.

To establish semantic interoperability with other clinical information systems (eg, from primary care), the SHD were annotated using LOINC codes, and the PROM questionnaire was annotated using postcoordinated UMLS codes. For semantic annotation of the PROM exercise diary, we used a self-defined code system based on the exercise program. HL7 FHIR profiles, concrete resource examples, and validation information for the data model can be found in Multimedia Appendix 3.

Security, Authentication, and Authorization

For general security, all messages exchanged between the components of the RPM system were encrypted using Transport Layer Security [59] using a minimum version of 1.2. The Realm database used to cache patient-generated data on the iPhone was encrypted using the Advanced Encryption Standard-256+Secure Hash Algorithm 2 algorithm and could not be analyzed if the device was lost. The encryption key of the database was stored in the secure Keychain [60] of the iPhone and could only be accessed through the iPhone app.

Authentication and authorization to the RPM system distinguished between the roles of patient and study center staff using distinct technical approaches for each. For the patient role, the QR code scanned during onboarding contained a signed JSON Web Token (JWT) [61] valid for study enrollment, storing authentication information and the patient's pseudonym in the iPhone's secure Keychain. This JWT was used when transmitting patient-generated data, ensuring authentication and data provenance. The role of study center staff, authenticated using X.509 client certificates [62], could retrieve patient-generated data and stored push notifications on the data server. Revoking compromised certificates or JWTs was managed via configuration options on the data server. The server's authentication to APNs used a JWT as well that was signed and encrypted by the study center data server using a private key from Apple that was revocable on the Apple developer website if compromised.

Evaluation

The evaluation of the RPM system was carried out with patients who completed the activeDCM study protocol between October 2021 and February 2024 (N=110). A total of 13.6% (15/110) of the patients were excluded from the evaluation because of missing answers in the evaluation questionnaire on experience or SUS answers. The evaluated cohort consisted of 95 patients (n=28, 29% female) with a mean age of 50 (SD 12) years at the end of study participation. Of these 95 patients, 39 (41%) had previous experience using Apple devices (Exp+, n=30, 77% using iPhone only and n=9, 23% using iPhone and Apple Watch), and 56 (59%) had no experience (Exp–) at the time of enrollment in the study. A total of 26% (25/95) of the patients were randomized into the intervention group with an individualized exercise program and feedback messages (IG+), 36% (34/95) were randomized into the intervention group with an individualized exercise program but without feedback messages (IG–), and 38% (36/95) were randomized into the CG study arm. The mean enrollment time of these patients in the activeDCM study was 396 (SD 39) days, which corresponds to 56 (SD 5) weeks. The baseline characteristics of the evaluated patient cohort are summarized in Table 1.

Table 1. Baseline characteristics of patients by device experience and study arm membership in the activeDCM study (N=95).

Variable	Total sample	Exp–[a] (n=56)	Exp+[b] (n=39)	CG[c] (n=36)	IG–[d] (n=34)	IG+[e] (n=25)
Sex, n (%)[f]						
Male	67 (71)	40 (71)	27 (69)	27 (75)	24 (71)	16 (64)
Female	28 (29)	16 (29)	12 (31)	9 (25)	10 (29)	9 (36)
Age (y)[g], mean (SD; range)	50 (12; 23-66)	51 (10; 23-66)	49 (13; 24-66)	50 (11; 24-65)	48 (13; 23-66)	53 (11; 24-66)
Time in study (d)[h], mean (SD; range)	396 (39; 315-625)	398 (44; 315-625)	394 (30; 330-456)	402 (50; 315-625)	395 (28; 336-448)	389 (31; 330-484)

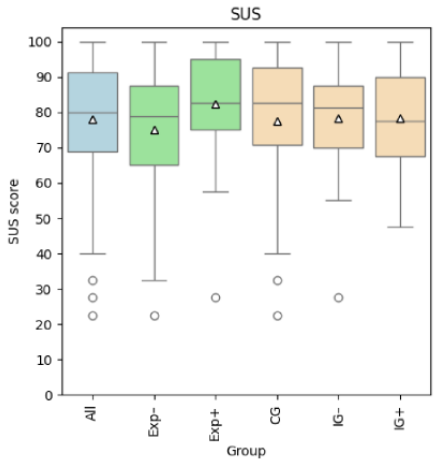
The results of the patients' subjective perspective on the RPM system based on the evaluation questionnaire were divided into 2 end points. The results of the first end point, analyzing the usability of the wearable and smartphone app based on the SUS, are summarized using box plots in Figure 5. The app achieved a mean SUS score of 78 (SD 17). A total of 25% (24/95) of the patients reported an SUS score of <68 (insufficient usability), of whom 75% (18/24) were aged >50 years and 75% (18/24) had no previous experience using Apple devices (Exp–). Patients with previous experience using Apple (Exp+) devices rated usability more highly, with a mean SUS score of 82 (SD 15), compared with patients without any experience (Exp–), who reported a mean SUS score of 75 (SD 18). There were no major differences among patients in the study arms. Patients in the intervention group with feedback messages (IG+) reported a mean SUS score of 78 (SD 15), patients in the intervention group without feedback messages (IG–) reported a mean score of 78 (SD 15), and patients in the CG reported a mean score of 77 (SD 20).

Figure 5. Results of the wearable and smartphone app usability analysis using the System Usability Scale (SUS) displayed as box plots. All data combined are shown in blue, experience using Apple devices is shown in green, and study arm membership is shown in orange. Triangles show mean values. CG: control group; Exp–: without previous device experience; Exp+: with previous device experience; IG–: intervention group without feedback messages; IG+: intervention group with feedback messages.



As shown in Table 2, the bias-corrected and accelerated bootstrapped multiple linear regression analysis of the SUS scores resulted in a significant effect for those with previous experience (Exp+) with a 95% CI of 0.25-13.47 and an estimate of 6.75. This means that patients with Apple device experience were estimated to rate the usability of the wearable and smartphone app 6.75 points higher on the SUS than patients without Apple device experience. This is similar to the measured differences in SUS scores between those without and with previous experience (7-point difference). Age approached significance with a 95% CI of −0.46 to 0.14. The estimate of −0.19 showed that a 40-year age difference between 2 patients was estimated to result in a 7.60-point worse SUS score for the wearable and smartphone app from the older patient.

Table 2. Bias-corrected and accelerated bootstrapped multiple linear regression analysis of the System Usability Scale (SUS) scores, the wearable interaction frequency (percentage of days enrolled in the study), the sensor-based health data (SHD; percentage of days enrolled in the study), and patient-reported outcome measure (PROM) completeness (percentage of weeks enrolled in the study).

Variable	Estimate, mean (95% CI)
SUS score	
Sex (male)	−3.61 (−10.35 to 4.54)
Age	−0.19 (−0.46 to 0.14)

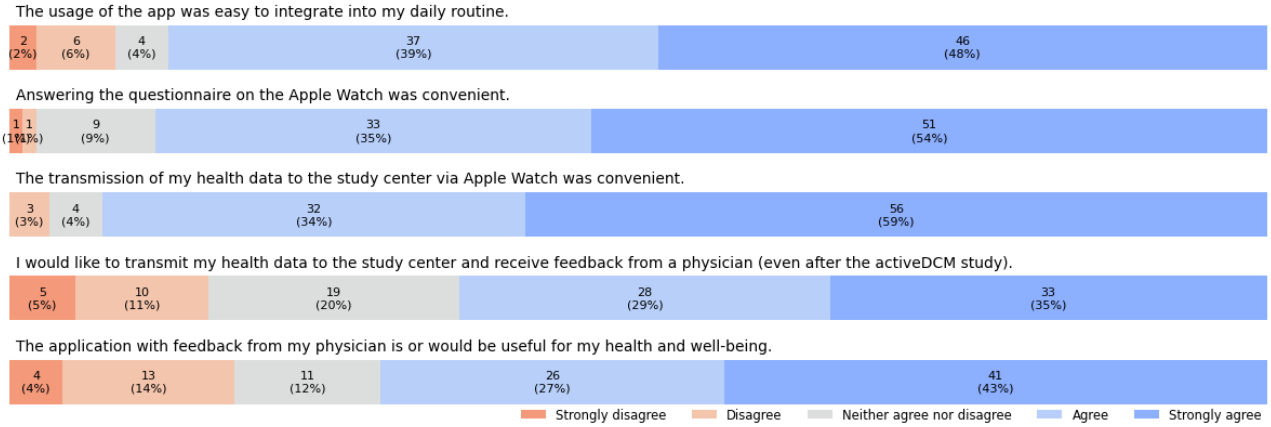
[d]IG–: intervention group without feedback messages.

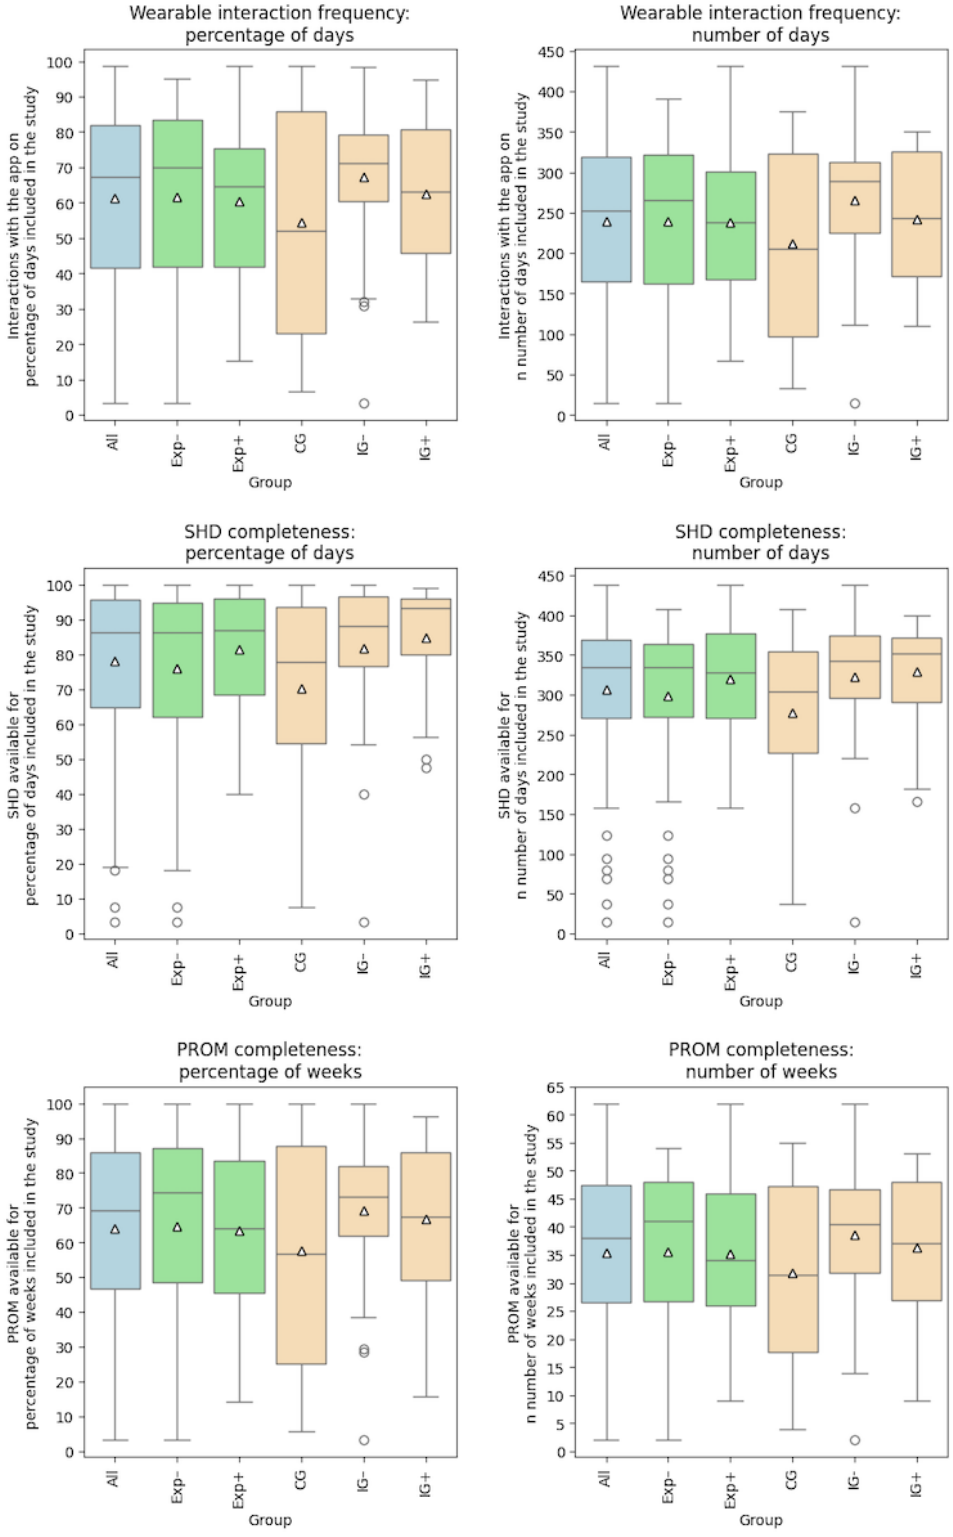
The results of the second evaluation questionnaire end point, regarding the 5 self-designed questions about the patients' attitudes toward using the RPM system as well as their participation in the study, are shown in Figure 6. A total of 87% (83/95) of the patients (strongly) agreed that the use of the app was easy to integrate into their daily routine. Similarly, 88% (84/95) and 93% (88/95) of the patients considered answering the PROM questionnaire and transmitting their SHD to the study center via Apple Watch as convenient, respectively. In total, 64% (61/95) of the patients would like to submit their health data to the study center and receive feedback from a physician (even after the activeDCM study), and the app with feedback from their physician was or would be useful for 71% (67/95) of the patients regarding their health and well-being.

Figure 6. Results of the 5 self-designed questions regarding the patients' attitudes toward using the remote patient monitoring system as well as their participation in the activeDCM study. Responses to the statements were provided by patients using a 5-point ordinal Likert scale ranging from strongly disagree in orange to strongly agree in blue.



In Figure 7, the results of patients' objective use of the wearable device are summarized using box plots, showing wearable interaction frequency and SHD as well as PROM completeness for end points 3, 4, and 5. On average, patients interacted with the wearable app on 61% (SD 26%) of the days that they were enrolled in the study, which corresponds to 239 (SD 99) of 396 (SD 39) days. On average, SHD were available for 78% (SD 23%) of the days that patients were enrolled in the study, which corresponds to 307 (SD 87) of 396 (SD 39) days. In terms of PROM questionnaires answered, data were available on average for 64% (SD 27%) of the weeks that the patients were enrolled in the study, which corresponds to 35 (SD 15) of 56 (SD 5) weeks. There were no major differences between those without and with previous experience (wearable interaction frequency: mean 62%, SD 27% of days [240, SD 103 of 398, SD 44 days] vs mean 60%, SD 23% of days [238, SD 91 of 394, SD 30 days], respectively; SHD completeness: mean 76%, SD 25% of days [299, SD 97 of 398, SD 44 days] vs mean 81%, SD 17% of days [319, SD 69 of 394, SD 30 days], respectively; PROM completeness: mean 65%, SD 28% of weeks [36, SD 15 of 56, SD 6 weeks] vs mean 63%, SD 24% of weeks [35, SD 14 of 56, SD 4 weeks], respectively). Only the dispersion of the data was slightly narrower for those with previous experience (Exp+). Regarding the 3 different study arms, the interaction with the wearable was more frequent and patient-generated data completeness was higher in both the IG– (wearable interaction frequency: mean 67%, SD 20% of days [266, SD 84 of 395, SD 28 days]; SHD completeness: mean 82%, SD 20% of days [322, SD 80 of 395, SD 28 days]; PROM completeness: mean 69%, SD 21% of weeks [39, SD 12 of 56, SD 4 weeks]) and IG+ (wearable interaction frequency: mean 62%, SD 20% of days [242, SD 78 of 389, SD 31 days]; SHD completeness: mean 85%, SD 16% of days [330, SD 63 of 389, SD 31 days]; PROM completeness: mean 67%, SD 23% of weeks [36, SD 12 of 55, SD 4 weeks]) than in the CG (wearable interaction frequency: mean 54%, SD 31% of days [212, SD 115 of 402, SD 50 days]; SHD completeness: mean 70%, SD 26% of days [277, SD 99 of 402, SD 50 days]; PROM completeness: mean 58%, SD 32% of weeks [32, SD 17 of 57, SD 7 weeks]). In both the IG+ and IG–, the dispersion of the data was smaller than in the CG.

Figure 7. Results of patients' wearable interaction frequency as well as completeness of recorded and transmitted patient-generated data classified into sensor-based health data (SHD) and electronic patient-reported outcome measures (PROMs) of the wearable and smartphone app as box plots. All data combined are shown in blue, experience using Apple devices is shown in green, and study arm membership is shown in orange. Triangles show mean values. CG: control group; Exp–: without previous device experience; Exp+: with previous device experience; IG–: intervention group without feedback messages; IG+: intervention group with feedback messages.



The data volume recorded and transferred per patient to the data server varied based on health status, physical activity levels, and workout duration, which influenced both recorded data point density and the number of ECG recordings. On average, the data volume amounted to approximately 300 MB per patient and year in the HL7 FHIR database on the data server.

The bias-corrected and accelerated bootstrapped multiple linear regression analysis (Table 2) resulted in a significant influence of IG– membership on the wearable interaction frequency and SHD completeness end points and approached significance for the PROM completeness end point (wearable interaction frequency estimate: 13.53%, 95% CI 1.02%-25.4%; SHD

completeness estimate: 11.73%, 95% CI 1.17%-21.86%; PROM completeness estimate: 12.22%, 95% CI –0.37% to 24.29%). This means that, on average, a patient in the IG– was expected to interact with the wearable app on 13.35% more days enrolled in study than a patient in the CG and that both SHD and PROM data were expected to be available on 11.73% more days and 12.22% more weeks that a patient was enrolled in the study, respectively.

Discussion

Principal Findings

In this paper, we presented a concept, implementation, and evaluation of a reusable RPM system following a patient-centric approach for RPM without direct physician-patient contact using asynchronous feedback mechanisms. The system was based on patient-generated data such as SHD and PROMs. It leveraged a consumer wearable device (smartwatch) instead of a smartphone as the primary input device. The implementation of the concept and its subsequent use as part of the activeDCM randomized controlled clinical trial demonstrated that the identified challenges and requirements of a sophisticated precision digital health trial could be addressed. The implementation relied on wearable devices and smartphones from Apple Inc and their notification service, but the concept should be versatile enough to be used with devices based on other operating systems, such as the Android-based Wear OS for the Samsung Galaxy Watch or the Google Pixel Watch.

Decisions during RPM system conceptualization and implementation aimed to minimize barriers to use, enhancing usability and ensuring high patient acceptance as well as compliance. The study team established a device preparation and distribution scheme providing patients with ready-to-use devices, thereby reducing the configuration efforts to scanning an onboarding QR code. Patient education sessions focused not only on the medical aspects of the study but also on digital literacy and provided written and video-based material about the wearable and smartphone app, requiring additional effort from patient educational sessions. Opting for a wearable as the primary input device likely played a pivotal role in seamlessly integrating the RPM system into the patients' daily routines. Its proximity to the patient and its intuitive interaction, aligned with the chosen device, operating system, and study-specific app, contributed to a successful integration and reduced the interaction time to a few seconds per day. To enhance the wearable and smartphone app usability, we implemented only the essential functionalities in a straightforward, simplistic manner, trying to reduce the interactions for these functionalities to a minimum. This was significantly shaped by the official human interface guidelines provided by Apple [63,64]. Storing authentication information during onboarding further streamlined data transmissions, eliminating the need for patients to remember usernames and passwords.

The Apple Watch sensors capture heart rate measurements in an interval of seconds during an activity session [65], and active burned energy and step data can be extracted in hourly intervals. Given this vast amount of data points, the physician-centered data viewer prioritized simplicity, presenting summarized information. In total, 3 visualization granularity levels allowed physicians to analyze patient-generated data, identifying short-, medium-, and long-term trends, and compare data from multiple patients effortlessly. Direct remote push notifications from the data viewer interface streamlined physician support, eliminating the need to switch between various communication channels, as observed in other wearable-based studies [66,67].

The HL7 FHIR standard enhanced medical data exchange by addressing health care challenges beyond the capabilities of previous standards, such as HL7 version 2, HL7 version 3, and Clinical Document Architecture [68]. Therefore, HL7 FHIR's standardized API and data models used in combination with the LOINC and UMLS medical terminologies ensured syntactic and semantic interoperability with other clinical information systems. However, complete integration with other clinical information systems requires these systems to provide standardized interfaces as well. Without these interfaces, integration becomes more complex, necessitating adaptations and mappings. In Germany, legislative efforts are promoting the adoption of HL7 FHIR interfaces for clinical information systems [69].

The wearable and smartphone app, data server, and data viewer implementation were not bound to a specific medical domain and could be used independently beyond the activeDCM study as long as the counterpart supported the HL7 FHIR standard as well. The components of the wearable and smartphone app and the data viewer were built iteratively in a modular system and, thus, can be adapted for further studies and other diseases such as diabetes or chronic obstructive pulmonary disease without major effort. If required, new modules could be implemented, integrating additional sensors and data types. Similarly, not required data types could be removed easily.

By equipping patients with dedicated devices, it was possible to ensure that data transmissions only took place in a pseudonymized form. During the educational session, patients were briefed on the RPM system's privacy and security mechanisms, emphasizing the storage of only the pseudonym on devices after handover. This ensured that no data were stored in a cloud solution provided by the manufacturer of the devices. As such, the smartphone and wearable were setup using Apple Configurator 2, and the app was deployed using the over-the-air method without the need to sign in using an Apple ID. Furthermore, by separating patient identification from device identification, feedback messages could be sent via the manufacturer's notification service without having to know the patient's identity or pseudonym. The connection of the pseudonym to the device could only be established on the data server.

The SUS evaluation, resulting in a mean score of 78 (SD 17), indicated that the wearable and smartphone app was considered user-friendly by patients [50]. The significant difference between patients with and without experience using Apple devices (estimate: 6.75, 95% CI 0.25-13.47) suggests that patients are generally more comfortable using devices they are familiar with. However, to allow use of wearables from different manufacturers in the RPM system, achieving comparable sensor accuracies for the same SHD recordings would be essential, but

the literature shows that there are measurable differences [70,71], posing challenges for physicians in comparing patient data and providing feedback. Despite the additional effort to explain the devices and study-specific app, patient age had an influence on the SUS score approaching significance (estimate: −0.19, 95% CI –0.46 to 0.14). Insufficient usability (SUS score of <68; 24/95, 25% of the patients) was mainly reported by patients aged >50 years (18/24, 75%) and with no previous Apple device experience (18/24, 75%). This suggests that the challenges faced by these individuals may not have been due to problems with the usability of the wearable and smartphone app but rather with the general use of the devices. These findings are consistent with results reported by Sonderegger et al [72] and illustrate the importance of digital literacy and the supplementary material provided for patients during the onboarding process.

On average, patients engaged with the wearable more than every other day (61%, SD 26% of days, 239, SD 99 of 396, SD 39 days). For SHD recording and transmission, as few as 1 interaction per week would suffice for complying with the activeDCM study protocol. Complete datasets would still be transferred as Apple Watch sensors store SHD for up to 10 days. The data server algorithm that monitored transmission frequency and sent automatic reminders likely played a crucial role in obtaining complete datasets. The measured user-friendliness was also reflected in the completeness of SHD data, which was available on average for 3 out of 4 days (78%, SD 23% of days, 307, SD 87 of 396, SD 39 days). This aligns with the results by Werhahn et al [73], where heart rate measurements and step counts based on a worn Apple Watch were recorded on 84.8% and 83.5%, respectively, of days that patients were included in their study. However, the monitoring period lasted only 2 months, which is significantly shorter than that in activeDCM. The average completeness of PROM questionnaires showed similar results, which were sufficient to see relevant health changes in patients and corresponds to a transmission of a complete PROM questionnaires more than every second week (mean 64%, SD 27% of weeks, 35, SD 15 of 56, SD 5 weeks).

Gaps in data, whether SHD or PROMs, could be attributed to various factors, such as illness, hospitalization, vacation, or lapses in wearing the Apple Watch. Technical issues, poor internet connection, or oversight in configuring the patient device's Wi-Fi connection at home may also have resulted in missing patient-generated data.

However, home-based Wi-Fi connection did not restrict patient recruitment, the daily use of the wearable and smartphone app, or recording of patient-generated data. Data were still collected even without a current Wi-Fi connection. The Wi-Fi connection was only necessary for data transmission to the study center, thereby transmitting all recorded data since the last transmission. A mobile data volume contract is possible for data transfer, enabling transfers outside the patient's home. However, as the devices and the wearable and smartphone app can temporarily store patient-generated data until they can be transferred to the data server, data completeness would remain unchanged.

There was a notable difference in the evaluation results of objective RPM use between the CG, IG–, and IG+, showing significance for wearable interaction frequency (estimate: 13.53%, 95% CI 1.02%-25.4%) and SHD completeness (estimate: 11.73%, 95% CI 1.17%-21.86%), as well as approaching significance for PROM completeness (estimate: 12.22%, 95% CI −0.37%-24.29%) in the IG– in comparison with the CG. This suggests the presence of a Hawthorne effect [74] for increased RPM system use as anticipated given the expected behavioral impact of the activeDCM study in the intervention groups. Within each randomized controlled trial, a potential bias exists in the case of a Hawthorne effect that could have increased compliance with the treatment and the use of the wearables in this study. To study the use of the RPM system in real-world settings, another design of an observational trial would be needed.

The inferior performance of the IG+ (only significant SHD completeness with an estimate of 12.18%, 95% CI 1.65%-22.43% compared with the CG) in comparison with the IG– may be attributed to more patients with no Apple device experience and more patients aged >50 years in the IG+ compared with the IG–.

Positive responses from patients to self-designed questions 1 to 3 regarding the wearable as a primary input device and its integration into daily routines aligned with the usability and data completeness results, affirming our design decisions. In addition, responses to questions 4 and 5 indicated a strong willingness among patients to share patient-generated data, acknowledging the benefits of an RPM system with feedback mechanisms. This reflects a positive attitude from patients toward using technology for chronic disease management, which is consistent with the evaluations by Turner et al [75] and Rising et al [5].

While sensors for cardiovascular monitoring and smartphone apps for PROM recording are advanced, RPM systems are not commonly used in cardiology research or standardized clinical workflows, highlighting the need for more guidance on the design and implementation of such systems. In a systematic review, Kinast et al [76] found a limited number of studies (between January 1, 2001, and March 31, 2021) implementing wearables and noninvasive sensors, as in the activeDCM study, for the management of cardiovascular diseases. In contrast, activeDCM featured continuous recording and transmission of patient-generated data for at least 12 months—more than twice the duration of most studies in the review. This extended time frame offers initial evidence supporting the feasibility of an RPM system for the longitudinal monitoring of patients with chronic diseases. A systematic review by Vegesna et al [11] examining RPM systems for various other chronic diseases, including cardiac, respiratory, neurological, and metabolic conditions, revealed similar distinctions. Only a few studies for each disease type could be identified, shorter monitoring time frames were mainly applied, and the use of wearables as primary device was rather modest (computerized systems, smartphones, websites, biosensors, or a combination of these were often used). Finally, many studies in both aforementioned reviews predominantly emphasized clinical outcomes, with limited attention given to providing in-depth insights into the technical design and implementation of the RPM system as well as its usability, which in turn impacts patient adherence and

completeness of patient-generated data—all factors influencing the sustained long-term success of RPM systems [77].

Limitations

This study has several potential limitations. First, the evaluated cohort consisted of twice as many men than women, which is typical in cardiovascular trials and especially in DCM trials as men are more often affected than women and the activeDCM study design enrolled independently of gender selection. The RPM system can be used in its current implementation state only with iOS devices and requires a Wi-Fi or cellular data connection of the smartphone for data transfers.

Furthermore, the RPM system was only used and evaluated in a research context. We hypothesize that the experience and evaluation results obtained from this research can facilitate the transition of the RPM system into primary care. We anticipate that this transition will maintain high levels of interaction frequency and completeness of patient-generated data, as observed in the research setting. Nevertheless, additional investigation is required to ensure the successful integration and adoption of the RPM system into standardized clinical workflows. Potential challenges, especially in managing a considerably larger number of patients and their devices, may necessitate adjustments to current physician-patient interaction workflows as established for the activeDCM study. Who would bear the costs for the RPM-based treatment approach would also have to be clarified. One possibility for a reimbursement scheme to explore in Germany would be to certify the RPM system as a digital health application [78,79]. As a result, the wearable and smartphone app and the monitoring process could be prescribed by physicians and, thus, paid for by health insurance companies. In addition, cardiologists would need training in interpreting patient-generated data. The calculation of scores and the implementation of clinical decision support tools would streamline the analysis of patient-generated data, thereby saving time and increasing the scalability of RPM-based clinical workflows.

The RPM system module to answer PROM questionnaires has limited response options, using *yes* or *no*, or a scale from 1 to 4. Future efforts should explore methods for adapting more complex PROM questionnaires with diverse response options for use on wearables, maintaining their role as primary input devices. An example could be the Kansas City Cardiomyopathy Questionnaire–Short Version [80], an important questionnaire in cardiology that may require adaptation for wearable use.

Finally, the RPM system's reliance on manually triggered data transmission by patients, coupled with the consequent time delay in analysis by study physicians, makes it unsuitable for monitoring acute medical emergencies such as myocardial infarctions. To enable real-time monitoring, algorithms would need to be developed for direct analysis of patient-generated data on wearables. Nevertheless, the observational data collected as part of the activeDCM study could serve as a foundation for the future development of such algorithms.

Conclusions

As life expectancy increases and the older adult population experiences more chronic diseases, there is a growing need for ready-to-use RPM systems. In addition, physicians and researchers require more guidance on designing and implementing such systems for both primary care settings and research purposes [77]. This paper presents a blueprint of an RPM system concept, its subsequent implementation, and its procedure for use as part of the activeDCM study. The selected patient-centric approach and the evaluation results show the feasibility of creating a user-friendly, reusable, interoperable, and secure RPM system including an asynchronous feedback mechanism using a consumer wearable without a designated medical purpose as the primary input device for patient-generated data such as SHD and PROMs. The main factors influencing usability and patient acceptance of the RPM system were device experience, age, and intervention group membership. Our research provides a first step toward integrating RPM systems into standardized clinical workflows and could help other researchers in tailoring RPM systems for their studies. Further research is needed to translate such systems into primary care settings. If this translation is successful, the RPM systems have the potential to change the traditional patient-physician interaction in the future [81].

Acknowledgments

This project was kindly supported by the German Cardiac Society eCardiology program, the German Heart Foundation, and Informatics for Life (Klaus Tschira Foundation). The authors acknowledge Apple Inc for generously providing Apple Watch devices as part of a research agreement with the Institute for Cardiomyopathies Heidelberg, Heidelberg University Hospital, Heidelberg, Germany. The authors extend their sincere gratitude to the study nurses and team assistants for their support in using the remote patient monitoring system and providing technical assistance to their patients, with special recognition to Anja Rippert.

Abstract

Background: Mobile mental health apps are a cost-effective option for managing mental health problems, such as posttraumatic stress disorder (PTSD). The efficacy of mobile health (mHealth) apps depends on engagement with the app, but few studies have examined how users engage with different features of mHealth apps for PTSD.

Objective: This study aims to examine the relationship between app engagement indices and PTSD symptom reduction using data from an unblinded pilot randomized controlled trial of "Renew" (Vertical Design), an exposure-based app for PTSD with and without coaching support. Because exposure is an effective approach for treating PTSD, we expected that engagement with exposure activities would be positively related to symptom reduction, over and above overall app usage.

Methods: Participants were veterans (N=69) with clinically significant PTSD symptoms who were recruited online using Facebook advertisements and invited to use the Renew app as often as they wanted over a 6-week period. Participants completed screening and assessments online but provided informed consent, toured the app, and completed feedback interviews via telephone. We assessed users' self-reported PTSD symptoms before and after a 6-week intervention period and collected app usage data using a research-instrumented dashboard. To examine overall app engagement, we used data on the total time spent in the app, the number of log-in days, and the number of points that the user gained in the app. To examine engagement with exposure components, we used data on total time spent completing exposure activities (both in vivo and imaginal), the number of in vivo exposure activities completed, and the number of characters written in response to imaginal exposure prompts. We used hierarchical regression analyses to test the effect of engagement indices on change in PTSD symptoms.

Results: Usage varied widely. Participants spent an average of 166.09 (SD 156.52) minutes using Renew, over an average of 14.7 (SD 10.71) mean log-in days. Engagement with the exposure components of the app was positively associated with PTSD symptom reduction ($F_{6,62}$=2.31; P=.04). Moreover, this relationship remained significant when controlling for overall engagement with the app ($\Delta F_{3,62}$=4.42; P=.007). The number of characters written during imaginal exposure (β=.37; P=.009) and the amount of time spent completing exposure activities (β=.36; P=.03) were significant contributors to the model.

Conclusions: To our knowledge, this is the first study to show a relationship between symptom improvement and engagement with the active therapeutic components of an mHealth app (ie, exposure) for PTSD. This relationship held when controlling for overall app use, which suggests that it was engagement with exposure, specifically, that was associated with symptom change. Future work to identify ways of promoting greater engagement with self-guided exposure may help improve the effectiveness of mHealth apps for PTSD.

Introduction

Overview

Mobile mental health apps have continued to proliferate in recent years [1]. As of last year, more than 80 mobile mental health (mHealth) apps aimed at managing posttraumatic stress disorder (PTSD)—a significant public health concern with an estimated 7% lifetime prevalence in the United States of America—are now available for download [2,3]. Research on mHealth apps for PTSD has also increased and suggests that these tools are generally feasible and acceptable to users [4]. However, a recent review found that evidence for the efficacy of PTSD mHealth apps was not consistently superior to inactive control conditions [5].

The efficacy of an mHealth app for PTSD will depend upon how the user engages with the tool. Only one study has examined the relationship between engagement with a PTSD self-management app and symptom change. This study found that the number of log-ins to the mHealth app PTSD Coach (Vertical Design) was not related to PTSD symptom reduction [6]. This contrasts with findings from depression mHealth apps showing that number of log-ins [7] and number of activities per log-in [8] are linked with change in depressive symptoms. Additional research on the relationship between app engagement and PTSD symptom change is clearly needed and could inform user guidance on how to benefit from using PTSD mHealth self-management apps.

Objectives

The current analysis aims to address this gap by exploring the relationship between user engagement indices and symptom reduction in users of a PTSD mHealth self-management app called "Renew" [9,10]. Based on principles of exposure therapy, Renew uses gamified elements and activities designed to help users target their PTSD symptoms using in vivo and written exposure. Given the evidence supporting exposure as an efficacious therapeutic approach for treating PTSD [11], we hypothesized that engagement with the exposure activities in Renew would be uniquely related to symptom reduction, over and above general app use.

Methods

Participants

Potential participants were recruited through Facebook (Meta) advertisements because we were interested in examining a nationally representative sample of veterans. As of the Veterans Health Administration's last publicly released report, more than half of veterans do not receive care through the Department of Veterans Affairs (VA) [12], so a sample recruited strictly from among VA patients would not necessarily represent veterans as a whole. Potential participants completed an online screening measure through REDCap (Research Electronic Data Capture; Vanderbilt University) [13] to assess veteran status, trauma exposure [14], and PTSD symptoms. Eligible participants were veterans with clinically significant PTSD symptoms, defined by a score of ≥31 on the Posttraumatic Stress Disorder Checklist for *DSM-5* (PCL-5) [14]; access to an Android phone (Renew was only developed for Android OS); and sufficient smartphone literacy and internet connection to successfully download the app with telephone guidance from study staff. There were no exclusion criteria.

Ethical Considerations

All participants gave their informed consent for inclusion before they participated in this trial. The protocol was approved by the Stanford University Institutional Review Board (52829).

Renew

Renew is a research-instrumented mobile app designed to reduce symptoms of PTSD using in vivo exposure and imaginal exposure, developed by Vertical Design. Other components include psychoeducation, behavioral activation through self-care, and assessment. Users gain points for completing activities in the app. Renew was designed to be used both with and without human coaching support, provided through a one-way messaging function. Users downloaded Renew from the Google Play Store and accessed the intervention using an invitation code provided by the study team during app orientation. Readers of this article who possess an Android phone may email the corresponding author to receive a Renew invitation code if they wish to access the intervention. Before this trial, we tested the feasibility and acceptability of Renew in a small pilot study, after which the content of Renew was updated according to user feedback and frozen throughout the duration of the current trial. Miller et al [10] and McLean et al [9] give more details about Renew, including the details of the feasibility and acceptability pilot study.

Measures

Renew Usage Data

Participant usage data were collected through a secure research dashboard. User access to the app was restricted to only those users who were provided with an individualized code. Once linked with a given user's app, this code allowed researchers to track the user's engagement with the Renew app through the secure research dashboard, including time-stamped button presses, time spent on each screen, number of characters typed into free text boxes, log-ins, and dates of use.

Consistent with previous mHealth app studies that have used multiple objective engagement criteria [15], we examined several indices of overall app engagement: total time spent in Renew, number of log-in days, and number of points gained in Renew. To specifically capture engagement with exposure, we examined time spent completing exposure activities (both imaginal and in vivo), the number of in vivo exposure activities completed, and the number of characters written during imaginal exposure. Number of characters was chosen as a proxy for the degree to which users engaged with their worst traumatic memory.

Posttraumatic Stress Symptoms

The PCL-5 [15] is a 20-item self-report measure of PTSD symptoms as defined by the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) [16]. The PCL-5 has demonstrated strong psychometric properties [17,18] and has been validated for online use [19]. The Cronbach α in the

current sample was 0.84. The PCL-5 was administered to each participant at 3 time points. For participants immediately assigned to one of the active use conditions, the PCL-5 was completed through REDCap before app use as part of the study screening procedures, after the 6-week active use period, and after a 6-week follow-up period. Participants assigned to the delayed use condition completed the PCL-5 before the delayed use period, at the end of the delayed use period before receiving a code to access Renew, and after their 6-week active use period.

Procedures

The Stanford University Institutional Review Board approved the study. Informed consent was collected via telephone call, in which the study staff read a script that included information about Renew and the 3 study conditions to which they could be randomized. Study staff then allowed participants to ask questions about the study before providing consent. Eligible participants who consented to the study were randomly assigned to either 6 weeks of (1) Renew without study staff support, (2) Renew with a study support person as a support team member, or (3) delayed use. Neither participants nor study staff were blinded to conditions. Participants in the delayed use group were invited to use the app for 6 weeks after a 6-week wait period. Immediately before beginning the 6-week active use period, participants received a 30-minute app orientation by phone. During the orientation, a study staff member walked participants through each section of the app, described the features of Renew, and offered participants the chance to ask questions. Following the orientation, participants were then asked to use the app as often as they wanted for the next 6 weeks. Participants could choose to set reminders to use the app. Participants completed postuse measures through the REDCap online survey platform [13] at the end of the app-use period. Usage data were collected using a secure research dashboard. All participants who were assigned to the delayed use condition were given an access code for Renew at the end of the 6-week delayed use period. Data about their app usage was collected during a 6-week follow-up period, in addition to pre- and postuse symptom measures. For the current analysis, data were pooled from participants assigned to all 3 conditions, because there were no significant (P=.31) differences in PTSD symptom change during the active use periods across groups [9]. The majority of data collection took place online or through the online research dashboard that recorded Renew usage data, however, participants did complete postuse feedback interviews with study staff via telephone. Of the 93 participants who enrolled in the parent pilot trial [9], 69 participants had completed both pre- and postuse symptom measures and were included in this study.

Data Analysis

Analyses were conducted using SPSS (version 26; IBM Corp) [20]. Descriptive and correlational analyses were conducted for all engagement variables. A hierarchical linear regression analysis was conducted with the overall app engagement variables entered in step 1 and exposure engagement variables entered in step 2. The dependent variable was change on the PCL-5. All app use data in the analysis came from the participants' active use period (ie, for participants initially assigned to delayed use, usage data was taken from the active use period that followed the delayed use period).

Results

Participant demographics are reported in Table 1. Participants were predominantly middle-aged, women, and White. More than half of participants in this subsample were army veterans (n=36, 52.17%), and the average PCL-5 score was well above the cutoff for clinically significant PTSD symptoms.

Means and SDs for user engagement variables are presented in Table 2.

Table . Participant demographic characteristics (N=69).

Variable	Value
Age (years), mean (SD)	45.28 (9.05)
Gender [a] , n (%)	
Men	22 (33.33)
Women	47 (66.67)
Race or ethnicity [b] , n (%)	
White	47 (68.12%)
Black or African American	13 (18.84)
Asian or Asian American	2 (2.89)
American Indian or Alaska Native	4 (5.8)
Middle Eastern or North African	1 (14.49)
Other	2 (2.89)
Military branch, n (%)	
Army	36 (52.17)
Navy	13 (18.84)
Air force	15 (21.74)
Marines	5 (7.25)
Baseline PCL-5[c] score, mean (SD)	55.94 (9.87)

[a]No participants identified as transgender, nonbinary, or another gender identity.

[b]Participants could select more than one race or ethnicity. Because of this, percentages sum to >100%.

[c]PCL-5: Posttraumatic Stress Disorder Checklist for *DSM-5*.

Table . Descriptive statistics for app engagement indices.

Overall engagement variables	Value, mean (SD)
Log-in days	14.7 (10.71)
Minutes in Renew	166.09 (156.52)
Number of points gained	350.14 (451.42)
Exposure engagement variables	
Number of in vivo exposure activities completed	1.84 (4.22)
Minutes spent completing exposure activities	78.19 (135.35)
Number of characters written during imaginal exposure activities	5116 (8522.43)

Over the 6-week active use period, participants logged into Renew about one-third of the days. Users spent a little over 2.5 hours total engaging with Renew, not including their initial 30-minute orientation. Users spent over an hour engaging in exposure activities, averaging more than one complete in vivo exposure activity. In response to exposure prompts, participants wrote over 5000 characters on average, which roughly equals 750 - 1000 words.

Correlations between app usage variables are presented in Table 3. Given the overlap in the engagement variables, there was high intercorrelation between the general and exposure-specific usage variables. Relationships between all variables were significant. The variable “minutes spent completing exposure activities” reflects minutes spent practicing both imaginal and in vivo exposure. Time spent on imaginal and in vivo exposure were combined in order to examine the impact of overall engagement with exposure in addition to the individual effects of engagement with imaginal and in vivo alone.

Table . Correlations (Pearson *r*) among usage variables.

Variables	Log-in days	Minutes in Renew	Number of points gained	Number of in vivo exposure activities completed	Minutes spent completing exposure activities	Number of characters written during imaginal exposure
Overall usage variables						
Log-in days						
r	1	0.74	0.81	0.47	0.41	0.45
P value	—[a]	<.001	<.001	<.001	<.001	<.001
Minutes in Renew

Minutes spent completing exposure activities						
r	0.41	0.65	0.41	0.58	1	0.38
P value	<.001	<.001	<.001	<.001	—	0
Number of characters written during imaginal exposure						
r	0.45	0.54	0.46	0.33	0.38	1
P value	<.001	<.001	<.001	.01	0	—

[a]Not applicable.

The results of the regression analysis are presented in Table 4. The initial model with overall engagement predicting PTSD symptom change was not significant and accounted for 1% of the variance observed in the model. However, the model with the exposure engagement variables added was significant and accounted for an additional 18% of variance in the model. Time spent completing exposure activities (*P*=.03) and the number of characters written during imaginal exposure (*P*=.009) were significant contributors to the final model.

Table . Hierarchical linear regression model (N=69).

Model steps and variables	β[a]	R	R^2	ΔR^2	*F* test (*df*)	*P* value[b]	Δ*F* test (*df*)	*P* value[c]

Discussion

Overview

We examined the relationship between engagement with imaginal and in vivo exposure and PTSD symptom reduction in an mHealth app, Renew. Few randomized controlled trials have examined mobile app-delivered interventions for PTSD [21], and even fewer studies have evaluated the impact of usage factors on symptom change in digital PTSD interventions [22,23]. As hypothesized, we found that engagement with exposure was associated with greater PTSD symptom reduction over and above overall use of the app in general. Our finding that overall app use was unrelated to PTSD symptom change is consistent with previous research on PTSD Coach [6] but inconsistent with meta-analytic findings showing that engagement with mHealth apps in general is associated with symptom change [24]. To our knowledge, this is the first study to demonstrate a relationship between engagement with the active therapeutic components of an mHealth app and improvement in PTSD symptoms.

Our findings are consistent with the limited research on the relationship between app usage and symptom change in self-management apps for depression and anxiety, which suggests that higher rates of engagement with active intervention components are associated with symptom change. Specifically, Zhang et al [25] found that participants' depressive symptom reduction was associated with greater engagement in self-tracking and moderate engagement with learning and goal setting, but anxiety symptom reduction was unrelated to engagement with specific app components. One other study, Nardi et al [26], examined data from a clinical trial of a mindfulness app and also found evidence that engagement with specific components, such as meditation, was linked to improvement in generalized anxiety symptom reduction. To our knowledge, there are no studies of PTSD apps that have examined how engagement with different intervention components relates to symptom change. Even among apps for more common mental health concerns, robust reporting on usage metrics remains scant [27]. Our analysis of exposure-specific use metrics in this study contributes to a profound gap in the literature on digital mental health interventions. Our finding that exposure may be helpful for reducing PTSD symptoms through a self-guided mHealth app is consistent with the broader literature on efficacious PTSD interventions [28]. Future work should examine digital interventions that include active cognitive behavioral therapy (CBT) components such as exposure, which are associated with symptom change. Indeed, in a large meta-analysis of 176 randomized controlled trials, effect sizes were larger for self-management apps for anxiety and depression that included CBT components compared to those that did not [29].

The number of characters entered during imaginal exposure, which we considered a proxy for the degree to which

participants engaged with and recounted their worst traumatic memory, and the time spent in any exposure activity, both significantly contributed to the model predicting PTSD symptom change, whereas the number of exposure activities did not. This may suggest that the depth of engagement and time spent approaching trauma-related memories and situations is important for therapeutic change in the context of mHealth apps for PTSD. This pattern of findings maps to the literature on in-person psychotherapy, where most exposure therapies emphasize the importance of imaginal exposure [30].

Limitations

Several study limitations should be noted. Data for this study were drawn from a pilot trial, and replication of the current findings is needed. Participants were veterans with clinically significant symptoms of PTSD; findings may not generalize to other populations diagnosed with PTSD. Data were cross-sectional, which prevents causal interpretations. In addition, many of the usage variables were highly intercorrelated and there is no established gold standard approach for operationalizing app engagement. These limitations notwithstanding, this study provides preliminary evidence of a unique relationship between engagement with exposure and PTSD symptom change among veterans with clinically significant symptoms of PTSD who used a self-guided mHealth app (Renew) for a 6-week period.

Acknowledgments

The authors would like to thank Vertical Inc and Yuzu Labs Inc for their assistance with app development and participant recruitment, respectively. Abstract

Background: Hypertension is highly prevalent among patients undergoing hemodialysis, with a significant proportion experiencing poorly controlled blood pressure (BP). Digital BP management in this population has been underused.

Objective: This study aimed to explore the efficacy of a web-based home BP monitoring (HBPM) program in improving predialysis BP control and enhancing knowledge, perception, and adherence to HBPM among patients with hypertension undergoing hemodialysis.

Methods: A multicenter, open-label, randomized controlled trial was conducted at 2 hemodialysis units. Patients were randomly allocated in a 1:1 ratio to either the web-based HBPM program as the intervention group or to usual care as the control group over a 6-month period. The primary outcomes were the predialysis BP control rate, defined as less than 140/90 mm Hg, and the predialysis systolic and diastolic BP, assessed from baseline to the 6-month follow-up. Secondary outcomes included patient knowledge, perception, and adherence to HBPM, evaluated using the HBPM Knowledge Questionnaire, HBPM Perception Scale, and HBPM Adherence Scale, respectively. A generalized estimating equations analysis was used to analyze the primary outcomes in the intention-to-treat analysis.

Results: Of the 165 patients enrolled in the program (n=84, 50.9% in the web-based HBPM group and n=81, 49.1% in the control group), 145 (87.9%) completed the follow-up assessment. During the follow-up period, 11 instances of hypotension occurred in 9 patients in the web-based HBPM group, compared to 15 instances in 14 patients in the control group. The predialysis BP control rate increased from 30% (25/84) to 48% (40/84) in the web-based HBPM group after the 6-month intervention, whereas in the control group, it decreased from 37% (30/81) to 25% (20/81; χ^2_2=16.82, *P*<.001; odds ratio 5.11, 95% CI 2.14-12.23, *P*<.001). The web-based HBPM group demonstrated a significant reduction after the 6-month intervention in the predialysis systolic BP (t_{163}=2.46, *P*=.02; β=−6.09, 95 % CI −10.94 to −1.24, *P*=.01) and the predialysis diastolic BP (t_{163}=3.20, *P*=.002; β=−4.93, 95% CI −7.93 to −1.93, *P*=.001). Scores on the HBPM Knowledge Questionnaire (t_{163}=−9.18, *P*<.001), HBPM Perception Scale (t_{163}=−10.65, *P*<.001), and HBPM Adherence Scale (t_{163}=−8.04, *P*<.001) were significantly higher after 6 months of intervention.

Conclusions: The implementation of a web-based HBPM program can enhance predialysis BP control and the knowledge, perception, and adherence to HBPM among patients undergoing hemodialysis. This web-based HBPM program should be promoted in appropriate clinical settings.

Introduction

Background

Hemodialysis has become the predominant renal replacement therapy for individuals with end-stage renal disease, the final stage of chronic kidney disease. The prevalence of patients receiving hemodialysis has surged alongside the increasing incidence of end-stage renal disease cases. Globally, the number of patients requiring renal replacement therapy is expected to reach 5.4 million by 2030, with nearly 89% of them undergoing hemodialysis [1]. According to the Chinese National Renal Data System, more than 1 million patients underwent dialysis in 2022 [2].

Hypertension is nearly ubiquitous among patients receiving hemodialysis, who often have suboptimal blood pressure (BP) control. The epidemiology of hypertension in this population varies across studies, depending on the definition of hypertension and the method used to measure BP. The overall prevalence of hypertension in patients undergoing hemodialysis ranged from 80% to 90% [3-5]. The European Registry of Cardiovascular and Renal Medicine of the European Renal Association—European Dialysis and Transplant Association showed that hypertension, defined as having ambulatory BP ≥130/80 mm Hg at 48 hours or current use of medications to reduce BP, was prevalent in 84.3% of patients undergoing hemodialysis [3]. Another study based on the criteria of predialysis BP ≥140/90 mm Hg or current use of antihypertensives indicated that 86.2% of patients undergoing hemodialysis have hypertension [4]. Additionally, the China Dialysis Outcomes and Practice Patterns Study reported that 87.3% of patients undergoing hemodialysis were complicated by hypertension [5]. Although 86.8% of these patients received pharmacological treatment, fewer than 30% had their BP well controlled [3].

Increased BP in patients undergoing hemodialysis has been found to have a linear association with adverse cardiovascular events and mortality. Recent studies have identified a U-shaped or J-shaped correlation between BP before or after dialysis and the risk of all-cause mortality in patients undergoing hemodialysis. This phenomenon, termed the “reverse epidemiology” of hypertension, is predominantly observed within dialysis units [6,7]. Elevated BP levels measured outside the dialysis unit demonstrated better prognostic capacity for adverse cardiovascular events and mortality compared to measurements taken within the dialysis unit [8-10]. Therefore, it is imperative to develop a more effective BP management model for patients undergoing hemodialysis, especially BP measurements taken outside the dialysis unit, to optimize the reduction in mortality risk.

BP monitoring plays a crucial role in the management of BP, representing a fundamental prerequisite therein, and is a crucial tool for the identification, diagnosis, and prognostic evaluation of hypertension. For patients undergoing hemodialysis, BP measurements are taken at the hemodialysis unit and outside the hemodialysis unit, and the latter consists of home BP monitoring (HBPM) and ambulatory BP monitoring [11]. Despite the conventional clinical application of BP measurements taken within dialysis units for diagnosing hypertension, the limitations of this approach persist [11]. In contrast, HBPM offers improved reproducibility [12], superior diagnostic accuracy [13], a more intimate nexus with target organ damage [14], and more prognostic information [15] and serves as a guide for long-term antihypertensive regimens [15]. Compared to ambulatory BP monitoring, HBPM has advantages in terms of lower cost, simpler operation, and greater patient acceptance [11]. Furthermore, the existing literature highlighted that positive behavior with HBPM can promote patient adherence to obtaining or reporting home BP, achieving better management of BP [16].

Under the proposal of national information health care policies [17,18], the maturation of information technology, and the amalgamation of network information, medical health services have engendered novel perceptions for the management of BP. Within the realm of existing digital interventions for BP, a variety of modalities such as BP telemonitoring, smartphone app-based tracking, phone calls, websites, emails, and SMS text messages have been used, demonstrating notable efficacious results [19]. Compared to conventional BP management paradigms, digital BP management is more convenient and flexible, with greater patient acceptance [19]. However, digital BP management has been applied predominantly in the primary hypertension population, rather than in patients undergoing hemodialysis [19]. It is unclear whether the efficacy of digital BP management modalities has the potential to influence predialysis BP control in patients with hypertension undergoing hemodialysis.

Objective

To bridge this knowledge gap, our goal was to develop a customized digital BP management program for patients with hypertension undergoing hemodialysis and to evaluate its long-term feasibility, efficacy, and safety in these patients. A 6-month, prospective, multicenter, randomized controlled trial was designed, with the aim of a comprehensive investigation of the efficacy of a digital BP management program in improving predialysis BP control rates, along with an evaluation of its implications for cognition, perception, and adherence to HBPM among patients with hypertension undergoing hemodialysis.

Methods

Study Design

This study was a multicenter, open-label, randomized controlled trial comparing the web-based HBPM program against usual care for patients with hypertension undergoing hemodialysis, which was performed at the dialysis centers of 2 tertiary hospitals in Guangdong Province, China, from August 2022 to February 2023. The design of the study was in accordance with the specifications outlined in the CONSORT-eHEALTH checklist (Checklist 1).

Ethical Considerations

The study protocol was registered with the Chinese Clinical Trial Registry (ChiCTR2100051535) and was approved by the ethics committees of Zhongshan Third Affiliated Hospital of

Sun Yat-sen University ([2019] 02-520-01) and Zhongshan Fifth Affiliated Hospital of Sun Yat-sen University ([2022] K141-1). The authors adhered to the tenets of the Declaration of Helsinki and its amendments. Written informed consent was obtained from each participant. All data collected from participants were recorded in an anonymized format. Participants in both groups were paid equally, such as a sphygmomanometer or an equivalent gift. These details were conveyed to the participants at the time of signing the informed consent form.

Participants

The inclusion criteria were (1) aged between 18 to 80 years; (2) mean predialysis systolic BP (SBP) of ≥140 mm Hg, mean diastolic BP (DBP) of ≥90 mm Hg over 3 consecutive sessions, the use of antihypertensive medication [20], or any combination of the above; (3) stage 5 and estimated glomerular filtration rate less than 15 mL/(min×1.73 m^2); (4) dialysis initiation period exceeding 3 months; (5) competencies in communication, perception, and learning; and (6) proficiency in smartphone operation and willingness to participate in the study. Exclusion criteria included patients who (1) transferred to intensive care units for any reason; (2) experienced complicating infection or bleeding; (3) died during the research period; (4) had mental or physical disabilities impairing their ability to respond to inquiries; (5) were unable to see or hear or were unable to measure BP due to upper-limb disability; or (6) demonstrated an inability to engage in self-care, as indicated by a score below 60 on the Activities of Daily Living scale. Participants were enrolled by researchers (YC and JY).

A simple randomization procedure was performed by researchers (JZ and MZ) using a random number table generated from the list of patients undergoing hemodialysis, at a 1:1 randomization ratio. Since patient dialysis management was conducted by different groups, each group of 8 - 10 patients had a relatively fixed dialysis time, dialysis area, and group of attending nurses. To minimize bias, the allocation of participants into study groups was conducted using a block randomization procedure. The random allocation sequence was generated according to the dialysis group through a publicly available web-based tool [21].

Intervention

Intervention Group

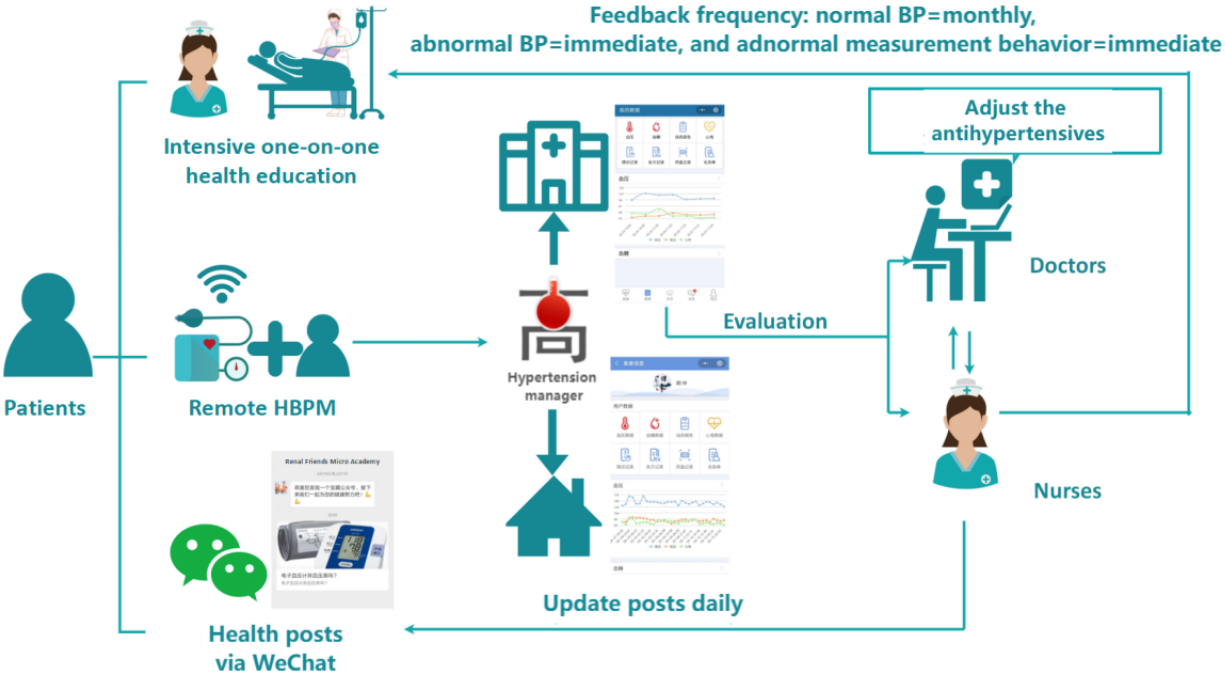
Development of the Web-Based HBPM Program

Concomitant with the management of the disease according to the *Chinese Standard Operating Procedures for Blood Purification* [22], the patients in the intervention group received complementary management of BP in the form of the web-based HBPM program. The theoretical framework of this program was developed according to the Health Promotion Model [23]. The program protocol was methodically formulated by the research group by systematically searching, screening, evaluating, and synthesizing the literature and based on clinical experience. Subsequently, the final version of the web-based HBPM program was validated using a peer-reviewed expert consensus approach.

Web-Based HBPM Program Protocol

The web-based HBPM program was characterized by a tripartite framework that encompassed intensive one-on-one health education; remote HBPM; and health posts disseminated through the WeChat platform (Figure 1). The program was implemented by health care professionals, including doctors and nurses in the hemodialysis centers, who received training in hypertension management conducted by the research group prior to the intervention.

Figure 1. The framework of the web-based HBPM program. BP: blood pressure; HBPM: home blood pressure monitoring.



Intensive Individualized Health Education

Intensive, one-on-one health education was a component of the web-based HBPM program. At the beginning of the intervention, the nurses in charge of the patients in the web-based HBPM group implemented dedicated, intensive, and individualized health education according to the *Nurse Education Manual*, which was formulated through a review of the literature. First, nurse leaders provided comprehensive instruction to participants that included the proper techniques for normative BP measurement, including the required measurement frequency, time, and recording of BP readings. The instruction was provided in half an hour. Subsequently, nurse leaders connected the patient's sphygmomanometers to the WeChat platform to facilitate remote HBPM. After that, nurse leaders provided monthly one-on-one education for 6 months. Nurse leaders offered feedback according to patients' home BP readings from the previous month; laboratory test results; and assessments of patient knowledge, perceptions, and adherence to HBPM. They provided personalized coaching to patients monthly, using positive encouragement to improve patients' confidence in monitoring their BP at home appropriately. Furthermore, if patients developed conditions (abnormal BP, abnormal measurement behavior, and relative interdialytic weight gain ≥5%), immediate education was required. Two researchers (TC and WZ) were responsible for providing web-based counseling and responding to patients at any time.

Remote HBPM

The core component of the web-based HBPM program was remote HBPM. To establish a digital conduit for the transmission and recording of BP data, internet-connected sphygmomanometers were used. These devices automatically uploaded BP measurement data to the cloud for monitoring purposes. The cloud was divided into 2 portals: the health care professional portal and the patient portal. Both health care professionals and patients used this cloud on the internet to collaboratively monitor patients' home BP.

After registering the sphygmomanometers, which automatically transmitted BP measurement data to the patient's WeChat account, nurse leaders guided patients to check BP reports on the web. The patients were then instructed to monitor their home BP with these sphygmomanometers following the nurse's instructions. The requirements for HBPM behavior were as follows: for patients whose BP met the standards (home BP <135/85 mm Hg [24]), it was recommended that they monitor their BP 1-2 days per week; for patients with unstable or substandard BP, it was recommended that they measure their BP 5-7 days per week. During these monitoring sessions, measurements were performed both in the morning and in the evening, following a rest period of 1-2 minutes.

Nurse leaders tracked both home BP and dialysis BP using the health care professional portal via the cloud and hemodialysis machine. Nurse leaders observed and evaluated the measurements of BP monthly through the health care professional portal and hemodialysis machine. They observed abnormal BP instances, including uncontrolled home BP (defined as an average home BP of ≥135/85 mm Hg [24]), interdialytic hypotension (defined as a reduction in SBP of 20 mm Hg or more or a decrease in mean arterial pressure by 10 mm Hg, accompanied by symptoms on nondialysis days), intradialytic hypotension (a decrease in BP accompanied by symptoms in dialysis procedure [25]), and uncontrolled predialysis BP (an average predialysis BP of ≥140/90 mm Hg [22]). They provided feedback to physicians about abnormal BP and discussed the adjustments to achieve BP management. Meanwhile, nurse leaders evaluated patient compliance with HBPM through the health care professional portal.

The physicians used the health care professional portal on the cloud and hemodialysis machine to monitor the patients. Initially, they adopted comprehensive nonpharmacological strategies, such as adjusting patient's dry weight and controlling fluid and sodium intake. If these measures did not normalize the patient's BP (predialysis BP <140/90 mm Hg), the patient's antihypertensive regimen would be adjusted. Additionally, adjustments to ultrafiltration and dry weight would be made, and instructions on managing interdialytic hypotension would be conducted according to the *China Standard Operating Procedures for Blood Purification* [22] to ensure safety at home. Throughout the continuum of BP management, health care professionals remained concerned about the effect of BP reduction, patient feelings, and adverse events through BP management and set goals for the next stage.

Health Posts via WeChat

Health posts via WeChat served as an integral component of the web-based HBPM program. Before the intervention, nurse leaders assisted patients in subscribing to a public WeChat account dedicated to self-care knowledge and skills related to BP management for patients undergoing hemodialysis, created by the researchers in this study. A researcher updated the health posts on this public WeChat account and distributed them to patients daily, while also monitoring their engagement and encouraging active participation. The WeChat health posts covered 35 topics consisting of 196 posts, including discussions on HBPM, fluid management, and calcium-phosphorus management. The content was regularly updated to ensure relevance and timeliness.

Control Group

Participants assigned to the control group received routine disease management based on the *China Standard Operating Procedures for Blood Purification* [22]. Patients were advised to measure their home BP, record the results in a notebook, and return it to the health care professional voluntarily 1 or several months later. If the home BP of the patients did not reach the standard BP, the physicians would adjust treatment through nonpharmacological or pharmacological methods to control the BP of the patients according to *Chinese Standard Operating Procedures for Blood Purification* [22]. Patients were provided with education from nurses on BP self-monitoring and BP management at the initiation of antihypertensive therapy.

Outcomes and Instruments

The primary outcomes were the predialysis BP control rate, with targets set at a predialysis BP of less than 140/90 mm Hg [22], and the predialysis SBP and DBP. Secondary outcomes

included patient knowledge, perception, and adherence to HBPM.

The Predialysis BP and HBPM Instrument

Predialysis BP was obtained before dialysis treatment using the automated BP monitor attached to the hemodialysis machine (Dialog+) in the dialysis unit. Predialysis BP was measured using standardized in-office methods [11]. At baseline and at each follow-up (after 1, 3, and 6 months of the study period), the BP readings were collected and averaged from the latest week, measured by the automated BP monitor attached to the hemodialysis machine. The outcome assessors (QP and CW) for BP were blinded to the intervention assignment.

Home BP was measured by an automatic electronic sphygmomanometer (A666G; Kangkang Shengshi Information Technology Co., Ltd [26]) in the web-based HBPM group.

HBPM Knowledge Questionnaire

Cognition of hypertension prevention and BP monitoring was measured using the HBPM Knowledge Questionnaire (HBPMKQ), which was developed according to the guidelines [27,28] by the research group. It consists of 20 multiple-choice questions with a potential total score ranging from 0 to 60, with lower scores indicating weaker knowledge. The difficulty coefficient and discrimination indices of the questionnaire were moderate and well defined [29].

HBPM Perception Scale

The perception of HBPM was assessed using the HBPM Perception Scale (HBPMPS) [29]. This scale is a 5-point Likert scale comprising 27 items across 5 dimensions: perceived benefit of HBPM, perceived barriers to HBPM, perceived self-efficacy of HBPM, situational influence, commitment to an HBPM plan. The total score ranges from 27 to 135, with lower scores indicating a worse attitude toward HBPM.

HBPM Adherence Scale

Adherence to HBPM was measured using the HBPM Adherence Scale (HBPMAS) [30]. The HBPMAS uses a 5-point Likert scale and consists of 8 items, with lower scores indicating poorer adherence to HBPM.

Data Collection

A trained investigator collected the data by interviewing patients. Sociodemographic and clinical characteristics were collected by a trained investigator using electronic questionnaires and by retrieving clinical data from the charts at the beginning of the study. The predialysis BP values between the 2 groups were recorded by a trained investigator and measured during the same period at baseline (T0) and at the 1-, 3-, and 6-month follow-ups (T1, T2, and T3, respectively). Electronic questionnaires for the HBPMKQ, HBPMPS, and HBPMAS were completed by both groups at the beginning of the study and at the 1-, 3-, and 6-month follow-ups.

Statistical Analysis

To test the differences between the 2 groups, α was set at .05 and the test power ($1 - \beta$) was set at .90. A previous study reported a predialysis BP control rate of 28.2% (defined as <140/90 mm Hg) [3]. Assuming a 25% improvement after the intervention, the sample size was calculated to be 124 cases according to the 2 independent sample rates. Considering a dropout rate of 20%, at least 155 patients must be enrolled.

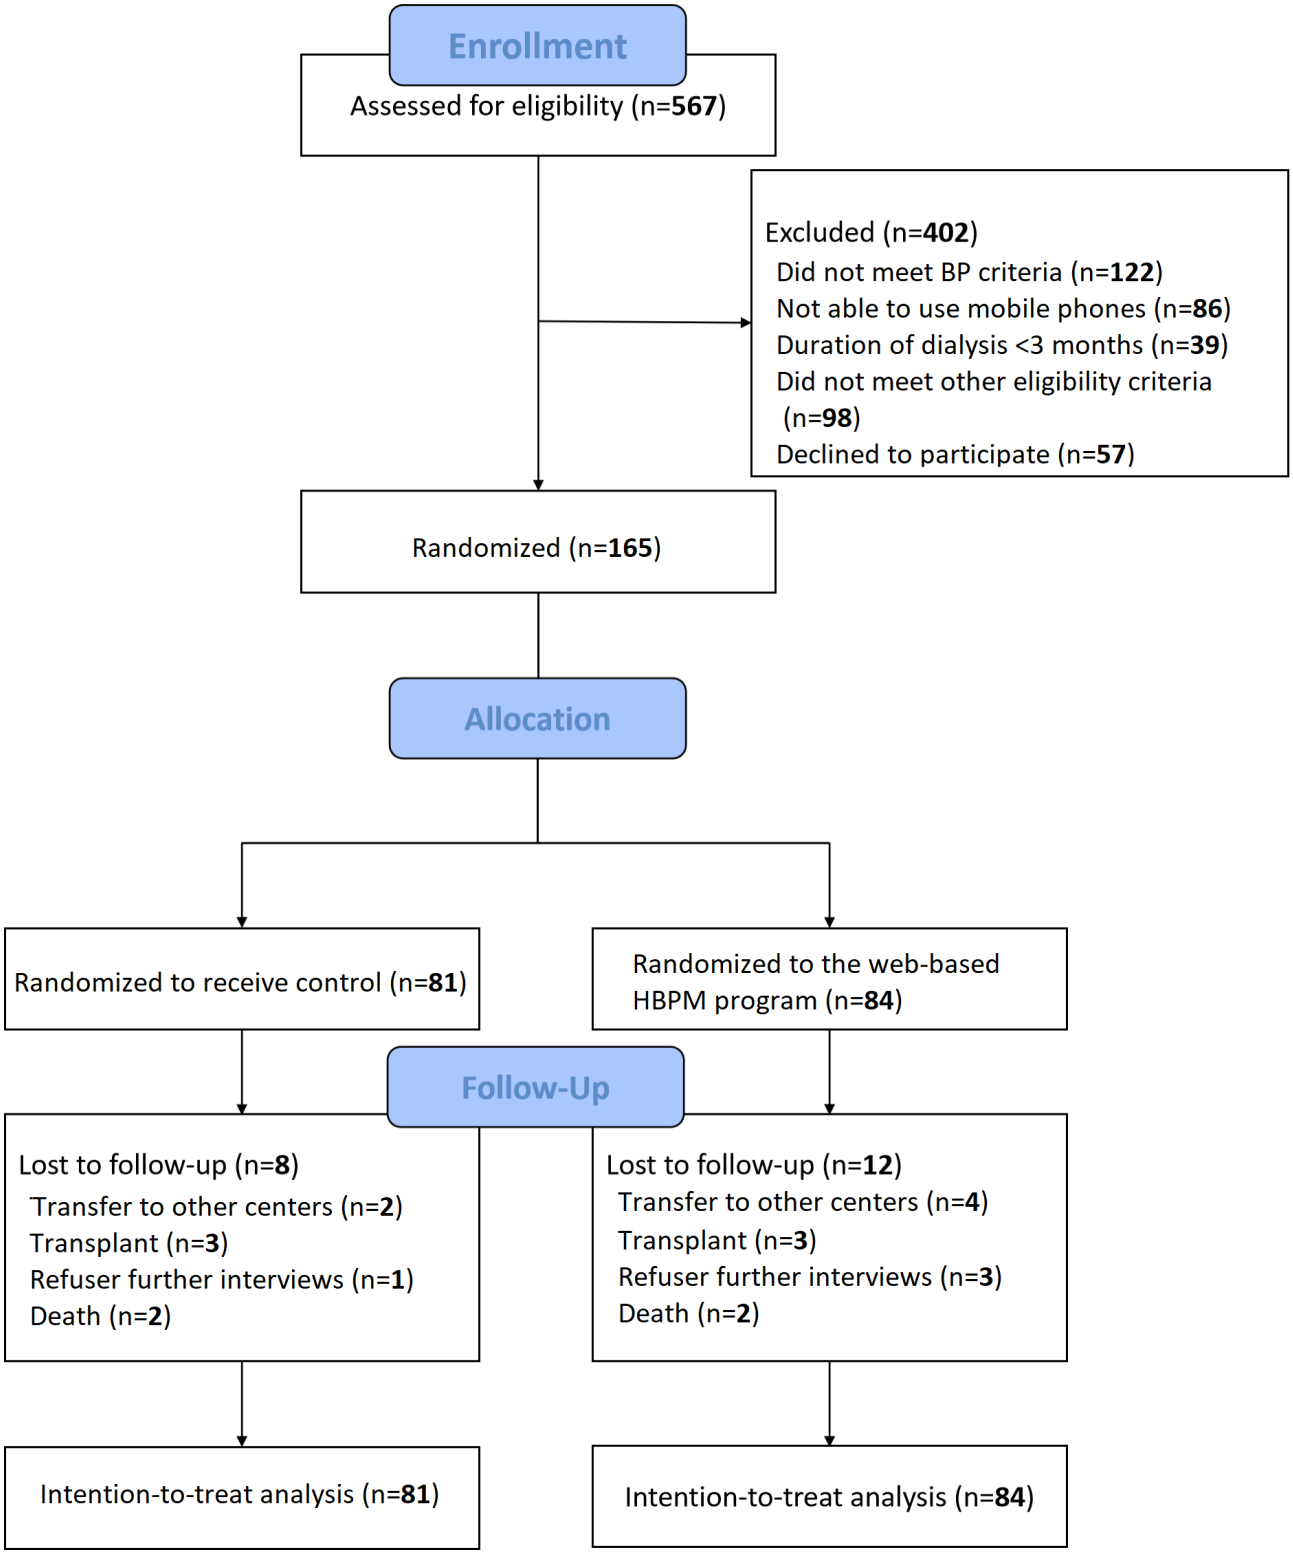
All analyses used intention-to-treat principles, and missing data were input using the last-observation-carried-forward approach. Sociodemographic and clinical characteristics and study outcomes were described as mean (SD) or n (%). The comparison of sociodemographic and clinical variables and study outcomes between the 2 groups was conducted using independent-sample (2-tailed) *t* tests and χ^2 tests. The primary outcomes were analyzed using generalized estimating equations. Model 1 was adjusted for group and time. Model 2 also controlled for hospital, age, sex, education, employment status, and marital status. Model 3 additionally controlled for smoking, BMI, the number of antihypertensive agents, duration of dialysis, interdialytic weight gain, urea clearance index, and weekly dialysis frequency. All analyses were processed in SPSS software (version 25.0; IBM Corp).

Results

Enrollment and Participant Allocation

During the recruitment periods, a total of 567 patients undergoing hemodialysis were assessed for eligibility. Among them, 165 enrolled patients were randomly assigned to either the web-based HBPM program group (n=84, 50.9%) or the usual care group (n=81, 49.1%; Figure 2). Dialysis unit A comprised 81 (49.1%) patients, whereas dialysis unit B comprised 84 (50.9%) patients. No statistically significant differences were observed in the demographic and clinical characteristics of the participants between the 2 dialysis units (all *P*>.05). A total of 20 participants prematurely discontinued the study, primarily due to transferring to other dialysis centers, receiving kidney transplantation, declining further interviews, and death. Throughout the follow-up period, the web-based HBPM program group reported 11 instances of hypotension in 9 patients, including 10 instances of intradialytic hypotension and 1 instance of interdialytic hypotension. The control group reported 15 instances of hypotension in 14 patients, including 11 instances of intradialytic hypotension and 4 instances of interdialytic hypotension. No hypotension-related adverse events, such as cardiovascular events (eg, acute myocardial infarction or ischemic stroke) or falls, were observed in either group.

Figure 2. Flow diagram of the web-based HBPM program. BP: blood pressure; HBPM: home blood pressure monitoring.



Demographic and Clinical Characteristics of the Participants

Of the 165 patients, the mean age was 53.7 (14.0) years and 66.1% (n=109) were male. The mean duration of hemodialysis was 57.8 (45.9) months. Glomerulonephritis (n=70, 42.4%) was the main etiology of renal disease. A total of 84.8% (n=140) of patients received treatment for their hypertension, 43.6% (61/140) were treated with 1 antihypertensive agent, and 56.4% (79/140) were given a combination of antihypertensives. Among those who received a combination of antihypertensives, the combination of calcium channel blockers+β-blockers+angiotensin II receptor antagonists was the most common (25/79, 32%), followed by calcium channel blockers+β-blockers (22/79, 28%). Except for education, other characteristics were similar between the 2 groups (Table 1).

Predialysis BP Control Rate, BP, Knowledge of Patients, Perception, and Adherence to the HBPM

Descriptive statistics were used to describe the control rate of predialysis BP; predialysis BP; and HBPMKQ, HBPMPS, and HBPMAS scores at baseline and at the 1-, 3-, and 6-month follow-ups (Table 2). Preliminary calculations suggested that the web-based HBPM program improved patient' predialysis BP control rate; predialysis BP; and the patients' knowledge, perception, and adherence to the HBPM after the 6-month intervention.

Table . Descriptive statistics for outcomes from baseline to the 6-month postintervention follow-up.

Variables and time point	Web-based HBPM[a] group (n=84)	Δ (T3 – T0)	Control group (n=81)	Δ (T3 – T0)	*t* test or chi-square (*df*)	*P* value

Effect of the Web-Based HBPM Program on Predialysis BP

The results of the generalized estimating equation analysis demonstrated the importance of the duration of follow-up and intergroup interaction across various models (Table 3 and Multimedia Appendix 1). In model 1, controlling for groups and time effects, a significant difference was found between the web-based HBPM group and the control group regarding the predialysis BP control rate at T1 (odds ratio [OR] 2.29, 95% CI 1.16 - 4.53; *P*=.02), T2 (OR 2.20, 95% CI 1.19 - 4.08; *P*=.01), and T3 (OR 3.85, 95% CI 1.89 - 7.83; *P*<.001). The OR of the predialysis BP control rate increased slightly after an additional adjustment for the demographic data of the patients in model 2, while after further adjustment for the clinical characteristics of the patients in model 3, the odds markedly increased. The 2 groups were affected differently during the follow-up period. The 3 models indicated a significant reduction in both predialysis SBP and DBP after 6 months of intervention (Multimedia Appendix 2).

Table . Analysis of the general estimating equations for the effect of the intervention on predialysis BP[a] control rate (n=165). Model 1 controlled for group and time; model 2 also controlled for hospital, age, sex, education, employment status, and marital status; and model 3 additionally controlled for smoking, BMI, the number of antihypertensive agents, duration of dialysis, interdialytic weight gain, urea clearance index, and frequency of weekly dialysis.

Outcomes		Model 1, OR[b] (95% CI)	*P* value	Model 2, OR (95% CI)	*P* value	Model 3, OR (95% CI)	*P* value

Discussion

Principal Findings

To our knowledge, this is the first study to develop a digital BP management program specifically tailored for patients with hypertension undergoing hemodialysis. Additionally, it explores the application of a web-based HBPM program to manage BP outside of the hemodialysis unit in this patient population. Unlike previous studies that have focused on the management of BP in patients undergoing hemodialysis by adopting conventional HBPM [12,15,16,31]; modifications to hemodialysis regimens [32-34]; patient education and counseling intervention [35,36]; reduction in dry weight [37,38]; dietary sodium restriction [37]; physical exercise [39]; continuity of care through web-based education, telephone visits, and outpatient visits [40]; and cognitive behavior therapy [41], our study innovatively used remote HBPM. Sheppard et al [42] highlighted the categorization of HBPM interventions into 4 intensity levels for managing hypertension. They emphasized that a multicomponent approach integrating goal setting, health education, telemonitoring, and prompt feedback from health care professionals could achieve better BP control. The web-based HBPM program is a high-intensity, level-4 intervention for people with hypertension undergoing hemodialysis, which was complemented by 2 educational approaches: health posts via WeChat and intensive personalized health education. In this study, a total of 165 patients with hypertension undergoing hemodialysis were initially included, with 145 patients ultimately completing the study. The results

unequivocally demonstrated the beneficial impact of the web-based HBPM program in patients undergoing hemodialysis. The program led to enhancements in predialysis BP control rates; predialysis BP; and patient knowledge, perception, and adherence to HBPM, which were particularly evident at the 6-month follow-up assessment. These findings support the viability, efficacy, and security of implementing the web-based HBPM program in patients undergoing maintenance hemodialysis.

In this study, preliminary analysis suggested a notable improvement in the predialysis BP control rate among patients who participated in the web-based HBPM program. Specifically, the proportion of the patients achieving predialysis BP control in the web-based HBPM group increased from 30% (25/84) to 48% (40/84), whereas in the control group, it decreased from 37% (30/81) to 25% (20/81; *P*<.001). Similar results were also observed in patients with essential hypertension [43], revealing an 11.6% improvement in the BP control rate after a 12-week HBPM intervention. The initial predialysis BP control rate among all participants in our study was 33.3% (55/165), which is consistent with the study by Sarafidis et al [3], which reported a rate of 28.2% among European patients undergoing hemodialysis. The implementation of a web-based HBPM program resulted in a remarkable elevation in the predialysis BP control rate. The elevated rate was assumed to be a consequence of improved adherence to treatment, resulting in better control of predialysis BP. The OR of the control rate for BP before dialysis increased when further controlling for clinical characteristics, compared to controlling for demographic characteristics alone. The multivariate adjustment models demonstrated that the predialysis BP control rate in the web-based HBPM group was 2.74 times that of the control group at the 1-month intervention time point, 2.62 times at the 3-month intervention time point, and 5.11 times at the 6-month follow-up. This indicated that the predialysis BP control rate was also affected by clinical characteristics, especially dry weight, ultrafiltration, dialysis adequacy, and weekly dialysis frequency. The intricate interaction between BP and volume management is well recognized in patients undergoing hemodialysis [44]. By controlling for clinical characteristics, the web-based HBPM program has been found to more effectively promote the predialysis BP control rate.

The results showed a significant reduction in predialysis SBP and DBP in the web-based HBPM group compared to the control group at the 6-month follow-up (SBP: β=−6.09, 95% CI −10.94 to −1.24; DBP: β=−4.93, 95% CI −7.93 to −1.93; Multimedia Appendix 2), despite no significant reduction in BP at the 1-month and 3-month follow-ups (*P*>.05). These findings aligned with a previous study, which found that guiding antihypertensive therapy based on BP measurements at home and before dialysis exhibited a significant 6 - to 10–mm Hg change in BP compared to those subjected only to predialysis BP measurements [15]. Our findings contribute substantially to the literature on the utility of HBPM in reducing BP among patients undergoing hemodialysis. Despite these promising findings, the development of HBPM to treat patients with hypertension undergoing hemodialysis is limited [11,45]. Adoption rates among these patients are low [11], with only 2% adhering to standardized BP measurement protocols and 61.1% measuring their BP independently at home [45]. Therefore, it is imperative to advocate for the widespread implementation of standardized HBPM in patients undergoing hemodialysis to improve hypertension management. Information technology under favorable conditions could promote efficient management of BP among patients.

In this study, to systematically investigate knowledge, perception, and adherence to HBPM, improvements in secondary outcomes were observed after a 6-month intervention (Δ_{HBPMKQ}=14.4, SD 8.3; Δ_{HBPMPS}=22.5, SD 9.4; Δ_{HBPMAS}=8.9, SD 6.0), which was consistent with primary hypertension research [46]. In a study by Sun et al [46], a remote interactive approach “Internet+” was used to promote the management of BP, leading to a 50.25% increase in the proportion of timely measurements and a 45.18% increase in high-degree disease awareness after the intervention. In the short term, the web-based HBPM program used health education to improve the patient’s knowledge and improved perception of the benefits, barriers, and self-efficacy associated with HBPM. This, in turn, facilitated the adoption of health-orientated behaviors by patients. In essence, the knowledge, perception, and behavior of the patients about HBPM exhibited a rapid increase and eventually stabilized over a period of time. However, translating these enhanced perceptions and behaviors into favorable health outcomes presented a certain temporal delay, indicating an existing delay. Thus, the introduction of the clinically relevant health management model should consider the overall participation of individuals, as well as the impact on cognition, perception, and behavior of the corresponding health management, to promote the improvement of outcomes.

Limitations

In general, there were several limitations in this trial. First, due to the nature of the health behavior intervention, participant blinding was not feasible. Similarly, health care professionals could not be blinded as the same individuals enrolled participants and conducted follow-ups. Second, due to resource constraints, the study relied on a relatively short follow-up period. Lastly, given the modest sample size, the web-based HBPM program appeared to have improved BP control. However, its impact on health outcomes, such as cardiovascular events or the enhancement of dialysis services, remained uncertain. This underscores the necessity for further research with larger sample sizes across multiple centers to verify the web-based HBPM program’s clinical applicability and reliability in future studies.

Conclusions

The web-based HBPM program introduced in this study produced significant improvements in the predialysis BP control rate and the knowledge, perception, and adherence to HBPM by patients with hypertension undergoing hemodialysis. BP was only significantly decreased at the 6-month follow-up. The web-based HBPM program exhibited benefits in BP control, potentially stemming from improved treatment adherence and optimized prescriptions. This study advocates for the implementation of the web-based HBPM program within the

framework of a hemodialysis unit, as aligned with the prevailing circumstances.

Acknowledgments

We are grateful to all the experts who provided valuable feedback and suggestions for this program, including those from the Division of Rehabilitation at Sun Yat-Sen Memorial Hospital of Sun Yat-sen University; the Division of Cardiology, Nephrology, and Psychology at the Third Affiliated Hospital of Sun Yat-Sen University; as well as the Division of Nutrition at the Fifth Affiliated Hospital of Sun Yat-Sen University. We also thank all health care providers from both The Third Affiliated Hospital of Sun Yat-sen University and The Fifth Affiliated Hospital of Sun Yat-sen University for their collaboration and support in carrying out the project. Finally, we express our appreciation to the patients who participated in this study at the Blood Purification Centres of both hospitals. This research was supported by the Natural Science Foundation of Guangdong Province, China (grant 2018A030313514).

Authors' Contributions

TC, WZ, CW, and JZ designed the whole study. TC and WZ managed the intervention. YC and JY provided the intervention program. QP contributed to data collection. MZ conducted the statistical analysis. TC and WZ prepared the manuscript. JZ and CW supervised the study process. All authors reviewed and edited the manuscript. TC and WZ are joint first authors. CW is the co-corresponding author, with an email address of wangch2@mail.sysu.edu.cn.

Abstract

Background: Due to aging of the population, the prevalence of aortic valve stenosis will increase drastically in upcoming years. Consequently, transcatheter aortic valve implantation (TAVI) procedures will also expand worldwide. Optimal selection of patients who benefit with improved symptoms and prognoses is key, since TAVI is not without its risks. Currently, we are not able to adequately predict functional outcomes after TAVI. Quality of life measurement tools and traditional functional assessment tests do not always agree and can depend on factors unrelated to heart disease. Activity tracking using wearable devices might provide a more comprehensive assessment.

Objective: This study aimed to identify objective parameters (eg, change in heart rate) associated with improvement after TAVI for severe aortic stenosis from a wearable device.

Methods: In total, 100 patients undergoing routine TAVI wore a Philips Health Watch device for 1 week before and after the procedure. Watch data were analyzed offline—before TAVI for 97 patients and after TAVI for 75 patients.

Results: Parameters such as the total number of steps and activity time did not change, in contrast to improvements in the 6-minute walking test (6MWT) and physical limitation domain of the transformed WHOQOL-BREF questionnaire.

Conclusions: These findings, in an older TAVI population, show that watch-based parameters, such as the number of steps, do not change after TAVI, unlike traditional 6MWT and QoL assessments. Basic wearable device parameters might be less appropriate for measuring treatment effects from TAVI.

Introduction

As transcatheter aortic valve implantation (TAVI) for severe aortic stenosis is increasingly used for older adults, including a high percentage of patients with substantial comorbidity, improvement in quality of life (QoL) is as important as extending life expectancy [1,2]. Not all TAVI patients benefit from improved physical activity, as assessed by a 6-minute walking test (6MWT) or the QoL questionnaire [3,4], nor does physical activity change the incidence of aortic stenosis [5]. Nevertheless, improvement in, for example, the baseline 6MWT distance in TAVI studies can be a marker for better survival [6,7]. However, these tests could be influenced by other factors and comorbidities such as peripheral vascular disease for the 6MWT or depression for the QoL questionnaire. Another concern with such tools is that they merely provide a snapshot of a patient's life and might change under different circumstances. Consequently, an unbiased and longer-term tool

to anticipate the benefit from TAVI would allow physicians and patients to personalize treatment and expectations.

In recent years, digital health has begun to transform medicine [8]. Smart phones and health watches, in particular, have found their way into the clinic [9]. These devices can detect atrial fibrillation [10], predict the wearer's 5-year risk of dying [11], and aid in primary prevention to reduce the risk of atherosclerotic cardiovascular disease [12]. The wearable device used in this study, the Philips Health Watch [13], continuously measures physical parameters such as heart rate (HR), number of steps, and amount of physical activity. Combining parameters from the health watch might facilitate a more physiological and comprehensive assessment of functional status before and after TAVI. After intervention for aortic stenosis, patient symptoms often improve (as measured using a QoL questionnaire), but the question arises whether they objectively become more active as measured using a wearable tracker (cq, do patients become more active after TAVI or do they exhibit the same daily routine as that prior to TAVI?). Despite advancements in digital health, current controlled clinical assessments often rely on controlled tests such as the 6MWT and a QoL questionnaire, which may not fully capture the nuances of patients' daily lives.

In this study, we evaluated the change in parameters collected using the Philips Health Watch ("daily activity parameters" such as walking distance) among patients before and after TAVI in comparison to standard clinical and research tests ("controlled environment tests" such as the 6MWT and QoL questionnaire). We hypothesized that after a TAVI procedure, physiological parameters such as step count, total activity time, and daily total energy expenditure (TEE) would increase, whereas respiration rate and HR would decrease.

Methods

This prospective exploratory study sought to identify parameters from the Philips Health Watch (DL8791, Philips) that changed after successful TAVI, and their relationship with standard clinical and research tests (including the 6MWT and QoL questionnaire).

Ethical Considerations

The study complied with the tenets of the Declaration of Helsinki and local regulations. All participants provided written informed consent, and this study was approved by an independent medical ethics committee (MEC-U approval ID: W16.141).

Study Population

Between July 2017 and September 2018, a total of 100 consecutive patients (aged ≥18 years) with severe aortic valve stenosis undergoing a clinically indicated TAVI after the Heart Team's decision were included. Exclusion criteria were immobility and not being able to wear an electronic health watch. All patients were recruited at the Catharina Hospital in Eindhoven, the Netherlands.

Study Protocol

Before TAVI, all patients underwent transthoracic echocardiography, computed tomography for valve sizing and access site evaluation, laboratory testing, and clinical assessment per local protocol. Patients were screened at the outpatient clinic, and eligible and consenting patients received the Philips Health Watch. The watch was placed around the patient's wrist after configuration with patient-specific parameters (height, weight, resting HR, and birth year). It was locked on the time screen, thereby blinding patients from all activity parameters, and worn for a week before being returned for data extraction. TAVI took place within 3-6 months of the baseline assessment. Three months after the TAVI procedure, patients visited the outpatient clinic for follow-up and again wore the Philips Health Watch for 1 week. At baseline and follow-up, a 6MWT and questionnaire (transformed WHOQOL-BREF) were administered [14].

Analysis of the Health Watch Data

The Philips Health Watch is a wrist-worn, photoplethysmography-based, HR and activity monitor (Figure 1). Once per minute, it measures parameters such as HR, respiration rate, step count, and TEE (ie, the number of calories needed to carry out physiological functions such as breathing and physical activity, but excluding the energy required for digesting food) as described previously by Hendrikx et al [13]. Parameters are measured at a 1-Hz sampling rate and stored on the device as 1-minute average values. Data can be extracted via Bluetooth by means of an iPod, using a proprietary iOS application from Philips, and sent to a Philips Research server for use in analyses.

A full report including primary data from the watch and derived parameters consists of a summary averaged over 1 day (Table 1), distributions of HR and respiration rate (Figure 2), and log plot of the HR and TEE (Figure 3). TEE is divided into subcategories of the Metabolic Equivalent Task (MET) scale. As the older TAVI population of this cohort seemed rather inactive, a subdivision of the MET scale was designed: basal activity corresponded to a MET score of 1.5 to 2, light activity from 2 to 3, moderate activity from 3 to 6, and high activity from 6 upwards (we used standard thresholds for the last 2 categories) [15].

Each red dot in Figure 3 represents a particular measurement: the 1-minute average HR and corresponding energy expenditure level. The fitted line quantifies the cardiac energy expenditure slope (CEES): as the HR increases, more energy is needed to maintain the resulting hemodynamic state. When the slope is less steep, more energy is needed to maintain an HR of, for example, 60 beats per minute. Conversely, when the slope is steeper, less energy is needed to maintain the same hemodynamic state. The steepness of the CEES potentially serves as an indicator for the energy efficiency of the cardiovascular system.

The report and concept of CEES were proposed and made available as data derived from the raw data from the health watch by HtH from Philips Research Eindhoven and used in clinical data analysis at Catharina Hospital in Eindhoven.

Figure 1. The Philips Health Watch. The Philips Health Watch is a wrist-worn, photoplethysmography-based, heart rate and activity monitor. It measures parameters such as heart rate, respiratory rate, step count, total energy expenditure, and activity time. Measurements use a 1-Hz sampling rate and are stored on the device as 1-minute average values. Data can be extracted in the hospital via Bluetooth using a proprietary iOS application and sent through Wi-Fi to the Philips Research server for analysis.

Table . Watch data before and after transcatheter aortic valve implantation (TAVI; overall and good responders cohorts).

Parameter	Before TAVI (n=97)	After TAVI (n=75)	*P* value	Good responders before TAVI (n=43)	*P* value[a]
Resting heart rate (1/minute), mean (SD)	62.5 (8.9)	62.3 (8.2)	.88	62.6 (10.3)	.90
Respiratory rate at rest (1/minute), mean (SD)	16.5 (1.9)	16.2 (1.8)	.54	16.5 (2.0)	.70
Heart rate (1/minute), mean (SD)	69.9 (8.3)	69.5 (7.3)	.72	70.2 (9.6)	.95
Heart rate during sleep (1/minute), mean (SD)	63.9 (8.9)	63.3 (8.5)	.57	64.3 (10.0)	.61
Respiratory rate during sleep (1/minute), mean (SD)	16.1 (2.1)	15.9 (2.1)	.92	16.1 (2.3)	.67
Daily percentage of HR[b] observations <60: bradycardia, median (IQR)	10.1 (1.2-34.5)	14.7 (2.4-35.4)	.92	13.3 (0.8-3.0)	.46
Daily percentage of HR observations >100: tachycardia, median (IQR)	1.3 (0.3-2.9)	1.3 (0.5-2.2)	.96	1.0 (0.3-1.0)	.86
Daily total number of steps, median (IQR)	3586 (2607-4946)	4341 (2093-6083)	.36	3633 (2763-5135)	.18
Daily cumulative active energy expenditure (kcal), mean (SD)	718.5 (206.5)	722.6 (226.6)	.98	733.0 (221.4)	.15
Daily cumulative total energy expenditure (kcal), mean (SD)	2313.3 (401.3)	2296.1 (436.6)	.72	2310.7 (428.1)	.19
Slope of log(HR/TEE[c])	0.27 (0.21-0.34)[d]	0.29 (0.23-0.36)[d]	.26	0.26 (0.1)[e]	.04
Daily sleep time (hours)	7.9 (1.8)[e]	10.1 (15.7)[e]	.23	8.2 (7.0-8.7)[d]	.28
Daily basal activity time (minutes), median (IQR)	209 (173-253)	198 (167-262)	.43	209 (173-261)	.94
Daily light activity time (minutes), mean (SD)	183.1 (83.8)	190.3 (100.3)	.63	195.2 (88.8)	.63
Daily moderate activity time (minutes)	48.8 (60.7)[e]	58.3 (51.3)[e]	.10	20.2 (8.8-66.3)[d]	.01
Daily high activity time (minutes), median (IQR)	0.0 (0.0-0.0)	0.0 (0.0-1.5)	.18	0.0 (0.0-0.0)	.19
Daily total active (minutes), mean (SD)	101.9 (91.4)	102.3 (71.9)	.98	108.3 (100.3)	.41

[a]*P* values apply to the comparison between pre- and post-TAVI values in the good responders cohort. See Table S3 in Multimedia Appendix 1 for the full comparison.

[b]HR: heart rate.

[c]TEE: total energy expenditure.

[d]Median (IQR) values.

[e]Mean (SD) values.

Figure 2. Distributions of heart and respiratory rate (overall percentage of heart rate observations <60: 57.9%; overall percentage of heart rate observations >100: 0.3%). This page of the output report from the health watch depicts density plots of the heart and respiration rates during the day and during sleep. It also shows the frequency of resting heart rate and the distribution of activity levels for heart rate observations >100 beats per minute.

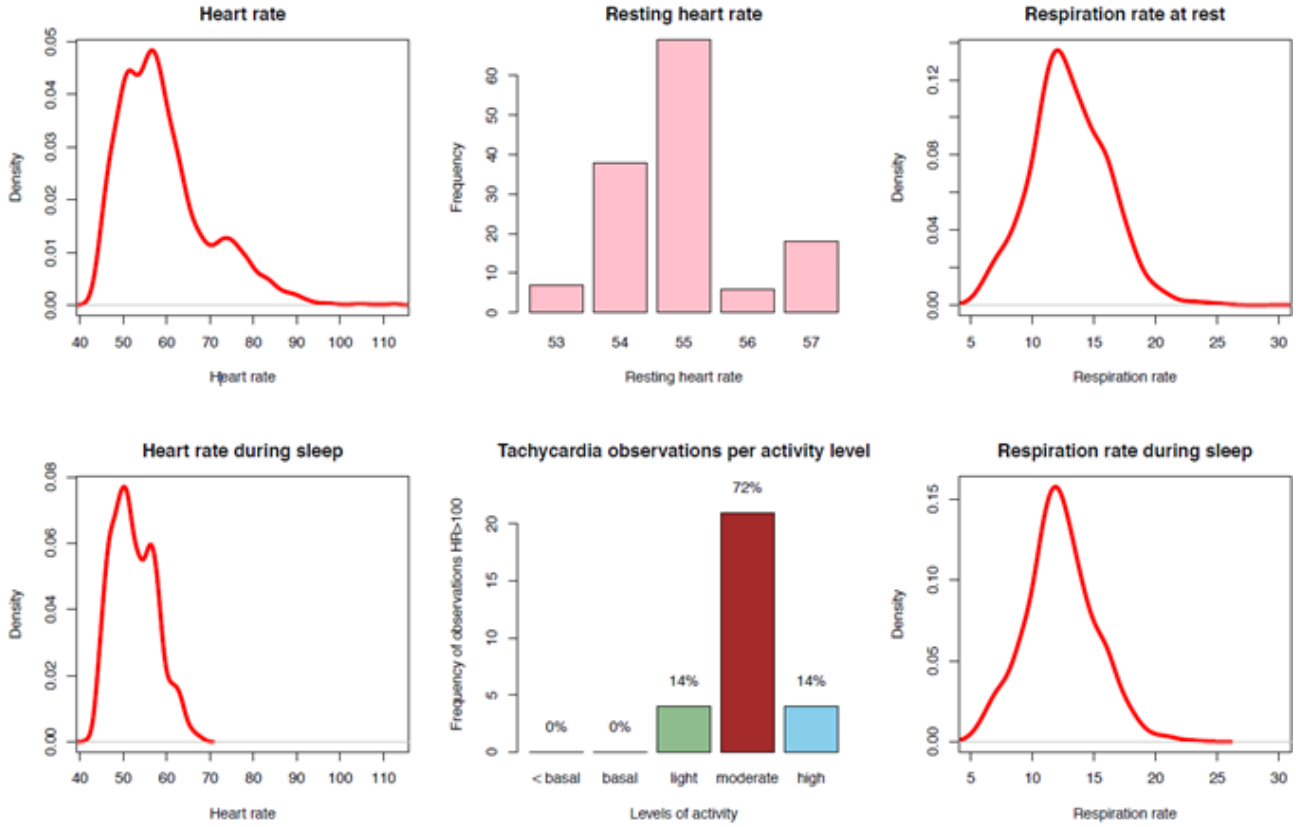

Figure 3. Log plot of heart rate versus total energy expenditure. Another page of the report plots each heart rate and corresponding total energy expenditure on a log plot, divided into subcategories of the Metabolic Equivalent Task (MET) scale. The fitted line relates to the energy efficiency of the cardiovascular system. bpm: beats per minute.

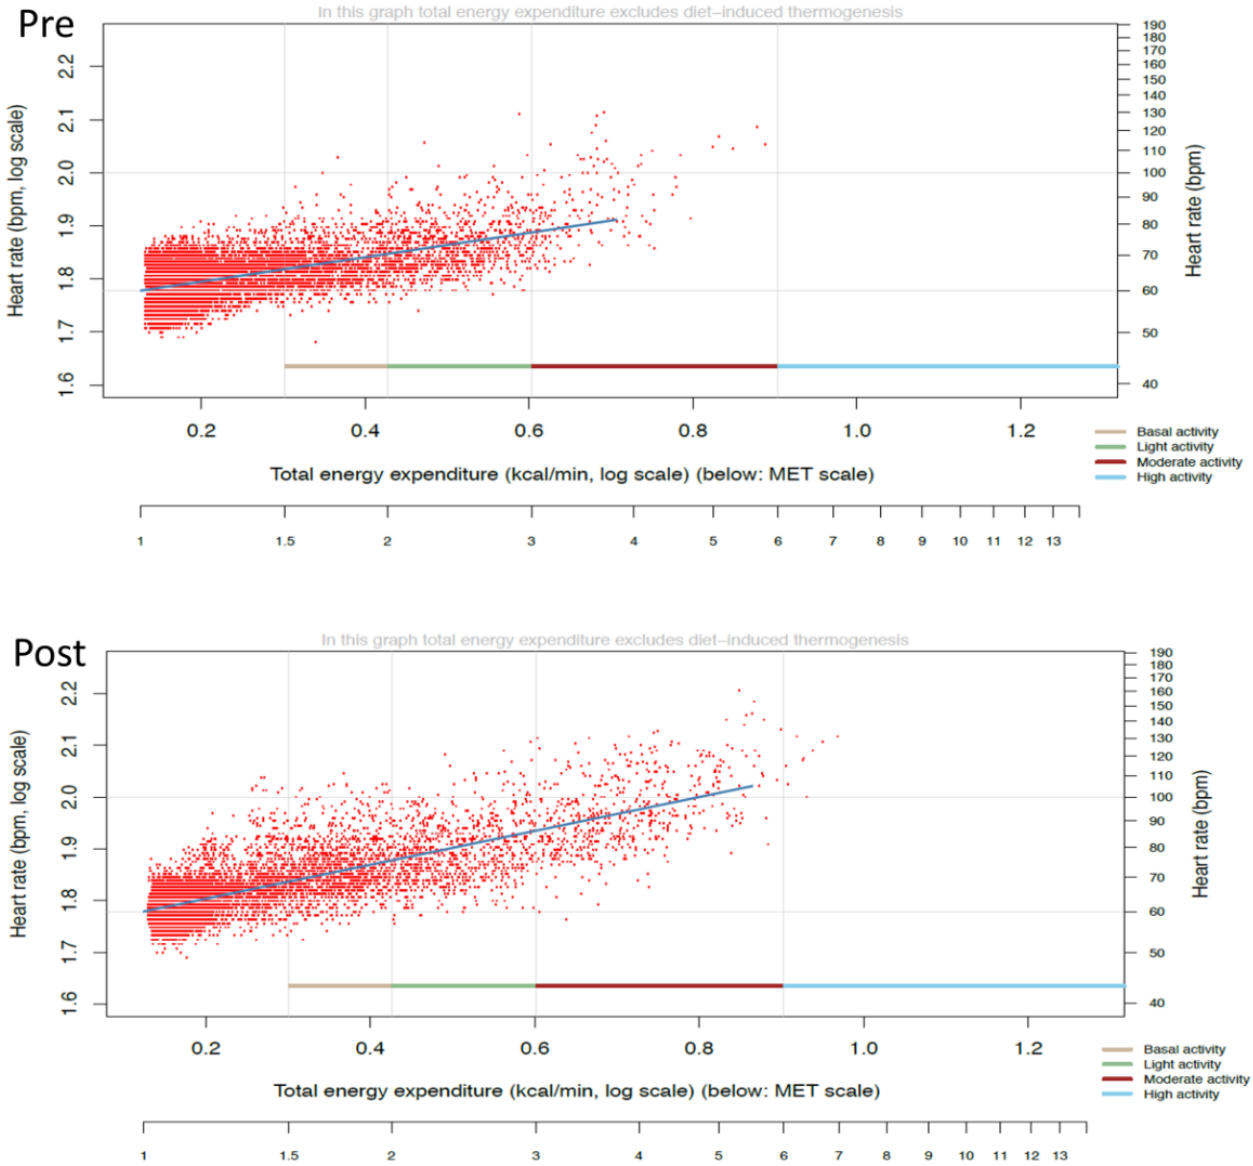

Statistical Analysis

Analyses were performed using SPSS (version 29.0; IBM Corp). The data are displayed as mean and SD values unless stated otherwise. Dichotomous variables are displayed as percentages (%) and absolute numbers (n). Applicable tests were 2-tailed, and $P<.05$ was considered statistically significant. Student *t* tests were used to compare normally distributed variables. Categorical variables were analyzed using the chi-square test, Fisher exact test, or McNemar-Bowker test, whichever was appropriate. As this was an exploratory study, no sample size was prespecified. Analyses were performed for the overall population ("overall cohort"), men versus women ("gender cohort"), those older than and those younger than 81 years ("81 y cohort"), those older than and those younger than 85 years ("85 y cohort"), and a cohort that had an increase of >40 m on the 6MWT after TAVI ("good responders cohort"). The 81-year cutoff is based on the median age, the 85-year cutoff was arbitrary, and the good responders cutoff is based on data from Tuttle et al [16].

Results

Demographic Characteristics

A total of 100 participants were enrolled. Their demographics and medications (before and after TAVI) are displayed in Table 2 and Table 3, respectively. After TAVI, 11 patients died and 11 patients were lost to follow-up. Data extraction for 3 patients failed before TAVI. Complete watch data were thus obtained for 97 patients before TAVI and 75 patients post TAVI. The population consisted of more men (n=57, 57%) than women. Demographic characteristics were representative of a clinical TAVI population with a median age of 81.0 years, NYHA (New York Heart Association) class II or higher in 92% (n=92) of patients, hypertension in 66% (n=66) of patients, and dyslipidemia in two-thirds of patients (n=67, 67%). All patients

fulfilled the criteria for severe aortic stenosis. Procedural data can be found in the supplemental material in Multimedia Appendix 1.

Table . Demographic characteristics at baseline.

Characteristics			Overall cohort (N=100)	Pre-TAVI[a] good responders cohort (n=43)	*P* value[b]
Age (years), median (IQR)			81.0 (76.0-84.0)	81.0 (74.0-84.0)	N/A[c]
Male participants, n (%)			57 (57)	22 (51)	N/A
Risk factors, n (%)					
	Active smoking		8 (8)	5 (12)	.19
	Hypertension		66 (66)	31 (72)	.15

Health Watch Parameters

Changes in all health watch parameters before and after TAVI are displayed in Table 1 and Table S3 in Multimedia Appendix 1 for the good responders cohort. Notably, in the total cohort, no parameter changed significantly. For the female cohort, there was a small increase in the light-to-moderate activity time (206.6 minutes before vs 207.3 minutes after TAVI, *P*=.03). For responders younger than 81 years in the good responders cohort, there was an increase in daily moderate activity: 14.2 minutes versus 39.3 minutes (*P*=.02) and 20.2 minutes versus 71.5 minutes (*P*=.01), respectively. A slight decrease was seen in the respiratory rate for responders older than 81 years (16.1 vs 15.1 per minute, *P*=.04). Heart rate, total number of steps, and daily total active minutes did not change after TAVI compared to those before TAVI for the overall group or for the different subgroups. There was no decrease in HR after TAVI despite a trend toward decreased use of beta-blockers (70% before TAVI vs 48% post TAVI, *P*=.26). Univariate analysis of health watch data could not identify a predictor for the good responders cohort (a >40 m improvement during the 6MWT). The results are displayed in Table S2 in Multimedia Appendix 1.

Energy Efficiency of the Cardiovascular System

The CEES—the slope of the fitted line in Figure 3 between HR and TEE on a log scale—serves as an indicator for the energy efficiency of the cardiovascular system. The CEES did not change significantly before versus after TAVI for the overall cohort (*P*=.26) but increased significantly for the good responders cohort (*P*=.04).

6MWT and the Transformed WHOQOL-BREF Questionnaire

The distance on the 6MWT increased after TAVI compared to that before TAVI (342.8 vs 289.7 m, respectively; *P*<.001) both for the total cohort as well as all subgroups. An improvement in the physical limitation score (domain 1 of the questionnaire) could be seen in the overall cohort (from 54.5 to 61.4, *P*=.005); on subgroup analyses, male participants (55.4 vs 62.0, *P*=.03), those younger than 81 years (51.8 vs 61.1, *P*=.001), and those younger than 85 years (54.4 vs 60.8, *P*=.01) showed a similar improvement. Results from the other domains (psychological, level of independence, social relationships, and overall) did not change for the total cohort. However, we detected an improvement in the psychological domain score among participants older than 81 years (67.6 vs 71.7, *P*=.03) and in the overall score among participants younger than 81 years (248.4

vs 267.1, *P*=.009). The parameters in the 6MWT and QoL questionnaire are summarized in Table 4 and Table 5, respectively.

Table . Parameters in the 6-minute walking test (6MWT) before and after TAVI[a].

Parameter	Before TAVI (N=100)	Post TAVI (n=76)	*P* value
Heart rate before the 6MWT (beats per minute), median (IQR)	69 (62 to 79)	70 (61 to 75)	.66
SpO_2[b] before the 6MWT (%), median (IQR)	97 (96 to 98)	98 (97 to 99)	.005
Distance (m), mean (SD)	289.7 (123.0)	342.8 (121.6)	<.001
Heart rate post the 6MWT (beats per minute), median (IQR)	88 (77 to 103)	89 (79 to 98)	.88
SpO_2 after the 6MWT (%), median (IQR)	97 (95 to 98)	97 (94 to 98)	.17
Beats Above Baseline Index, median (IQR)	19 (10 to 28)	20 (12 to 29)	.99
SpO_2 difference (%), IQR	–1 to 1	N/A[c] to 3	.09
Walking speed (m/second), mean (SD)	0.8 (0.3)	1.0 (0.3)	<.001

[a]TAVI: transcatheter aortic valve implantation.

[b]SpO_2: peripheral pulse oximeter saturation.

[c]N/A: not applicable.

Table . Quality of life questionnaire before versus post TAVI[a].

	Before TAVI (N=100)	Post TAVI (n=76)	*P* value
Domain I - physical, mean (SD)	54.5 (18.7)	61.4 (19.7)	.005
Domain II - psychological, mean (SD)	68.1 (14.7)	67.4 (14.4)	.64
Domain III - level of independence, median (IQR)	69 (53-75)	69 (56-75)	.88
Domain IV - social relationships, mean (SD)	71.4 (15.2)	73.5 (15.8)	.31
Overall score, mean (SD)	258.8 (53.6)	268.7 (58.7)	.16

[a]TAVI: transcatheter aortic valve implantation.

Discussion

Principal Findings

To our knowledge, this is the first study in which extensive 1-week physiological data before and after TAVI were assessed using a sophisticated wearable sensor, the Philips Health Watch. Watch parameters such as activity time and step count did not increase after TAVI for the overall cohort, in contrast with significant improvements in distance on the 6MWT (53 m; an 18% increase from baseline) and physical limitation score from the QoL questionnaire (7 points; a 13% increase from baseline). The increase in distance on the 6MWT mirrors the results obtained in a previous randomized trial: 254 m at baseline, 288 m at 30 days, and 297 m 1 year after TAVI [16].

One explanation for our findings is that daily activity does not actually increase in a relatively older population after TAVI, simply because they do not have to or do not want to increase it (ie, lack of necessity or motivation). In such cases, step count and HR are not expected to increase. However, distance on the 6MWT increased significantly after 1 year in a cohort randomized to TAVI compared to no change in those randomized to medical therapy [17], arguing against a Hawthorne effect. A second explanation for our findings is that QoL questionnaires and the 6MWT [4] generate abundant motivation in the hospital setting, which does not correspond with daily life. In this case, the findings on standard tests (including the 6MWT and QoL questionnaires) would appear to have improved, whereas parameters on the health watch would remain unchanged (eg, the daily total number of steps). Thus, both tests may be accurate given their circumstances. A third explanation is that the health watch parameters contain bias or imprecision, which their paired comparison, even in a reasonably sized cohorts such as our own. This seems to be an interesting topic for further research.

Novel metrics such as the CEES may be valuable parameters in the future or in other settings for evaluating cardiac energy efficiency. The steepness of the slope objectively quantifies the relationship between HR and TEE. A less steep slope corresponds with a lower CEES value. In such cases, more energy is needed to maintain HR than when the slope is steeper (and CEES value higher). In this study, there was a significant increase in the CEES for the good responders cohort, which was accompanied by a significant increase in moderate activity time. There was no significant improvement in the CEES or moderate daily activity time in patients who had no or moderate improvement in distance on the 6MWT (<40 m) after TAVI. This novel metric could be used in future research as a tool to identify patient improvement after a TAVI intervention, independent of subjective variables. More research on this metric is warranted.

How to best identify patients whose symptoms benefit from treatment with TAVI remains an important and unanswered clinical question. A post hoc analysis of a randomized trial of TAVI compared to a surgical aortic valve replacement demonstrated that 36% of patients had no change in 6MWT after outcomes after 30 days and 12 months, and 23%-28% of patients demonstrated no improvement in their QoL questionnaire scores (albeit using a different tool than the one used in our study) [16]. When considering an intervention, both procedural risks and economic costs should be balanced against the potential improvement in QoL. Since the patients who commonly qualify for TAVI treatment are relatively older and frailer, an increase in physical performance can be equally or even more important than an increase in life expectancy. With increasing health care costs, the benefit of an intervention should be clear and personalized [18], and for TAVI, this cost-benefit ratio has been disputed [19]. Unfortunately, the overall findings from this study cannot identify patients using the health watch who would be expected to have an above-average response.

The impact of health watches and other sensor technologies on cardiologic care warrants more research. The Apple Heart study [10] found an irregular cardiac rhythm in only 0.52% of over 400,000 people followed up for 8 months, of whom, only 21% completed further testing, and of them, a 34% minority were ultimately diagnosed with atrial fibrillation, accounting for a paltry yield of 153 people, or much lesser than 0.1% of the total. Findings such as these show the inevitable trade-offs between mass testing and the pretest probability of an actionable diagnosis.

Limitations

Not all patients had available follow-up data, including 11 patients who died. However, follow-up and health watch data were complete for >80% of patients. The second health watch measurement was performed 3 months after the procedure as that timing fit best with the local follow-up protocol. It might be speculated that not all patients have completely recovered at 3 months already. However, most studies comparing TAVI to surgical aortic valve replacement have reported good functional improvement in the TAVI cohort at 30 days and at 6 months [20] compared to the surgical aortic valve replacement group, with no further improvement in the TAVI cohort in 1 year. This implies that most patients are already at full capacity at 3 months' follow-up.

Conclusions

This is the first study that compares pre- and post-TAVI outcomes with extensive, 1-week functional assessment with a sophisticated wearable sensor, the Philips Health Watch. Data from the health watch did not register an increase in activity time, total step count, or other parameters after TAVI, whereas the traditional 6MWT and QoL assessment outcomes improved. Watch-based parameters such as these might be less appropriate for measuring treatment effects in the TAVI population. However, our findings relating to the good responder subpopulation suggest that using data such as the CEES parameter derived from wearable device data, might be useful to objectively identify patient improvement after TAVI intervention. This seems to be interesting for further research.

Conflicts of Interest

As this is part of the EURValve project, a European project, we received funding from Horizon 2020. RE, JZ, CC, MvV, DK, MK, GA, TK, GB, and IW report no additional support or industry relationships. HtH is from Philips Research, which provided the health watches used in this study. PT reports research grants from Biosensors, ZonMW (10070012010001), and opSens. NJ received internal funding from the Weatherhead PET Center for Preventing and Reversing Atherosclerosis; outside of this study, NJ and PT have a pending patent on diagnostic methods for quantifying aortic stenosis and TAVI physiology.

Abstract

Background: The enactment of the “Act to Improve Healthcare Provision through Digitalisation and Innovation ” (Digital Healthcare Act; *Digitale-Versorgung-Gesetz* [DVG]) in Germany has introduced a paradigm shift in medical practice, allowing physicians to prescribe mobile health (mHealth) apps alongside traditional medications. This transformation imposes a dual responsibility on physicians to acquaint themselves with qualifying apps and align them with patient diagnoses, while requiring patients to adhere to the prescribed app use, similar to pharmaceutical adherence. This transition, particularly challenging for older generations who are less skilled with technology, underscores a significant evolution in Germany’s medical landscape.

Objective: This study aims to investigate physicians’ responses to this novel treatment option, their strategies for adapting to this form of prescription, and the willingness of patients to adhere to prescribed mHealth apps.

Methods: Using an exploratory qualitative study design, we conducted semistructured interviews with 28 physicians and 30 potential patients aged 50 years and older from August 2020 to June 2021.

Results: The findings reveal several factors influencing the adoption of mHealth apps, prompting a nuanced understanding of adoption research. Notably, both physicians and patients demonstrated a lack of information regarding mHealth apps and their positive health impacts, contributing to a deficiency in trust. Physicians’ self-perceived digital competence and their evaluation of patients’ digital proficiency emerge as pivotal factors influencing the prescription of mHealth apps.

Conclusions: Our study provides comprehensive insights into the prescription process and the fundamental factors shaping the adoption of mHealth apps in Germany. The identified information gaps on both the physicians’ and patients’ sides contribute to a trust deficit and hindered digital competence. This research advances the understanding of adoption dynamics regarding digital health technologies and highlights crucial considerations for the successful integration of digital health apps into medical practice.

KEYWORDS

mobile health apps; DiGA; adoption; prescription; mHealth; aging and individual differences

Introduction

Mobile devices have enormous potential to enhance the way patients receive medical care and health education [1]. Mobile health (mHealth) is a dynamic and expanding area of health care with short innovation cycles [1,2]. mHealth is closely related to telemedicine and eHealth. The fundamental difference lies in how the related services are delivered to the patient. According to the World Health Organization (WHO), mHealth expands the spectrum of functionalities to include a mobile component. Thus, mHealth is delivered through any mobile

device, from simple mobile phones, smartphones, and tablets to wearable devices used in health care settings [2].

To accommodate the growing number of mHealth apps (ie, software products for smartphones designed to support good health), Germany passed the "Act to Improve Healthcare Provision through Digitalisation and Innovation" (Digital Healthcare Act; *Digitale-Versorgung-Gesetz* [DVG]) in December 2019 and the Digital Health Applications Ordinance (*Digitale-Gesundheitsanwendungen-Verordnung* [DiGAV]) in October 2020 [3,4]. This ordinance enables physicians to prescribe mHealth apps (in German referred to as *Digitale Gesundheitsanwendungen* [DiGAs; digital health applications]) to their patients in the same way as any other medicine. A DiGA supports the recognition, monitoring, treatment, and alleviation of diseases, injuries, or disabilities [5]. To qualify as a DiGA, an mHealth app has to successfully pass the evaluation of the Federal Institute for Drugs and Medical Devices (*Bundesinstitut für Arzneimittel und Medizinprodukte*; BfArM). Only then will an app be included in the list of reimbursable digital health apps, the so-called DiGA directory. In September 2023, this directory comprised 48 admitted DiGAs [6]. DiGAs cover a wide array of the medical spectra. Popular examples are "Endo-App" (to treat endometriosis), "Kaia COPD" (for chronic obstructive pulmonary diseases), or "sinCephalea" (for the treatment of migraine).

The introduction of the "Act to Improve Healthcare Provision through Digitalisation and Innovation" represents a significant and innovative change to the German health care system [7]. The new legal framework elevates DiGAs to the ranks of medical devices [5]. Therefore, if physicians want to prescribe a DiGA, they are required to thoroughly inform themselves about which apps can help their patients, how they are to be used, and how a positive influence is expected to manifest. Patients are required and need to be able to adhere to the prescription; for example, they have to use the DiGA as stated by the physician. Thus, the physician needs to assess (implicitly or explicitly) whether the patient is likely to use the DiGA as prescribed. This does not only include adherence to, for example, training intervals (for orthopedic DiGAs) but also the general technology savviness of the patient, for example, whether the patient is able to download the app, install it on the smartphone, maintain updates, and so on. This question is specifically challenging when it comes to older users, who are often regarded as being not technology savvy.

Consequently, this innovation raises several questions for technology adoption research. Typically, adoption research concerns the individual user's decision whether to use technology, either mandatory [8,9] or voluntary [10]. Now, a concerned third party (the physician) decides on behalf of the user whether the patient is expected to be willing and able to use an app on their smartphone voluntarily. Therefore, the physician's assessment now includes not only the medical relevance of the DiGA but also whether the user might be able and willing to use it as prescribed. Although the latter assessment seems easy for younger people, the case is much more difficult for older patients. Potential doctor misperception raises concerns about a possible digital divide and ageism by doctors. A recent report by the WHO and the United Nations (UN) raises awareness of this issue and urges action to combat ageism, as it negatively impacts well-being and can lead to premature death and higher health care costs [11].

In the health care context, the resulting research questions are specifically relevant, as the influence of age on the adoption of mHealth apps has not yet received sufficient attention in the scientific discourse [12]. Therefore, this research addresses the complementary research questions:

1. What factors enable or hinder physicians to prescribe DiGAs?
2. What factors enable or hinder older users' adoption of DiGAs?

Methods

Study Design

We developed an exploratory qualitative study design to answer the research questions and gain insights through semistructured interviews with representatives of the 2 relevant stakeholder groups: physicians and patients. The study adhered to the standards for reporting on qualitative research [13].

Study Setting

The data for our research were gathered in Germany.

Participants

The first qualitative study was conducted from August 2020 to June 2021. We interviewed 28 physicians (demographics are provided in Table 1) to assess how DiGAs can improve the health of their patients. Physicians were chosen as research objects because of their unique role as prescribers of DiGAs. The interviewees had different backgrounds in terms of IT affinity and previous experience with mHealth apps in general.

Table 1. Demographics of the physicians.

Code	Specialty	Sex	Age (years)
E1	General practitioner and cardiologist	Male	63
E2	Dermatologist	Male	67
E3	Dermatologist	Male	45
E4	Urologist	Male	48
E5	General practitioner	Female	63
E6	Dermatologist	Female	54
E7	Dermatologist	Male	41
E8	Internist and gerontologist	Male	38
E9	Orthopedist	Male	53
E10	General practitioner	Male	64
E11	Geriatric therapist	Female	58
E12	Urologist	Male	38
E13	General practitioner and pain therapist	Male	59
E14	Assistant doctor cardiology	Male	35
E15	Urologist	Male	42
E16	General practitioner	Male	68
E17	Dermatologist	Female	36
E18	General practitioner	Female	38
E19	General practitioner	Female	59
E20	General practitioner	Female	41
E21	General practitioner	Female	45
E22	General practitioner	Male	45
E23	Neurologist	Male	44
E24	General practitioner	Male	67
E25	Neurologist	Male	65
E26	Neurologist	Male	42
E27	Molecular neurologist	Female	45
E28	General practitioner	Female	37

In the second study, we interviewed patients (ie, the potential users of a DiGA). To reflect the specific issues of aging patients, we chose interview partners over 50 years of age. Evidence shows that from this age onward, chronic diseases increase significantly [14]. Therefore, this age group is likely to represent a large part of the target group for the prescription of DiGAs. Furthermore, studies suggest that there are still age disparities in attitudes toward technology and that the aging population is often less comfortable using technology [15].

We conducted 30 interviews to determine the factors that influence potential patients to adopt DiGAs or not. Demographics of the interviewees are given in Table 2.

Table 2. Demographics of the patients.

Code	Sex	Age (years)
P1	Male	68
P2	Female	60
P3	Female	57
P4	Female	76

P29	Female	64
P30	Female	68

Recruitment

We recruited physicians by telephone from a community-based physician network in Germany and via social media. For the interviews with patients, we promoted our study to doctors and approached medical centers and clinics. To identify suitable interview partners (ie, *potential* patients), we presented the research project to local sports, communication, and civic groups; promoted the study on various social media platforms; and spoke to the local press. In this way, we motivated suitable candidates to contact us. The participation of all study participants, both physicians and patients, was voluntary.

Data Collection

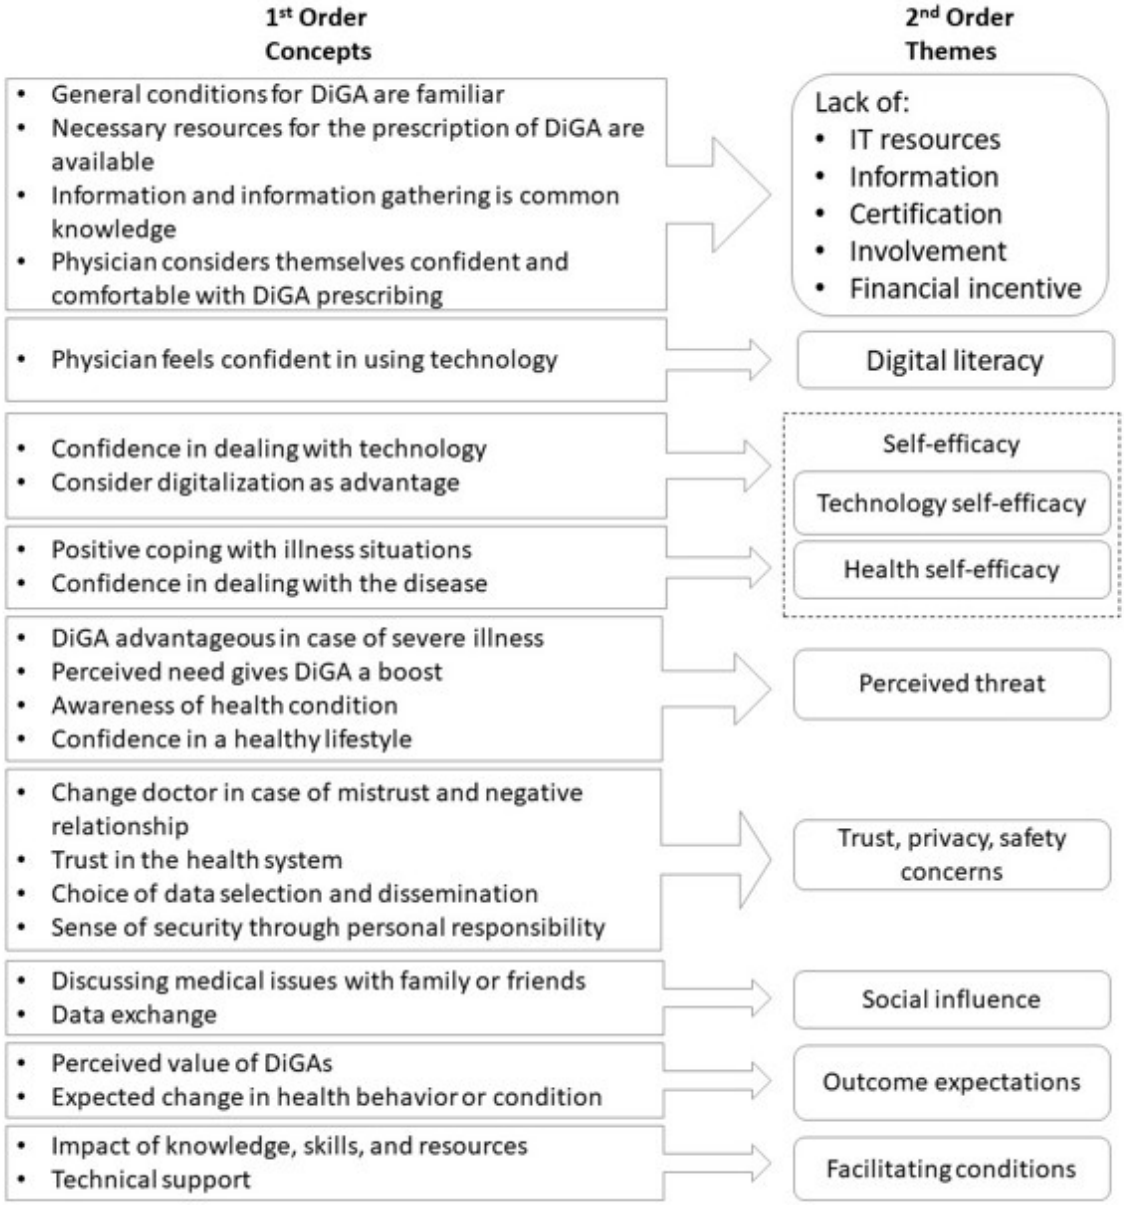
All interviews were semistructured and led by a list of questions and general topics that the interviewers were supposed to address. The semistructured interview guidelines are provided in Multimedia Appendix 1. As a structure and topic basis for creating the questions, the constructs from well-known technology adoption research models (unified theory of acceptance and use of technology [UTAUT] [9]) and models for the analysis of health behavior (health belief model [HBM] [16]) were considered. The questions were primarily open and allowed the interviewees to explore their experiences and views. Supported by a systematic and comprehensive interview process, the interviewers had high degrees of freedom to conduct the interview in order to gain deeper insights. The questions were adjusted correspondingly for the following interviews to gain

more profound knowledge for each interview. Interviews lasted around 20-45 minutes and were conducted face-to-face or over the phone by 1 researcher (TS). The interviews were conducted in German and were recorded, transcribed, and translated into English for further analysis [17].

Data Analysis

For the coding process, we used the NVivo10 software (QSR International). The research was conducted using an interpretative phenomenological analysis (IPA) [18]. IPA aims to examine the world perspective of the participants and, if possible, take an "insider perspective" [18] of the phenomenon under investigation. At the same time, IPA recognizes that research is a dynamic process. In parallel with the data collection, we scanned and coded the data from the first round of analysis. One researcher (TS) conducted a thematic analysis to identify patterns and themes. After analyzing the first 3 interview transcripts, 2 researchers (MH and TS) developed a coding framework using an inductive approach that allowed for identification of predominant themes. All emerging themes were cross-checked and discussed within the whole research team and developed iteratively to ensure definition and reliability. In the process, commonalities and differences between the respective perspectives were identified. This led to 9 different key themes concerning benefits and barriers, influencing factors on the intention to adopt a DiGA, and the outcome expectation from different perspectives as the main areas. Figure 1 lists the corresponding coding scheme according to Gioia et al [19]. The aim was to understand the specific properties of these areas and the influence of these factors in the context of the introduction of DiGAs.

Figure 1. Coding scheme using the methodology by Giola et al. DiGA: Digitale Gesundheitsanwendungen (digital health application).



Ethical Considerations

This study did not require ethical approval according to the guideline of the applicable Ethics Committee of the Bavarian Universities [20], as no risks or harm was brought forward to the participants. All participants received an information and consent form explaining the requirements for participation. This included the opportunity to have the form explained to them if needed. All interviewees gave written or verbal consent before the interview started. Data collection, storage, and analysis were conducted in adherence to European Union General Data Protection Regulation (EU-GDPR). None of the participants were compensated.

Results

Overview

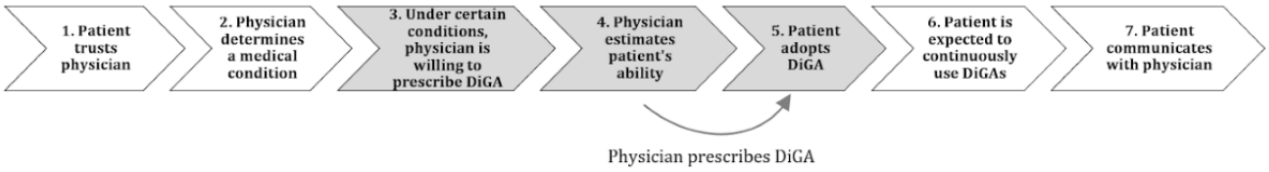
Our data demonstrate that only 4 of the interviewed physicians already prescribed DiGAs and none of the patients had used a DiGA before (Table S1 in Multimedia Appendix 1). Nevertheless, most physicians have experienced mHealth apps themselves. These were mostly used for medical information in their professional routine or privately for personal fitness and nutrition goals.

On the patient side, 20 participants had already had experience with mHealth apps or were actively using them (Table S2 in Multimedia Appendix 1). In this context, only fitness and nutrition apps were mentioned. These apps have a preventive character to help people to consciously lead a healthier and more active life. Most of the apps mentioned were those used in conjunction with smartwatches to measure activity, such as pedometers.

The DiGA Adoption Process of Physicians and Patients

The analysis indicates that for DiGAs in particular, additional steps are added to the traditional prescribing process. Because of the special role of the doctor as a gatekeeper, the doctor is the first to decide whether the patient is suitable for a DiGA. First, the familiar steps such as the patient's trust in the doctor and the treating doctor's determination of the patient's medical condition represent the keystone of the process. Following these steps, when prescribing a DiGA, the next steps are the doctor's consent to prescribe a DiGA under certain conditions and the assessment of the patient's ability to use a DiGA. Thereafter, the doctor prescribes a DiGA, and the patient is given the opportunity to adopt it. The process ends with the expectation that the patient will continuously use the prescribed DiGA and report the results to the treating physician. This process is visualized in Figure 2, with the doctor and the patient being influenced by different factors that determine whether the DiGA is prescribed (doctor's perspective) and accepted (patient's perspective).

Figure 2. The adoption process for DiGAs by the physician and patient. DiGA: Digitale Gesundheitsanwendungen (digital health application).



Factors Enabling or Hindering Physicians to Prescribe DiGAs

Overview

Our results indicated that DiGAs are not yet widely known and used at this early stage by the physicians we interviewed. They indicated that the level of information is still insufficient and that very few DiGAs are prescribed compared with the prescription of drugs. DiGAs represent a completely new and innovative approach, so entry challenges are not considered unusual. Nevertheless, these challenges are initially barriers to prescribing DiGAs according to our participants. We were able to identify the following factors that influence physicians to prescribe a DiGA or not.

Lack of IT Resources

The lack of IT resources was mentioned by the interviewed doctors as a barrier to prescribing DiGAs within the framework of the DVG. Numerous efforts have been made toward digitalization. These include networking with various players in the German health system, such as doctors, hospitals, pharmacies, and health insurance companies. So far, only limited resources are available for the implementation of these plans. The doctors interviewed describe that, for example, the provision of services for an electronic health record (EHR) could help to digitalize various processes and information. They see the benefit of a DiGA for their work as low as long as the patient files and the exchange between other actors in the health care system are not fully digitized. The introduction of an EHR in Germany has failed so far because of technical challenges.

Lack of Information

Another reason often mentioned in connection with rejection was a lack of information. Physicians often do not know which DiGAs are available and where they could get the necessary information. As a result, physicians are often reluctant and skeptical about prescribing DiGAs ("No, I have not been educated on what DiGAs are available, how to prescribe, and how to tell if a DiGA is effective. I would not know where to look for this information" [E2, E3, E8, E12, E16, E20, E21, E25, and E28]; "I have little time to search for all the information I need to prescribe a DiGA in good conscience" [E1, E4, E8, E15, E16, E20, and E21]). They tend to be negative out of concern for malpractice and the resulting liability risk. Likewise, the physicians described the requirements for evidence of a DiGA (requirements for security, functionality, data protection, information security and quality, and positive effects on care) in the assessment procedure of a DiGA as insufficient. Along with this concern is the fact that for provisionally included DiGAs, evidence-based studies on the benefit of the

app are not yet available, and the apps are therefore only provisionally included in the directory. A comprehensive explanation of the BfArM authorization process of a DiGA can counteract these problems. However, participants reported receiving little information from insurers, DiGA manufacturers, or the BfArM. Physician respondents stated that proactive communication from DiGA providers was limited and possible involvement in the development process was unknown ("These apps have often been developed without the support of physicians and are now being 'fast-tracked' to market—that is not exactly building trust" [E25]). This statement reflects a high level of mistrust. In contrast, one participant stated that he worked with an app development company to develop an app in his field and described that this approach was extremely helpful to reduce the information deficit, mistrust, and gain more confidence. This shows that involvement is possible, but that an exchange of information is necessary.

Lack of Certification

In medical circles, a lack of certification has been widely mentioned. Half of all interviewed physicians agree that DiGAs, similar to other medical products (eg, drugs and medical aids such as wheelchairs or bandages), should be provided with a known official certification to ensure more trust in the product ("I think a well-known and recognized certification in medicine could help to build confidence in DiGAs" [E2, E13, E15, E17, E26, and E28]). Certification would make it easy to recognize that the DiGAs are safe as a medical device and are also medically or technically suitable within the scope of the intended purpose stated by the manufacturer. A certification equivalent to that for medicines could be conceivable in this context.

Lack of Involvement

Another aspect that our interviewees criticized was the lack of involvement after the prescription of a DiGA. They described that they are little involved in the procedure after prescribing a DiGA and in many cases currently only take on the role of a "prescriber" ("I would like to be involved in the whole process from the manufacturing to the evaluation of the data with the patient" [E5]). This shows that the participating physicians apparently make a great distinction between a traditional medicine in the form of medication administration and the use of digital components. After prescribing a traditional medicine, the physician only gets feedback when the patient comes back after some time and tells them how the medicine works. But with digital options such as DiGAs, the requirement is now higher: participants demanded an adjustment of the involvement in the postprescription process. A preview of future digitization plans shows that the involvement of physicians in the digital feedback process will be considered.

Lack of Financial Incentives

Participants further stated that counseling for a DiGA is much more time-consuming than for medicines, but the monetary incentive is not there. As a result, we identified a lack of financial incentive. Financial pressure weighs on the physicians in this regard, which is not compensated for by health insurance companies. As a result, the incentive for prescribing (€2 [US $2.16] per prescription) and treatment support (eg, successful monitoring) is currently considered too low ("2 euros for prescribing or 7 euros for treatment support are in no way an incentive to prescribe a DiGA" [E2]).

Finally, the study also found differences in physicians' skills, knowledge, and attitudes toward digital technology. We define this factor as digital literacy, which has 2 specific characteristics. Some of the surveyed physicians stated that they have the impression that a physician is either digitally interested and very open-minded or completely ignorant of new innovations, so that even educational conversations might fail ("Either you find it good as a physician and have dealt with it once or recommended it to your patients. Or you ignore it at first" [E6]). Along with this result, the physicians interviewed expressed the fear that they might lack knowledge, for example, when it comes to patients' technical questions or that they would have to become a kind of "technical support" in the event of problems in this area or in the evaluation of DiGA analyses. Others, however, considered the introduction of DiGAs to be an advantage for their work and less of a hindrance or a problem.

Factors Enabling or Hindering Older Users' Adoption of DiGAs

Overview

As indicated above, a process of influencing factors leads to the adoption of DiGAs by patients. Thus, if the physician determines a medical condition, is willing to prescribe a DiGA, and considers the patient's ability to use a DiGA to be positive, the physician will eventually prescribe a DiGA so that the patient will have the opportunity to adopt it.

Lack of Information

Similar to the physicians, we also identified a lack of information on the patient side. The DiGA concept is rather rarely known by the patients, and experiences were only described in 3 of the 30 interviewed participants. Nevertheless, from the patient perspective, DiGAs are recognized as an innovative and profitable treatment option that can be carried out independently of the time and place of the doctor's visit ("I want to have the flexibility to do my therapy when it suits me" [P1, P6, P9, P12, P18, P26, P29, and P30]). Patients described DiGAs as a helpful "bridge" and a refresher or repetition of therapy content, especially for patients waiting for an appointment with a specialist (eg, psychotherapist). Some patients pointed to a long history of illness and low chances of success of conventional therapies and considered DiGAs as another treatment option. The interviews thus confirmed that the population's willingness for DiGAs is high. However, many patients lack further information ("My physician or my health insurance company haven't informed me about it yet—how should I know?" [P2, P3, P12, P16, P19, P22, and P29]).

The factors influencing the adoption of DiGAs are discussed in more detail below. In this context, we are oriented toward the most well-known models in adoption research: the UTAUT [9], a model from information systems that measures the acceptance of a technology by users to gain access to individual user behavior, and the HBM [16], a theoretical model from health psychology that analyzes and predicts health-related behavior.

Self-Efficacy

Self-efficacy refers to a sense of control over one's environment and behavior. Participants considered self-efficacy important but also taken for granted. A distinction was made between technology self-efficacy about the DiGA and health self-efficacy with a health aspect. We define technology self-efficacy as the patient's belief in their competence to use the DiGA. Health self-efficacy here describes the patient being confident in managing their health. Participants expressed confidence in their technology self-efficacy. For all participants, everyday use of smartphones and various apps was normal and regular. Some indicated that they still prefer paper calendars or dislike apps for health prevention but saw digital documentation and treatment support as an advantage in case of possible illness ("I'm more used to pen and paper, but if you get used to it, it certainly has its advantages" [P1, P4, P12, P14, P21, and P29]). In terms of health self-efficacy, participants were mostly self-confident. No participant stated that they did not want to deal with illnesses or would rather not know how healthy or ill their body was. Most participants seemed to have a high level of health literacy and wanted to actively deal with their health ("Yes, I would rather be the person who would then say, I would like to know this to know my enemy and then fight against it" [P19]). Participants indicated that a personal sense of control facilitates health behavior change ("Then an app like that would be great because you can calm down a bit more and have more security for yourself" [P10]). Participants confirmed that they focus on the opportunities rather than the obstacles ("Yes, I usually don't go right away, but after a short scare I always face all the problems, so I'm more for problem solving rather than suppression" [P3]).

Perceived Threat

Perceived threat was mentioned as a crucial central factor for the use of a DiGA in the context of an impending or existing chronic disease. According to the HBM, perceived threat stems from beliefs about perceived susceptibility to disease and the perceived severity of disease consequences [16]. Susceptibility here refers to a person's risk of contracting a disease. Severity refers not only to the medical consequences but also to the potential impact of an illness on a person's daily life, family life, and social relationships. Participants indicated that a threat has a strong influence on health behavior. They explained that if they were seriously ill, they would use any means to support treatment, both digital and analogue ("So, I would say if I got sick now, I would be very interested in a DiGA already" [P29]; "Yes, when I get sick, I try everything possible to get better, whether digital or not" [P3]). Nevertheless, participants indicated that they generally felt very body and health conscious ("I eat healthy and exercise as much as I can, that's part of my everyday life" [P9, P11, P15, P16, P21, P23, P26, and P29]). Only 1 respondent indicated that they felt an increased fear of possible illness. All participants indicated that they were primarily concerned with their health and well-being and that preventive measures were a natural part of their lives ("I prefer to focus positively on my health instead of worrying daily about illness and negative health" [P23, P29, and P31]).

Trust in the Physician, Attitudes Toward Privacy, and Safety Concerns

Partly different from classical adoption research, trust in the physician, attitudes toward privacy, and safety concerns were mentioned as key characteristics. Due to the medical field, the existing models require expansion. Trust does not describe a direct influencing factor but rather a precondition. For the participants, a deep trust relationship with their physician was crucial to consult a physician in case of a health problem and to receive good medical treatment. If this precondition is not given, an exchange about digital treatment options does not take place ("If I feel that I cannot trust him, then I would change" [P1, P7, P10, P13, and P22]; "The most important thing is the trust relationship. If I don't trust my physician, I change physicians" [P27]). Subordinated are the characteristics of privacy and security. All participants considered it important to be able to set privacy settings themselves. The vast majority said that they did not particularly care about the content of privacy settings, but wanted to decide for themselves who could access which health data ("I would like to know who knows what about me" [P6, P7, P8, P15, and P26]; "There should be settings options. I don't want to transmit everyday occurrences" [P9, P10, P11, P13, and P27]). Based on the accreditation of a DiGA as a medical device and the assessment by the BfArM, they have no concerns about the safety of DiGAs and feel confident in using DiGAs ("I trust that our federal system is highly secure" [P11]). On the basis of these correlations, we categorized the 3 concepts together. We rank the trust factor as the most important, as the privacy and security factors can be mitigated by a high level of trust.

Social Influence

The concept of social influence reflects the effect of environmental factors, for example, the opinion of friends and family, and is a significant factor in traditional adoption research [21]. However, in this study, we could not find any relevant results. Here, the medical context seems to have an important role. Most participants indicated that they did not discuss their health behaviors, personal diagnosis, or treatment plans with their social circle ("I don't want to share all health data, including the fact that I use a health app, with other people" [P9]). We suspect that social influence may be a factor that is difficult to capture due to the sensitive nature of the data.

Outcome Expectations

Outcome expectations are defined as the expected consequences of a certain health behavior, which can be negative or positive [22], that is, what does the patient expect from using a DiGA. Participants stated that they would be able to reduce the frequency of visits to the physician, thus saving travel and time; that an existing illness would be better monitored by the physician; that they would feel safe and well cared for as a result; and that they would receive health-promoting treatment in the form of the DiGA. However, these expectations were tied to the continued use of features of the DiGA. Participants agreed that a DiGA must be simple to use, regardless of age. Many participants expect the app to provide more detailed information about the disease, symptoms, medication, and contraindications. However, this information needs to be understandable,

meaningful, and informative for every patient, regardless of age, education level, and professional background ("It should be easy for me, and I should be able to understand and comprehend it. The ease of use." [P1, P5, P16, P19, and P21]).

Facilitating Conditions

Eventually, these expectations also cross over to the facilitating conditions, which includes the impact of the patient's knowledge, skills, and resources. Here, the participants considered technical support to be particularly important. This was not because they felt unsure about using the technology but rather because it was a new type of health intervention. Some participants considered the physician to be an appropriate point of contact when difficulties arose in a few cases. Other participants stated that if they had difficulties or questions, they would ask their family and friends for help, as they do with other technical matters ("I think it would be good to have a number that I can call and that can help me" [P2]; "Well, I trust my son, he knows me anyway. And he would also know the diseases I have" [P18]). In summary, this study distinguishes between technical infrastructure and health support, with the health aspect (eg, knowledge and understanding of the diseases and their treatment) being more important here.

Post Hoc Analysis: Physician Assessment of the Patient's Ability to Use a DiGA

During our interviews with the physicians, we discovered a phenomenon that we did not initially anticipate and that has not yet been described in the relevant technology adoption literature: the pre–user adoption decision of another instance, whether the user will be able and willing to voluntary use a technology. Typically, in technology adoption research analyses, this means whether a user is willing to use a technology in an either voluntary or mandatory environment. In any case, the decision remains with the user.

Now we see a new phenomenon: the assessment of one instance (physician), whether a subsequent instance (patient) would be able to use the DiGA. Only if the assessment is positive would the physician offer the DiGA to the patient, which will then trigger the traditional adoption questions and corresponding behavior of the user, as described in the well-researched technology adoption models such as the technology acceptance model, UTAUT, and HBM [9,16,23].

There are no guidelines under which circumstances a patient should be assumed to be able to use a DiGA. Thus, each physician needs to do this assessment individually. If they conclude that the patient will likely not be able to install, maintain, and use the app as foreseen by its developers, there is no point in prescribing the DiGA. As there are no objective guidelines, the assessment is either done explicitly, by asking the patient, or implicitly, by assuming what the patient is capable of.

Interestingly, the physicians interviewed were very consistent regarding the assessment of digital literacy of their patients. They indicated that prioritization of certain patient groups is facilitated by anticipating the digital literacy of their patients. Unfortunately, this often leads to a negative bias toward older users; the physicians described the typical DiGA user as a young and tech-savvy patient ("I would not consider my older patients for the use of DiGAs" [E1, E2, E4, E7, E8, E11, E12, E15, E16, E17, E20, E21, E22, and E28]; "There are certainly exceptions, but most of my older patients are totally overwhelmed with a tablet or a smartphone, because the interest would not even be there" [E11]). Consistently, physicians expressed that they would not even consider an older patient as a DiGA user.

As mentioned before, these findings arose from the data and were not anticipated before. Thus, both issues, the second-order technology adoption process and the (possible) systematic disadvantage of older users, need deeper investigation in further research.

Discussion

Overview

In this research, we identified the salient factors that were either beneficial or hindering the adoption of DiGAs from the physician and the patient perspective. Furthermore, the results of our study suggest that the adoption process for a DiGA does not only depend on patient behavior but also on the physician's behavior.

Most informants have a positive attitude toward the digitalization in general. Nevertheless, physicians' demands on DiGAs are high, and their perceptions can be affected by a lack of facilitating conditions, trust, and digital competence. Certain influencing factors for the adoption of DiGAs by patients are consistent with the literature on established adoption research [9,24-28].

Principal Implications

Our study contributes to the field by investigating factors influencing the adoption of DiGAs to inform future research and guide strategies and efforts for this user group. DiGAs represent a wide range of assistive apps that aim to support disease behaviors, manage various health conditions, and maintain the well-being of those with chronic diseases. There are very few empirical studies addressing the factors influencing users' adoption of DiGAs [7,29,30]; hence, there is limited knowledge and guidance from the existing literature.

First, it is important to demonstrate that existing technology acceptance models reach their limits when used in the context of DiGAs. In contrast to Davis [23] and Venkatesh et al [9], our interviews with physicians and potential patients led to the assumption that, in addition to usefulness and ease of use, there are more constructs that play a significant role. We found that technology and health aspects such as technology- and health-related self-efficacy, trust, and a trustful doctor-patient relationship play a major role in the intention to use DiGAs. So far, these aspects have rarely been brought together. A study by Uncovska et al [30] confirms this finding. However, we note that there are few studies on the adoption process of DiGA. Other studies regarding mHealth app adoption have highlighted that health consciousness of individuals is a factor that directly influences both the intention to use mHealth apps and the actual use behavior [31,32]. Public trust in the health care system [33] and a strong doctor-patient relationship can empower patients to contribute to treatment decision-making [34].

Second, we found that our interviewees on the patient side distinguished between technology-related and health-related self-efficacy. The consideration of a health component is not integrated into traditional technology adoption research. To date, it has not seemed necessary to consider the health domain in adopting general technologies. However, this is an important difference in the adoption of DiGAs. With DiGAs, the focus is on the health aspect for both the physician and the patient. Patients who may have low self-efficacy with technology do not simultaneously have to have low self-efficacy with their health. Older people, in particular, may have very sophisticated health self-efficacy while lacking technology self-efficacy [35-38]. Distinguishing these forms of self-efficacy provides a more detailed explanation of adoption behavior, increasing our understanding in the context of DiGAs. Personal beliefs, such as outcome expectations and self-efficacy expectations, are among the most critical variables in terms of intention formation and bridging the gap between intention and behavior, according to existing literature [39-41]. Nevertheless, a division into different areas of self-efficacy has not yet been made in information systems research but also in research on health adoption. As technology and health self-efficacy positively impact the adoption of DiGAs, we believe that it is important to consider both factors.

Third, related to the previous aspect, is the construct of perceived threat. Previous research shows that people are concerned about adopting technology in different areas, such as privacy, effort, or performance [7,42,43]. However, when using DiGAs, health is firmly in focus from a medical perspective. Therefore, the perceived threat of diseases and the need to use a DiGA strongly influenced the adoption of a DiGA. In our interviews, this construct was strongly emphasized, and we suspect moderation effects on other constructs, such as technology and health self-efficacy. A high perceived threat can increase the influence of the perceived health self-efficacy on adopting a DiGA because a threat can be better assessed by someone with high health self-efficacy and is, therefore, more likely to act. As a result, it is also possible that DiGAs will have a higher use rate, especially for hazardous diseases. A recent study by Pourhaji et al [44] investigated the perceived threat and stress response to the COVID-19 pandemic and found that the Iranian population's health behavior was influenced by the perceived severity and susceptibility of the infection, which meant that preventive interventions were more likely to be accepted. Further studies related to COVID-19 found that risk severity also tends to increase with age, but the perception of susceptibility to contracting COVID-19 decreases [45-47]. Thus, risk perception does not seem to increase with age, but vulnerability and severity show opposite patterns [48]. The HBM postulates that individual beliefs about risk can be influenced by various factors such as sociodemographic and sociopsychological variables as well as knowledge, experience, and awareness [16]. However, patient awareness can also become an important issue, as these patients may not perceive a threat and, therefore, not adopt a DiGA.

Fourth, in addition to the patient, this study involves another important stakeholder, the physician. This stakeholder is not considered in the technology adoption models as they do not provide a specific gatekeeper for the technology or basically consider different stakeholders. But in the case of DiGA adoption by the patient, the first step requires the physician's adoption of a DiGA. This observation has also been noted in previous studies [7,49-52]. Subsequently, the physician's positive assessment of the patient's competence to perform a certain behavior is one of the essential conditions for a patient to consistently perform a health intervention. This result relates to previous research without reference to DiGAs as well as with reference to DiGAs [7,53]. Similarly, this view can be developed in a negative direction when doctors decide that the patient is not capable of adopting and using a DiGA, which could be justified by digital ageism. Ageism is a societal bias conceptualized as (1) prejudicial attitudes toward older adults, (2) discriminatory practices toward older adults, or (3) institutionalized policies and social practices that promote these attitudes [54]. Ball et al [55] show that both the development and use of technology have excluded older adults, resulting in a "physical-digital divide," which exists when a group feels excluded because they are unable to engage with the technologies used around them. Some studies suggest that ageism is widespread in the health care system [56-58]. For example, Walter et al [59] showed that physicians promote less preventive care for older patients. Chu et al [60] emphasized that the exclusion of older people from technology development leads to a broader cycle of inequity and ageist social attitudes, widening the digital divide. In contrast, we noticed that the trust factor impacts a patient's health behavior, which is in line with Wildenbos et al [61]. Beyond this, we also found that the physician's trust in the DiGA is equally important for their prescription of a DiGA. A physician needs a strong relationship of trust with the patient to convince the patient of the treatment methods. By motivating their patients to adopt a DiGA and use it to support their therapy, physicians focus on their social influence on the patient [7,62]. We provide justification for the incorporation of the physician as an important influence on adoption behavior in this context. After all, DiGAs live and die with physicians' willingness to prescribe to their patients and influence them to understand the technology's necessity. We argue for an adoption model that does not only incorporate a human-technology interaction but also a human-human-technology interaction.

Implication for Practice

The results of our study demonstrated that there is insufficient information available and published for both physicians and patients, as well as a lack of comprehensive technical support. Some statements (eg, the involvement of medical professionals in the development process of a DiGA, DiGA list unknown, and lack of evidence-based sources) confirm the knowledge deficit. It is important for health policy makers and public authorities such as the Ministry of Health, the Medical Association, and insurers to address these issues. Extensive information and source references are needed to take into account the needs of physicians and to enable DiGAs to get started more effectively. Including the consideration of conflicting goals in technology development from the beginning seems necessary. Codevelopment can improve app use and effectiveness in the long term by using a user-centered design

to develop DiGAs that are effective in chronic disease self-management [63,64]. Likewise, we demonstrated that physicians distinguish clearly between digital and traditional treatment options and have significantly higher expectations of digital resources. Despite a previously excluded position of the physician in the development and introduction process of medicines, the physician now anticipates more involvement in digital developments. In order to counteract the feeling of exclusion and disconnection from the supposedly nonmedically focused DiGA development, appropriate education seems to be required. One way to achieve this is through promotion within public networks, local authorities, and medical associations.

Insufficient participation in the follow-up to a prescription was also a concern for medical practitioners. In this context, it is important to fully communicate to physicians the many opportunities DiGAs offer. DiGAs have higher potential than other treatment interventions such as medicines to maintain a meaningful exchange of information and stay in touch with the patient even after prescription. We found that physicians feel a loss of control when the DiGA is prescribed and then used by the patient. A high degree of self-management is demanded of the patient, leaving the physician feeling incapable of action. Digital monitoring with the help of a DiGA also results in an advantage after the prescription compared with the conventional prescription of medical devices and medicines. Furthermore, negative attitudes and lack of digital competence among physicians are major barriers to physician prescription of DiGAs and, thus, patient adoption. At the same time, the lack of facilitating conditions and the high demands regarding the introduction of various digital changes (eg, EHR) exert excessive pressure on physicians. In this case, further information and education of physicians would be useful. In addition, a trial period of the DiGA can demonstrate digital connectivity to the physician.

Limitations and Future Research

Because of the exploratory character of the research design, our findings naturally lack generalizability and should be regarded as a first starting point on the investigation of a new phenomenon. As DiGAs are a new option for physicians, several interview partners have not really experienced them yet. We found that some participants, especially those who had not yet heard of DiGAs, found it difficult to properly understand the use and benefits of DiGAs.

Another issue corresponding to the novelty of the phenomenon is that informants' perceptions change quickly. Therefore, our findings reflect the perceptions of interview partners in the early phase of introductions of DiGAs into the market. It is likely that some of the issues raised will not be present in a couple of years, when DiGAs are more common to the market and perceived as natural to prescribe as all other medicines today.

This poses interesting questions for further research. It would be interesting to conduct longitudinal studies to gain a better understanding about the diffusion of such innovations in the medical space from the legislative setting into the physicians' toolkit and finally to the patients. This could generate valuable insights for future management of digital innovations in the medical area. In close conjunction to these questions, a cross-national comparison could generate advice for policy to smoothen the introduction phases of digital medical innovations in new other countries.

Finally, the study of the second-order adoption mechanisms—highlighted earlier in the document—could lead to interesting theoretical insights and valuable advice for practitioners to enhance the prescription and adoption of DiGAs and comparable digital innovations.

Conclusions

DiGAs provide an opportunity to support people with severe (often chronic) diseases, to live independently with greater confidence and understanding of their condition, better symptom management, and ultimately enhanced quality of life. Our study provides deep insights into the needs and circumstantial evidence that enables a better understanding of the perspectives and preferences for adopting DiGAs by physicians and potential patients. We found that there is a considerable lack of information on both physicians' and patients' sides, resulting in poor trust and digital competence. Furthermore, we identified several factors influencing the adoption of DiGAs, which led to a new understanding of adoption research concerning digital health technologies.

Abstract

Background: Multiparametric remote measurement technologies (RMTs), which comprise smartphones and wearable devices, have the potential to revolutionize understanding of the etiology and trajectory of major depressive disorder (MDD). Engagement with RMTs in MDD research is of the utmost importance for the validity of predictive analytical methods and long-term use and can be conceptualized as both objective engagement (data availability) and subjective engagement (system usability and experiential factors). Positioning the design of user interfaces within the theoretical framework of the Behavior Change Wheel can help maximize effectiveness. In-app components containing information from credible sources, visual feedback, and access to support provide an opportunity to promote engagement with RMTs while minimizing team resources. Randomized controlled trials are the gold standard in quantifying the effects of in-app components on engagement with RMTs in patients with MDD.

Objective: This study aims to evaluate whether a multiparametric RMT system with theoretically informed notifications, visual progress tracking, and access to research team contact details could promote engagement with remote symptom tracking over and above the system as usual. We hypothesized that participants using the adapted app (intervention group) would have higher engagement in symptom monitoring, as measured by objective and subjective engagement.

Methods: A 2-arm, parallel-group randomized controlled trial (participant-blinded) with 1:1 randomization was conducted with 100 participants with MDD over 12 weeks. Participants in both arms used the RADAR-base system, comprising a smartphone app for weekly symptom assessments and a wearable Fitbit device for continuous passive tracking. Participants in the intervention arm (n=50, 50%) also had access to additional in-app components. The primary outcome was objective engagement, measured as the percentage of weekly questionnaires completed during follow-up. The secondary outcomes measured subjective engagement (system engagement, system usability, and emotional self-awareness).

Results: The levels of completion of the Patient Health Questionnaire-8 (PHQ-8) were similar between the control (67/97, 69%) and intervention (66/97, 68%) arms (P value for the difference between the arms=.83, 95% CI −9.32 to 11.65). The intervention

group participants reported slightly higher user engagement (1.93, 95% CI −1.91 to 5.78), emotional self-awareness (1.13, 95% CI −2.93 to 5.19), and system usability (2.29, 95% CI −5.93 to 10.52) scores than the control group participants at follow-up; however, all CIs were wide and included 0. Process evaluation suggested that participants saw the in-app components as helpful in increasing task completion.

Conclusions: The adapted system did not increase objective or subjective engagement in remote symptom tracking in our research cohort. This study provides an important foundation for understanding engagement with RMTs for research and the methodologies by which this work can be replicated in both community and clinical settings.

Introduction

Background

Multiparametric remote measurement technologies (RMTs), which comprise smartphone apps and wearable devices, have the potential to revolutionize the clinical care of people with chronic, episodic health conditions [1]. Major depressive disorder (MDD) is one such condition, characterized by the relapse and remission of low mood and anhedonia over time [2]. Continuously measured longitudinal RMT data on the symptoms of MDD (mood variability, activity, cognition, and sleep) can capture a less biased picture of clinical state than retrospective self-report data [3]. Research using multiparametric sources might identify signals that could potentially predict future depressive episodes [4]. Such data could be ultimately implemented in patient self-management and shared decision-making in clinical practice [5].

It is important to understand how users engage with RMTs for depression symptom tracking. A recent systematic review found that engagement with RMTs can be measured objectively, for example, as the number of app-based symptom-tracking assessments completed, and subjectively, for example, as the perceived usability of and experience of using the RMT system [6]. Higher levels of objective engagement result in increased data availability, which, in turn, increases the validity of the machine learning approaches used for relapse prediction [7]. Objective engagement can also be used as an indicator of real-world uptake [8,9]. Further evidence suggests that increased satisfaction with mobile health apps is positively associated with the intention to continually use the tools [10]. Therefore, understanding engagement with RMTs is key to realizing their potential for relapse prediction.

Previous studies have reported inconsistent levels of engagement with RMT systems. Data completion, based on the total data expected, ranges from 42% to 82% for app-based symptom reporting and from 50% to 75% for device wear time [11]. The largest, multisite study of multiparametric RMTs for tracking depression to date, Remote Assessment of Disease and Relapse–Major Depressive Disorder (RADAR-MDD) [12], tracked 623 participants for 2 years using a smartphone app for mood tracking and a wrist-worn wearable for continuous passive data collection. The study has recently reported data availability metrics; 55.4% (345/623) of the sample completed >50% of the self-reported mood questionnaires expected to be completed, and 70.1% (437/623) had wearable heart rate data for >50% of the study days. Qualitative analyses from RADAR-MDD have revealed that the presence of a physical research team providing technological support and planned task reminders was a fundamental facilitator of long-term engagement in the study [13]. To ensure the scalability and real-world implementation of RMT systems, it is important to investigate methods that maximize engagement with RMTs while minimizing the human resources needed.

Focusing on the user interface (UI) of RMT systems is the logical first step for promoting engagement. Positioning the design of system UI within a theoretical framework of behavior change could help maximize effectiveness [14]. The Behavior Change Wheel [15] posits that researchers should begin by identifying a target behavior before considering the barriers to and facilitators of this behavior in terms of capability, opportunity, and motivation (the capability, opportunity, motivation, and behavior [COM-B] model). In the case of RMTs, the target behavior can be defined as objective engagement with symptom monitoring tasks. A series of published studies have evaluated both perceived [11,16] and experienced [13] barriers to RMT use in MDD research. Factors such as the knowledge of the utility of the research (capability), motivation linked to mood (motivation), and confirmation of logged data (opportunity) have been suggested to be prominent. The Behavior Change Wheel further provides a series of “intervention functions” best suited to address these factors, each with its own related behavior change techniques. With regard to RMTs, these have been suggested to be the provision of information from credible sources, visual feedback on behavior, and access to support.

The app design literature provides several options for incorporating behavior change techniques into RMT system design. First, following the Fogg behavioral model [17], push notifications can provide a trigger to perform a behavior, such as completing a monitoring task. Notifications can include tailored content, such as insights into the benefits of self-monitoring, which serves to simultaneously motivate the

user to respond to the notification and engage them in future tasks [18]. Second, visual incentives, such as graphs, can be embedded into the app to reflect on patterns in user progress and spark intrinsic motivation to complete future tasks [19]. Visualization can also help users manage uncertainty by attending to information about themselves [20]. A combination of qualitative and single-arm evaluation studies supports the perceived value of data visualization [21,22] and progress viewing [19] in encouraging symptom-tracking completion. Provision of contact details directly within an app can allow the user to directly and immediately access support, if required.

Without a control group, it is difficult to quantify the effect of in-app components on engagement [23]. A randomized controlled trial (RCT) of a substance abuse tracking app [20] suggested that users were 5% more likely to self-report on a day if they received a prior notification with an inspirational quote, although these results were not statistically significant. Conversely, users were 2% less likely to self-report following the provision of personalized visual data summaries; however, this main effect was significantly moderated by the prior day task completion such that those who had not completed the previous task were 36% more likely to self-report after receiving data visualization [20]. Users receiving prompts with tailored health messages, such as those highlighting the beneficial effects of symptom monitoring, were 4% more likely to engage in self-monitoring via another app for mental well-being [24]. It is important to replicate this work with multiparametric symptom monitoring systems, as it is currently unclear which combination of in-app features best promotes engagement with these technologies.

This Study

This study aimed to evaluate whether in-app components could promote engagement with a multiparametric RMT system for symptom tracking in depression. We conducted a 2-arm RCT to compare the system as usual with an adapted system that contained informative notifications, a visual progress report, and access to the research team contact details as a substitute for planned research team contact. We measured engagement as both objective and subjective concepts. This study had the following four specific objectives: (1) to describe data availability in an RCT of a multiparametric RMT system for tracking depression, (2) to test whether in-app components increase the rates of objective data completion, (3) to explore how in-app components influence the subjective experience of using the app, and (4) to understand how the components of the system are used by participants via process evaluation measures.

For objectives 2 and 3, we hypothesized that participants using the adapted app (intervention group) would have higher engagement in symptom monitoring, as measured by both objective engagement (completion of mood questionnaires) and subjective engagement (usability, utility, and emotional self-awareness).

Methods

Ethical Considerations

This study was approved by the Psychiatry, Nursing, and Midwifery Research Ethics Subcommittee at King's College London (reference number: RESCM-20/21-21083) and registered as a clinical trial (reference number: NCT04972474). A trial protocol has been previously published [25].

Trial Design

This was a single-center, 2-arm, parallel-group RCT (participant-blinded) with 1:1 randomization conducted in London, United Kingdom. We compared a remote symptom-tracking system (RADAR-base [26]; the control arm) with a system that contained additional in-app components (the intervention arm). Both the control and intervention arms were delivered via the RADAR-base system [26] using a smartphone app and a wearable Fitbit Charge (Fitbit Inc) device. Participants in the intervention arm had additional access to (1) theoretically informed notifications, (2) progress visualization, and (3) research team contact details through the study app. All participants were asked to use the system for 12 weeks.

Data were collected at baseline (0 weeks) and follow-up (12 weeks after randomization). Participants in both arms were sent 3 symptom-tracking tasks each week via the app; Fitbit data were collected continuously.

Participants

All participants were recruited from the RADAR-MDD study between April and May 2021. The inclusion criteria were as follows: (1) previous participation in the RADAR-MDD study at the London site (which required experiencing at least 1 episode of MDD in the 2 years before enrollment), (2) consent to be contacted, (3) willingness and ability to continue to use an Android (Google LLC) smartphone (provided for use by RADAR-MDD; see the study by Matcham et al [3] for the full study protocol), and (4) willingness and ability to complete a remote enrollment session owing to the COVID-19 pandemic. Participants were excluded if they were diagnosed with one of the following comorbid psychiatric disorders: bipolar disorder, schizophrenia, psychosis, schizoaffective disorder, or dementia.

Potential participants were invited to take part (up to 3 invitations were sent per participant, as per ethical considerations) and subsequently checked for eligibility, both via email. If eligible, contact details were entered into the REDCap (Research Electronic Data Capture [27]) system, which emailed an automated link to the informed consent form and baseline questionnaires. After participants provided consent and completed the baseline questionnaires, they were sent a link to book an enrollment session (via email, phone call, or video call).

On the day of the enrollment session, the principal investigator (KMW) initiated the REDCap randomization module and generated unique QR codes to link the study devices to the RADAR-base management portal. Each participant was sent a personalized set of instructions for downloading and logging

into the system using the QR codes at the chosen enrollment time, accompanied by a phone or video call as requested.

Participants were purposefully not contacted by the research team during the follow-up period, aside from sending 1 check-in email at the 6-week time point. However, participants were able to initiate contact with the team if they had any queries during follow-up. The research team did not make withdrawals based on "lost to follow up," given the fundamental aims of the study; however, participants were aware that they could withdraw at any point.

Suicidal ideation was assessed at baseline and follow-up using the Inventory of Depressive Symptomatology–Self-Report [28] item "thoughts of death or suicide." Participants who reported suicidal ideation and intent at either time point were contacted via phone call by the principal investigator, advised to contact their treating physician, and emailed a list of signposting resources.

At the 12-week end point, participants were directed to debrief information that explained the aims of the study and provided instructions for logging out of the system.

RADAR-Base

The RADAR-base system is an open-source platform that supports data collection via remote devices [3,26]. It requires users to download and log into an Android smartphone app in addition to wearing and syncing a wearable device. All participants were asked to complete the following three validated symptom-tracking tasks per week via the study app: (1) Patient Health Questionnaire-8 (PHQ-8 [29]); (2) Rosenberg Self-Esteem Scale (RSES [30]); and (3) a speech task, during which the user records themselves reading aloud a short paragraph (Multimedia Appendix 1). All tasks became available on the same day each week, 1 hour apart, beginning at the point of enrollment. All tasks had to be completed within 24 hours.

Interventions

Control Arm

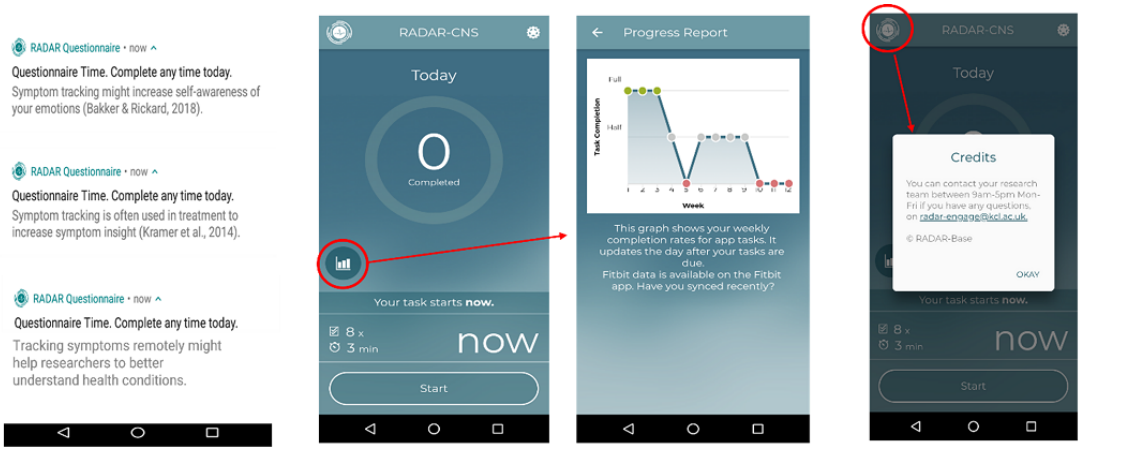
Participants were sent 3 tasks per week via the RADAR-base study app, as outlined in the previous section. For each task, they received a notification on the day that the task was due that read, "Questionnaire Time. Won't usually take longer than 3 minutes." They were unable to view any data other than those available on the Fitbit app.

Intervention Arm

The design of the additional in-app components was grounded in behavioral theory and user research on the barriers to and facilitators of RMT use in patients with MDD [11,13,16]. The COM-B [31] framework of behavior change highlighted education, incentivization, and enablement as the most suitable forms of intervention function. Findings from research with users of the RADAR-base system allowed for the translation of these functions into tangible components tailored specifically to the needs and preferences of the target cohort [32]. It was decided that an engaging app should include notifications with information on symptom tracking from a credible source, behavioral feedback via progress visualization, and instant access to researcher contact details (see the study by White et al [25] and Multimedia Appendix 2 for a detailed overview of this process).

Participants in the intervention arm received notifications and tasks at the same time as those in the control arm but with the following additional content (Figure 1):

Figure 1. Screenshots of the in-app components included in the intervention arm.



(A) Theoretically informed notifications alternating between 3 phrases

(B) Progress visualization, which is accessible through an icon on the home page, displaying full, half, or non-completion of weekly tasks for each of the 12 weeks

(C) Research team contact details, which are accessible through an icon on the home page

1. Theoretically informed notifications: the notifications included additional sentences that described the potential benefits of symptom monitoring for emotional self-awareness, clinical practice, and research. Participants were also reminded that they could complete the task "any time today."

2. Progress visualization: participants were provided with a graph in the app that tracked the completion of the tasks. This graph could be viewed at any time from the main app home page.
3. Researcher contact details: the main app home page included a phone number, an email address, and contact hours of the research team for the reporting of technical issues or requests for support.

Measures

A summary of measures and data collection time points is presented in Table 1. The measures were identical between the intervention and control arms.

Table 1. A summary of measures and data collection points across the 12-week follow-up period.

[m]RSES: Rosenberg Self-Esteem Scale.

Questionnaires

After registration for the study, participants completed web-based baseline questionnaires via REDCap, providing information on sociodemographics and physical and mental health history, including the presence of depression, recent life events, and service use. The principal investigator also manually extracted data pertaining to previous participation in the RADAR-MDD study, including participation length and technology use. At the 12-week time point, participants repeated these questionnaires.

Outcome Measures

The primary outcome was objective engagement with the system, measured as the number and percentage of weekly PHQ-8 questionnaires completed during follow-up (compared with the total of 12 questionnaires that were sent). Completion of 1 PHQ-8 questionnaire was defined as the completion of all 8 questions.

There were four secondary outcomes, three of which measured subjective engagement with the system:

1. User engagement: this was measured using the User Engagement Scale (UES) [33] adapted to mobile health use [34], a 30-item questionnaire measuring focused attention, perceived usability, esthetic appeal, and reward. All items are scored on a Likert scale ranging from 1 (“strongly disagree”) to 5 (“strongly agree”). Total scores are calculated by summing the scores for each item in each of the 4 subscales and dividing the resultant value by the number of items in each subscale. An overall engagement score can be calculated using the average of each subscale. A higher average score indicates higher user engagement. The UES has been widely adopted and shows good reliability and construct validity [35].
2. Emotional self-awareness: this was measured using the Emotional Self-Awareness Questionnaire (ESQ) [36], a 33-item scale measuring recognition, contextualization, and decision-making in relation to self-emotion. All items are scored on a 5-point Likert scale ranging from 0 (“never”) to 4 (“a lot”). The total score is calculated as a continuous variable that ranges from 0 to 132, with a higher score reflecting higher emotional self-awareness. The ESQ has a reliability of 0.92 and shows significant positive correlations with the Emotional Intelligence Test [36].
3. System usability: this was measured using the mHealth App Usability Questionnaire (MAUQ) for stand-alone apps [37]. The MAUQ is an 18-item scale that measures the immediate and long-term self-reported usability of an app, including its ease of use and utility for self-management (overall Cronbach α=.914). All items are scored on a 7-point Likert scale ranging from 1 (“disagree”) to 7 (“agree”). The app usability score is calculated as the sum of scores across the items for each participant, ranging from 18 to 126, with a higher score reflecting higher reported usability of the app.
4. Overall adherence to the RADAR-base system: a participant was considered to have adhered to the system if they (1) responded to at least 50% of the 3 weekly tasks and (2) >2 heart rate data points were recorded by the Fitbit device on at least 50% of the days during the 12-week intervention period. This measure was chosen to align with previous data availability reporting [12] and other studies [38].

Process evaluation measures were collected to evaluate the use of the in-app components. Quantitative measures covered app engagement, in-app interactions, and notification engagement. A total of 20 participants, split evenly across the 2 arms, were also invited at the study endpoint to qualitatively discuss their experiences with the components through a 1:1 interview (Multimedia Appendix 3).

Sample Size

Power calculations were performed based on data availability from the RADAR-MDD study [12]. To detect a difference of 25% completion of PHQ-8 tasks between the control and intervention arms, with 80% power and 95% CIs, 132 participants were required (66 per arm). We decided on 25% as the minimum difference that would be practically useful for analyses.

Randomization and Blinding

Participants were randomly allocated in a 1:1 ratio to either the control or intervention arm using simple randomization via the REDCap randomization module.

The principal investigator was unblinded to allocation to ensure that remote enrollments had been carried out successfully and had access to incoming data throughout the study. The trial data manager (DL) was blinded to arm allocation, as this information was stored elsewhere. Participants had previously used the RADAR-base system and, therefore, could not be fully blinded to arm allocation. However, the explicit aims and arm assignments of the study were not revealed until study debrief.

Statistical Methods

Sociodemographic and clinical variables at baseline were described by arm using appropriate summary statistics (counts and percentages for categorical variables and mean and SD or median and IQR for continuous variables). We reported data availability for all outcomes. Data availability for each study app task (PHQ-8, RSES, and speech task) was summarized as the median (IQR) number of weekly tasks completed. Fitbit wear time was summarized as mean (SD) days with >2 heart rate data points. The overall completion of all 4 data sources was also reported, calculated as a percentage of the total expected count (n=12) for the study app tasks and the total expected days of wear time (n=84) for the Fitbit.

The primary outcome, objective engagement, was analyzed using 2-sample 2-tailed *t* tests, which tested the difference in the mean percentage of PHQ-8 completion over 12 weeks between the study arms.

Three secondary outcomes (UES, ESQ, and MAUQ) were analyzed using separate linear regression models. Each model included the follow-up score as the dependent variable and arm allocation (0=control; 1=intervention) as the only covariate. Models for outcomes measured at baseline and follow-up (UES and ESQ) additionally included the baseline values of the outcomes. Differences in the combined adherence to the system (0=<50% total data completion; 1=>50% total data completion)

were tested using Pearson chi-square test. The threshold for statistical significance in all the analyses was *P*=.05.

All outcomes were analyzed under the intention-to-treat principle using R (version 4.1; R Foundation for Statistical Computing) [39]. All data, including those from withdrawn participants, were included in the analyses.

Supplementary Analysis

A supplementary analysis of all outcomes was conducted to estimate complier average causal effect (CACE) [40]. We defined compliers as participants in the intervention group who viewed the progress report page at least once in the 12 weeks. The CACE analyses were performed using a 2-stage least squares regression with arm allocation as the instrumental variable.

Process Evaluation

We examined quantitative app use measures from data retrieved from Google Analytics (Google LLC). These were reported under the following three categories: (1) app engagement (user-initiated app opening and active weeks), (2) in-app interactions (questionnaire initiation, progress report viewing, viewed progress report >1 time, and progress report viewing duration), and (3) notification engagement (notifications received, notifications opened, and the percentage of notifications opened out of notifications received). The number of active weeks was calculated as the number of weeks the participant was active out of the total 12 weeks, with at least 3 screen view or user engagement metrics recorded per participant. Each indicator was summarized by arm as mean (SD) and median (IQR). The qualitative experiences of the study were thematically analyzed and reported as a brief narrative synthesis. These data will be reported in more detail elsewhere.

Results

Recruitment

A total of 347 individuals were contacted between April and May 2021. Of them, 114 (32.9%) agreed to participate, and 100 (28.8%) completed an enrollment session and were enrolled in the study. Enrollment sessions took place via email (89/100, 89%), video call (9/100, 9%), or phone call (2/100, 2%). Figure 2 details the participation rate and reasons for nonparticipation.

Sample Characteristics

All (100/100, 100%) participants completed the baseline outcome assessment, and 87 (87%) participants completed the 12-week follow-up assessment. Among the total 100 participants, 1 (1%) participant in the intervention group withdrew from the study before the 12-week point, citing technological issues with the study apps as the main reason for withdrawal. The follow-up period was from April to September 2021.

Baseline characteristics were similar between the 2 groups (Table 2). The groups contained an equal number of participants (n=50). The mean age of the sample was 53.3 (SD 14.3) years, and 76 (76%) of the 100 participants were female. Most participants reported mild (36/100, 36%) or moderate (29/100, 29%) symptoms of depression at enrollment, as measured by the Inventory of Depressive Symptomatology–Self-Report. Overall, 12 (12%) participants reported suicidal ideation at baseline. Among the 100 participants, 59 (59%) “strongly agreed” that they were confident in using the smartphone they were using for the study, and 51 (51%) “strongly agreed” that they were confident in using the Fitbit device.

Data Availability

Of the 100 participants, 97 (97%) provided any data via the study app, and 93 (93%) had any recorded Fitbit data. A total of 2 (2%) participants were unable to use either the study app or Fitbit immediately following enrollment, 1 (1%) received no notifications from the study app during follow-up, and 4 (4%) were unable to sync the Fitbit with their smartphone. Moreover, 1 (1%) participant opted out of using a Fitbit for the study at enrollment. As data from the sources were unavailable owing to technical limitations, rather than nonengagement, these participants were excluded from the respective analyses (3/100, 3% for primary analysis and 8/100, 8% for the secondary combined adherence analysis).

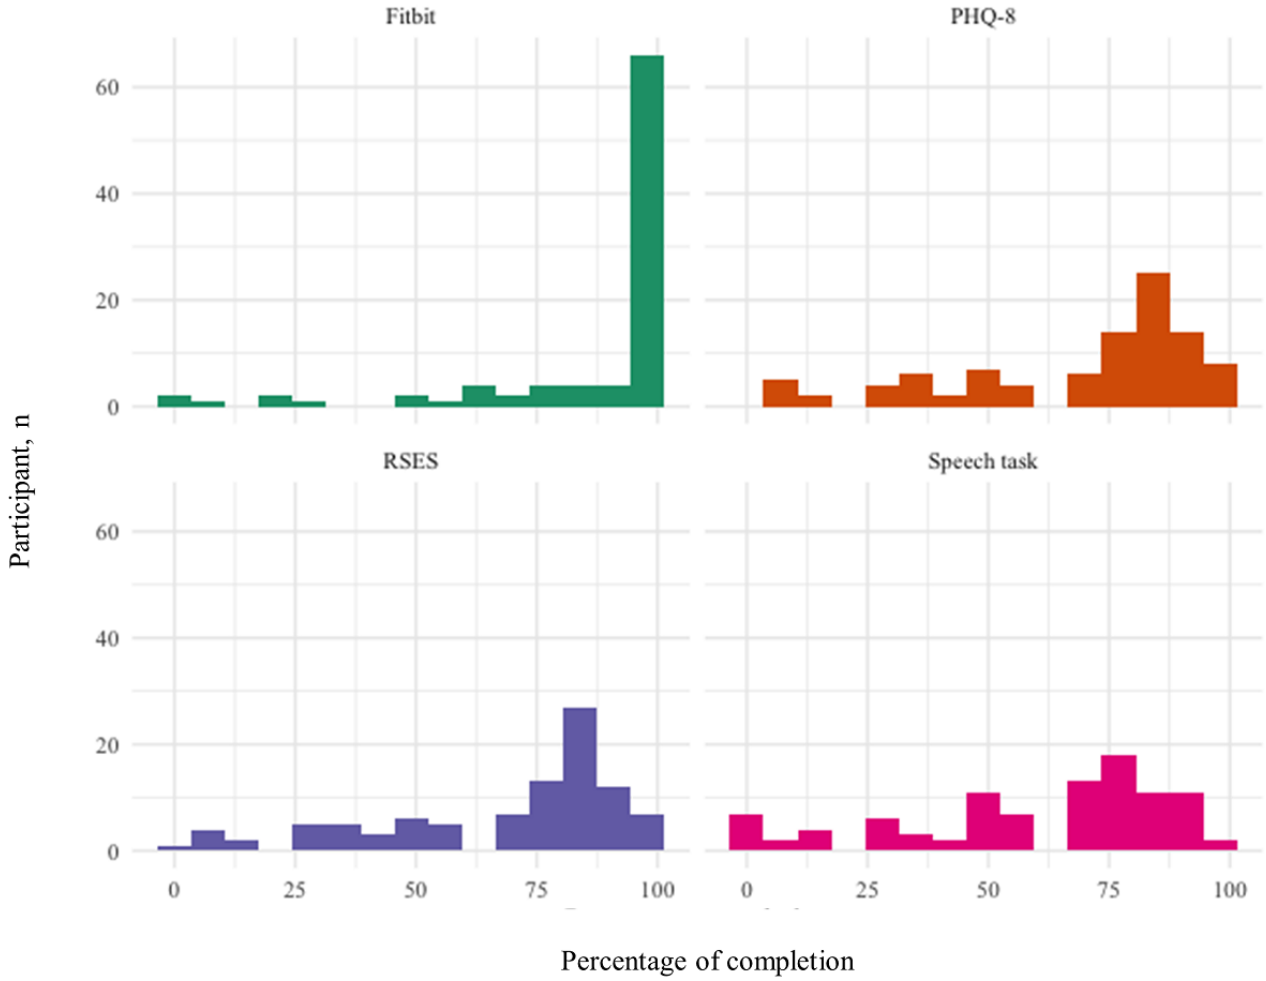
Each app task had a maximum count of 12 (1 per week). Overall, participants completed a median of 9 (IQR 6-10) PHQ-8 tasks, 9 (IQR 6-10) RSES tasks, and 8 (IQR 6-9) speech tasks. Among the 100 participants, 2 (2%) completed all available tasks, and 7 (7%) completed all available PHQ-8 tasks. A total of 35 (35%)

participants completed all 3 tasks at each point when they completed a PHQ-8 task.

The participants provided sufficient Fitbit data (at least 2 recordings per day) on a mean average of 74 (SD 19.7) days per participant during the 12-week (84-day) intervention period.

Figure 3 shows the percentage of completion for all 4 data sources across the sample.

Figure 3. Percentage of completion for the Fitbit and the 3 active tasks (Patient Health Questionnaire-8 [PHQ-8], Rosenberg Self-Esteem Scale [RSES], and speech task).



Primary and Secondary Outcomes

The primary analysis included 97 participants. The levels of completion of the PHQ-8 task were similar between the control (67/97, 69%) and intervention (66/97, 68%) arms (*P* value for the difference between the arms=.83, 95% CI −9.32 to 11.65).

For the secondary outcomes (Table 3), we found that those in the intervention group reported slightly higher UES (1.93, 95% CI −1.91 to 5.78), ESQ (1.13, 95% CI −2.93 to 5.19), and MAUQ (2.29, 95% CI −5.93 to 10.52) scores than those in the control group at follow-up. However, all CIs were wide and included 0.

Table 3. Linear regression model coefficients for each of the 3 secondary outcomes.

Subjective engagement outcome	Treatment effect (95% CI)	Participant (N=100), n (%)[a]
UES[b]	1.93 (−1.91 to 5.78)	89 (89)
ESQ[c]	1.13 (−2.93 to 5.19)	89 (89)
MAUQ[d,e]	2.29 (−5.93 to 10.52)	87 (87)

[a]For end point measures only.

[b]UES: User Engagement Scale.

[c]ESQ: Emotional Self-Awareness Questionnaire.

[d]MAUQ: mHealth App Usability Questionnaire.

[e]Only includes end point measure.

The combined adherence secondary analysis included 92 participants. The proportion of participants adhering to the system was similar between both arms (control=32/48, 67%; intervention=35/44, 80%; *P* value for difference between arms=.98).

For the CACE analyses, of the 48 participants in the intervention group, 29 (60%) met the complier definition of viewing the progress report at least once during the intervention period (Table 4). Table 5 presents the CACE treatment estimates for the primary and secondary outcomes. The between-arm difference in PHQ-8 completion was −1.92 (95% CI −19.93 to 15.54; *P*=.83), showing no evidence of a statistical difference. The treatment effect estimates for the UES, ESQ, and MAUQ were larger than the intention-to-treat estimates in favor of the intervention, but the effect sizes remained small.

Table 4. Number of participants and mean percentage of completion among the control group, intervention group compliers, and intervention group noncompliers (n=97).

Study arm	Participant, n (%)	Completion (%), mean (SD)
Intervention group compliers[a]	29 (30)	75.3 (23.9)
Intervention group noncompliers[b]	19 (20)	57.0 (28.0)
Control group	49 (50)	69.2 (25.1)

[a]Viewed the progress report module at least once during the intervention period.

[b]Did not view the progress report module during the intervention period.

Table 5. Intention-to-treat (ITT) and complier average causal effect (CACE) treatment estimates for the primary and secondary outcomes.

Outcome	Participant, n (%)	ITT		CACE[a]	
		Treatment effect (95% CI)	*P* value	Treatment effect (95% CI)	*P* value
PHQ-8[b]	97 (100)	−1.16 (−11.65 to 9.32)	.83	−1.92 (−19.39 to 15.54)	.83
UES[c]	89 (92)	1.93 (−1.91 to 5.78)	.32	3.49 (−3.75 to 10.73)	.34

MAUQ[e]	87 (90)	2.29 (−5.93 to 10.52)	.58	4.21 (−10.87 to 19.28)	.58

[a]Complier average causal effect estimates of intervention group compliers, defined as those who viewed the progress report module at least once during the intervention period.

[b]PHQ-8: Patient Health Questionnaire-8.

[c]UES: User Engagement Scale.

[d]ESQ: Emotional Self-Awareness Questionnaire.

[e]MAUQ: mHealth App Usability Questionnaire.

Process Evaluation

Table 6 presents the quantitative process evaluation measures collected throughout the study. Over the entire study period, participants in the intervention arm opened the app a mean average of 21.2 (SD 13.5) times, whereas the participants in the control group opened the app a mean average of 19.0 (SD 9.10) times. In total, 60% (35/58) of the participants who were able to view the progress report viewed it multiple times throughout the study, viewing for a mean average of 14.7 (SD 10.9) seconds per time. Participants in both groups received a similar number of notifications, although those in the control group opened a higher mean percentage (39.9, SD 25.9) of the notifications.

Table 6. Process evaluation use statistics by arm over the 12-week follow-up period.

	Intervention (n=48)	Control (n=49)
App engagement, mean (SD)		
User-initiated app opening	21.2 (13.5)	19.0 (9.10)
Active weeks[a]	8.96 (3.14)	8.88 (2.60)
In-app interactions		
Questionnaire initiation, mean (SD)	23.6 (10.3)	25.0 (10.5)
Progress report viewing		
Values, mean (SD)	3.60 (7.64)	N/A[b]
Values, median (IQR)	1.00 (0-2.25)	N/A
Viewed progress report >1 time , n (%)		
No	19 (40)	49 (100)
Yes	29 (60)	N/A
Progress report viewing duration (seconds), mean (SD)	14.7 (10.9)	N/A
Notification engagement		
Notifications received, mean (SD)	22.0 (13.3)	22.6 (9.82)
Notifications opened, mean (SD)	6.58 (6.45)	8.69 (6.36)
Percentage of notifications opened, mean (SD)[c]	34.3 (31.8)	39.9 (25.9)
None received, n (%)	2 (4)	1 (2)

[a]Calculated as the number of weeks over the 12-week period with at least 3 screen view or user engagement metrics recorded, as per Google Analytics (Google LLC) data.

[b]N/A: not applicable; participants in the control arm were unable to view the progress report.

[c]Percentage of notifications opened based on the total notifications received for each participant.

Participants generally liked the new in-app components. They felt that the progress report could motivate task completion by providing clarity that previous tasks had been successfully logged:

> *[It allowed me] certainly to feel more engaged and understand...how it contributes, but also to gain an overview of my own input into it, so not just I enter the data and it disappears.* [P99]

Most participants found the notifications somewhat informative:

> *The pop up things with little quotes about "doing this helps you"...yeah I liked those, I thought that was really good. You're doing it for a purpose.* [P29]

However, many participants were unsure whether they had seen all the notifications that their phone had received. Some highlighted the potentially demotivating effects of the progress report, depending on previous completion:

> *I think it depends what mood you're in...if I hadn't completed everything and I wasn't in a good mind space I could be thinking "ooh I've failed.*" [P40]

Whereas most participants agreed that the components might motivate others, the impact of the components on participants' own task completion was more nuanced. Instead, participating in the research study seemed to be the strongest motivation for task completion:

> *Because I had committed to do the study it meant that I said I am going to do it so I can't be half-hearted about it...I want to do the best I could because it was for somebody else's use.*" [P99]

Many participants discussed the beneficial effects of taking part in symptom monitoring generally, such as increased awareness of their depression and communication with others. Several additional in-app components were suggested, including a direct communication channel between the app and research team.

Harms and Protocol Violations

No adverse or serious adverse events were reported. Among the 100 participants, 1 (1%) withdrew owing to technological issues.

Discussion

Principal Findings

This study conducted the first, fully remote RCT of the RADAR-base symptom-tracking system to test the effect of additional in-app components, based on behavioral change theory, on objective and subjective engagement. Overall, objective engagement was high across the sample. We found that the participants who received the adapted system (incorporating theoretically informed notifications, real-time progress reports, and researcher contact details) did not show higher levels of engagement with the system than the participants who received the system as usual. Although

subjective engagement (emotional self-awareness, system utility, and usability) was slightly higher in those who received the adapted app, the difference was small and did not reach statistical significance.

Implications and Links With Previous Work

Previous research, both usability studies [19,21,22] and RCTs [20,24], has suggested that providing notifications and progress visualization can prompt objective engagement in remote symptom monitoring. We propose several explanations as to why our results did not reflect past findings.

First, our findings may reflect the sample used. Participants were recruited from a previous study that used the RADAR-base system. This meant that they had prior experience of and interest in symptom monitoring. Previous work has also highlighted the impact of the academic setting on engagement through altruistic motivations [41]. It is possible that our results reflect a ceiling effect, whereby participants in both groups were motivated to participate in the research and complete symptom monitoring regardless of the changes to the app. This is particularly apparent given that 2 of the in-app components were designed to reflect individual achievement and benefits, aspects that might not have been as relevant in this research context.

Second, the combination of in-app components used in the adapted system might not have been sufficiently tailored to the user. The development of the app was grounded in both behavioral theory [31] and user involvement [21], which suggested that viewing real-time progress and being reminded of the proposed benefits of symptom monitoring might combat the barriers to engagement. However, although these components are proposed to encourage future tracking behavior, in practice, it is unclear how they interact with the *motivation* section of the COM-B model, in this case, the low motivation linked to low mood in our cohort of people with depression. Previous work has focused on symptom tracking for substance abuse [20] or general population [18,24] cohorts, both of which might react to incentivization in different ways from those with depression. Our qualitative discussions indeed suggested that the impact of viewing data progress might be affected by individual mood and motivational fluctuations. The addition of other virtual incentives, such as gamification [42], might have been more effective in promoting engagement with the tasks here, alongside the ability to personalize which components are seen and when they are seen.

Moreover, our components were static in that they were accessible to all the participants in the intervention group at the same time and frequency. Previous work has suggested that several factors can significantly moderate the relationship between in-app components and engagement. For example, Nahum-Shani and colleagues [20] found that receiving data insights only increased the likelihood of future self-reporting in those who were not frequent users of the app, suggesting that visualizing progress is not incentivizing (or is even perhaps "irritating") for those who are actively engaged in the task from the beginning. Several studies have found a link between notification timing and engagement [20,24], although attempts at sensor-driven notification sending based on location have so far been unsuccessful in improving data availability [43]. Taken together, this suggests that future work is needed to understand the process of interacting with in-app components in this cohort.

Third, with regard to subjective engagement, the measures used in this study might not have reflected the experience of self-monitoring in the most nuanced manner. We used previous findings [6,41] to inform our operationalization of subjective engagement with RMTs as usability (UES), emotional self-awareness (ESQ), and utility (MAUQ). Our qualitative evaluation suggested that participants generally saw the in-app components as helpful in increasing task completion, which, in turn, might have promoted the feelings of emotional self-awareness they gained from monitoring their symptoms. We also saw that participants who viewed the progress report did so for around 15 seconds at a time, often repeatedly, which suggests a sustained interest in viewing progress. Although we did not see significant differences in either objective or subjective engagement, we did see slight treatment effects for all 3 subjective measures, which were higher still when adjusting for those who viewed the progress report. It is possible that different measures might have revealed a more significant change. For example, the UES is a tool designed primarily for digital health interventions and measures concepts such as focused attention, which are not as relevant to RMTs [6]. Measures tapping into other aspects of the experience of symptom monitoring, such as being seen as an individual [44] or the provision of a safety net [45], might have provided a more detailed understanding of the interaction among the in-app components, objective engagement, and subjective engagement in the study; however, to our knowledge, these have yet to be developed.

Strengths and Limitations

To our knowledge, this was the first study to attempt to quantify the effect of in-app components on objective and subjective engagement with a multiparametric symptom-tracking system for depression. We used an established system that was previously used to conduct the largest, longitudinal study on RMT in MDD to date [12] and demonstrated the successful transference of the system to a remote RCT design. Methodologically, this study laid the foundation for future work to measure both objective and subjective engagements with symptom-tracking devices. We used an adapted system with in-app components, which allowed for an active control group (the system as usual) and embedded data collection to reduce confounding factors associated with the delivery medium [46]. In reference to our first aim, we have shown good data availability in the first fully remote trial of the system, with 87% (87/100) of the participants completing follow-up data collection, a median of 75% completion of symptom-tracking tasks, and a mean of 74 of 84 days of wear time data without planned researcher contact.

There are several limitations to this study. First, as mentioned, the sample was previously engaged in remote symptom tracking and driven by research altruism. This allowed for the recruitment of a large sample from an established group, obtaining results quickly and efficiently. However, it is unclear how far these results might generalize to community cohorts using symptom tracking in their daily life. Second, the study was conducted

during the COVID-19 lockdown periods in the United Kingdom. A combination of increased free time and interest in health tracking could have resulted in increased engagement rates. Third, despite the large sample size, the study did not reach the intended number of participants needed to achieve the optimum statistical power. Fourth, although the app design was grounded in previous research, working within the confines of an established system gave way to certain design constraints. Some additional facilitators that arose from the COM-B analysis, such as the in-app reporting of technological malfunctions, could not be included or assessed in terms of their impact on engagement.

Avenues for Future Work

Future work should use these findings as a basis for further RCTs quantifying the effects of RMT system design on objective and subjective engagement with remote symptom tracking. Context-specific, dynamic tailoring of notifications and data insights could be key here. Although in-app components reduce the need for human resources, the impact of external factors should not be dismissed. Our system amendments did not promote engagement over and above the system as usual; future work could seek to understand how incentives such as research team support could interact with in-app components to increase engagement, such as the use of supportive chatbots [23]. Of major importance is replicating this work with different cohorts. Using the adapted system with non–help-seeking participants or those with lower technological literacy might affect the impact of the components that we tested. For example, the impact of the theoretically informed notifications might be greater in those who are less aware of the proposed benefits of symptom monitoring. Similarly, engagement with the app is likely to vary if the app is implemented in clinical practice; progress tracking and notification content might be more impactful for those who use the system for their own direct benefit. This work could also seek to complement the RCT design with additional analysis manuscripts for increased insight into the impact of UI features. For example, this could include correlational analyses of in-app component use with the measures of objective and subjective engagement or exploring whether baseline demographics are predictive of engagement in such trials. Another area for exploration is the measurement of the subjective experience of remote symptom tracking. The development of a suitable instrument that encapsulates experiential engagement would propel the understanding of the promotion of engagement across the field.

Conclusions

This study found that a combination of informative notifications, progress visualization, and research team contact details did not increase engagement in remote symptom tracking in our research cohort. However, the system provided good data availability, and the process evaluation measures suggested that participants saw benefits in using the adapted system. We have provided the methodology and scope for future exploration in this area, as well as opportunities to replicate this work in both community and clinical cohorts to further the promotion of engagement in remote health symptom tracking for both data collection and clinical management.

Acknowledgments

This paper represents independent research partly funded by the National Institute for Health and Care Research (NIHR) Maudsley Biomedical Research Centre at South London and Maudsley National Health Service (NHS) Foundation Trust and King's College London. The views expressed are those of the authors and not necessarily those of the NHS, NIHR, or Department of Health and Social Care.

The Remote Assessment of Disease and Relapse–Central Nervous System project received funding from the Innovative Medicines Initiative 2 Joint Undertaking under grant agreement number 115902. This joint undertaking receives support from the European Union's Horizon 2020 research and innovation program and European Federation of Pharmaceutical Industries and Associations (EFPIA). This communication reflects the views of the RADAR-CNS consortium, and neither Innovative Medicines Initiative nor the European Union and EFPIA are liable for any use that may be made of the information contained herein. The funding body was not involved in the design of the study or the collection, analysis, or interpretation of the data. This research was reviewed by a team with experience of mental health problems and their carers who were specially trained to advise on research proposals and documentation through the Feasibility and Acceptability Support Team for Researchers: a free, confidential service in England provided by the NIHR Maudsley Biomedical Research Centre via King's College London and South London and Maudsley NHS Foundation Trust. Finally, the authors would like to thank all members of the RADAR-CNS patient advisory board who have experience of living with or supporting those who are living with depression, epilepsy, or multiple sclerosis.

Authors' Contributions

KMW designed, coordinated, and conducted the study as well as led data processing, data coding, data analysis, and the writing of this manuscript. EC contributed to the design of the study and advised on data analysis. DL contributed to the design of the study and aided with data extraction. FM contributed to the design of the study. PC contributed to in-app component development and data extraction. YR contributed to app development and data extraction. SS contributed to service user involvement research and in-app component development. ED-L contributed to service user involvement research and in-app component development. LW contributed to the coding and thematic analysis of the interview data. CH contributed to the development and design of the study, reviewed data analysis, and supervised the first author. MH contributed to the development and design of the study, reviewed data analysis, and supervised the first author.

Conflicts of Interest

MH is the principal investigator of the RADAR-CNS consortium, a private-public precompetitive consortium with research funding from Janssen, Union Chimique Belge, Merck Sharp & Dohme, Biogen, and Lundbeck. All other authors declare no other conflicts of interest.

Abstract

Background: Androgen deprivation therapy (ADT), a standard treatment for prostate cancer (PC), causes many physical side effects. In particular, it causes metabolic changes such as fasting glucose abnormalities or accumulation of body fat, and its continuation can lead to metabolic syndrome (MetS), which is closely related to diabetes and cardiovascular disease. Therefore, it is important to maintain and practice a healthy lifestyle in patients with PC.

Objective: This study aims to evaluate the effectiveness of a nurse-led mobile-based program that aims to promote a healthy lifestyle in patients with PC undergoing ADT with MetS risk factors.

Methods: This was a single-blind, randomized, waitlist control interventional study. A total of 48 patients were randomly assigned to the experimental and waitlist control groups at the urology cancer clinic of a tertiary general hospital in South Korea. The inclusion criteria were patients who had undergone ADT for >6 months, had at least 1 of the 5 MetS components in the abnormal range, and could access a mobile-based education program. The experimental group attended a 4-week mobile-based program on exercise and diet that included counseling and encouragement to maintain a healthy lifestyle, whereas the control group was placed on a waitlist and received usual care during the follow-up period, followed by the intervention. The primary outcome was a change in the lifestyle score. The secondary outcomes were changes in 5 MetS components, body composition, and health-related quality of life. The outcomes were measured at 6 weeks and 12 weeks after the initiation of the intervention. Each participant was assigned to each group in a sequential order of enrollment in a 4×4 permuted block design randomization table generated in the SAS (SAS Institute) statistical program. A linear mixed model was used for statistical analysis.

Results: A total of 24 participants were randomly assigned to each group; however, 2 participants in the experimental group dropped out for personal reasons before starting the intervention. Finally, 46 participants were included in the intention-to-treat analysis. The experimental group showed more positive changes in the healthy lifestyle score (β=29.23; P≤.001), level of each MetS component (fasting blood sugar: β=−12.0; P=.05 and abdominal circumference: β=−2.49; P=.049), body composition (body weight: β=−1.52; P<.001 and BMI: β=−0.55; P<.001), and the urinary irritative and obstructive domain of health-related quality of life (β=14.63; P<.001) over time than the waitlist control group.

Conclusions: Lifestyle changes through nurse-led education can improve level of each MetS components, body composition, and ADT side effects. Nurses can induce positive changes in patients' lifestyles and improve the self-management of patients starting ADT through this program.

Introduction

Adverse Effects of Androgen Deprivation Therapy in Prostate Cancer

Prostate cancer (PC) is a commonly occurring cancer in men worldwide, and it is the fourth most common cancer among adult men in South Korea [1]. The incidence of PC in South Korea has increased rapidly in recent years, from 2.2% in 2000 to 14.3% in 2018 [1], owing to changes in dietary patterns and the development of new diagnostic technologies. PC is affected by androgenic activity in the body [2]. Therefore, the goal of treatment is to either remove androgens using castration or neutralize the effects of androgens. Androgen deprivation therapy (ADT), which disrupts the mechanisms that create androgens, is a standard treatment for PC [3]. Initially, ADT was used to treat patients with metastatic PC or older persons with cancer with limited treatment options. However, in recent years, there has been a gradual expansion in the use of ADT to include treating patients in the early stages of PC [4,5].

Repeated ADT can lead to climacteric symptoms in male individuals [6], including sexual dysfunction, hot flashes [7], gynecomastia [8], depression, fatigue, changes in sleep patterns [9], loss of muscle strength [10,11], osteoporosis [12], metabolic syndrome (MetS) [13], and cardiovascular disease [14,15]. These issues can reduce the quality of life of patients and may even be life threatening [16,17]. Specifically, evidence suggests that ADT leads to metabolic changes [13,18]. MetS, also called insulin resistance syndrome, is the clustering of several risk factors associated with obesity. It is closely related to diabetes [14,15,19] and has also been identified as a major cause of cardiovascular disease owing to its association with dyslipidemia, diabetes, and hypertension [14,15]. PC and MetS have a close relationship: patients with PC who received ADT were found to be 2.5 times more likely to have MetS than those who did not receive ADT [18]. A cross-sectional analysis using Korean National Health Insurance Service data found that the prevalence rate of MetS in patients with PC was 40.1%, which is higher than the 34.5% prevalence rate in older Korean male adults [20]. In addition, as age increases, MetS has been found to increase by 8 times in patients with PC [21]. Given that most patients with PC are older adults, ADT-induced metabolic problems coupled with aging can lead to deterioration of health, resulting in cardiovascular disease or death [22]. Despite the necessity of severe side effects management for ADT, >50% of patients with PC are unaware of these problems [23], and most health care providers tend to focus on cancer treatment. Moreover, no protocols have been developed to manage ADT-induced MetS in patients with PC [24,25].

Importance of Improving Self-Management Skill for ADT-Induced MetS

ADT-induced MetS causes metabolic changes that are different from those caused by classic MetS including changes in body composition [26]. Androgens are a group of male sex hormones, and androgen level reduction leads to an increase in body fat percentage and a decrease in fat-free mass, such as muscle loss and decreased bone density. Although classic MetS is characterized by an increase in visceral fat, there is insufficient evidence to determine whether or not this also occurs in patients with PC [27,28]. Implementing a classic MetS management program is not suitable for patients with PC because ADT-induced MetS has different characteristics than classic MetS, and each patient experiences different side effects, including physical and emotional problems. For example, 80% of patients with PC experience hot flashes and 12% to 14% experience breast tenderness and depression [29].

MetS is a representative chronic lifestyle disease that requires individual self-management. The World Health Organization emphasizes that lifestyle is the most critical factor affecting health status [30]. The current health care system appears to focus its attention and investments toward the discovery and treatment of the causes of disease rather than lifestyle. However, lifestyle modification is the most effective way to reduce the incidence of cardiovascular complications caused by MetS [31]. In general, lifestyle modifications, including exercise and a nutritional diet, are known to result in lower occurrence rates of MetS and a lower risk of cardiovascular disease [31]. Such lifestyle modifications require improving self-management skills. Self-management is a lifelong task that requires engagement in activities that promote good health [32]. Improving self-management allows patients to maintain active lives, leading to a better quality of life [32].

Although the optimal duration of ADT remains undefined, patients with PC typically receive ADT for 2 to 3 years [33]. Furthermore, as metabolic changes begin at least 3 months after ADT initiation, it is very important for patients with PCs to improve their self-management skills from the beginning of ADT. In addition, health care providers should be aware of ADT-related side effects from an early stage and mediate metabolic changes of PC through education. Therefore, newly developed health coaching programs for patients with PC should be configured differently from previous iterations [34-36]. In other words, the focus should be on improving self-management skills to encourage lifestyle changes that take into consideration the side effects of ADT from the beginning of ADT administration. However, effective self-management can be

challenging to maintain. In addition, the COVID-19 pandemic has diminished physical activity and nutritional quality worldwide [37]. The World Health Organization has emphasized the importance of exercise and maintaining a healthy lifestyle during the pandemic [38]. Web-based education has relatively few limitations in terms of time and space, and it has the advantage of being able to feature various types of media and teaching and learning materials compared with offline education programs [39].

Aims

This study aimed to evaluate the effectiveness of a nurse-led mobile-based health coaching program that promotes healthy lifestyle changes, normal range of MetS components, and health-related quality of life (HRQoL) for patients with PC receiving ADT. The primary aim was to identify the changes in (1) healthy lifestyle through this program, and the secondary aims were to identify the changes in (1) the levels of each MetS component, including blood pressure, fasting blood sugar (FBS), high-density lipoprotein (HDL) cholesterol, triglyceride, and abdominal circumference (AC); (2) body composition, such as body weight, BMI, skeletal muscle mass, fat mass, and fat percentage; and (3) quality of life.

Methods

Participants

The study population consisted of men who were diagnosed with PC at the urology cancer center of a single tertiary general hospital in South Korea. The inclusion criteria were (1) patients with PC who had been receiving ADT for >6 months at the time of enrollment in this study, (2) those with an abnormal range of at least 1 of the 5 MetS components, (3) those who were fully aware of the object and contents of the study and voluntarily participated, (4) those who understood spoken and written Korean and who could communicate without cognitive impairment, and (5) those who had a smartphone and were able to access the mobile-based education program. The exclusion criteria were (1) patients diagnosed with and treated for cancers other than PC; (2) those who had undergone surgery or chemotherapy for <3 months before the start of the study; (3) those who answered “yes” to ≥1 question of the Physical Activity Readiness Questionnaires; (4) those with cardiovascular diseases such as unstable angina pectoris, uncontrolled blood pressure, myocardial infarction, or comorbidities such as a musculoskeletal or nervous system disease; (5) those who were participating in other research programs; (6) those who had a change in medication to control their blood pressure, cholesterol, or blood sugar <3 months before the start of the study; and (7) those who had difficulty with typical daily activities.

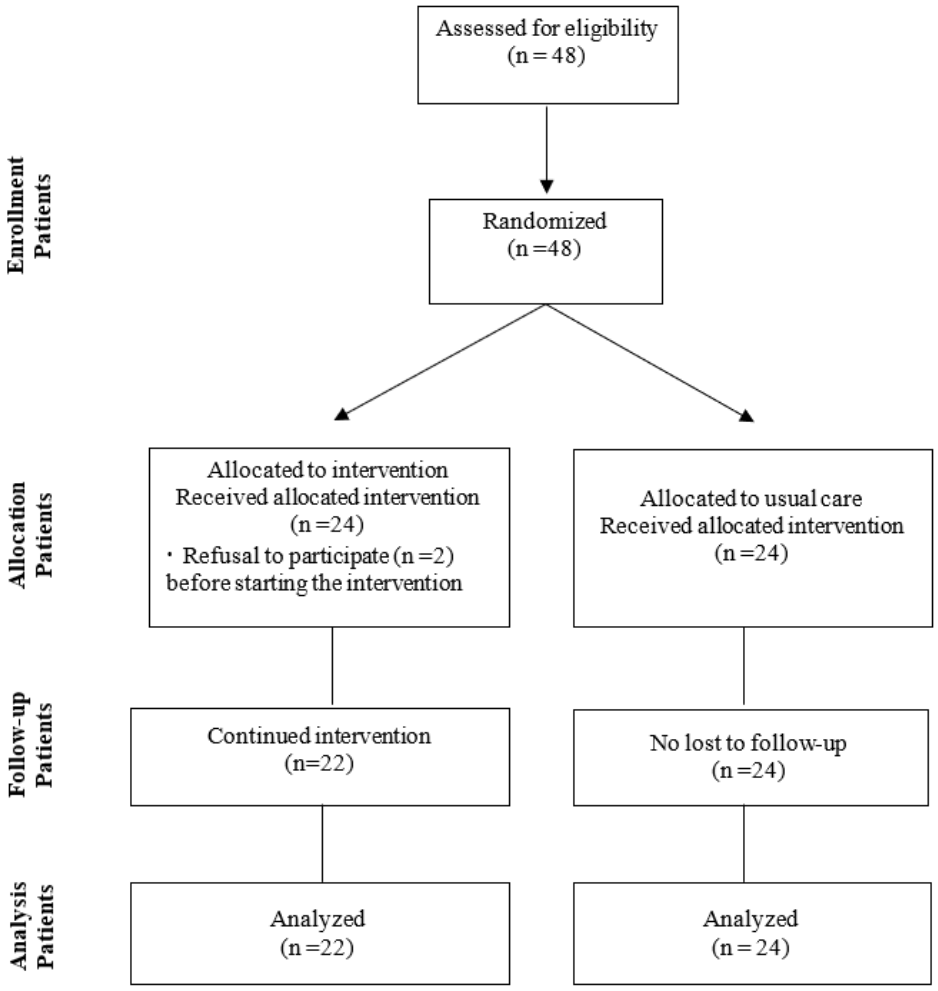
Ethical Considerations

This study was approved by the Institutional Review Board of the Severance Hospital, Yonsei University Health System (4-2020-0889). We informed all participants of the purpose of this study, process, methods, voluntary participation terms, and the possible risks and benefits of participation. Furthermore, we gave the participants 1 week to consider their participation in the study before deciding whether to sign the informed consent form. All study participants were compensated with KRW 50,000 (approximately US $43) as a gift at both the beginning and end of the study.

Enrollment Process

To recruit participants, we posted recruitment announcements on the bulletin board of a urology cancer center. On the day of outpatient visits, we met face-to-face with patients who indicated an interest in participating in the study. We provided potential participants with the opportune time to ask questions. Then, we fully informed the potential participants about all facets of the study and invited them to voluntarily sign the informed consent form. Finally, we registered the participants after screening for the inclusion and exclusion criteria (Figure 1). The allocation process for this study was conducted jointly with a research assistant to ensure that all enrollments were transparent.

Figure 1. Modified CONSORT (Consolidated Standards of Reporting Trials) flow diagram for individual randomized controlled trials.



Using *F* test in the G*Power program version 3.1 (Heinrich Heine University) [40], we calculated the sample size to identify the variance difference of repeated data between the 2 groups. The minimum number of participants was calculated to be 41 based on an effect size of 0.51, which was derived from the study by Bourke et al [41], with a significance level of .05, a power of 0.08, and 3 repeat measures. Considering a projected dropout rate of 15% [41], the total sample size was set at 48. Therefore, 24 participants were registered in each group. We assigned the participants randomly into experimental and waitlist control groups using a pregenerated sequence in SAS 9.4 (SAS Institute) based on the 2×2 permuted randomized block method. Using this method, 4 people are grouped as 1 block, and the 1 block is then divided into 2 groups. Then, we assigned the groups at a 1:1 ratio. The participants did not know which group they were assigned to. They received the intervention individually, which minimized the risk of contamination between groups.

Research Design and Setting

This was a single-blind, single-center randomized waitlist controlled trial. It used a pre- and posttest design and a 2×2 permuted randomization block method. We prepared an allocation table for each group before participants were enrolled. Each participant was assigned to an experimental or a waitlist control group in the order of enrollment using a 2×2 randomization table generated in the SAS program (SAS Institute). The protocol for this study was registered with the Clinical Research Information Service (registration no. KCT0006560). We recruited the participants from a tertiary general hospital located in Seoul, South Korea.

Intervention

To improve the positive health behaviors of patients with PC receiving ADT, a nurse-led mobile-based health coaching program based on the analyze, design, develop, implement, and evaluate model and the information-motivation-behavioral (IMB) skills model was developed. The analyze, design, develop, implement, and evaluate model, known as an instructional design model, is a representative framework used by teaching and learning methods. The IMB model has been widely used as a theoretical basis for developing interventions that aim to encourage patients with chronic diseases to maintain positive health behaviors. According to the IMB model, acquiring sufficient information, enhancing motivation, acquiring the skills required to perform a behavior, and improving self-efficacy are the factors that lead to long-term behavioral changes that improve subjective and objective health outcomes [42]. The nurse-led mobile-based health coaching program used an individualized approach to ensure that the IMB

skills addressed in the program were best suited to each patient to improve their specific lifestyle patterns. In this program, self-management information included personalized recommendations for diet and exercise and strategies to manage both individual ADT-induced side effects and common side effects from other prescribed drugs. Motivation strategies included health contracting, individual goal setting, encouragement and continuous counseling, and rewarding. In addition, we encouraged the patients' main caregivers to become involved in their patients' behavioral self-management. Behavioral self-management skills included sharing vicarious experiences (eg, sharing success stories), self-monitoring through exercises, and maintaining a nutrition diary.

The program consisted of a 4-week intensive program conducted via one-on-one Zoom (Zoom Video Communication, Inc) meetings, followed by an 8-week maintenance program conducted via individual contact through telephone calls and KakaoTalk (Kakao Corporation), which is a popular Korean SMS text messaging app (Figure 2). Participants were provided with relevant information and a to-do list regarding exercise and diet once a week for 4 weeks in an intensive program. We provided an educational package that included a booklet containing PowerPoint (Microsoft Corporation) slides, exercise and nutritional diaries, exercise video files, TheraBand resistance bands (THERABAND), and a pedometer. We focused on overcoming barriers to healthy diet and exercise. For example, we recommended alternative exercises for participants with knee pain, which included a higher proportion of movements performed in a sitting position. Furthermore, the participants received feedback to address problems at the end of every web-based meeting during the intensive program and via SMS text messages and telephone calls during the maintenance program. When participants felt uncertain about an exercise motion, they recorded a video of themselves performing the exercise and sent it to us. We then provided feedback describing the correct motion, using the video as a reference. Regarding diet, we focused on changing unhealthy eating habits, controlling participants' daily calorie intake, encouraging a low-fat and low-carbohydrate diet, and ensuring adequate protein intake. Participants were educated on the proportions of food from each food group they required per day according to their individual daily recommended calories and the diabetic exchange diet. Feedback and questions related to the diet program were addressed via KakaoTalk. We recommended implementing the following strategies for maintaining healthy behaviors and enhancing self-efficacy once a week or more during the maintenance period: vicarious experiences (eg, sharing success stories), emotional support, encouragement, keeping an exercise and nutrition diary, and goal reminders. To minimize the expected bias that can occur in an intervention study, we conducted the intervention according to the study protocol and used a checklist to ensure consistency between the experimental and waitlist control groups. The control group was placed on a waitlist and only received usual care during the intervention period. After completing data collection, we provided them with the same mobile-based program and educational materials as the experimental group (time point 3; T3). A group of experts evaluated this program to confirm its content and construct validity.

Figure 2. Educational material: (A) education on information and management of metabolic syndrome via the internet using Zoom (Zoom Video Communications, Inc), (B) personalized diet coaching, and (C) personalized exercise coaching: providing feedback describing the correct motion.

Data Collection

Data collection happened at 3 different time points: baseline (time point 1; T1), 6 weeks after the beginning of the intervention (time point 2; T2), and 12 weeks after the beginning of the intervention (T3). We collected T1 and T3 data on a face-to-face basis on the day the patient visited the urology cancer center. Variables that required physical contact, such as AC and grip strength, were measured together using a web-based survey at T1 and T3 but not at T2. At T2, we collected data collection on variables, including lifestyle score and HRQoL, on a non–face-to-face basis using a web-based survey. Clinical data that were obtained included treatment type, ADT exposure time, cancer stage, biochemical data, and Gleason score from electronic medical records (EMRs) at T1.

Outcomes

Lifestyle Score

Lifestyle score was the primary outcome of this study. Lifestyle changes were evaluated using the lifestyle evaluation tool by Kang [43] to assess the health behaviors of patients with MetS. A higher score indicates better self-management behaviors. This assessment consists of 36 items across 6 domains: physical activity and weight control, dietary habits, drinking and smoking, sleep and rest, stress, and drug and health management [43].

We recorded responses on a 4-point scale with the options *not at all*, *sometimes*, *often*, and *always*. Total scores could range from 36 to 144 points, with a higher score indicating a healthier lifestyle. The Cronbach α of the original study was .92 (physical activity and weight control=.87, dietary habits=.87, drinking and smoking=.87, sleep and rest=.86, stress=.74, and drug and health management=.70). In this study, Cronbach α was .82 (physical activity and weight control=.90, dietary habits=.86, drinking and smoking=.41, sleep and rest=.67, stress=.63, and drug and health management=.54).

MetS Components

The components of MetS consist of FBS, AC, blood pressure (both systolic and diastolic), fasting triglyceride level, and fasting HDL cholesterol. We instructed the participants not to have a meal and not to take antihypertensive drugs on the test day. Then, at the urology cancer center, we first measured AC using a tape at the umbilicus between the highest point of the iliac crest and the lower edge of the 12th rib with an error range of 0.5 cm while the participants fasted. Second, we measured the blood pressure twice on the participant's nondominant arm using a TM-2657P device (A&D Company Limited) after they had rested for at least 10 minutes. The average systolic blood pressure (SBP) and diastolic blood pressure (DBP) were calculated.

Biochemical Data

Biochemical data included the levels of the following MetS components: fasting triglyceride, fasting HDL cholesterol, and FBS. These variables were measured using blood samples collected while participants had fasted for >6 hours, and the data were obtained from EMRs.

Body Composition

Body composition data were obtained using a body composition analyzer (InBody H20B [Biospace]). We instructed the participants to stand upright and hold the handle attached to the measurement device, which put them into contact with 8 electrodes (2 each on both hands and both feet). Body composition measurements included height (cm), body weight (kg), body fat mass (kg), body fat percentage (%), skeletal muscle mass (kg), and BMI (kg/m^2).

HRQoL Measurement Tool

We measured HRQoL using the Korean version of the 26-item Expanded Prostate Cancer Index Composite (EPIC-26). EPIC-26 is a short-form version of the original expanded PC index composite (EPIC) tool, which contains 50 items. The EPIC tool was developed to understand treatment-related symptoms with a higher degree of sensitivity than previous diagnostic tools and the impact of PC treatment on patients' lives [44]. Higher scores indicated a better HRQoL, with possible scores ranging from 0 to 100. EPIC-26 consists of 5 symptom domains: urinary incontinence, urinary irritation and obstruction, sexual, bowel, and hormonal. There is no Korean version of EPIC-26, but there is a Korean version of the original 50-item EPIC tool. Therefore, the 26 items from EPIC-26 were extracted from the Korean version of the original 50-item EPIC tool [45], and the survey was conducted using this tool. Permission to use both EPIC-26 and the original 50-item EPIC was granted by the original author.

The Cronbach α of EPIC-26 ranged from .70 to .90 in all domains except for the hormonal domain (Cronbach α=.62). The Cronbach α of the Korean version of EPIC was .83 [45]. The Cronbach α of the tool used in this study was .63 (urinary incontinence=.88, urinary irritation and obstruction=.64, sexual=.84, bowel=.13, and vitality or hormonal=.46).

Clinical Data

Disease-related patient information, treatment type, ADT exposure time, cancer stage, and Gleason score were obtained from EMRs.

Data Analysis

Demographic data, disease-related characteristics, and main outcome variables were analyzed using mean, SD, frequency, and percentage. An independent 1-tailed *t* test and a chi-square test were performed to identify differences between the groups. The equality of variance was assessed before using the pooled variance estimator for the *t* test. Fisher exact test was performed as appropriate. According to the International Conference on Harmonization E9 guideline [46], which provides guidance on statistical principles for clinical trials, a modified intention-to-treat analysis was conducted. As 2 participants withdrew from the study for personal reasons before initiating the intervention, there was a lack of data that could evaluate the effect of the main outcomes. We judged that there would be no difference in the intention-to-treat analysis owing to the low dropout rate (2/48, 4%) and high compliance rate (22/22, 81%). Hypothesis testing was conducted using a 1-tailed test and the PROC MIXED procedure in SAS (SAS Institute). SE estimates

were obtained as a result of the PROC MIXED procedure using the *empirical option* to adjust for skewed data from potentially different covariance structures. This method is based on the sandwich estimation approach [47]. It improves variance and covariance with robust and consistent estimates, irrespective of the covariance structure in the actual data. As a follow-up analysis, we determined statistically significant time points within the groups by calculating the difference in the least square means from the baseline at each time point.

Results

Overview

The data for this study were collected across 7 months, from March 24 to September 15, 2021. We took approximately 30 minutes per participant to complete data collection. A total of 48 participants were recruited. Two participants in the experimental group declined to participate in the program before starting the intervention, citing personal reasons. A total of 46 participants were finally included in the analysis, with an attrition rate of 4% (2/48).

Results of General and Disease-Related Characteristics

The general and disease-related characteristics are presented in Table 1. The mean age of the participants was 68.83 (SD 7.09) years. Most participants (41/46, 89%) lived with their spouses or families. Approximately 46% (21/46) of the participants were unemployed, and 35% (16/46) had jobs requiring relatively less physical activity, such as office workers, taxi drivers, and service workers. Most participants (27/46, 59%) were exsmokers, and the mean smoking duration was 16.13 (SD 21.38) pack-years.

Table 1. Homogeneity tests in general characteristics, disease-related characteristics, and main outcome variables between groups (N=46).

[a]N/A: not applicable.

[b]Fisher exact test.

[c]ADT: androgen deprivation therapy.

[d]LHRH: luteinizing hormone–releasing hormone.

[e]PSA: prostate-specific antigen.

[f]Lifestyle score measured by lifestyle evaluation; scores range from 36 to 144.

[g]MetS: metabolic syndrome.

[h]SBP: systolic blood pressure.

[i]DBP: diastolic blood pressure.

[j]AC: abdominal circumference.

[k]FBS: fasting blood sugar.

[l]HDL: high-density lipoprotein.

[m]HRQoL: health-related quality of life. Scores range from 0 to 100, higher scores represent better HRQoL.

The average number of comorbidities was 1.61 (SD 1.04), and the most common comorbid diseases were cardiovascular diseases such as hypertension or dyslipidemia (31/46, 67%). There was no difference in comorbidities between the experimental and waitlist control groups (*P*=.87). Of the 65 participants, 30 (65%) received antiandrogen monotherapy, and the rest received antiandrogen therapy with luteinizing hormone–releasing hormone. The average duration of ADT was 40.63 (SD 24.71) months, the mean prostate-specific antigen level was 0.07 (SD 0.19) ng/ml, and the mean Gleason score, which determines the prognosis and pathological status of cancer, was 7.80 (SD 0.98). The experimental and waitlist control groups showed no statistical differences between general and disease-related characteristics. The mean healthy lifestyle score was 99.07 (SD 13.56). The MetS components with mean values in an abnormal range were SBP (mean 136.42, SD 13.01 mm Hg), AC (mean 95.73, SD 5.97 cm), and FBS (mean 111.17, SD 22.22 mg/dL). There were no statistical differences in MetS components between the groups. The mean body weight and BMI were approximately 73 (SD 5.99) kg and 26 (SD 2.04) kg/m^2, respectively. The participants responded that they had problems in the urinary incontinence (mean 67.61, SD 25.99) and sexual (mean 19.28, SD 19.54) domains of HRQoL. The experimental and waitlist control groups were homogeneous in terms of their main outcome variables.

Results of Primary Outcome Variables Between Groups Over Time

Table 2 and Figure 3 show the results of the lifestyle score variables between the groups over time. The study found that there were no group differences in lifestyle scores at baseline (Table 1). However, over time, the experimental group's lifestyle scores consistently increased (T1=100.55, T2=125.82, and T3=130.27), whereas the waitlist control group's lifestyle scores showed no consistent increase (T1=97.71, T2=95.92, and T3=98.21). Over time, the lifestyle scores of the experimental group significantly increased (β=29.23; *P*≤.001) compared with the waitlist control group. The experimental group developed a healthier lifestyle with time, and remarkable changes were observed during the intervention period.

Table 2. Group comparison in lifestyle score, MetS[a] components, body composition, and HRQoL[b] domain parameters (N=46).

[a]MetS: metabolic syndrome.

[b]HRQoL: health-related quality of life.

[c]T1: time point 1.

[d]T2: time point 2.

[e]T3: time point 3.

[f]Reference: interaction between control group and T1.

[g]SBP: systolic blood pressure.

[h]N/A: not applicable.

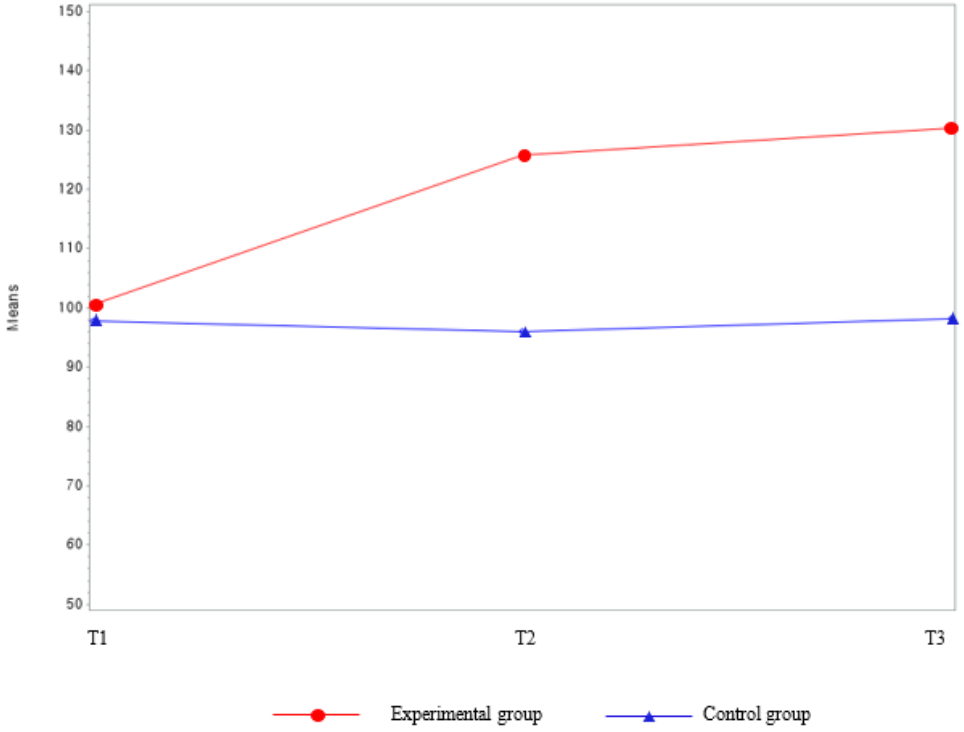
[i]DBP: diastolic blood pressure.

[j]FBS: fasting blood sugar.

[k]HDL cholesterol: high-density lipoprotein cholesterol.

[l]AC: abdominal circumference.

Figure 3. Group comparison among the main outcome variables (Lifestyle score) over time. T1: time point 1; T2: time point 2; T3: time point 3.



Results of Secondary Outcome Variables Between Groups Over Time

The difference in the prevalence of MetS before and after the intervention between the experimental group and the waitlist control group was not statistically significant (χ^2_1=1.1; *P*=.31 at T3 [not presented in the tables]). Among the MetS components, the parameters for FBS (β=−12.0; F_{44}=3.98; *P*=.05) and AC (β=−2.49; F_{44}=4.09; *P*=.049) showed significant interactions between group and time (Table 2 and Figures 4 and 5). Regarding body composition, the mean body weight and BMI in the experimental group decreased significantly by 1.52 kg and 0.55 kg/m^2, respectively (*P*<.001) compared with the baseline values. Group, time, and group and time interactions were also statistically significant between these variables (*P*<.001). Over time, the mean body weight (*P*<.001) and BMI (*P*<.001) decreased more in the experimental group than in the waitlist control group (Table 2 and Figures 6 and 7). Regarding HRQoL domains (Table 2 and Figure 8), a more significant improvement was observed in the experimental group than in the waitlist control group for the urinary irritative and obstructive domain. The mean changes in the urinary irritative and obstructive domain of HRQoL were statistically significant at each time point from the baseline, whereas the mean changes in the control group for this domain were not statistically significant. Group and time interactions were not significant, except in the urinary irritative and obstructive domain of HRQoL in the experimental group (β=14.63; $F_{8,8}$=7.01; *P*<.001).

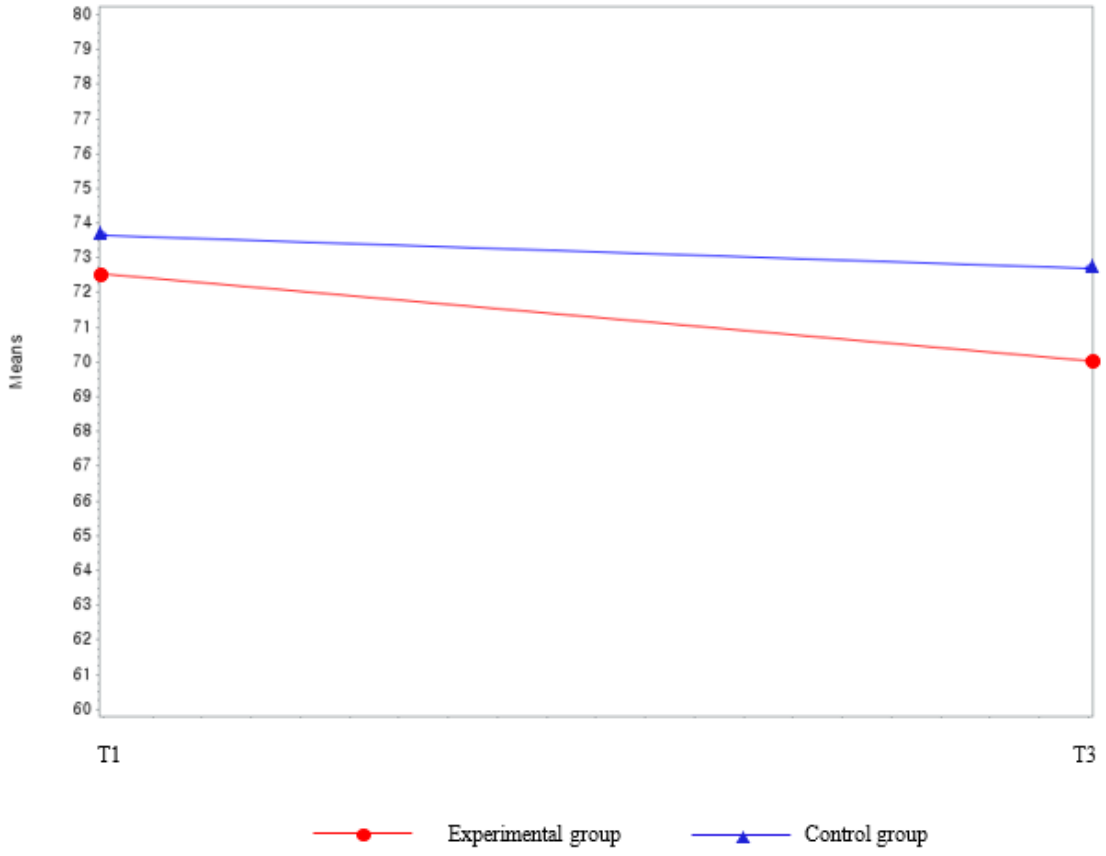

Figure 7. Group comparison among the main outcome variables (BMI) over time. T1: time point 1; T3: time point 3.

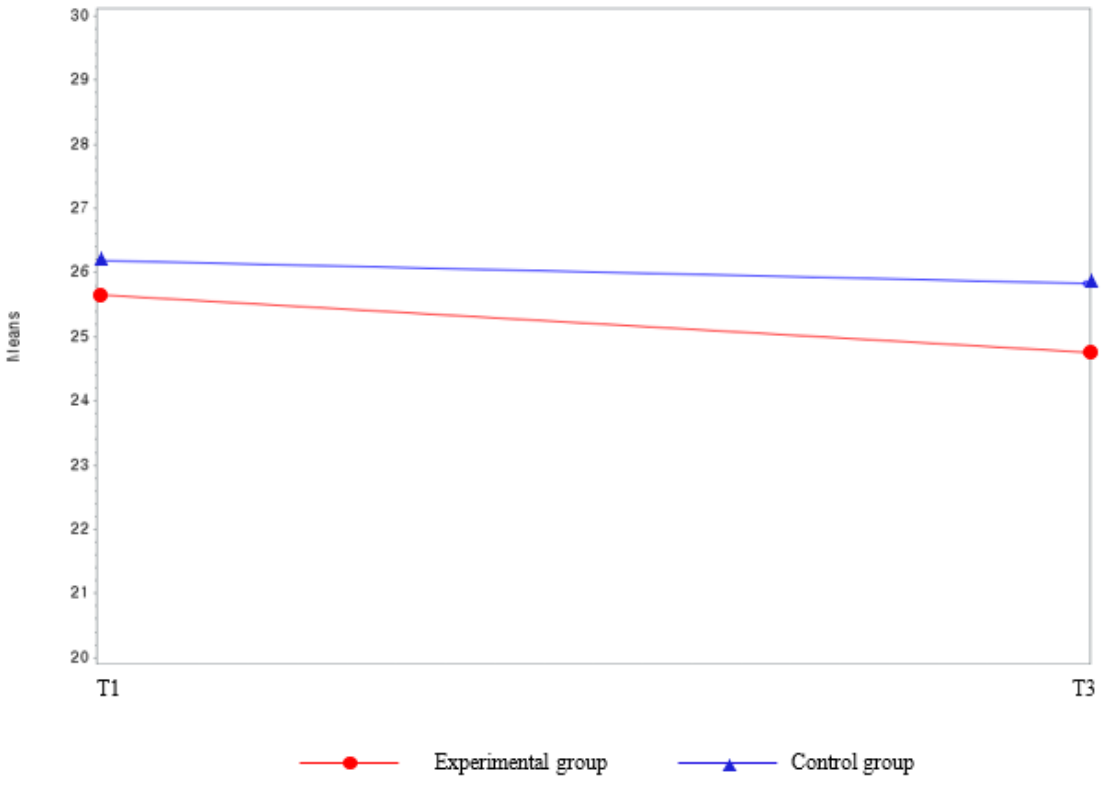

Figure 8. Group comparison among the main outcome variables (urinary irritation and obstruction) over time. T1: time point 1; T2; time point 2; T3: time point 3.

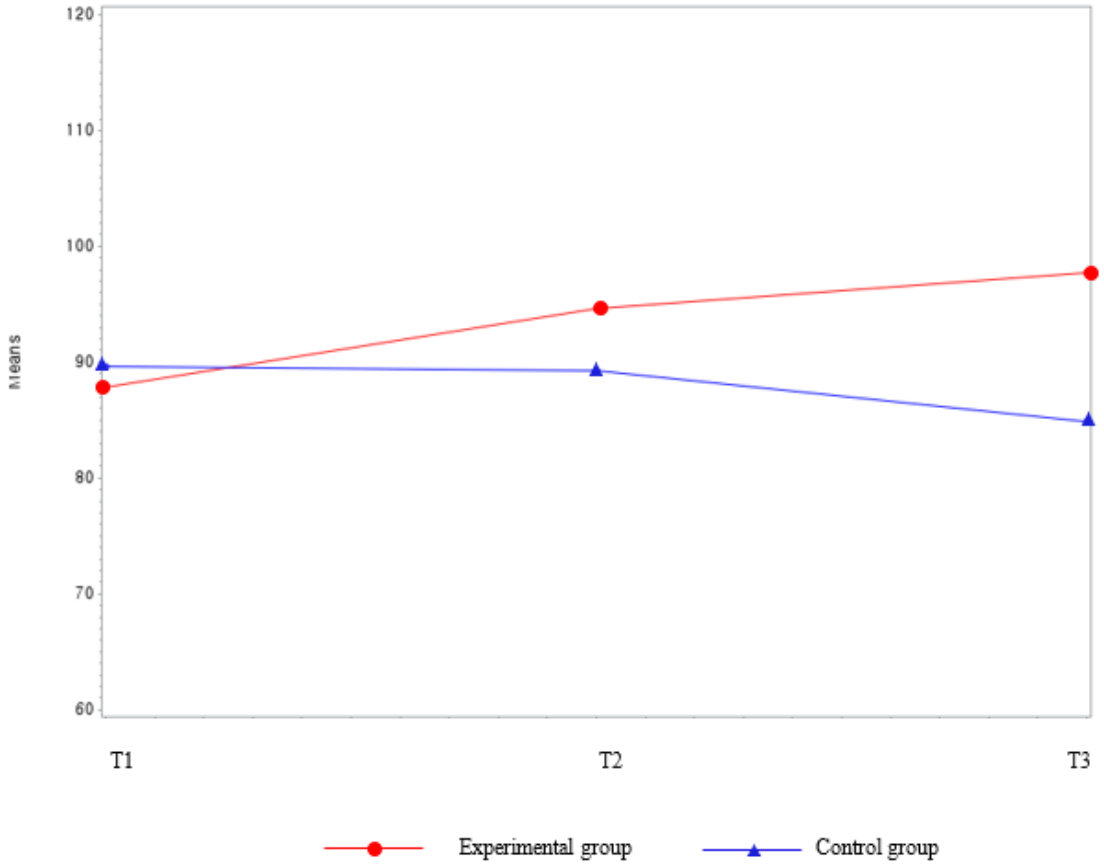

Discussion

Principal Findings

This study was conducted to determine the effectiveness of a nurse-led mobile-based education program for patients with PC who are at risk of MetS. This study showed that a nurse-led mobile-based health coaching program promoted a healthy lifestyle in patients with PC receiving ADT, which ultimately improved the levels of some MetS components (eg, reduction in FBS and AC), body composition (eg, reduction in weight and BMI), and HRQoL (eg, the urinary irritative and obstructive domain).

In this study, with a 3-month intervention, the results indicated that each variable required a different amount of time to show changes. In a previous study, a period of at least 3 to 8 weeks was required to confirm significant changes in weight, BMI, and the levels of each MetS component following lifestyle intervention programs [48-50]. Specifically, AC, FBS, body weight, and BMI have been found to decrease significantly over short periods [49,51]. However, in studies with intervention periods of ≥6 months, significant results were confirmed for MetS components including HDL cholesterol, SBP, and DBP [52,53]. Even in weight control programs that included strict diet control and exercise intervention guidelines, MetS components, including HDL cholesterol, did not change over a period of 8 weeks and only showed a significant change in both men and women 10 months after the end of the intervention [54].

The study by Dawson et al [55] observed decreases in body weight and AC but not in HDL cholesterol level among the MetS components in patients with PC. Focht and colleagues [56] also reported decreased bodyweight in patients with PC. These studies included lifestyle interventions lasting 3 months for patients with PC who had received ADT. The mean duration of ADT was 14 months in the study by Focht et al [56] and 30 months in the study by Dawson et al [55]. Specifically, Focht et al [56] confirmed that the body composition of body weight and body fat decreased significantly at 3 months compared with the control group. Furthermore, Dawson et al [55] conducted a program that emphasized exercise and protein supplementation for 3 months in patients with PC receiving ADT. As a result, of the MetS components, the AC of participants decreased most significantly in the experimental group than in the waitlist control group.

Reductions in body weight, AC, and FBS levels were closely related. When beginning to lose weight, the body temporarily lowers its metabolic function to maintain homeostasis and first metabolizes glucose, which is a basic energy source. When stored glycogen is broken down, the insulin mechanism is activated for additional energy consumption [57]. Weight loss causes a decrease in FBS level along with the action of insulin, which reactivates FBS, stored in the form of excess fat in the liver or abdomen. This fat is continuously used to generate energy, consequently, the fat accumulated in the liver or abdomen is consumed, leading to a reduced volume [58]. In this study, although no significant decrease in body fat was observed, a decrease in AC was observed. Similarly, in previous

studies, decreases in body weight [56], AC [55], and FBS levels [49] were confirmed 3 months after the intervention.

In this study, there were no significant changes in body composition related to body fat and skeletal muscle mass or in MetS components related to blood pressure (SBP and DBP) and lipids (HDL cholesterol and triglyceride). Insulin resistance develops over a long period, which increases the risk of obesity, diabetes, and MetS. In addition, it affects the lipid ratio, leading to an increase in low-density lipoprotein cholesterol and a decrease in HDL cholesterol [58], and causes inflammatory changes, resulting in changes in blood pressure owing to an increase in the residual amount of sodium in the blood [59]. Moreover, in a study that examined prediabetic patients diagnosed with impaired fasting glucose levels over the course of a 10-year follow-up period, 37% of the patients developed diabetes [60]. This finding indicates that the disease mechanism does not change over a short period but rather progresses slowly. Therefore, a long-term follow-up study is required to more accurately confirm the effectiveness of a lifestyle intervention program for MetS.

Among the HRQoL domains, an effect was observed only in the urinary irritative and obstructive domain, which may be caused by the education on how to manage the side effects of ADT treatment in the third and fourth weeks of the intervention. Patients with PC who have undergone multiple surgeries or frequent radiation therapy complained of side effects [61], such as urinary irritation and frequency. During the intervention in this study, information about appropriate water intake and pelvic floor muscle exercises to relieve urinary irritative and obstructive symptoms such as urinary irritation and frequency were included in an educational brochure [57], and appropriate water intake and pelvic floor muscle exercise were recommended for the participants depending on the presence or absence of symptoms. Thus, participants with these symptoms may have experienced relief through this intervention. Of the remaining HRQoL domains, the urinary incontinence, bowel, sexual, and hormonal domains did not show statistically significant changes. HRQoL was assessed using a questionnaire on treatment side effects and symptoms during the preceding 4 weeks. Most participants in this study were receiving long-term treatment after surgery, with an average of 40 (SD 24.71) months of ADT treatment. The bowel domain contains questions about whether the participants had diarrhea and bloody stools, which are acute side effects of participants who have undergone PC resection surgery. This domain had a higher mean score than the other HRQoL domains, with an average of ≥95 beginning at the baseline; therefore, these questions might not be relevant for participants of this study who were not in the acute stage after surgery. In addition, most questions in the hormonal domain examined the side effects that appear toward the start of ADT such as breast tenderness, bloody stools, and weight loss. Therefore, the insignificant changes in this domain might be because the participants in this study had already been taking medication for these side effects. At 19 points, the sexual domain had the lowest mean score of all the HRQoL domains. Sexual function might be limited in recovery as a result of a short-term health coaching program [62,63]. Although a previous study found that exercise can improve sexual function [64], sexual function requires interaction with a partner [65]. To restore sexual function, it is necessary to combine both psychological intervention and drug treatment [66].

This study found lifestyle changes to be critical in reducing the risk of MetS and that improved exercise and nutritional regimens should be implemented consistently for at least 3 months. Furthermore, a patient-centered, individualized approach that considers the side effects of ADT is needed to increase adherence.

Limitations

This study had some limitations. First, the criteria for participant selection included patients with at least 1 MetS component. To more thoroughly examine the effectiveness of this program on MetS management, stricter inclusion criteria should have been applied, such as only including those who were being treated with luteinizing hormone–releasing hormone, which is a type of ADT that causes the occurrence of more MetS components MetS components; those with ≥3 MetS components; those with a sedentary lifestyle; or those with a specific time after radical prostatectomy. Owing to data unavailability, this study only collected the Gleason score but not the information on TNM classification as the patient's pathological data. It is important to establish accurate patient pathological criteria; hence, future studies should incorporate both the TNM classification and the Gleason score with accurate criteria. Second, the 3-month intervention period planned in this study was limited to evaluating the continuation of self-management and improvement in MetS risk factors. It is necessary to extend the intervention period to at least 6 months to further evaluate the persistence of self-management. As older men with PC receiving ADT are at high risk of osteoporosis, measuring bone health–related indicators in addition to changes in body composition is highly recommended for future studies. Third, it is difficult to generalize the results of this study because the participants were recruited from a single hospital and not from a multicenter. Fourth, obtaining low Cronbach α values for some items in the lifestyle score may indicate a mismatch between the measurement and the participant's lifestyle. This is because the lifestyle score was created for the general adult population; however, the participants in this study were older adults who had PC, had undergone surgery, and were taking hormone-suppressing medications.

Conclusions

A nurse-led mobile-based health coaching program was developed to promote a healthy lifestyle among patients with PC receiving ADT. The research findings confirmed that lifestyle changes through nurse-led education can improve the components of MetS, body composition, and ADT's side effects. Therefore, by participating in this program, nurses were capable of creating changes in patients' lifestyles and improving the self-management of patients who were beginning ADT for the first time. In addition, this study can provide a basis for the development of other mobile-based education programs and tools.

Abstract

Background: Patient engagement attrition in mobile health (mHealth) remote patient monitoring (RPM) programs decreases program benefits. Systemic disparities lead to inequities in RPM adoption and use. There is an urgent need to understand patients' experiences with RPM in the real world, especially for patients who have stopped using the programs, as addressing issues faced by patients can increase the value of mHealth for patients and subsequently decrease attrition.

Objective: This study sought to understand patient engagement and experiences in an RPM mHealth intervention in lung transplant recipients.

Methods: Between May 4, 2020, and November 1, 2022, a total of 601 lung transplant recipients were enrolled in an mHealth RPM intervention to monitor lung function. The predictors of patient engagement were evaluated using multivariable logistic and linear regression. Semistructured interviews were conducted with 6 of 39 patients who had engaged in the first month but stopped using the program, and common themes were identified.

Results: Patients who underwent transplant more than 1 year before enrollment in the program had 84% lower odds of engaging (odds ratio [OR] 0.16, 95% CI 0.07-0.35), 82% lower odds of submitting pulmonary function measurements (OR 0.18, 95% CI 0.09-0.33), and 78% lower odds of completing symptom checklists (OR 0.22, 95% CI 0.10-0.43). Patients whose primary language was not English had 78% lower odds of engaging compared to English speakers (OR 0.22, 95% CI 0.07-0.67). Interviews revealed 4 prominent themes: challenges with devices, communication breakdowns, a desire for more personal interactions and specific feedback with the care team about their results, understanding the purpose of the chat, and understanding how their data are used.

Conclusions: Care delivery and patient experiences with RPM in lung transplant mHealth can be improved and made more equitable by tailoring outreach and enhancements toward non-English speakers and patients with a longer time between transplant and enrollment. Attention to designing programs to provide personalization through supplementary provider contact, education, and information transparency may decrease attrition rates.

Introduction

Many large health systems have turned to remote patient monitoring (RPM) programs to improve population health outcomes, consistently engage with patients, and deliver care more efficiently at scale. RPM uses technology such as mobile devices (mHealth), wearables, or digital devices to communicate health information between patients and providers [1]. A 2022 systemic review found 268 published studies involving the use of RPM, reporting outcomes such as reduced health system costs, decreased hospitalizations, and improved patient quality of life [2,3]. The diversity of RPM clinical use cases includes dementia, diabetes, inflammatory bowel disease, sleep disorders, COVID-19, and cardiovascular disease, among many others [4-7].

However, RPM mHealth programs are most valuable when they maintain consistent patient engagement, allowing for adequate remote monitoring and increased data quality. High patient drop-off in RPM programs is common and seemingly inevitable upon implementation [8]. In a meta-analysis of 17 studies, 43% of patients stopped using the intervention before study completion [9]. In the same meta-analysis, observational real-world studies had even higher (49%) attrition compared to randomized controlled trials. Individual disengagement in RPM programs may arise from a wide range of factors, such as technological difficulties, lack of face-to-face encounters, or irrelevant content [10]. In addition, systemic disparities exist in terms of digital access and literacy, especially among vulnerable populations, leading to inequities in RPM adoption and use [10-13]. There is an urgent need to understand the patient experiences of RPM in real-world studies, especially for patients who have dropped off in engagement, as these patients may face untraditional and uncommunicated needs and challenges.

At the University of California, San Francisco (UCSF), a real-world RPM program for lung transplant recipients was launched in 2020 and is currently ongoing [14]. Patients used Bluetooth-enabled home spirometers to monitor pulmonary function and reported results and outcomes using a web-based chat interface. With the goal of engaging a higher proportion of patients and improving RPM compliance, we used a mixed methods approach to quantitatively identify the clinical and demographic predictors of patient engagement and conducted qualitative semistructured interviews with patients who had stopped using the home spirometry program after the first month to understand the nuances behind patient drop-off.

Methods

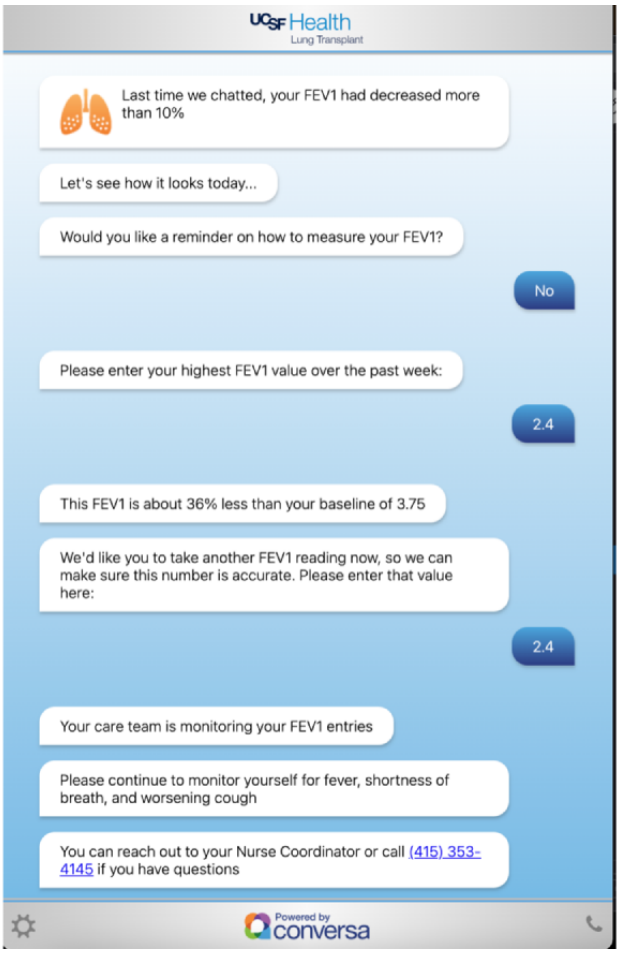
Home Spirometry Program

All patients who have had a lung transplant at UCSF are enrolled in an ongoing real-world RPM mHealth intervention that was implemented as a change in routine care [14]. The intervention is composed of an automated, English-only, chatbot-based symptom monitoring experience powered by a third-party vendor (Conversa Health, Inc), paired with a Bluetooth-enabled handheld home spirometer (Spirobank Smart or SmartOne, MIR Medical International Research) that allows patients to record their forced expiratory volume in the first second (FEV_1) to assess and track their pulmonary function (Figure 1). The program was launched in May 2020, with all patients transplanted after May 1, 2020, automatically enrolled and given the chance to opt out. Additionally, all UCSF patients who had ever had a lung transplant were offered an opportunity to self-enroll (opt in) to the program at the time. In August 2020, all patients who had previously received a lung transplant and who had not self-enrolled were automatically bulk enrolled in the program, allowing them to opt out. Patients transplanted after May 2020 were onboarded in person during their posttransplant care, while patients transplanted before May 2020 were onboarded either digitally through mailed guides or during a routine outpatient follow-up visit.

Through the automated chat, patients can complete individual modules, in which they can report symptoms, manually input new FEV_1 measurements recorded from their Bluetooth spirometer, and receive educational content embedded into chat modules (Figure 2). The goal of the program is early detection of acute and chronic allograft dysfunction and infections. Any abnormal drops in pulmonary function (>10% from baseline for each patient) or concerning patient symptoms generated an immediate alert to an electronic health record shared in-basket that was monitored by the lung transplant care team. Patients were also provided with the clinic contact information and instructed to reach out for additional advice. The transplant team managed clinical findings at their discretion. Additionally, patients are expected to engage with routine automated chat prompts as part of their posttransplant care indefinitely to provide the most up-to-date spirometry and symptom data to their providers, who review with patients during outpatient follow-up visits. Initially, all patients were on a weekly chat reminder cadence, with a reversion to a daily reminder cadence if their condition deteriorated (as defined by a 10% drop in FEV_1 or the reporting of concerning symptoms). In May 2021, the chat reminder cadence was changed to allow patients 1-year posttransplant with stable conditions to opt into a monthly cadence, with the possibility to return to a weekly or daily cadence if their condition deteriorated, and the eventual regraduation to weekly or monthly once they began to recover. Patients could self-initiate chat sessions at will.

Figure 1. Home spirometry device and onboarding.

Figure 2. Screenshot of patient chat experience. FEV1: forced expiratory volume in the first second.



Predictors of Patient Engagement

The 3 primary outcomes were patient engagement with the intervention, including (1) module engagement, defined as completing at least 1 module of any chat, (2) spirometry engagement, defined as patients who submitted at least 1 home spirometry FEV_1 value, or (3) symptom checklist engagement, defined as patients who responded to a symptom-reporting checklist at least once. Unengaged patients were defined as those who did not (1) complete any modules, (2) submit FEV_1 values, or (3) complete symptom checklists. As submitting a FEV_1 or a symptom checklist inherently resulted in the completion of a module, all patients classified as engaged by definitions 2 and 3 were also classified as engaged by definition 1, with definition 1 serving as the broadest outcome. It was possible for patients to have only engaged in educational modules without FEV_1 or symptom submission, resulting in only meeting the module engagement definition without meeting the other 2. Additionally, as secondary outcomes, the number of times patients completed the chat, submitted FEV_1 values, and symptom checklists were also calculated for each patient within the first year after enrollment. Since patients were asked to complete the chat at regularly scheduled repeated intervals, patients who died during their first year of enrollment were excluded from this secondary analysis.

Patient demographic and scheduling data were extracted from the electronic health record. This included patient age, transplant date, sex, race or ethnicity, address, insurance payor, primary language, and marital status. The primary diagnosis resulting in a need for transplantation was classified into 5 categories: restrictive disease, obstructive disease, cystic fibrosis or bronchiectasis, pulmonary hypertension, and other disease. Rural or urban status was assigned at the zip code level using the rural-urban community area codes classification [15]. Area Deprivation Index (ADI) national percentiles, based on a patient's US census block group location, were used as a proxy measure of socioeconomic status [16].

Differences in the patient cohort conditioned on engagement status based on whether or not patients had completed any modules were compared using the chi-square test for categorical features and the 2-sample *t* test (2-tailed) for continuous features. Multivariate logistic and linear regression models were created to assess the predictors of engagement defined by chat module completion and longitudinal engagement, respectively. All analyses were performed using R (version 3.5.1; R Foundation for Statistical Computing), and a P value <.05 was considered significant.

Qualitative Interviews

A convenience sample of patients (n=6) who initially engaged with the mHealth program in the first month but subsequently stopped using it (n=39) were recruited to participate in 40-minute semistructured qualitative interviews. The interviews were led by 1 of 2 user experience designers (NEM and ARM) and conducted through Zoom videoconferencing (Zoom Technologies Inc). Patients were invited to include their significant others or caretakers in the call to help provide additional context and reassurance. Patients were compensated with a US $25 gift card. Interviews were audio-recorded and transcribed. NEM, ARM, AWL, and OB then collaboratively synthesized results to determine concepts and themes by pairing quotes and notes to relevant themes. Three individuals who did not participate in the interviews (AWL, WB III, and AYO) reviewed the selected themes with accompanying quotes and selected quotes for presentation.

The qualitative interview opened with topics concerning the patient's background, including transplant experience, current condition, the frequency of home spirometry, and chat use. Patients were prompted with screenshots of the chat experience and asked about their perceptions, program expectations, reasons for opting out and nonuse, and any challenges they experienced. Patients were also asked about whether solving the challenges they brought up would cause them to reengage at a higher rate. Finally, patients were also given the opportunity to ask questions and provide comments on anything not already touched upon.

Ethical Considerations

The retrospective quantitative and prospective qualitative portions of this study, including patient compensation, were separately reviewed and approved by the University of California, San Francisco institutional review board (22-35950 and 22-35948).

Results

Overview

Between May 4, 2020, and November 1, 2022, a total of 626 patients were enrolled in the chat and 25 patients opted out, resulting in a total of 601 patients included in multivariate logistic regression analysis. Additionally, 33 patients died within their first year of enrollment, resulting in 568 patients included in multivariate linear regression modeling.

In total, 479 (79.7%) patients completed ≥1 module, 433 (72%) patients submitted ≥1 FEV_1 value, and 438 (72.9%) patients submitted ≥1 symptom assessment. The engaged or unengaged cohorts when compared by module completion status were composed of patients of similar sex, race or ethnicity, rural or urban zip code status, marital status, primary language, insurance type, and diagnosis. Engaged patients were marginally younger (66.1 vs 65.2 years; P<.01), had more recent transplants (1.6 years since transplant for engaged patients vs 5.7 years for nonengaged patients; P<.01), and lived in areas with lower ADI national percentiles (14 vs 16; P<.01; Table 1).

Table 1. Patient demographics by module completion (engagement) status (n=601). Patients were considered engaged if they completed any chat modules, including the forced expiratory volume in the first second (FEV1)and symptom submission modules (definition 1).

	Not engaged participants (n=122)	Engaged participants (n=479)	*P* value

Predictors of Engagement

In a multivariate logistic regression model to identify predictors of engagement as defined by completion of a module (definition 1), patients who were enrolled ≥1 year from their transplant had 84% lower odds of engaging compared to those with more recent transplants (odds ratio [OR] 0.16, 95% CI 0.07-0.35; *P*<.01) when demographic factors (race or ethnicity, age, zip code status, insurance type, marital status, diagnosis, and socioeconomic status) were held constant. Similarly, patients

with ≥1 year between transplant and enrollment had 82% lower odds of submitting pulmonary function measurements (OR 0.18, 95% CI 0.09-0.33; *P*<.01) and 78% lower odds of completing symptom checklists (OR 0.22, 95% CI 0.10-0.43; *P*<.01). Patients whose primary language was not English had 78% lower odds of engaging compared to primarily English speakers (OR 0.22, 95% CI 0.07-0.67; *P*<.01). Patient age, race or ethnicity, marital status, insurance type, sex, rural or urban zip code status, ADI national percentile ranking, and diagnosis were not found to have significant associations with engagement in the multivariate logistic regression model (Table 2).

In multivariate linear regression evaluating the number of modules completed in the first year of enrollment, single patient completed 8.69 fewer modules (95% CI –13.75 to –3.64; *P*<.01), patients with non-English primary languages completed 11.89 fewer modules (95% CI –20.62 to –3.17; *P*<.01), and patients with longer duration since transplant completed 15.22 fewer modules (95% CI –19.69 to –10.75; *P*<.01; Table 3). Multivariate analysis conducted on the number of FEV_1 and symptom submissions within the first year found that longer duration between transplant and enrollment and having single or separated or other marital status remained predictors for longitudinal engagement (Table S1 in Multimedia Appendix 1).

Table 2. Predictors of the degree of engagement.[a]

Predictors	Number of FEV_1 submissions		Number of symptom submissions	
	Estimate (95% CI)	*P* value	Estimate (95% CI)	*P* value

Qualitative Interviews

Overview

Interviews were conducted with 2 male and 4 female patients, aged 35-70 years, and White and Latinx. Patients ranged from 1 to 18 years posttransplantation. One patient had his primary caretaker present as his proxy (Table 4). From the interviews, 4 key thematic concepts emerged: challenges with devices, communication breakdowns, desire for more personal interactions and specific feedback with the care team about data and concerns, and understanding the purpose of the care chat.

Table 4. Interviewed patient demographics (n=6). Patients were chosen based on having previously engaged in the first month but then subsequently having had no engagement afterward.

Patient	Age (years); sex	Time since transplant and final date of analysis[a] (years)	Brief background
P1 and PR1	69; male	1.07	Latinx, primary language Spanish, and primary caretaker (PR1) present as proxy
P2	57; male	2.4	White, primary language English, and lives with a partner
P3	36; female	2.17	White and lives alone
P4	30; female	11.18	White and lives alone
P5	44; female	17.84	White and live with partner
P6	70; female	7.31	White and primary caretaker of the spouse

[a]November 1, 2022.

Patients Had Challenges With Devices

Patients reported a diverse set of difficulties associated with the use of their spirometer and mobile devices at home. Challenges encompassed all facets of the experience, such as difficulties with installing the spirometer app on their mobile device and connecting their spirometers through Bluetooth.

> *My machine will not connect to my phone or anybody else's phone. I tried unloading it, reloading it, even took it to AT&T because I'm not very tech savvy.* [Participant 3]

Low technological literacy was a barrier to engagement, and further product development is needed to make it easier to troubleshoot difficulties. One patient reported their preference to carry around an oximeter instead of using their spirometer due to a lack of confidence in their spirometer from experiencing device issues.

Upon use, patients also reported having issues with properly using their spirometer device. Changes in their position or actions led to inconsistent FEV_1 measurements, which were perceived as unreliable in their eyes. For patients, receiving inconsistent FEV_1 readings decreased their confidence, often triggering them to call their care team for guidance.

> *I have a hard time because I have to hold my phone, and I got to blow into it.... if I'm holding the phone down, now I'm having my neck down, it restricts some of my air.* [Participant 2]

Relatedly, patients reported frustration from using their home spirometer.

> *... it deflates me emotionally because it's always low.... I'm not hitting the 3. I'm hitting like, 1.9. So medically, I'm okay. But to me, it keeps on failing.* [Participant 2]

Communication Breakdowns

The transition for patients from using the automated care chat to reaching out to their care team via phone call or secure portal message led to communication breakdowns. Phone calls would occur back and forth between patients and different clinic staff before they were able to reach the right individual and receive relevant answers.

> *Sometimes if you have a question, I guess you have to call your nurse coordinator. And at times you have to wait for them to call you back.... So, I'm at work, so sometimes I miss their phone calls. Sometimes we play phone tag...* [PR1]

Patients Desire More Personal Interactions and Specific Feedback With the Care Team About Data and Concerns

Patients wanted additional opportunities to stay directly connected to their care team. They preferred to communicate with a member of their care team as opposed to entering their FEV_1 or symptom measurements into the chat. “The chat doesn't really offer that opportunity to talk to someone in real life” [PR1].

The automated aspect of the care chat also resulted in a perceived technological barrier between patients and their care team. Patients were keenly aware of the automation and felt it did not provide enough incentive to stay engaged.

> *Lung transplant is a partnership and a lot of hands and a lot of faith and a lot of luck. And a lot of things came together to make a successful surgery.… You’re part of me now, you know. So yeah, any interaction is great. I’d rather talk to you. It's [the Care Chat] not very personal, very impersonal for the drastic surgery that we've had.* [Participant 4]

To patients, the automated chat responses did not provide enough contextual feedback after a FEV_1 measurement was properly submitted to bring patients peace of mind. This resulted in concerns and a lack of confidence in at-home FEV_1 measurements.

> *I don't know what I'm doing in the sense that I'm not getting any feedback from the other end. So,... thinking like, well, what am I doing ?]* [Participant 2]

Patients also wanted to know how their data were being used by the care team to assess their condition and wanted some acknowledgment that someone had reviewed their latest FEV_1 measurement. The lack of feedback from their care team about their inputted values caused patients to want to disengage. There was a strong desire for additional patient-provider interaction around the FEV_1 submission so that patients knew that their data were not going to be ignored.

> *I don't even know if the team ever looks at my what I submit via the care chat, because I don't ever get any feedback from them. So, it's kind of like, I think they see it, but I really don't know. And in that sense, it's like, well, do they really care? Maybe they do. Maybe they don't? This instantly makes me go, oh, well, if Dr. Hays is looking at these numbers, then I definitely want to provide them.* [Participant 5]

Patients Understand the Purpose of the Care Chat Experience

Patients strongly understood that their use of the care chat allowed providers to monitor their progress posttransplant. This resulted in patients being responsive to chat prompts. Furthermore, patients understood the clinical purpose of specifically collecting their FEV_1 measurement.

> *I think the purpose is to monitor our lung function from a distance and for the doctors to be able to get more frequent measurements of our FEV1 without having us come in to do spirometry, or even go into our local hospital. It's kind of a way to keep tabs on us from home in a way that's safe for us and easier for them.* [Participant 5]

At its core, home spirometry helps capture a more comprehensive view of a patient's well-being through consistent remote clinical data measurements and symptom reporting. This more comprehensive view not only allows their care team to be better informed but also respond faster to concerning changes in condition.

> *I think it's pretty great. I found it really helpful. And it's been nice for me to have like a reason to do my FEV1 and have a record of that. I like having more of a stand-up baseline that has more frequent measurements because I've always in clinic other than when I've been sick, it's been really stable, but it's nice to know at home like, oh yeah, this is really kind of where [my condition] lives.* [Participant 5]

Discussion

Principal Findings

We sought to understand engagement in a cohort of 601 patients who underwent lung transplant engaged in a real-world home spirometry mHealth intervention. Engagement and continued use of mHealth tools are critical to effective remote care. However, consistent, quality engagement in mHealth is a difficult challenge and often requires the tailoring of interventions to specific subpopulations [17,18]. We describe several novel predictors of engagement in this intervention and report major themes resulting from qualitative interviews. During our interviews, we found that patients who underwent lung transplant and who had engaged in mHealth RPM spirometry have a strong desire for improved connection to their care team and that when they feel disconnected, are unsure if their data are being received or reviewed, have trouble escalating their concerns to their care team, or experience device difficulties, they are more likely to stop using mobile health (mHealth) tools and home monitoring devices. As the first study (to our knowledge) to focus on in-depth lung transplant patient experiences with drop-off and RPM, this study brings to light patient perspectives that future interventions can learn from for program design specifics.

Multivariate modeling found that having a recent lung transplant (within 1 year of a patient's enrollment date) was consistently found to have a positive association with engagement with the chatbot. One possibility of this is that patients with longer times since transplants might be more confident managing their care without the use of an mHealth app. However, as the potential for chronic allograft dysfunction remains high even 1-year posttransplant, it remains important to engage and reengage patients to reduce the risk of missed allograft dysfunction. Future outreach efforts toward long-term transplant patients to show them the benefits of participation will be required. Additionally, the factors serving as proxies for socioeconomic status (urban or rural status, ADI percentile, and health insurance type) were not found to be associated with engagement in the mHealth program while controlled for other factors during multivariate modeling. This may be due to the fact the spirometers and the chat were provided to patients at no charge. Other factors such as race or ethnicity and age were also not consistently found to be predictive under our 3 definitions of engagement. Finally, our multivariate analysis centered on examining binary engagement with the chat found that having a non-English primary language was associated with lower engagement. Previous literature has shown that patients with a non-English primary language are significantly less likely to engage in mHealth and telemedicine [18]. Our finding has led us to plan to translate the program into Spanish, which is our second largest language cohort (6% of patients), as a next step toward equity.

Comparison With Previous Studies

Our study is not only the first to evaluate predictors of engagement of a mHealth RPM intervention in lung transplant recipients but also one of the first to examine RPM in a practice-wide, real-world setting, as opposed to a randomized controlled trial. Overall, the literature on factors influencing engagement in mHealth is mixed. Previous studies analyzing RPM programs have found age, income, and shorter time in program to be predictive of engagement [19]. Other studies have reported that drops in engagement are not associated with race or ethnicity, disease status, or geography [20]. Our analysis adds to the literature on RPM engagement: reporting that attrition over time remains a large complicated and multifaceted barrier and that trends in engagement are likely program and condition specific rather than being strongly influenced by socioeconomic factors. There is a need to continue to understand how social and clinical factors affect engagement in mHealth interventions to better engage vulnerable populations and not exacerbate existing disparities in care access. In addition, future work can be focused on comparative analyses between differences in engagement rates and outcome measurements (eg, emergency department visits, hospital readmissions).

In addition, interviews also revealed that some patients find the automated chatbot impersonal and crave additional interactions with their care teams. Program design can take this into account by creating defined instances and scenarios where providers

should reach out in case of stress or confusion. Patients desire human contact during their posttransplant care; however, it remains a challenge to balance the need to remotely monitor a large cohort of patients in an automated fashion without overwhelming clinical teams with notifications and also providing a meaningful experience that patients value. Future developments can focus on determining chat design and flow improvements that will offer patients more individualization and education, fine-tuning automated triage mechanisms to identify the right time to have patient-provider interactions, and streamlining patient-provider communication channels to keep patients informed and engaged. Content creation can also be initiated with patient reassurance in mind, such as the development of educational videos featuring their providers or trusted sources. Finally, many patients struggled with proper device setup, spirometer technological difficulties, and confidently using the device to obtain consistent results, leading to confusion and a lack of trust in program quality. These results are consistent with findings showing that low technological literacy and confusion remain major barriers toward even more widespread adoption of RPM and mHealth [10,21,22]. Spirometry device satisfaction levels have been found to greatly influence patient engagement levels, as well as constant contact and follow-up by physicians to increase patient satisfaction [23,24]. In response, program enhancements were built to alleviate the cognitive burden on patients by streamlining onboarding and reducing the number of unnecessary chats. Future developments can aim to help patients build confidence and trust with home spirometry, by adding staff for more detailed onboarding, focusing on education for patients who have technological issues or concerns during the onboarding period, and chat design incorporating more person-to-person real-time feedback by providers.

Limitations

Our study has several limitations. Our multivariate analysis did not account for health and digital literacy levels as these were not systematically assessed as part of routine clinical care and both have been shown to play major roles in a patient's abilities to access health care. While our analysis factored in disease diagnosis type, there are likely additional clinical factors that may affect patient engagement, as transplant recipients with worse pulmonary function may be more apt to consistently engage to monitor their health. Future work can examine the efficacy of home spirometry monitoring in detecting adverse events when controlling for patients' clinical conditions. Next, our study is a single-institution study of patients who have received lung transplant, and therefore the overall generalizability is reduced due to the specific nature of the patient's condition, progression, and experiences with the program specifics such as Bluetooth spirometry. Interviewed patients were recruited only from those who initially dropped out after 1 month, and therefore the themes noted may only be representative of a dropped off in the engagement cohort. More work is required to elucidate the perspectives and reasons for continual engagement from patients whose engagements were consistent, steadily decreased over time, or dropped off at a later point in the program. In the future, we plan to interview patients who had excellent adherence to understand what factors are promoting adherence in these cases. Furthermore, the small sample size of our interview cohort increases the possibility of bias during the process of thematic analysis, particularly because we only interviewed 1 non-English speaker (using an interpreter, with the patient's proxy present). Analyses from numerous implemented mHealth programs have shown that non-English speakers and patients of minority race or ethnicity are significantly less likely to engage in telemedicine [13,25,26]. Patient motivations for drop-off are nuanced and are likely strongly associated with sociocultural factors that can only be uncovered in larger, more diverse studies.

Conclusions

An mHealth intervention consisting of home spirometry paired with an automated care chat results in high engagement rates in patients who have received a lung transplant, particularly in those with more recent transplants. Interviews conducted on patients who have dropped off in engagement revealed program challenges and areas where mHealth care delivery can be improved to reduce engagement attrition, including addressing technological barriers and improving patient confidence.

Abstract

Background: Hypertension significantly impacts the well-being and health of individuals globally. Hypertension management apps (HMAs) have been shown to assist patients in controlling blood pressure (BP), with their efficacy validated in clinical trials. However, the utilization of HMAs continues to be suboptimal. Presently, there is a dearth of real-world research based on big data and exploratory mining that compares Chinese and American HMAs.

Objective: This study aims to systematically gather HMAs and their user reviews from both China and the United States. Subsequently, using data mining techniques, the study aims to compare the user experience, satisfaction levels, influencing factors, and asymmetry between Chinese and American users of HMAs. In addition, the study seeks to assess the disparities in satisfaction and its determinants while delving into the asymmetry of these factors.

Methods: The study sourced HMAs and user reviews from 10 prominent Chinese and American app stores globally. Using the latent Dirichlet allocation (LDA) topic model, the research identified various topics within user reviews. Subsequently, the Tobit model was used to investigate the impact and distinctions of each topic on user satisfaction. The Wald test was applied to analyze differences in effects across various factors.

Results: We examined a total of 261 HMAs along with their associated user reviews, amounting to 116,686 reviews in total. In terms of quantity and overall satisfaction levels, Chinese HMAs (n=91) and corresponding reviews (n=16,561) were notably fewer compared with their American counterparts (n=220 HMAs and n=100,125 reviews). The overall satisfaction rate among HMA users was 75.22% (87,773/116,686), with Chinese HMAs demonstrating a higher satisfaction rate (13,866/16,561, 83.73%) compared with that for American HMAs (73,907/100,125, 73.81%). Chinese users primarily focus on reliability (2165/16,561, 13.07%) and measurement accuracy (2091/16,561, 12.63%) when considering HMAs, whereas American users prioritize BP tracking (17,285/100,125, 17.26%) and data synchronization (12,837/100,125, 12.82%). Seven factors (easy to use: $P<.001$; measurement accuracy: $P<.001$; compatibility: $P<.001$; cost: $P<.001$; heart rate detection function: $P=.02$; blood pressure tracking function: $P<.001$; and interface design: $P=.01$) significantly influenced the positive deviation (PD) of Chinese HMA user satisfaction, while 8 factors (easy to use: $P<.001$; reliability: $P<.001$; measurement accuracy: $P<.001$; compatibility: $P<.001$; cost: $P<.001$; interface design: $P<.001$; real-time: $P<.001$; and data privacy: $P=.001$) affected the negative deviation (ND). Notably, BP tracking had the greatest effect on PD ($\beta=.354$, $P<.001$), while cost had the most significant impact on ND ($\beta=3.703$, $P<.001$). All 12 factors (easy to use: $P<.001$; blood pressure tracking function: $P<.001$; data synchronization: $P<.001$; blood pressure management effect: $P<.001$; heart rate detection function: $P<.001$; data sharing: $P<.001$; reliability: $P<.001$; compatibility: $P<.001$; interface design: $P<.001$; advertisement distribution: $P<.001$; measurement accuracy: $P<.001$; and cost: $P<.001$) significantly influenced the PD and ND of American HMA user satisfaction. Notably, BP tracking had the greatest effect on PD ($\beta=0.312$, $P<.001$), while data synchronization had the most significant impact on ND ($\beta=2.662$, $P<.001$). In addition, the influencing factors of PD and ND in user satisfaction of HMA in China and the United States are different.

Conclusions: User satisfaction factors varied significantly between different countries, showing considerable asymmetry. For Chinese HMA users, ease of use and interface design emerged as motivational factors, while factors such as cost, measurement accuracy, and compatibility primarily contributed to user dissatisfaction. For American HMA users, motivational factors were ease of use, BP tracking, BP management effect, interface design, measurement accuracy, and cost. Moreover, users expect features such as data sharing, synchronization, software reliability, compatibility, heart rate detection, and nonintrusive advertisement distribution. Tailored experience plans should be devised for different user groups in various countries to address these diverse preferences and requirements.

Introduction

The global prevalence of hypertension is on the rise. Hypertension management apps (HMAs) serve as convenient tools for effectively managing blood pressure (BP). These apps enhance users' awareness of self-management, dietary and exercise habits, and medication adherence through features such as BP tracking, dietary guidance, exercise monitoring, educational resources, and medication reminders. The ultimate aim is to achieve effective BP control. Their effectiveness has been demonstrated in experimental settings. Globally, the number of patients with hypertension surged from 648 million in 1990 to 1.278 billion in 2019, marking a prevalence of 33% [1]. HMAs represent digital health tools with the potential for effectively controlling BP [2-9]. Their usability [10,11] and effectiveness [12] have been demonstrated in randomized controlled trials. In a systematic review and meta-analysis of 18 randomized controlled trials, Han et al [13] found that HMAs could significantly reduce BP and improve BP control rates. Moreover, within the framework of the current value-based medical policy, a hospital's treatment efficacy relies not only on its in-hospital care but also on postdischarge patient attention and management. As a collaborative tool for out-of-hospital medical services, HMAs can assist patients in sustaining the effects of in-hospital treatments, thereby reducing the rate of hospital readmissions. McManus et al [14] demonstrated that compared with traditional nursing interventions, apps yield superior BP control effects within a year and incur lower incremental costs. However, in practical settings, many HMAs have been developed without adhering to evidence-based medicine [15] and lacked clinical certification before marketing [16], potentially posing adverse effects on hypertension management [17,18].

Although HMAs show significant BP management effects in controlled environments, their real-world outcomes are often unsatisfactory. Both user engagement and retention rates are low, with 62% of mobile health (mHealth) apps having fewer than 1000 monthly active users [19] and only 6.6% of patients with hypertension continuing to use HMAs [20]. These situations directly correlate with user satisfaction [21-24]. Therefore, enhancing user satisfaction can significantly improve the effectiveness of the app [25]. According to the Food and Drug Administration (FDA), in real-world scenarios, health information technology (HIT) is integrated into a complex sociotechnical system, and its actual impact is influenced by 4 primary factors aside from the product itself: people (whether they are involved or not), technologies (including HIT hardware and software), processes (the workflow of health care delivery), and organization (the procedure for HIT installation and configuration). Among these factors, external environmental elements (such as the policies and cultures of different countries) play a significant role [26]. The actual impacts of HMAs can vary significantly among user groups in different countries. Therefore, it is essential to explore and compare the satisfaction levels and influencing factors of user groups across various

countries. This comparative analysis can enable targeted efforts to enhance the practical effectiveness of HMAs.

Traditional studies on user satisfaction of HMAs primarily consist of qualitative analyses [27,28]. However, these studies often lack breadth and depth, characterized by limitations such as small sample sizes, susceptibility to adverse observer effects and recall bias, and limited generalizability of conclusions. Furthermore, these studies often overlook the impact of external environmental factors and do not compare or analyze the satisfaction levels of user groups across different countries. For instance, Li et al [29] conducted semistructured interviews with 13 English-speaking patients with hypertension to explore their surface-level satisfaction with HMAs and analyze factors contributing to dissatisfaction. Kang and Park [30] developed an English HMA grounded on clinical guidelines for hypertension management. They used the modified Morisky Scale to assess perceived usefulness and satisfaction with this app among 38 patients diagnosed with hypertension. Although qualitative analyses allow for a deep exploration of individual attitudes, they have limitations such as a restricted number of apps that can be analyzed [31,32], a small sample size confined to a specific region [33], high research costs, and potential biases in conclusions [34].

Research on user satisfaction with HMAs lacks both quantitative studies driven by large volumes of user-generated content and in-depth exploration of the factors influencing satisfaction, particularly in terms of asymmetry. In addition, there is a notable absence of comparative analyses of user groups across different countries. Plante et al [35] manually annotated and summarized English user reviews of an HMA (Instant BP) from an online app store, discovering that users expressed greater satisfaction with apps yielding lower measurement results. Similarly, Wang et al [36] and Nuo et al [37] conducted quantitative analyses of user reviews for weight and sleep management apps to investigate user satisfaction and influencing factors. However, none of these studies conducted an in-depth evaluation of variations in satisfaction and influencing factors among user groups across different countries. The renowned Herzberg 2-factor theory [38] in management suggests that the factors influencing user satisfaction exhibit asymmetry and can be categorized into motivational factors that enhance satisfaction and hygienic factors that mitigate dissatisfaction. Using large-sample data and incorporating the asymmetry of factors impacting app user satisfaction, while also considering variations among user groups in different countries, can effectively mitigate errors in constructing explanatory models. This approach enhances the predictability and generalizability of the model [39].

Therefore, this study adopts the 2-factor model and uses unsupervised clustering algorithms to quantitatively analyze user reviews of HMAs from major Chinese and American app stores globally. By considering the macro usage environment, the study aims to extract and compare the primary opinions of Chinese and American users, assess differences in satisfaction and its influencing factors, and explore the asymmetry within these factors.

Methods

Informed Consent and Study Approval Statement

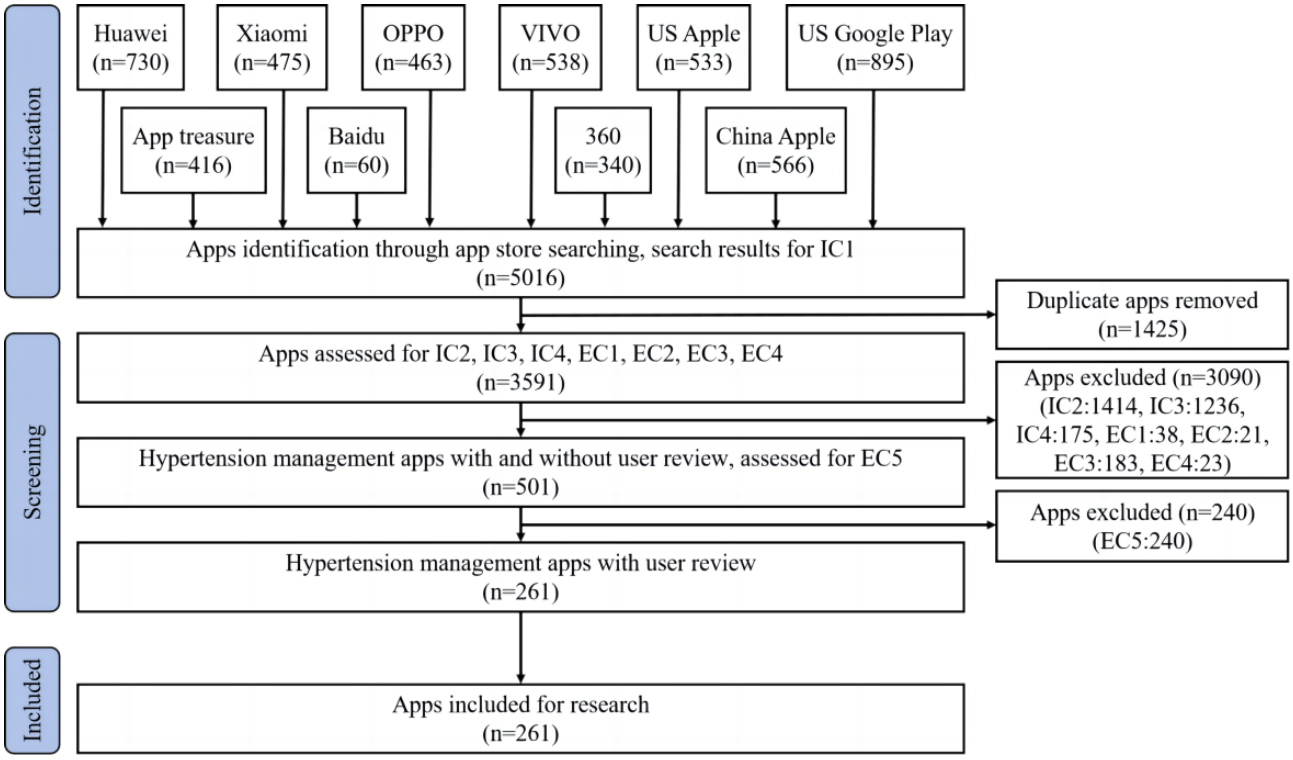
All data used in this study were sourced from publicly accessible internet mobile app stores, encompassing app information and user reviews. Hence, this study does not entail any medical ethics concerns.

Data Collection

HMA Identification

In this comparative study, to conduct a comprehensive review of the primary HMAs, we consulted previous studies [36,37] and identified 10 widely used Chinese and American app stores from the 2 major mobile phone platforms (iOS [Apple Inc.] and Android [Google LLC]). These include 8 Chinese platforms (China Apple, Huawei, Xiaomi, OPPO, VIVO, Baidu, 360, and Application Treasure) and 2 American platforms (US Apple App Store and US Google Play Store). App stores in different countries can only access user data from their respective regions. Therefore, in April 2023, we conducted searches across the aforementioned 10 Chinese and American app stores using keywords such as “hypertension,” “high blood pressure,” “blood pressure management,” and “blood pressure recording.” We retrieved a total of 5016 apps, out of which 3591 remained after deduplication (Table S1 in Multimedia Appendix 1). Following guidelines from previous studies [40], we formulated detailed inclusion and exclusion criteria (Table S2 in Multimedia Appendix 1), which were independently screened by 2 researchers (YFH and J Liang). Both researchers underwent standardized training before the screening process, resulting in high consistency in their screening results (κ=0.84). Any discrepancies between the researchers were resolved through arbitration by another cardiovascular clinical expert (WZ). The specific screening process, following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines [41], is depicted in Figure 1.

Figure 1. Flowchart of the hypertension management app screening process; IC: inclusion criteria; EC: exclusion criteria.



User Review Collection

All 10 Chinese and American app platforms offer user ratings and review features, enabling users to provide quantitative ratings and qualitative descriptions of their satisfaction with apps. These ratings typically range from 1 (very poor) to 5 (very good). We used Python scripts (Python Foundation) and the Qimai mobile app data analysis platform [42] to extract all quantitative ratings and qualitative user reviews of the included HMAs. As of April 23, 2023, we collected a total of 295,927 quantitative ratings and qualitative user reviews, comprising 250,193 reviews from American users and 45,734 reviews from Chinese users. The proportion of Chinese reviews and downloads (16,561/24,204,832, 0.07%) is similar to that of American reviews and downloads (100,125/148,869,181, 0.07%).

User Review Preprocessing

The presence of false and meaningless user reviews in the app store data significantly impacted the topic mining of user reviews and interfered with the assessment of user satisfaction with HMAs. Hence, we conducted preprocessing on the user reviews with the following steps:

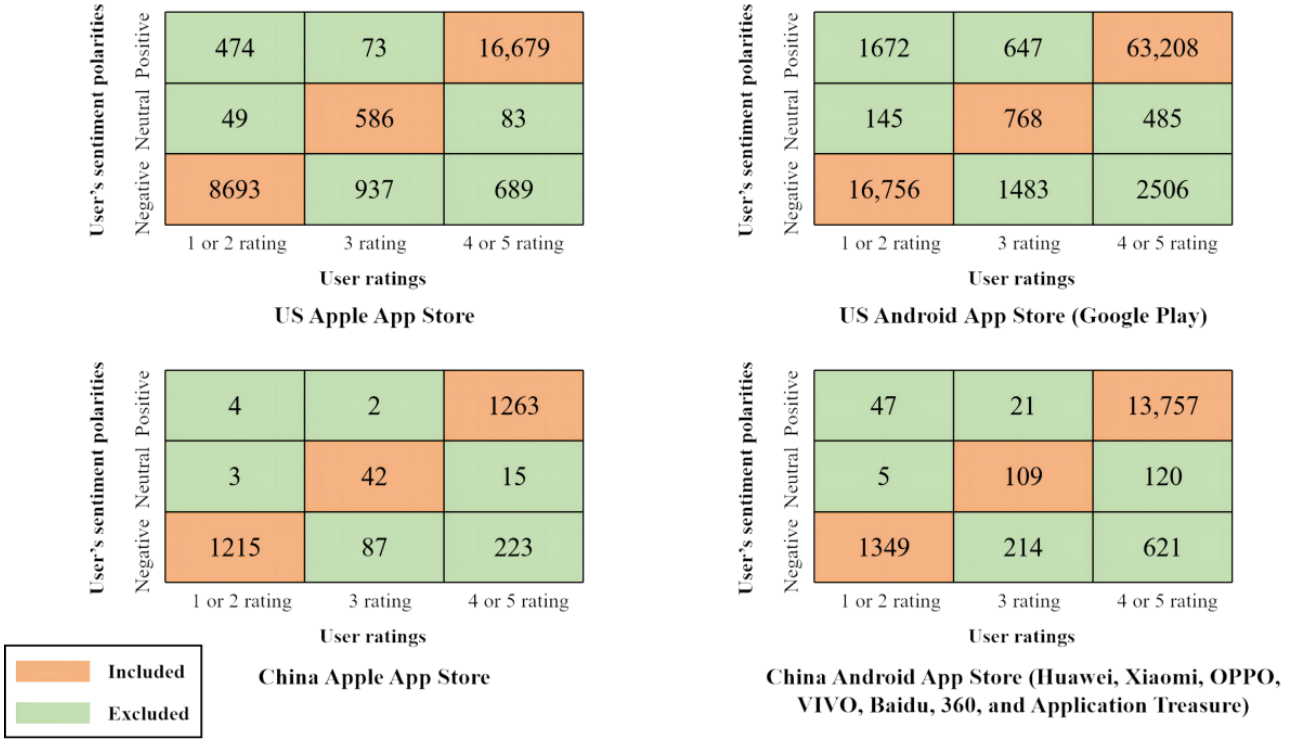
Removing data containing only ratings without accompanying user reviews.

Excluding user reviews posted on bot accounts, using the tweetbotornot package in R [43]. This resulted in the exclusion of 53,431 American and 16,940 Chinese reviews.

Eliminating duplicate reviews, blank values, non-Chinese or English reviews, garbled characters, and reviews deemed meaningless. This process led to the exclusion of 80,829 American and 9697 Chinese reviews.

Following this, we used the sentiment knowledge–enhanced pretraining algorithm [44] to calculate the emotional polarity of each user review, categorized into negative, neutral, and positive sentiments. Furthermore, contradictory data showing inconsistencies between user ratings and reviews were eliminated [45], resulting in the exclusion of 9243 American and 1362 Chinese reviews. Specifically, we removed data with user ratings of 1 or 2 points that lacked negative emotional polarities in user reviews, data with user ratings of 3 points that lacked neutral emotional polarities in user reviews, and data with user ratings of 4 or 5 points that missed positive emotional polarities in user reviews (Figure 2). Finally, we uniformly labeled different data with the same concept (Table S3 in Multimedia Appendix 1). Following the initial data preprocessing steps, a total of 124,425 user reviews were included in the LDA model for topic modeling, comprising 106,690 American reviews and 17,735 Chinese reviews.

Figure 2. Matching between user's sentiment polarities (rows) and user ratings (columns).



Data Analysis

Overview

We used natural language processing technology and the LDA topic model to extract the main topics from both Chinese and American user reviews. Subsequently, following the 2-factor model, we constructed a Tobit model to analyze the correlation between different topics and user satisfaction. Finally, we used the Wald test to analyze the differences in the impact of each topic on user satisfaction.

LDA Topic Modeling

LDA is a widely used probability-based topic modeling algorithm [46]. It is known for its ease of operation, high efficiency, and positive impact on topic clustering and prediction accuracy [47]. As LDA is primarily a language model rather than a classification prediction model, perplexity serves as a common and effective indicator for evaluating the quality of the language model, rather than sensitivity. To efficiently and accurately extract the primary opinions and topics from Chinese and American user reviews, we used LDA, which is a 3-level hierarchical Bayesian model. LDA calculates the distribution probabilities of words and topics, enabling the clustering of latent semantic structures within user reviews to summarize the main topics.

For the LDA model input, we used the word segmentation set and specified the number of Chinese and American review topics, along with manually induced topics. Consequently, we executed the LDA topic modeling process as follows: Initially, we used the Jieba [48] and NLTK packages [49] in Python to segment the Chinese and American reviews, respectively. We then used stop-word lists compiled from Baidu, Harbin Institute of Technology, Sichuan University Machine Intelligence Laboratory, and standard Chinese and English stop words [50]. These stop-word lists were applied to delete stop words, including numbers, punctuation marks, emoticons, and blank values, from both Chinese and English word segmentations. Subsequently, any blank reviews were removed after the stop words had been eliminated. In addition, we conducted morphological restoration of English word segmentation. Subsequently, based on the perplexity curve and actual clustering effect [51], we determined that 11 topics were optimal for Chinese reviews and 12 topics for American reviews (Figures S1–S4 in Multimedia Appendix 1). Furthermore, we used the Gensim package [52] in Python to construct the LDA topic models for both Chinese and American reviews. Two researchers (YFH and J Liang) independently summarized and named the topics for each keyword set in the Chinese and American review topic models, respectively. Any discrepancies were resolved through arbitration by a third expert (WZ). Finally, the topics for each user review were determined based on their distribution probabilities across all topics generated by the LDA model [53].

Statistical Analysis

To delve deeper into the factors influencing user satisfaction with HMAs, in line with the 2-factor theory [38], we introduced 2 variables: positive deviation (PD) and negative deviation (ND) [54]. These variables are defined by the disparity between the user's individual rating of HMAs and the overall rating displayed in the app store. They serve to indicate the discrepancy between the user's personal rating and the average rating. PD and ND are mutually exclusive if a user's deviation is positive and the ND value is 0, and vice versa. To simplify the calculation, we applied absolute value processing to ND. Consequently, the higher the ND value, the greater the degree of dissatisfaction. Both PD and ND values ranged between 0 and 4, calculated based on the difference between the user rating

range and the comprehensive rating range of the app store. We opted for the Tobit model [55], known for its effectiveness in handling limited dependent variables, to assess the factors influencing user satisfaction. The probability distribution of each LDA topic model for each user review served as the independent variable in our analysis. The PD and ND of each user review were used as dependent variables, and the specific model was defined in Multimedia Appendix 1. Finally, we used the Wald test [54] to perform a difference test on the absolute values of the PD and ND model parameters, aiming to identify the asymmetry of the factors influencing user satisfaction. Given that the Tobit model uses the maximum likelihood method to fit the best parameters, conventional methods cannot be applied for the robustness analysis of the model results. In addition, the exogenous variable in this study, namely, the distribution probability of each topic in user reviews, encompasses all factors affecting user satisfaction, thereby mitigating endogeneity concerns. Model establishment and data analysis were conducted using Stata 16.0 (StataCorp) [56], with a significance level set at a 2-sided $P<.05$ for the difference test.

Results

Chinese and American HMA User Review Topics

We initially retrieved 5016 related apps from both Chinese and American app stores, yielding a total of 295,927 original reviews in both languages. Following screening and data preprocessing, we identified 261 HMAs with user reviews. Among these, 41 (15.7%) were exclusively available in Chinese, 170 (65.1%) were exclusively available in American, and 50 (19.2%) were available in both app stores. Ultimately, 116,686 user reviews were included in the analysis, with 100,125 (85.81%) in English and 16,561 (14.19%) in Chinese. Among these reviews, 87,773 (including 73,907 American reviews and 13,866 Chinese reviews) were rated 4 stars and above, resulting in an overall satisfaction rate of 75.22%: 73,907/100,125 (73.81%) for American apps and 13,866/16,561 (83.73%) for Chinese apps.

The results of LDA modeling revealed differences between Chinese and American reviews. In Chinese reviews, the number of reviews related to software reliability (2165/16,561, 13.07%) and measurement accuracy (2091/16,561, 12.63%) substantially exceeded other topics. Conversely, specific hypertension management functions such as BP tracking (17,285/100,125, 17.26%) and data synchronization (12,837/100,125, 12.82%) substantially outnumbered other topics in American reviews.

The LDA modeling revealed 11 topics in the Chinese reviews, with 5 (ease of use: $P<.001$ in both PD and ND; interface design: $P=.01$ in PD and $P<.001$ in ND; measurement accuracy: $P<.001$ in both PD and ND; compatibility: $P<.001$ in both PD and ND; and cost: $P<.001$ in both PD and ND) of them being significant (including 2 motivational factors and 3 hygienic factors). By contrast, the American reviews yielded 12 topics, all of which were significant (easy to use: $P<.001$ in both PD and ND; blood pressure tracking function: $P<.001$ in both PD and ND; data synchronization: $P<.001$ in both PD and ND; blood pressure management effect: $P<.001$ in both PD and ND; heart rate detection function: $P<.001$ in both PD and ND; data sharing: $P<.001$ in both PD and ND; reliability: $P<.001$ in both PD and ND; compatibility: $P<.001$ in both PD and ND; interface design: $P<.001$ in both PD and ND; advertisement distribution: $P<.001$ in both PD and ND; measurement accuracy: $P<.001$ in both PD and ND; cost: $P<.001$ in both PD and ND), comprising 6 motivational factors and 6 hygienic factors (Tables 1 and 2; Tables S4–S7 in Multimedia Appendix 1).

Table 1. Topics and keywords of Chinese reviews formulated by latent Dirichlet allocation topic modeling (N=16,561).

Topics	Keywords	Reviews, n (%)
Topic 1: Easy to use	simple, convenient, easy to use, practical, rapid, recommended, easy to operate	6863 (41.44)
Topic 2: Reliability	healthy, quality, comprehensive, supportive, stable, professional, normal	2165 (13.07)
Topic 3: Measurement accuracy	measurement, accurate, collect, accuracy, test, data, inaccurate	2091 (12.63)
Topic 4: Attitude (positive)	very good, like, recommend, every day, awesome, useful, look forward to	1850 (11.17)
Topic 5: Compatibility	version, download, try, blood pressure monitor, Apple, connection, platform	878 (5.30)
Topic 6: Cost	fee, subscription, free, payment, upgrade, refund, paid	653 (3.94)
Topic 7: Heart rate detection function	heart rate, detection, value, body, monitor, watch, indicator	597 (3.60)
Topic 8: Blood pressure tracking function	blood pressure, function, record, tool, data, share, form	502 (3.03)
Topic 9: Interface design	updated, special, interface, clear, design, components, good-looking	471 (2.84)
Topic 10: Real-time	trial, view, status, anytime, anywhere, patient, daily	299 (1.81)
Topic 11: Data privacy	account, personal, information, security, management, privacy, licensing	192 (1.16)

Table 2. Topics and keywords of American reviews formulated by latent Dirichlet allocation topic modeling (N=100,125).

Topics	Keywords	Reviews, n (%)
Topic 1: Easy to use	easy, love, simple, handy, utility, recommend, worth	34,443 (34.40)
Topic 2: Blood pressure tracking function	blood, pressure, monitor, track, check, record, measure	17,285 (17.26)
Topic 3: Data synchronization	time, phone, update, synchronization, connect, omron, data	12,837 (12.82)
Topic 4: Blood pressure management effect	good, help, care, body, hypertension, maintain, condition	11,881 (11.87)
Topic 5: Heart rate detection function	heart, rate, pulse, check, measure, test, monitor	7065 (7.06)
Topic 6: Data sharing	data, email, export, send, share, access, require	4465 (4.46)
Topic 7: Reliability	quality, bad, screen, complete, fake, uninstalling, bug	3793 (3.79)
Topic 8: Compatibility	version, iphone, upgrade, fine, android, fail, reinstall	2586 (2.58)
Topic 9: Interface design	user, wonderful, friendly, interface, experience, unit, type	2390 (2.39)
Topic 10: Advertisement distribution	advertisement, download, watch, garbage, click, poor, difficult	1599 (1.60)
Topic 11: Measurement accuracy	accurate, cuff, feel, offer, result, manual, actual	1199 (1.20)
Topic 12: Cost	cost, fee, free, money, afford, pay, count	582 (0.58)

Factors Affecting Chinese and American HMA User Satisfaction

We computed the variance inflation factor of the PD and ND models for both Chinese and American reviews to assess multicollinearity among the independent variables. The regression variance inflation factors of all independent variables in the 4 models were found to be <5, indicating the absence of multicollinearity-related issues [22] (Tables S8-S11 in Multimedia Appendix 1). Furthermore, in Chinese reviews, the topic “attitude (positive)” pertains solely to users’ positive attitudes and does not encompass opinions regarding the functions and utility of apps. Therefore, it was not included in the Tobit regression model.

In Table 3, model 1 displays the PD model results for Chinese reviews. With the exception of reliability (P=.56), real-time (P=.21), and data privacy (P=.52), the other 7 topics (easy to use: P<.001; measurement accuracy: P<.001; compatibility: P<.001; cost: P<.001; heart rate detection function: P=.02; blood pressure tracking function: P<.001; and interface design: P=.01) discussed by users significantly influenced the PD of user satisfaction. Among them, the factors with the most substantial positive and negative effects were the BP tracking function (β=.354, P<.001) and cost (β=–.232, P<.001), respectively. Model 2 presents the ND model results for Chinese reviews. Except for the heart rate detection (P=.64) and BP tracking (P=.14) functions, the other 8 topics (easy to use: P<.001; reliability: P<.001; measurement accuracy: P<.001; compatibility: P<.001; cost: P<.001; interface design: P<.001; real-time: P<.001; and data privacy: P=.001) significantly impacted user satisfaction NDs. The factors with the most substantial positive and negative effects were cost (β=3.703, P<.001) and interface design (β=–1.619, P<.001), respectively. In Table 4, model 3 presents the PD model results for American reviews. All 12 topics (easy to use: P<.001; blood pressure tracking function: P<.001; data synchronization: P<.001; blood pressure management effect: P<.001; heart rate detection function: P<.001; data sharing: P<.001; reliability: P<.001; compatibility: P<.001; interface design: P<.001; advertisement distribution: P<.001; measurement accuracy: P<.001; and cost: P<.001) included in the model significantly influenced the user satisfaction PD. Among them, the factors with the most significant positive and negative effects were the BP tracking function (β=.312, P<.001) and data synchronization (β=–.593, P<.001), respectively. Model 4 displays the ND model results for American reviews. All 12 topics (easy to use: P<.001; blood pressure tracking function: P<.001; data synchronization: P<.001; blood pressure management effect: P<.001; heart rate detection function: P<.001; data sharing: P<.001; reliability: P<.001; compatibility: P<.001; interface design: P<.001; advertisement distribution: P<.001; measurement accuracy: P<.001; and cost: P<.001) significantly influenced the user satisfaction ND. Data synchronization (β=2.662, P<.001) had the greatest positive effect, while the BP management effect (β=–2.035, P<.001) had the most substantial negative effect.

Table 3. Determinant factors for rating deviations (Chinese reviews[a]).

Influencing factor	Model 1[b]			Model 2[c]		
	β (95% CI)	SE	*P* value	β (95% CI)	SE	*P* value
Topic 1: Easy to use	0.080 (0.043 to 0.117)	0.019	<.001	–1.575 (–1.792 to –1.358)	0.111	<.001
Topic 2: Reliability	0.013 (–0.030 to 0.055)	0.022	.56	–0.692 (–0.937 to –0.448)	0.125	<.001
Topic 3: Measurement accuracy	–0.181 (–0.224 to –0.138)	0.022	<.001	2.789 (2.564 to 3.014)	0.115	<.001
Topic 5: Compatibility	–0.219 (–0.275 to –0.163)	0.029	<.001	3.170 (2.906 to 3.434)	0.135	<.001
Topic 6: Cost	–0.232 (–0.293 to –0.171)	0.031	<.001	3.703 (3.424 to 3.981)	0.142	<.001
Topic 7: Heart rate detection function	–0.073 (–0.132 to –0.014)	0.030	.02	0.077 (–0.250 to 0.403)	0.167	.64
Topic 8: Blood pressure tracking function	0.354 (0.298 to 0.411)	0.029	<.001	–0.239 (–0.556 to 0.078)	0.162	.14
Topic 9: Interface design	0.082 (0.019 to 0.144)	0.032	.01	–1.619 (–1.934 to –1.304)	0.161	<.001
Topic 10: Real-time	–0.047 (–0.121 to 0.026)	0.038	.21	1.459 (1.091 to 1.826)	0.188	<.001

[b]Negative deviations: The maximum likelihood estimate of model 4 was –102855.05.

Motivational and Hygienic Factor Asymmetry

The effect asymmetry results are presented in Tables S12 and S13 in Multimedia Appendix 1. In models 1 and 2, with the exception of the heart rate detection and BP tracking functions, the remaining 8 factors exhibited significant differences in asymmetric effect (easy to use: *P*<.001; reliability: *P*<.001; measurement accuracy: *P*<.001; compatibility: *P*<.001; cost: *P*<.001; interface design: *P*<.001; real-time: *P*<.001; and data privacy: *P*=.001). In models 3 and 4, all 12 influencing factors demonstrated significant differences (easy to use: *P*<.001; blood pressure tracking function: *P*<.001; data synchronization: *P*<.001; blood pressure management effect: *P*<.001; heart rate detection function: *P*<.001; data sharing: *P*<.001; reliability: *P*<.001; compatibility: *P*<.001; interface design: *P*<.001; advertisement distribution: *P*<.001; measurement accuracy: *P*<.001; and cost: *P*<.001). Consequently, all factors exhibited a significant asymmetric effect on user satisfaction with Chinese (easy to use: *P*<.001; reliability: *P*<.001; measurement accuracy: *P*<.001; compatibility: *P*<.001; cost: *P*<.001; interface design:

P<.001; real-time: *P*<.001; and data privacy: *P*=.001) and American HMAs (easy to use: *P*<.001; blood pressure tracking function: *P*<.001; data synchronization: *P*<.001; blood pressure management effect: *P*<.001; heart rate detection function: *P*<.001; data sharing: *P*<.001; reliability: *P*<.001; compatibility: *P*<.001; interface design: *P*<.001; advertisement distribution: *P*<.001; measurement accuracy: *P*<.001; and cost: *P*=.001).

Regarding the influencing factors of user satisfaction with Chinese HMAs, both ease of use (*P*<.001 for both) and interface design (*P*=.01 and *P*<.001, respectively) had significant positive or negative effects on the PD or ND models, respectively. In addition, the effects on the 2 models were significantly different (*P*<.001). Similarly, measurement accuracy (*P*<.001 for both), compatibility (*P*<.001 for both), and cost (*P*<.001 for both) had a significant negative or positive impact on the PD or ND model, with a significant difference in the effect of the 2 models (*P*<.001).

Regarding the factors influencing user satisfaction with American HMAs, ease of use (*P*<.001 for both), BP tracking function (*P*<.001 for both), BP management effect (*P*<.001 for both), interface design (*P*<.001 for both), measurement accuracy (*P*<.001 for both), and cost (*P*<.001 for both) all exhibited significant positive or negative effects on the PD or ND model. Moreover, there was a significant difference in the effect on the 2 models (*P*<.001). Data synchronization (*P*<.001 for both), heart rate detection function (*P*<.001 for both), data sharing (*P*<.001 for both), reliability (*P*<.001 for both), compatibility (*P*<.001 for both), and advertisement distribution (*P*<.001 for both) each had a significant negative or positive impact on the PD or ND model. Furthermore, the impact on the 2 models was significantly different (*P*<.001).

Discussion

Principal Findings

To the best of our knowledge, this study represents the first quantitative analysis of user satisfaction, influencing factors, and asymmetry of HMA-related factors based on user reviews. By encompassing a large number of apps and user samples, our research achieved high credibility at a low cost, rendering the findings highly generalizable. Furthermore, leveraging the sociotechnical model widely used in HIT evaluation, we conducted a comparative analysis of Chinese and American HMAs, elucidating differences in user satisfaction and influencing factors between Chinese and American user groups. Consequently, we offer targeted improvement suggestions based on our findings. Although the numbers of Chinese HMAs and reviews were lower than those of American apps, user satisfaction was higher with Chinese HMAs. Furthermore, the main factors influencing user satisfaction and dissatisfaction with Chinese HMAs were the BP tracking function and cost, respectively. Conversely, the main factors affecting user satisfaction and dissatisfaction with American HMAs were the BP tracking function and data synchronization, respectively. Regarding the asymmetry of influencing factors, all factors exhibited significantly different effects on user satisfaction and dissatisfaction. Moreover, there were notable disparities in the motivational and hygienic factors between Chinese and American HMA users.

Differences in the Use of Chinese and American HMAs

Globally, users are distributed unevenly, with considerably lower usage of Chinese HMAs compared with American HMAs. As HMAs represent a typical form of digital health software, their usage status can be effectively analyzed using sociotechnical models [25], which are widely used in HIT. External environmental factors, such as medical policies, diagnosis and treatment methods, and payment methods in different countries, serve as major determinants of HIT. These factors may explain the significant disparities in the use of Chinese and American HMA. Regarding medical policies and treatment methods, Chinese patients tend to rely more on hospital-based doctors, while American patients often prefer active health management guided by family doctors. In China, a 3-level accreditation system for general hospitals has been implemented, and diagnosis and treatment modalities primarily revolve around hospital visits. This has resulted in the accumulation of many patients in a small number of tertiary hospitals with high-quality medical resources for offline diagnosis and treatment [57]. Consequently, personal active health management is rarely implemented. However, hierarchical diagnosis and treatment systems and family doctor consultation models have been primarily implemented in American countries [58]. In the American context, family doctors, who constitute around 80% of doctors, are responsible for 80%-90% of primary diagnosis and treatment services [59]. These services primarily entail disease prevention through active health management. Contrastingly, China relies predominantly on traditional hospitals and drug payments. As a result, Chinese hospitals primarily prioritize in-hospital drug efficacy and often overlook out-of-hospital patient management. In addition, limited software copyright protection in China restricts profits for HMA developers from software downloads. Consequently, the substantial economic costs have impeded the development of HMAs in China. However, American countries primarily implement medical value–based payment policies. Medical insurance payers prioritize patient rehospitalization rates, imposing fines on medical institutions for frequent patient rehospitalizations. This has prompted American medical institutions to use digital health apps to manage patients after discharge and monitor their health status in real-time, aiming to reduce rehospitalization rates. Furthermore, in the United States, HMAs can be prescribed to patients by family doctors or specialists through digital therapy prescriptions. Moreover, the software is granted patent rights, and app developers can cover app development–related costs through software downloads or paid functions, thereby promoting the continuous upgrading and iteration of HMAs.

Satisfaction and Focus of Chinese and American MHA Users

The overall user satisfaction with HMAs was generally poor, with Chinese HMAs exhibiting higher user satisfaction compared with American HMAs. The functions, software design, technical stability, and cost of HMAs were common areas of concern for both Chinese and American users, although

their specific focuses differed. The disparity in user satisfaction between Chinese and American HMAs was consistent with the topic *clustering results of user reviews*, with only Chinese HMA user reviews containing topics reflecting positive user attitudes. Furthermore, the overall user satisfaction obtained in this study, using big data generated by real-world users, was lower than that reported by previous small-sample surveys [60] (87,773/116,686, 75.22%, vs 93.5%). Nevertheless, HMA user engagement and intention to continue use were low [19,20], indicating that our study results are more reliable than those of previous small-sample questionnaire surveys.

Regarding qualitative user descriptions, both Chinese and American users expressed concerns about hypertension management functions, software design, technical stability, and costs. Specifically, most users were particularly concerned about hypertension management functions such as BP tracking and heart rate detection, including BP and heart rate measurements, BP recording, and the visual display of BP change trends. Software design, encompassing usability and interface design, was also a primary concern among users. Usability emerged as the topic of greatest concern among both Chinese (6863/16,561, 41.44%) and American (34,443/100,125, 34.40%) users. Attributes such as simple operating procedures, convenient usage environments, excellent interface design, and clear information display were highlighted as factors contributing to improved user satisfaction. Discussions on technical stability primarily revolved around software reliability, including issues such as software crashes and the inability to open software, as well as system compatibility problems such as software version mismatches and difficulties connecting via Bluetooth. In addition, concerns were raised about measurement accuracy. Finally, users also expressed concerns about software costs, including whether the software is free, its affordability, and the possibility of refunds.

However, there was a significant difference in the focus of HMAs between Chinese and American user groups. Chinese users primarily paid attention to technological stability, such as software reliability and measurement accuracy. By contrast, American users were more concerned about specific hypertension management functions. Moreover, Chinese and American users exhibited different concerns regarding software functions and design. Chinese users showed more interest in the real-time software monitoring function, while American users focused more on data synchronization, data sharing, and BP management effects. Furthermore, Chinese users mentioned software design and personalization, whereas American users were more inclined to allow advertisements that did not disrupt normal app use.

Motivation and Hygiene Factors of Chinese and American HMAs

Easy-to-use features and interface design, including simple software operation and convenience, were common motivational factors for both Chinese and American HMA users. Compatibility issues, such as mismatched software versions and the inability to connect via Bluetooth, were common hygienic factors. However, other motivational and hygienic factors differed considerably between the 2 user groups. Tobit model analysis and the Wald test revealed influencing factors with significantly different effects on user satisfaction PD and ND, indicating asymmetric impacts of related factors on Chinese and American HMA user satisfaction. This suggests the presence of both motivational and hygienic factors in influencing user satisfaction.

Simple operating procedures and convenient HMA usage effectively improve user satisfaction. However, other motivational factors had significantly different effects on user satisfaction. In addition to the motivational factors for Chinese users, American users prioritized factors such as the BP tracking function, BP management effect, measurement accuracy, and cost-effectiveness. The presence of these influencing factors in user reviews increased the degree of user satisfaction, while their absence had the opposite effect. Hence, these factors were identified as the main contributors to user satisfaction, although user dissatisfaction was less associated with them. Therefore, according to the 2-factor theory, the aforementioned influencing factors were considered motivational factors for HMA user satisfaction. Enhancing these factors can lead to increased user satisfaction and, consequently, strengthen users' intention to continue using the HMA.

Addressing issues such as software version mismatches and the inability to connect via Bluetooth can effectively mitigate user dissatisfaction. However, other hygienic factors had varying effects on user satisfaction. In addition to measurement accuracy and cost, hygienic factors for Chinese users encompassed aspects such as data sharing (ie, data uploadable to family doctors). By contrast, hygienic factors for American users included reliability, data synchronization, advertisements that did not affect normal use, and heart rate detection functions. The presence of the aforementioned influencing factors in user reviews increased the degree of user dissatisfaction, and vice versa. Hence, while users feel dissatisfied when these factors do not meet their expectations, their satisfaction is not significantly affected. Therefore, according to the 2-factor theory, the aforementioned influencing factors were considered hygienic factors for HMA user satisfaction. Improving these factors can help mitigate user dissatisfaction, thereby enhancing user participation.

Suggestions for Improving User Engagement and Continued Use of HMA

Given the considerable differences in motivational and hygienic factors for HMA use between Chinese and Americans, software developers should tailor improvements to hygienic factors based on the specific needs of each user group. This approach can effectively reduce user dissatisfaction and increase user participation. Furthermore, efforts should be directed toward enhancing motivational factors to improve user satisfaction and foster continued use intention among both Chinese and American users. Considering that hygiene factors have a direct impact on the utilization of HMA, it is advisable for developers to prioritize improving these factors to enhance user participation. Once hygiene factors are satisfactorily addressed, developers can then focus on enhancing motivational factors to increase users' willingness to continue using the HMA. By improving corresponding motivational and hygienic factors tailored to different user groups, developers can facilitate the

adoption and utilization of HMA, thereby aiding patients in effectively controlling BP. For Chinese HMAs, developers should prioritize enhancing the accuracy of indicator measurements by improving the sensitivity of measurement sensors and optimizing software measurement algorithms. This targeted improvement can effectively mitigate user abandonment of Chinese HMAs. In addition, HMA developers should promptly address technical issues related to software compatibility, such as mismatches between phone systems and software versions, as well as Bluetooth connectivity issues. Moreover, given that Chinese users are more price-sensitive, high software charges have resulted in the loss of a significant number of users. Therefore, developers should consider implementing pricing strategies that align with the preferences and financial capabilities of Chinese users to mitigate user attrition. Developers should consider reducing the number of charging items, shifting away from the traditional model of charging for software downloads, and exploring new business models to optimize profits. For instance, HMAs could be bundled with BP monitors or other relevant health devices to provide added value to users. Furthermore, government intervention is crucial to support the growth of digital medical companies and provide funding for the development of mHealth solutions, especially those focused on chronic disease management. Policy support can encourage entrepreneurship in the digital health sector and foster innovation in HMA development. Finally, HMA developers can enhance user satisfaction by focusing on improving app usability and interface design. This could involve streamlining the operation process, providing clear operation guides, and enhancing the overall user-friendliness of the software. By prioritizing these aspects, developers can create a more intuitive and enjoyable user experience, ultimately increasing user satisfaction and engagement with the HMA.

For American HMAs, developers should promptly address software compatibility issues to enhance HMA usage. This includes resolving mismatches between wearable devices and software, as well as fixing Bluetooth connection failures. In addition, HMA developers should consider incorporating health data sharing and export functions to fulfill the fundamental requirements of American users. Furthermore, developers should optimize HMA reliability and promptly address technical issues, such as software crashes and start-up failures. In addition, providing data synchronization functionality for wearable device monitoring software is essential to ensure real-time BP tracking. Furthermore, developers should consider developing additional heart rate detection functionality to meet users' needs for tracking heart rate indicators. In addition, HMA developers should reconsider the placement and frequency of advertisements to avoid disrupting routine HMA use. Finally, in addition to enhancing the satisfaction of American HMA users, developers can improve the effectiveness of BP management within the software, enhance indicator measurement accuracy, optimize interface design, and establish a reasonable charging model. For instance, they could refine BP measurement algorithms and validate measurement results against those obtained from a BP monitor. They can incorporate additional BP management features such as exercise and diet management, BP warnings, and visual displays of BP trends. Enhancing the interface aesthetics and integrating HMAs into medical insurance schemes are also crucial measures to consider.

Advantages Compared With Previous Research

This study marks a significant advancement by exploring user satisfaction and its influencing factors on HMAs based on real-world user reviews. Unlike previous research that primarily relied on on-site surveys and qualitative analysis, often gathering subjective comments through interviews or questionnaires, this study leverages real user feedback obtained from online reviews. By using advanced computational methods such as natural language processing and topic modeling, it provides a more comprehensive and data-driven analysis of user satisfaction factors. For instance, Breil et al [61] discovered, through questionnaire surveys, that both patients and doctors generally accept HMAs, with expected performance being a crucial determining factor. Similarly, Kang et al [30] developed an HMA and assessed user satisfaction using a scale. However, our study adopts a big data–driven approach to quantitatively explore the influencing factors of user satisfaction in HMAs. Using the LDA model, we mined user perspectives from user-generated content and established a connection between user perspectives and satisfaction through the Tobit model, rendering the results more objective and reliable. For practical applications, previous studies have primarily focused on user groups in specific regions, overlooking the exploration of user satisfaction asymmetry. For instance, Hui et al [62] evaluated the functional availability and user satisfaction of HMAs in the United Kingdom, highlighting the need for further improvement. Meanwhile, Melin et al [63] developed an app user satisfaction evaluation scale and assessed app user satisfaction using linear weighting methods. This study compared user satisfaction and influencing factors of HMAs in China and the United States, applying the 2-factor theory to analyze user satisfaction asymmetry. This provided deeper insights into the attributes of influencing factors and offered more accurate improvement suggestions.

Limitations

This study had several limitations. First, due to variations in medical policies, diagnoses, and treatment models between China and the United States, Chinese individuals use HMAs less frequently, resulting in a proportionately lower number of Chinese reviews and downloads (16,561/24,204,832, 0.07%) compared with American ones (100,125/148,869,181, 0.07%). Therefore, the number of collected Chinese HMA user reviews was significantly lower than that for the American apps. However, for the representativeness of user reviews, we did not conduct special sampling but obtained all user reviews. These user reviews were deemed sufficient to reflect user satisfaction and the influencing factors. Second, considering that some users used the HMA but did not leave reviews, there may have been bias in population selection, and we were unable to explore the satisfaction of such users. However, given that 116,686 reviews were included, and the process of user reviews is random, with users of various opinions possibly not leaving reviews, we believe our results are representative and provide useful data for discovering factors and attributes associated with HMA user satisfaction. Third, through user reviews, this study identified

the factors influencing user satisfaction and explored their asymmetry. However, an in-depth analysis of the impact paths could be further explored based on these influencing factors. Finally, through data screening and aggregation, we observed that the number of Chinese HMA user reviews was substantially lower than that of American HMA user reviews, and the factors affecting user satisfaction in China and the United States were considerably different. Although we provided a preliminary analysis of the reasons for these differences through a sociotechnical model, a more in-depth analysis is required in the future. In addition, as users are more concerned about the therapeutic effect of HMAs, it would be meaningful to pair clinical efficacy data with satisfaction in future research to further explore the relationship between user satisfaction and specific clinical efficacy.

Conclusions

Our study reveals that only 87,773/116,686 (75.22%) users are satisfied with HMA use. We also found that the factors influencing Chinese and American HMA user satisfaction exhibit asymmetry. Furthermore, because of differences in user groups and macro usage environments, the motivational and hygienic factors for users in China and the United States are significantly different. Thus, to enhance user participation, developers of HMAs should devise personalized and comprehensive strategies that address issues related to hygienic factors as a priority. Furthermore, efforts should be made to enhance motivational factors to encourage sustained HMA usage.

Data Availability

We used crawler technology and Qimai app data official website to obtain all hypertension management apps and user reviews in 8 Chinese app stores (China Apple App Store, Huawei App Store, Xiaomi App Store, OPPO App Store, VIVO App Store, Baidu App store, 360 App store, and Application Treasure App Store) and 2 American app stores (US Apple App Store and US Google Play Store). The source code for our analysis is publicly available on GitHub [64].

Authors' Contributions

J Liang conceptualized and designed the study, performed data screening, and made significant revisions to the manuscript. YFH drafted the manuscript; summarized the literature review; and performed the data acquisition, screening, analysis, and interpretation. J Lei supervised the data filtering and analysis process. J Liang and WZ supervised the review method and data interpretation and provided valuable suggestions for improvement. HC, JX, TW, and YCL critically revised the manuscript for important intellectual content.

Abstract

Background: Coronary heart disease is one of the leading causes of mortality worldwide. Secondary prevention is essential, as it reduces the risk of further coronary events. Mobile health (mHealth) technology could become a useful tool to improve lifestyles.

Objective: This study aimed to evaluate the effect of an mHealth intervention on people with coronary heart disease who received percutaneous coronary intervention. Improvements in lifestyle regarding diet, physical activity, and smoking; level of knowledge of a healthy lifestyle and the control of cardiovascular risk factors (CVRFs); and therapeutic adherence and quality of life were analyzed.

Methods: This was a randomized controlled trial with a parallel group design assigned 1:1 to either an intervention involving a smartphone app (mHealth group) or to standard health care (control group). The app was used for setting aims, the self-monitoring of lifestyle and CVRFs using measurements and records, educating people with access to information on their screens about healthy lifestyles and adhering to treatment, and giving motivation through feedback about achievements and aspects to improve. Both groups were assessed after 9 months. The primary outcome variables were adherence to the Mediterranean diet, frequency of food consumed, patient-reported physical activity, smoking, knowledge of healthy lifestyles and the control of CVRFs, adherence to treatment, quality of life, well-being, and satisfaction.

Results: The study analyzed 128 patients, 67 in the mHealth group and 61 in the control group; most were male (92/128, 71.9%), with a mean age of 59.49 (SD 8.97) years. Significant improvements were observed in the mHealth group compared with the control group regarding adherence to the Mediterranean diet (mean 11.83, SD 1.74 points vs mean 10.14, SD 2.02 points; $P<.001$), frequency of food consumption, patient-reported physical activity (mean 619.14, SD 318.21 min/week vs mean 471.70, SD 261.43 min/week; $P=.007$), giving up smoking (25/67, 75% vs 11/61, 42%; $P=.01$), level of knowledge of healthy lifestyles and the control of CVRFs (mean 118.70, SD 2.65 points vs mean 111.25, SD 9.05 points; $P<.001$), and the physical component of the quality of life 12-item Short Form survey (SF-12; mean 45.80, SD 10.79 points vs mean 41.40, SD 10.78 points; $P=.02$). Overall satisfaction was higher in the mHealth group (mean 48.22, SD 3.89 vs mean 46.00, SD 4.82 points; $P=.002$) and app satisfaction and usability were high (mean 44.38, SD 6.18 out of 50 points and mean 95.22, SD 7.37 out of 100).

Conclusions: The EVITE app was effective in improving the lifestyle of patients in terms of adherence to the Mediterranean diet, frequency of healthy food consumption, physical activity, giving up smoking, knowledge of healthy lifestyles and controlling CVRFs, quality of life, and overall satisfaction. The app satisfaction and usability were excellent.

KEYWORDS

coronary artery disease; healthy lifestyle; mHealth; mobile health; percutaneous coronary intervention; randomized controlled trial; secondary prevention; therapeutic adherence

Introduction

Ischemic heart disease, or coronary artery disease (CAD), remains one of the leading causes of mortality worldwide, accounting for 16% of all deaths [1,2]. Coronary revascularization using percutaneous coronary intervention (PCI) is the main treatment option in patients with CAD as it restores coronary blood flow and has excellent clinical outcomes [3]. This procedure, however, does not prevent either the formation of further obstructions in the coronary arteries treated or the disease from progressing with the appearance of new lesions in other parts of the coronary tree. Therefore, secondary prevention strategies aimed at achieving a healthy lifestyle and the control of cardiovascular risk factors (CVRFs) are essential [4].

Secondary prevention and cardiac rehabilitation programs can improve lifestyle, therapeutic adherence, and the control of CVRFs. This facilitates a decrease in the risk of a further cardiovascular event that requires another PCI or even surgery, leading to a reduction in health care costs [5,6]. However, a large number of patients do not make these recommendations a part of their everyday lifestyle or do not take their medication correctly after experiencing a cardiovascular event, which stops them from achieving the treatment goals established [4,7]. The data from the EUROASPIRE IV survey conducted in Europe demonstrated that only 51% of patients who had experienced a coronary event were advised to participate in a cardiac rehabilitation program, and of those, only 41% took part [7]. This suggests that the implementation of attendance-based secondary prevention programs after acute coronary syndrome has stagnated somewhat.

Moreover, during the COVID-19 pandemic, secondary prevention and cardiac rehabilitation programs were affected and even suspended, thereby seriously limiting patient access to available health services [8,9]. Thus, it is necessary to implement innovative secondary prevention strategies that improve adherence to a healthy lifestyle and the long-term treatment prescribed.

The use of information and communication technology may facilitate new communication pathways between patients and health professionals and allow patients more autonomy in the control of their disease while providing professionals with more information about their patients' health status. These days, over 57% of homes have access to the internet, and over 75% of the world's population has a mobile phone with internet access [10,11]. These data highlight that these technologies and smartphones should form part of the communication between patients and health care professionals, as they can be valuable tools for controlling health and lifestyle. The beneficial effects of mobile health (mHealth) systems have been observed in primary prevention patients at high risk of cardiovascular disease [12-15]. A recent systematic review with 2250 participants that analyzed the results obtained after implementing cardiac telerehabilitation programs concluded that these strategies are a way to improve the use and reach of cardiac rehabilitation programs [16]. Likewise, recent meta-analyses of clinical trials performed in patients with CAD concluded that secondary prevention programs involving telehealth interventions may be useful either in isolation or combined with on-site cardiac rehabilitation and that they are related to a decrease in adverse events, lifestyle improvements, and better control of CVRFs [17,18]. These studies reflect the need for further similar research to evaluate the effectiveness of telehealth interventions in this context.

This clinical trial aimed to evaluate the effect of an mHealth intervention on people with heart disease who had undergone PCI in terms of the following variables: improvements in lifestyle, namely diet, physical activity (PA), and smoking; level of knowledge of a healthy lifestyle and the control of CVRFs; and therapeutic adherence and quality of life.

Methods

Study Design

A statistician-blinded randomized controlled clinical trial with a parallel group design was conducted in patients with CAD who underwent a PCI with stent implantation in the cardiology unit of a public specialty reference hospital in the province of Cádiz, Spain, between November 2019 and June 2022.

Study Sample

A total of 134 patients participated, 67 in the intervention group and 67 in the control group. The initial sample size proposed was 240 participants, but the increase in hospital occupancy due to the COVID-19 pandemic reduced the number of patients scheduled for coronary intervention with a nonurgent pathology. However, this sample size is sufficient to detect an effect size (Cohen *d*) of 0.5 on adherence to the Mediterranean diet (mean 8.7, SD 2 points) [19], time spent doing PA (mean 416.8, SD 374 min/week) [20], level of knowledge of CVRFs (mean 104.7, SD 9.7) [21], and a difference in the prevalence of stopping smoking of over 20% [22], with a 95% CI and statistical power of 90%.

Eligibility Criteria

The study included patients with CAD aged between 18 and 75 years who owned a smartphone with an internet connection during the whole study period.

Those excluded from the study were people with severe heart failure, congenital, structural, or serious rheumatic heart disease, chronic kidney or liver disease, physical disability or dementia, and those who were already using a health control app or whose mobile phone was incompatible with the app.

Recruitment, Randomization, and Masking

Overview

The patients meeting the inclusion criteria were randomized and assigned to either the mHealth group or the control group receiving standard health care using a computerized random number generator 1:1. The randomization sequence was generated by staff at the study's coordination center at the university who were not involved in recruiting the participants. The coordinators did not know the randomization group. The researchers analyzing the results were blinded to the allocation of participants. Blinding the participants was not possible because of the nature of the intervention.

Eligible patients and their caregivers were approached during their hospital admission, after the PCI, and before discharge. All the patients were informed of the characteristics of the project and were invited to volunteer to participate and sign the informed consent form. The patients who agreed to participate underwent an initial assessment and were given a follow-up appointment 9 months later. The patients were given an email address and telephone number through which they could resolve any queries or doubts during the study period. Before their hospital discharge, all the patients were encouraged to lead healthy lifestyles. Moreover, they were given written information about CVRFs, lifestyle objectives, examples of healthy diets, and recommendations about the daily portions of each food group.

Control Group

The patients in the standard health care group received advice about medication and lifestyle, the Mediterranean diet, PA, stopping smoking, and therapeutic adherence. They were also provided with written recommendations.

mHealth Group

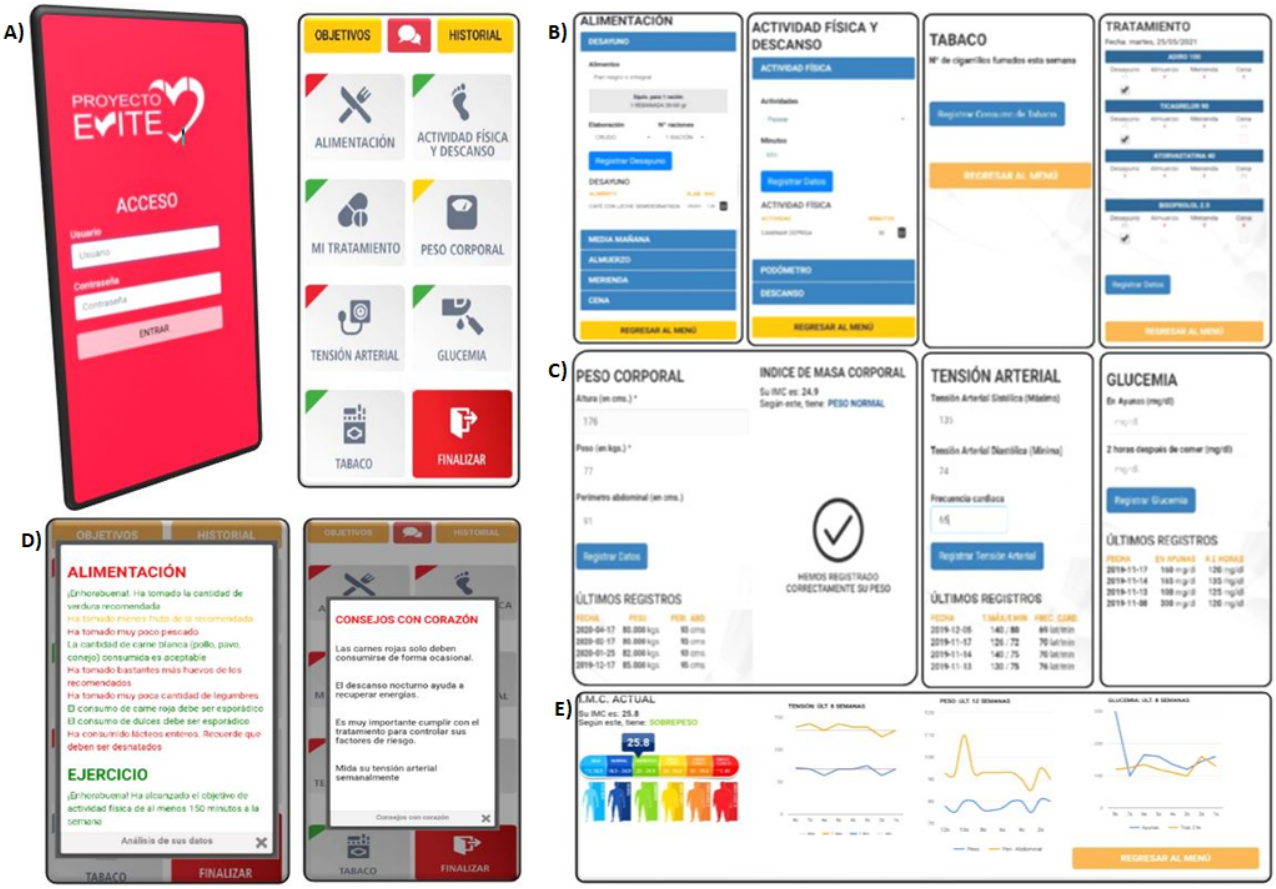
The mHealth intervention began during their hospital stay, after the coronary event. All the patients in this group had an app installed on their mobile phone or tablet and completed a brief online tutorial to learn how to use it. The participants were advised to use the app for a minimum of 15 minutes daily during the 36-week follow-up period. The app established aims to achieve self-control of PA, food consumption, blood pressure, smoking, and therapeutic adherence. The app is based on the phases of change theory (attention, retention, memory, action, and motivation) [23] and on making the process pleasing [24,25]. The user's attention was caught through warnings and bright, attractive colors on the user interface; retention was encouraged by reminders, repetition, and graphs; instructions, advice, and feedback prompted action; and motivation to change was boosted by internal comparisons (progress graphs), setting goals, self-monitoring, and feedback.

A nurse resolved any queries the participants had through the messaging function integrated into the app. The technical data about the website, app, and its contents and components were described previously in greater detail [26]. Briefly, the app provides (1) education about following a healthy lifestyle and about the recommended therapeutic goals in the clinical practice guidelines regarding food, PA, body weight, blood pressure, blood sugar, stopping smoking, and adhering to treatment. The app provided the participants with information on their screens to help them plan a healthier lifestyle and adhere to their treatment; (2) self-monitoring, using records, and a self-checking function to allow patients to monitor each behavioral goal about nutrition, PA, tobacco consumption, blood pressure, body weight, capillary blood glucose in patients with diabetes mellitus and treatment adherence; and (3) motivation to improve and maintain lifestyle habits through automatic reminders about healthy habits generated randomly in a pop-up screen and through personalized messages about reaching goals related with improving their lifestyle and treatment adherence, and recommendations about aspects to be improved (Figure 1).

The personalized messages are produced in response to the information recorded by the patient over the previous 7 days. The patients received weekly feedback through pop-ups that appeared when opening the app. The messages appeared as short sentences in green (when the set goals had been reached), yellow (if they had partially been reached), and red (when the goal was pending), depending on the degree of compliance and control of the goals. As a reminder of achievements and aspects to improve, the top left corner of each section of the app's main screen appeared in the color corresponding to the goals reached during the previous week. The participants could follow their evolution and progress through the graphics generated from the information they had recorded over the previous 8 weeks (Figure 1).

Through its different components (website, messages, emails, and calls), participants were encouraged to (1) follow a healthy eating pattern based on the Mediterranean diet; (2) perform PA of duration and intensity in line with the recommendations of their cardiologist; (3) stop smoking; (4) monitor their blood pressure; and (5) adhere to their treatment by associating taking medication with daily activities, establishing set times for taking it, and with support from a relative, etc. We hypothesize that information is the first step to following a healthy lifestyle. The self-monitoring and recording in the app improves the patients' awareness of their lifestyle behavior, and motivation promotes the initiation and continuation of changes in behavior over time.

Figure 1. (A) Start page app of the EVITE project. (B) Diet, physical activity, smoking cessation, and treatment in the top row (from left to right). (C) Body weight, BMI, blood pressure, and capillary blood glucose modules in the middle row (from left to right). (D) Weekly feedback traffic light and messages, automatic text message reminders. (E) Record: graphics of evolution and progress of BMI, blood pressure, body weight and waist circumference (WC), and capillary blood glucose in the bottom row (from left to right).



Follow-Up

All the participants in both the mHealth group and the control group were evaluated after 36 weeks. Their digital medical records were reviewed to check and record clinical data of medical visits, recent analyses (the same data from the baseline plasma analysis), and adverse events that occurred over that period. Due to the COVID-19 pandemic, the questionnaires were administered by telephone.

Outcome Variables

Overview

The primary outcome variables were adherence to the Mediterranean diet, frequency of consumption of foods, PA performed, smoking (giving up and nicotine dependence test), level of knowledge of a healthy lifestyle, and the control of CVRFs, therapeutic adherence, quality of life, well-being, and satisfaction.

The secondary outcome variables were BMI, WC, systolic blood pressure (SBP), diastolic blood pressure (DBP), heart rate, glycated hemoglobin (HbA_{1c}), total cholesterol, high-density lipoprotein (HDL) cholesterol, low-density lipoprotein (LDL) cholesterol, triglycerides, emotional status, major adverse cardiovascular events (MACEs), and other complications.

While the patients were hospitalized and before their discharge, measurements were taken of their weight and height to calculate their BMI, WC, SBP, and DBP following standard clinical methods. Moreover, records were made of sociodemographic variables (age, sex, and educational level), history of CVRFs (diabetes mellitus, arterial hypertension, hyperlipidemia, obesity, and tobacco consumption), and history of cardiovascular disease (infarction, angina, and stroke). Furthermore, the patient's digital medical records were used to obtain data about left ventricular ejection fraction [27] and plasma analysis (total cholesterol, LDL cholesterol, HDL cholesterol, baseline glycemia, HbA_{1c}, creatinine, and C-reactive protein).

Primary Outcomes

Smoking

Nicotine dependence was assessed using the Fagerström test [28], with scores below 4 points considered low dependence, scores between 4 and 7 considered moderate dependence, and scores from 8 to 10 considered points high dependence. Stopping smoking was self-reported.

Adherence to the Mediterranean Diet and Frequency of Food Consumption

To assess food intake, the following surveys were used: (1) the Mediterranean Adherence Score (maximum score of 14 points; scores below 9 are classified as low adherence, and scores above

9 are classified as high adherence) [19,29]; and (2) the food frequency questionnaire [30].

Physical Activity

Moreover, the time spent performing PA was assessed using the Minnesota Physical Activity Survey (min/week) [31,32], which includes detailed instructions and a list of defined activities. Participants are asked to mark those performed during the past year, month, and week (the activities are expressed in the number of days per week and minutes per day). Total energy expenditure from leisure time PA can be calculated with this questionnaire depending on the type performed: light (≤4 metabolic equivalents [METs]), moderate (4.5-5.5 METs), or heavy (≥6 METs). For this research, only the information referring to the past week was used as the min/week of light PA. The reason was that the participants only performed light PA after PCI. Furthermore, this allowed the comparison of results with other studies that expressed PA in min/week and with the recommendations of the cardiovascular disease prevention guidelines [4]. The PA in the household was omitted. Therapeutic adherence was assessed using the 4-item Morisky Green and Levine Medication Adherence Questionnaire (MGL MAQ). This was considered good if the 4 questions were answered correctly (NO/YES/NO/NO) [33,34].

Level of Knowledge of CVRFs and a Healthy Lifestyle

The level of knowledge of CVRFs and a healthy lifestyle was examined using a validated scale [21]. The scale consists of 24 items with 5 response options and a maximum score of 120 points. Each item is scored from 1 to 5 points, with the highest score corresponding to the most correct answer. The patient's level of knowledge was considered high when they responded correctly to over 75% of the items (90 points).

Quality of Life and Well-Being

The physical and mental dimensions of quality of life were assessed by the SF-12 survey [35], in which the highest scores imply better health-related quality of life. The possible answers for each item are presented as a Likert-type scale, with the number of options varying from 3 to 6 points, depending on the item. To calculate each dimension, the items were recoded, aggregated, and transformed into a score ranging from 0 (worse health status) to 100 points (better health status) [36,37]. Well-being was assessed using the World Health Organization-5 Well-Being Index questionnaire, on which the lowest score is 0 points and the highest 100, a higher score indicating greater well-being [38].

Patient Overall Satisfaction

Overall satisfaction with the health care received was assessed using a specific questionnaire developed by the research team. The questionnaire consists of 10 questions with 5 response options scored from 1 to 5, from the lowest to the highest level of satisfaction. The maximum score is 50 points, with higher scores corresponding to more satisfaction.

Secondary Outcomes

BMI, WC, SBP, DBP, Heart Rate, HbA1c, and Lipids

BMI, WC, SBP, DBP, heart rate, HbA_{1c}, total cholesterol, HDL cholesterol, LDL cholesterol, and triglycerides were obtained following the standard methods mentioned above.

Anxiety and Depression

Levels of anxiety and depression were analyzed using the questionnaire developed by Goldberg et al [39]. This questionnaire consists of 2 subscales; a score over 4 on the anxiety subscale is considered a diagnosis of anxiety, and a score over 2 on the depression subscale is considered a diagnosis of this disorder. The maximum score on each subscale is 9 points, with high scores reflecting a more serious problem [40].

MACEs and Other Complications

At the end of the follow-up period, each patient's digital medical records were analyzed for MACEs (cardiovascular death, acute myocardial infarction, stent thrombosis, new revascularization of target injury, stroke, and other possible complications that can occur, such as bleeding, angina, and the revascularization of another vessel) that had occurred.

Patient App Satisfaction and Usability

Satisfaction with the app itself was assessed using a specific questionnaire developed by the research team. The questionnaire consists of 10 questions with 5 response options scored from 1 to 5, from the lowest to the highest level of satisfaction. The maximum score is 50 points, with higher scores corresponding to more satisfaction.

The app's usability was assessed in the intervention group using the System Usability Scale (SUS) questionnaire, which evaluates user acceptance, with scores ranging from 0 to 100 points [41]. A higher score is an indication of better usability. The scores are classified as excellent for >80.3, good for 68-80.3, poor for 51-67, and very poor for <51.

Statistical Analysis

A descriptive statistical analysis was performed (mean, median, SD, 95% CI, interquartile interval, frequencies, and percentages). The primary quantitative results from the 2 groups—mHealth and control—were compared using the Student 2 tailed *t* test (variables with normal distribution) and the Mann-Whitney *U* test (variables not distributed normally). The χ^2 or Fisher test was used for the comparison of proportions. A 2-tailed *P* value of <.05 was considered statistically significant. The data analysis was performed using SPSS (version 24.0; IBM Corp) for Windows.

Ethical Considerations

The Biomedical Research Ethics Committee of Andalusia approved the study (003_ene19_PI-EVITE-18). The patients signed a written informed consent form. The app included data encryption mechanisms and guaranteed safety measures in accordance with current European Data Protection Regulations. This study was registered on ClinicalTrials.gov (NCT04118504).

Results

Overview

Figure 2 shows a flowchart of the process for recruiting the participants to the clinical trial. During the recruitment period, 1327 patients underwent a PCI and were evaluated for inclusion in the study. After applying the inclusion and exclusion criteria, 1153 were excluded, and 40 refused to participate. The 134 remaining patients were randomized: 67 to the control group and 67 to the mHealth group. There were 6 dropouts in the control group during the follow-up. No participants dropped out of the intervention group. In the end, 128 were analyzed: 61 from the control group and 67 from the mHealth group.

Table 1 shows the baseline characteristics of the participants. Most were male (92/128, 71.9%) with a mean age of 59.49 (SD 8.97) years. In general, both groups were homogeneous.

Figure 2. Flow diagram of the study.

[a]Mann-Whitney *U* test (median, IQR): Mediterranean diet adherence at baseline (median 7.00, IQR 6.00-9.00); Mediterranean diet adherence at 9 months (median 12.00, IQR 9.00-13.00); nicotine dependence at 9 months (median 0.00, IQR 0.00-3.00); cardiovascular risk factor knowledge at 9 months (median 119.00, IQR 112.00-120.00); 12-item Short Form survey physical component score at 9 months (median 43.04, IQR 34.13-55.19); satisfaction (median 50, IQR 46.00-50.00).

[b]CVRF: cardiovascular risk factor.

[c]MGL MAQ: Morisky Green and Levine Medication Adherence Questionnaire.

[d]SF-12: 12-item Short Form survey.

[e]PCS: physical component score.

[f]MCS: mental component score.

[g]WHO-5: World Health Organization-5 Well-Being Index.

Smoking

Regarding stopping smoking, more participants did so in the mHealth group compared with those receiving standard health care (25/67, 75% vs 11/61, 42%; *P*=.01). The level of nicotine dependence also fell more in the mHealth group than in the control group (mean 0.93, SD 2.29 points vs mean 2.27, SD 2.82 points; *P*=.02; Table 2).

Adherence to the Mediterranean Diet and Frequency of Food Consumption

The score for adherence to the Mediterranean diet was significantly higher among the patients from the mHealth group (mean 11.83, SD 1.74 points) compared with the control group (mean 10.14, SD 2.02 points; *P*<.001) with an effect size (Cohen *d*) of 0.8. Moreover, the prevalence of adherence to the Mediterranean diet (score >9 points) was higher in the mHealth group than in the control group (57/67, 90% vs 42/61, 75%; *P*=.02). Regarding the frequency of food consumption, a significant reduction was observed in the consumption of red meat (≤1/week: 60/67, 95% vs 44/61, 77%; *P*=.001), and industrial pastries (<2/week: 60/67, 93% vs 52/61, 91%; *P*=.003) among the participants of the mHealth group compared with the control group. Furthermore, the patients in the mHealth group significantly increased their intake of vegetables (≥2/day: 48/67, 75% vs 28/61, 49%; *P*=.03), fruit (≥2/day: 58/67, 90% vs 39/61, 68%; *P*=.02), and whole-meal cereals (≥1/day: 41/67, 64% vs 20/61, 35%; *P*=.003).

Physical Activity

Likewise, the patients in the mHealth group spent significantly more time doing PA (patient-reported) every week than those in the control group (mean 619.14, SD 318.21 min/week vs mean 471.70, SD 261.43 min/week; *P*=.007), with an effect size (Cohen *d*) of 0.6.

Knowledge of CVRFs and a Healthy Lifestyle

The patients in the mHealth group presented a significantly higher level of knowledge about a healthy lifestyle and the control of CVRFs than those in the control group (mean 118.70, SD 2.65 points vs mean 111.25, SD 9.05 points; *P*<.001). Therapeutic adherence improved to a similar extent in both groups at the end of the follow-up period, with no significant differences being found between the groups.

Quality of Life and Well-Being

Regarding the quality of life, the physical component was significantly better among the patients in the intervention group (mean 45.80, SD 10.79 points vs mean 41.40, SD 10.78 points; *P*=.02), while both groups presented similar values for the mental component. As for the well-being index, the patients in the mHealth group presented slightly better scores, but they did not reach statistical significance.

Patient Overall Satisfaction

Regarding overall satisfaction with the health care received, the patients in the mHealth group scored significantly higher than those receiving standard health care, with respective average scores of 48.22 (SD 3.89) points and 46.00 (SD 4.82) points (*P*=.002).

Secondary Outcomes

BMI, WC, SBP, DBP, Heart Rate, HbA1c, and Lipids

Regarding the secondary outcome variables (Multimedia Appendix 1), at the end of the follow-up period, lower values were obtained for BMI, WC, SBP, DBP, heart rate, total cholesterol, LDL cholesterol, HDL cholesterol, triglycerides, and HbA_{1c} in both the mHealth and control groups, with no significant differences being found.

Anxiety and Depression

Regarding emotional aspects, the levels of both anxiety and depression were lower at the end of the study than at the beginning, but no significant differences were observed between the groups after the follow-up.

MACE and Other Complications

Major adverse events (3/128, 2.4% of all the participants) and complications such as bleeding, angina, and coronary interventions on another vessel (9/128, 7.2% of all the participants) were scarce in both groups during the 9-month follow-up, with no significant differences being found between the intervention and control groups.

Patient App Satisfaction and Usability

The participants in the mHealth group gave high scores for both satisfaction with the app (mean 44.38, SD 6.176 points) and its usability (mean 95.22, SD 7.369 points).

Discussion

Main Results

This study of people with CAD after a PCI analyzed the effect of an educational intervention based on the use of an mHealth app on the following factors: changes in lifestyle in terms of diet, PA, and tobacco use; level of knowledge of a healthy lifestyle; and the control of CVRFs, therapeutic adherence, and quality of life. The results obtained show that the intervention led to significant improvements in lifestyle in terms of adherence to the Mediterranean diet, PA, and stopping smoking, and that the patients increased their knowledge about a healthy lifestyle and controlling CVRFs. The patients' quality of life improved, and they reported a high level of satisfaction with the health care they received.

Comparison With Previous Work

The Mediterranean diet is considered a cornerstone of a healthy lifestyle to prevent cardiovascular diseases [4,42,43]. In this study, adherence to the Mediterranean diet improved in both groups at the end of the study, but this improvement was more noticeable in the patients in the mHealth group. This group of patients also increased the frequency with which they consumed healthy foods, such as fruit, vegetables, and whole-meal cereals, and decreased the frequency with which they consumed unhealthy foods, such as red meat and industrial pastries, to a greater extent than those in the control group (Table 2). On the contrary, the clinical trial conducted by Choi et al [29] on the effectiveness of dietary advice provided to patients with heart conditions through a smartphone found that the mHealth intervention did not increase adherence to the Mediterranean diet. However, other authors, such as Widmer et al [44], reported a more favorable score for the consumption of healthy food among patients undergoing cardiac rehabilitation who used an mHealth app. Given our results, providing dietary guidance through a mobile app may be a practical way of achieving healthy changes in people's diets, with the added advantage of using fewer resources than face-to-face visits.

As our results show, the time spent performing PA (patient-reported) was significantly higher in the mHealth group than in the control group. These results are in line with other clinical trials that observed improvements in the PA performed associated with an mHealth intervention [45-47]. However, Johnston et al [48] Did not find significant increases in the PA performed by patients using a health app for smartphones. Nevertheless, a recent meta-analysis has highlighted that mHealth apps are effective at encouraging patients to increase the amount of PA they do after a coronary event [18]. In the secondary prevention of CAD, one of the essential lifestyle changes that patients have to make is to perform regular PA, such as walking for at least 30 minutes every day [4,43]. For this reason, our results show that the mobile app was able to encourage the participants to start and continue doing more PA. However, our study did not have data available from an accelerometer as the PA was self-reported.

This study found an important decrease in the proportion of smokers and nicotine dependence measured by the Fagerström test at the end of the follow-up period in both the mHealth and control groups. However, the decrease in this addictive behavior was significantly greater among the participants in the mHealth group. Moreover, 75% (25/67) of the smokers in the mHealth group stopped smoking, while in the group receiving standard health care, only 42% (11/61) did so, even though at the beginning of the study the prevalence of smokers in the 2 groups was similar. Several meta-analyses have studied the effect of telehealth interventions on the prevalence of smoking, obtaining mixed results. While some [18,49] did not find statistically significant improvements in tobacco use when these technologies were used, another meta-analysis did observe a beneficial effect on stopping smoking among patients with CAD through the use of mHealth strategies [50]. Our positive results about stopping smoking with the use of the digital intervention could be due to several reasons, such as the support perceived by the patients and the interaction with the app that kept them motivated to change.

Our results show a significant improvement in the level of knowledge of a healthy lifestyle and the control of CVRFs among the patients using the health app compared to the control group. Few clinical trials involving mHealth interventions analyze the effectiveness of these interventions in improving the patient's knowledge. Among these, Dorje et al [51] reported an increase in the level of knowledge among patients using a telehealth app. Furthermore, the results of the studies included in EUROASPIRE II highlighted that in patients who had experienced a coronary event, a correlation existed between knowledge of CAD and changes in lifestyle and therapeutic adherence [52]. Knowledge of the risk factors for the disease is an essential requirement for patients to decide to adopt behaviors in line with a healthy lifestyle. However, people also need to be motivated to incorporate such behavior into their daily lives [53-55]. Innovative mHealth technology could help to achieve both objectives by increasing the patients' knowledge and motivation.

Therapeutic adherence improved to a similar extent at the end of the follow-up period in both groups, mHealth (54/67, 84%) and standard health care (44/61, 78%). Although data from previous studies indicate that adherence to treatment decreases progressively after a coronary event, reaching around 50% a year after experiencing a myocardial infarction [56-58], our results do not seem to support these data since the therapeutic adherence in both groups was greater than the figures reported by other authors. In addition, recent meta-analyses [18,59] have observed improvements in adherence to treatment in patients with cardiovascular disease with the use of mHealth apps with medication reminders or alarms on mobile devices.

Our results show that the patients in the mHealth group benefited from significant improvements in the physical component of quality of life compared with the participants receiving standard health care. These results are in partial agreement with a recent meta-analysis [18] but not with another meta-analysis [49] that

did not observe significant increases in the quality of life of these patients. The favorable effects of the mHealth intervention highlighted by our results may partly be related to the remote health care option provided by this intervention, whereby patients could resolve queries without having to leave their homes. Patients were given support, thus enhancing their self-sufficiency and the perception they have of their health. Improvements in quality of life may, in turn, motivate patients to comply with secondary prevention recommendations.

The overall satisfaction with the health care received was significantly higher in the patients from the mHealth group than in the control group, and satisfaction with the mHealth app was also high (mean 44.38, SD 6.176 points out of 50). The average score for the usability of the app was 95.22 (SD 7.36) out of 100. These results agree with those obtained by Johnston et al [48]. Our positive results could be attributed to the fact that the patients perceived the app to be a support tool that provided them with information about their disease as well as the motivation to adopt a healthy lifestyle. Telehealth interventions have the potential to overcome barriers and could represent a ground-breaking alternative for providing cardiac rehabilitation to patients for whom face-to-face health care is more complicated. Factors to be taken into consideration when choosing this option could be the patient's risk profile, preferences, and accessibility to health services.

The EVITE interactive tool provided relevant information about the disease, increased the patient's knowledge of their health status, promoted the self-reporting of important CVRF variables, and supplied the patients with visual feedback about changes, motivating them to improve their health. The patients felt more connected with the health professionals, obviating the need for unnecessary visits for trivial reasons. Most of the patients in the mHealth group stated that they would like to continue using the interactive support tool and that they would recommend the tool to other patients.

Our results showed no significant differences between the 2 groups with regard to BMI and WC at the end of the study, although recent meta-analyses show controversial results [18,60].

Lipid variables, blood pressure, and HbA_{1c} did not show significant differences between the 2 groups. These results agree with recent meta-analyses [18,61], which could be due to the intensive prescription of secondary prevention medication among the participants.

Patients have been found to experience the symptoms of anxiety and depression straight after undergoing a PCI, and these may persist for months or even years [62,63]. However, our results show a decrease in the level of anxiety and depression during the follow-up period in both the mHealth group and the control group (Multimedia Appendix 1). These results are in line with previous studies [18], although not with another meta-analysis [60].

Major adverse events were very rare in both groups, as were hospital readmissions. As a result of the important improvements achieved in recent years in the treatment of patients with CAD, the prevalence of short-term adverse events is generally low in different trials.

Clinically Meaningful Improvements in Primary Outcomes

The improvements observed in the mHealth group are clinically relevant, according to scientific evidence [4]. One year after myocardial infarction, patients who continue to smoke have worse cardiovascular outcomes and death than nonsmokers, and the long-term outcomes among those who quit smoking are comparable with those of nonsmokers [64]. We observed a 33% higher prevalence of smoking cessation in the mHealth group than in the control group.

Adults are recommended to perform at least 150-300 minutes a week of moderate-intensity PA, and additional benefits are gained with even more [4,65]. In our study, cardiologists advised the patients to walk for at least 1 hour every day, resulting in 420 minutes per week of PA. While all the participants in our study complied with the PA recommendations, those in the mHealth group performed more, so they would be expected to benefit from this because they are more active than the control group, with an important effect size (Cohen *d*) of 0.6. It should be noted that this study was performed in a geographical area in which the weather is generally good, which encourages people to go outside for a walk.

Adherence to the Mediterranean diet improves survival rates and reduces the risk of cardiovascular disease in individuals with CVD [66]. Moreover, greater adherence to this diet is associated with a 10% reduction in cardiovascular events or mortality [67]. In our study, the prevalence of good adherence to the Mediterranean diet (>9 points) was 15% higher among participants in the mHealth group. A meta-analysis reported a 4% lower risk of cardiovascular mortality for each additional serving of fruit and vegetables per day [68]. Likewise, a high intake of processed meat and unprocessed red meat is associated with an increased risk of atherosclerotic cardiovascular disease of 7% and 3%, respectively [69]. In our study, the prevalence of red meat consumption of ≤1 time per week was 18% higher in the mHealth group.

Knowledge of cardiovascular disease helps patients control risk factors and adopt behaviors that promote cardiovascular health [53,54]. For this reason, it could be considered that the more favorable results in the level of knowledge observed in our patients in the mHealth group could have a clinical impact.

Improving quality of life is one of the most important objectives to be achieved with CAD [70]. Thus, assessing quality of life allows the impact of the disease and its treatment on daily life to be determined. In our study, the score in the physical dimension of quality of life was statistically higher in the mHealth group, a finding that may be related to the capacity of the EVITE app to provide support to patients.

Limitations and Strengths

Our study has a few limitations. First, the participants included in the mHealth group agreed to participate voluntarily and gave their written consent, meaning that they may have been more motivated to adhere to secondary prevention. A second

limitation could be that to participate in the mHealth programs, the patients had to have a mobile phone or tablet with an internet connection, which could suggest that the participants were younger. However, 99% of the European population currently has a mobile telephone, and 86% of homes have an internet connection [71], although our results could also be due to the fact that participants in the mHealth group had a higher socioeconomic status. Moreover, women were less represented in our study, as only 29% (36/128 of the participants belonged to this population group. The third limitation is the limited sample size and the duration of the follow-up. The barrier to recruiting more participants was that the hospital was occupied by patients with COVID-19. A larger sample size and a longer follow-up could enhance the knowledge gleaned about the efficacy of the intervention. The fourth limitation is that most of the primary outcomes were self-reported and the study was open-label, but we assumed the patients responded honestly since they filled out the questionnaire without indicating their names. The questionnaires only contained an identification number so that the statisticians could record information in the database. This was explained to the patients so that they could respond freely. The fifth limitation is detection and performance bias since the blinding of the participants was not possible because of the nature of the intervention. The coordinators and the researchers analyzing the results were blinded to the allocation of participants, however. Finally, this study was conducted at a single public specialty reference hospital, and it would be necessary to test whether the favorable effects observed are generalizable to other health care settings. Additionally, in our study, we did not carry out an economic evaluation that could provide useful information to clarify whether the implementation of this mHealth intervention in the health care of these patients is cost-effective.

This study also presents some strengths, such as the fact that the sample is representative of patients who experience a coronary event in different localities, as the study was conducted on patients treated in the cardiology unit of a reference hospital that receives patients from both rural and urban areas. In addition, all the instruments and tools used in the clinical trial were validated internationally, which allows for generalization and for the study to be compared with others. Another strength was that the trial was conducted using a smartphone app, so the intervention involved the latest, up-to-date technology. In addition, the study included exclusively patients with CAD, so the sample of patients was more homogeneous than in studies that included patients with cardiovascular disease. The inclusion of different kinds of behavioral, metabolic, and psychosocial variables provides a broad view of the results obtained with mHealth technology. Finally, most previous trials were conducted with apps that encouraged behavioral changes related to performing PA, weight loss, or therapeutic adherence but did not comprehensively tackle all the CVRFs as our app does.

Conclusions

Using the EVITE app with patients who have experienced a coronary event is an effective way to improve their lifestyle in terms of adherence to the Mediterranean diet, frequency of healthy food consumption, PA, stopping smoking, knowledge of a healthy lifestyle, and controlling CVRFs, quality of life, and satisfaction with the health care received.

More studies are required to examine the impact of smartphone interventions on people who have undergone a coronary event, with long-term follow-ups that analyze mortality and cardiac-cause hospitalization, because these are important yardsticks of the success of secondary prevention strategies that make it possible to establish the clinical importance of the findings. Cost analyses are also required to promote the generalized use of these tools, their implementation, and their feasibility.

Acknowledgments

We would like to thank the Andalusian Ministry of Health and Families, Spain, for the funding (public funding: PI-0067-2018). JAT is funded by CIBEROBN–Instituto de Salud Carlos III (CB12/03/30038) and co-funded by the European Regional Development Fund.

Abstract

Background: In emergency departments (EDs), triage nurses are under tremendous daily pressure to rapidly assess the acuity level of patients and log the collected information into computers. With self-service technologies, patients could complete data entry on their own, allowing nurses to focus on higher-order tasks. Kiosks are a popular working example of such self-service technologies; however, placing a sufficient number of unwieldy and fixed machines demands a spatial change in the greeting area and affects pretriage flow. Mobile technologies could offer a solution to these issues.

Objective: The aim of this study was to investigate the use of mobile technologies to improve pretriage flow in EDs.

Methods: The proposed stack of mobile technologies includes patient-carried smartphones and QR technology. The web address of the self-registration app is encoded into a QR code, which was posted directly outside the walk-in entrance to be seen by every ambulatory arrival. Registration is initiated immediately after patients or their proxies scan the code using their smartphones. Patients could complete data entry at any site on the way to the triage area. Upon completion, the result is saved locally on smartphones. At the triage area, the result is automatically decoded by a portable code reader and then loaded into the triage computer. This system was implemented in three busy metropolitan EDs in Shanghai, China. Both kiosks and smartphones were evaluated randomly while being used to direct pretriage patient flow. Data were collected during a 20-day period in each center. Timeliness and usability of medical students simulating ED arrivals were assessed with the After-Scenario Questionnaire. Usability was assessed by triage nurses with the Net Promoter Score (NPS). Observations made during system implementation were subject to qualitative thematic analysis.

Results: Overall, 5928 of 8575 patients performed self-registration on kiosks, and 7330 of 8532 patients checked in on their smartphones. Referring effort was significantly reduced (43.7% vs 8.8%; P<.001) and mean pretriage waiting times were significantly reduced (4.4, SD 1.7 vs 2.9, SD 1.0 minutes; P<.001) with the use of smartphones compared to kiosks. There was a significant difference in mean usability scores for “ease of task completion” (4.4, SD 1.5 vs 6.7, SD 0.7; P<.001), “satisfaction with completion time” (4.5, SD 1.4 vs 6.8, SD 0.6; P<.001), and “satisfaction with support” (4.9, SD 1.9 vs 6.6, SD 1.2; P<.001). Triage nurses provided a higher NPS after implementation of mobile self-registration compared to the use of kiosks (13.3% vs 93.3%; P<.001). A modified queueing model was identified and qualitative findings were grouped by sequential steps.

Conclusions: This study suggests patient-carried smartphones as a useful tool for ED self-registration. With increased usability and a tailored queueing model, the proposed system is expected to minimize pretriage waiting for patients in the ED.

Introduction

For outpatients, registration at the hospital is completed online via appointments initiated by the patients themselves. However, for patients arriving at the emergency department (ED), registration is normally completed by triage nurses who communicate with patients and then interact with computers for data entry. Such nurse-led registration often takes time and slows down the triage process [1,2].

When a patient presenting at the ED is seen, others have to wait [2]. During peak hours, pretriage waiting tends to be prolonged and unpredictable [2-4], representing one of the main factors contributing to ED overcrowding [5,6]. An extended waiting time in the ED has been associated with increased morbidity and mortality rates [7,8].

Recently, based on the experience in other industries [9], there has been research interest in the use of self-service technologies (SSTs) such as kiosks [10] in the ED setting. For example, Sinha et al [11] demonstrated that the registration process can be easily completed by patients or their proxies using kiosks. However, unlike unmanned retail stores [12], there is no evidence that the use of kiosks can completely replace human-based triage (ie, triage nurses). Without proper control, full self-triage could lead to disparities. For instance, some younger and more computer-literate patients would easily jump ahead of the older, frail, less educated, and less computer-facile patients.

Using ED kiosks requires patients, nurses, and machines to work together. For example, self-awareness and path-finding are required for new arrivals. Otherwise, a referring service is required from triage staff [13], which directs the patient flow to a specific location to complete self-registration. Kiosks could break down at any time, which interrupts the work of the triage staff to handle technical failures [13]. In addition, triage staff need to monitor the kiosk area because long lines at the kiosk could delay patient identification [13].

The coworking context has an impact on the overall triage efficiency, and kiosks work well in offline EDs, but there are still some barriers to overcome for their use as an effective SST. Outside the ED setting, more and more online medical encounters are based on mobile SSTs (ie, smartphones) via social apps [14-18]. For example, smartphones could improve data quality by reducing registration errors [19]. In China, WeChat is the most popular social app, which has more than 1000 million monthly active users [20]. WeChat is not only a popular app but can also serve as a platform to host other web-based apps [21,22]. These apps are built into WeChat and do not need a separate installation on patient smartphones. The apps can even be opened directly when the owner scans an eligible QR code. Beyond medical encounters, a mobile SST is also widely used in the context of mobile payment [23,24]. During COVID-19, the Chinese government used QR technologies to engage its citizens to fight the pandemic [25,26].

For security reasons, patient smartphones cannot be connected to ED triage servers, which limits the exploration of mobile SSTs in EDs. In a previous study, we used a tailored security architecture to send patient-reported data from patients' smartphones to hospital networks via an offline QR code reader [27]. Subsequently, Song et al [28] used a similar approach to transfer medical data to hospital information systems. In this study, we expanded on this work to explore a self-registration tool based on the stack of QR technologies and WeChat. To measure the impact on pretriage patient flow, we compared the use of mobile self-registration with the use of kiosks in a real-world setting. Our goal was to investigate the use of mobile technologies to improve pretriage flow in EDs.

Methods

Rationale

In March 2020, kiosks were introduced at a busy metropolitan ED in Shanghai with an annual census of 306,000 patients. In the crowded greeting area, the ED set up four kiosks to direct nonambulance arrivals for self-registration. With increasing uptake, lines to access the kiosk were frequently observed, prompting development of an alternative method.

Coworking Flow

This study was inspired by the concept of industry 5.0 [29]. With the increasing use of SSTs, the roles of nurses, patients, and machines were redefined in a coworking context (Figure 1A). Some repeated tasks shifted from nurses to tools and patients. Electronic forms were used to replace paper-based forms. The tool guides patients to complete some paperwork that was previously conducted by triage staff.

A patient needs to travel from the front end to the back end of the system, whether via kiosks (Figure 1B) or via smartphones (Figure 1C). The workflow was broken down into five different steps (Table 1). For kiosks, patients swipe their health cards on the front end for registration and present a paper document with a barcode to a triage nurse. After scanning the code with a hand-held device, the nurse quickly finds the record and then updates it with an acuity level based on the "quick-lookup" result [30-32].

For smartphone users, WeChat is used to scan a QR code at the front end. After filling out the form, the result is encoded into a QR code on patient smartphones using a structured format (Figure 1C). Patients show the digital proof to a triage nurse at the back end. The nurse scans the QR code and automatically creates a record after extracting the structured content. The nurse then uses the "quick-lookup" tool to assign an acuity level for patient triage.

Figure 1. Coworking context for self-registration at the emergency department. (A) The roles in the coworking context. (B) The kiosk-led pretriage flow. (C) The smartphone-led pretriage flow.

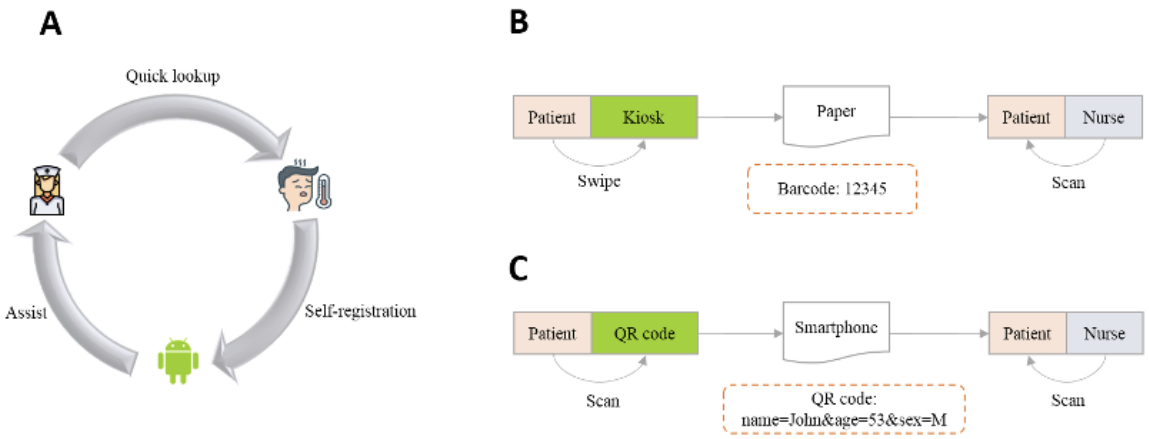

Table 1. Comparison of the workflow in self-registration at the emergency department using a kiosk and a smartphone.

Step	Kiosk	Smartphone
Reach	With or without a referral, a patient walks a certain distance to the kiosk area and finds an available machine for registration	With or without a referral, a patient scans a QR code posted along the route using WeChat. A web-based registration page is then displayed and they need to find a site nearby for registration
Initiate	A patient navigates to the homepage to find the launching icon and swipes a card for log-in or manually inputs the information when the card is not on hand or card-swiping fails	The patient enters the associated phone number to start
Input	On the public touchscreen	On the patient's smartphone
Print	The result is printed into a paper document	The result is printed into a QR code on the smartphone
Submit	The patient brings the printed paper result to the registration desk. The triage nurse uses a personal digital assistant equipped with a scanner to read the barcode.	The patient brings the smartphone to the registration desk. The triage nurse uses a personal digital assistant equipped with a scanner to read the QR code. A short confirmation message is sent to the patient via their registered contact number

Self-Registration Content

For registration, patients have to enter some personal information and the presenting reason for the ED visit (Table 2). With autocomplete-based suggestions for presenting problems [19], the system helps patients enter their chief complaints more efficiently and accurately. For kiosks, swiping a card is useful for saving time by avoiding having to input repeated data. However, when the card is not on hand, for security reasons, the patient has to enter all of the information manually. For kiosk users, the contact number is optional, thereby relying on triage nurses for patient validation. For smartphone users, the contact number is mandatory. When the content is scanned into the ED system by the triage staff, a confirmation message is sent to the patient according to the contact number. For experimental purposes, patients were required to fill out a field to indicate whether self-registration followed a referring service from clinical staff.

Technically, it is possible to use self-triage algorithms to assign an acuity level for a given patient condition [10]. However, this might lead to queue-jumping when the evaluation process is controlled by the patients themselves. In this study, the system was set up so that the evaluation result was not immediately available to patients after self-registration, but rather appeared as a suggestion to the triage staff on the hand-held screen. The triage nurse had the right to modify the result after human-based evaluation. The whole process was designed to mitigate paperwork burdens for triage staff.

Table 2. Content of the registration form.

Element code	Element description
Phone	Contact telephone number
Name	Patient name
Sex	Patient sex
Age	Patient age
Race	Patient race
Complaints	A list of standardized codes for chief complaints, separated by commas
Reason	Patient narrative text to explain the reason for presenting to the emergency department
Referred	Using the self-registration tool after being referred by an assistant

Security Architecture

For kiosks, the platform and the collected data were completely hosted in the hospital private network. Attacks from the internet were handled by the hospital firewall.

For smartphones, the front-end registration page was completely disconnected from the back end. Technically, this was designed as a static webpage hosted by the WeChat platform, which rendered a web form to allow patients to complete the registration online. However, the platform handled data submission in a different manner. Instead of transmitting the collected data over the internet, the data were saved to the local storage on the patient's smartphone, being displayed as a QR result. The QR result could then be read via the scanner held by the triage nurse. Thus, the data flow was executed from online to offline in a smart and secure manner. Since no third-party servers are involved, data security and privacy can be well protected. Hosting the static webpage on a mature platform with WeChat had benefits for both availability and scalability.

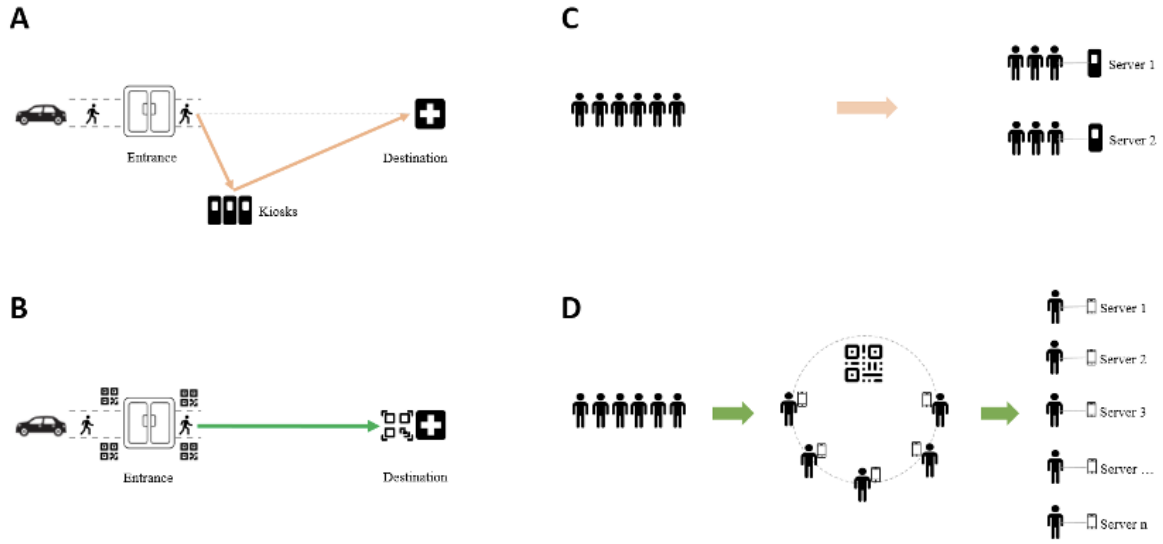
Multilingual Support

As a public machine, it is difficult for a kiosk to determine the language preference of an upcoming user. Therefore, a button for language switching was installed on the public screen. By contrast, for smartphone users, the system can automatically detect the language preference based on the location setting.

Signage

Based on best practice [13,33], the kiosk area was placed inside the ED (Figure 2A), visible from the registration desk. Roadmaps were provided. For smartphones, the signage was printed out as QR symbols, which were posted in four different places, inside and outside the entrance (Figure 2B). The size of the signage was appropriately determined so that it could be easily scanned within a distance (Figure 2D). These QR codes encoded a link to the self-service app.

Figure 2. Signage and queueing. (A) Signage and patient flow in the kiosk group. (B) Signage and patient flow in the smartphone group. (C) Queues in the kiosk group. (D) Queues in the smartphone group.



Study Design

The evaluation was performed during peak hours from 5 PM to 9 PM in three EDs. In each center, an assistant was recruited to work near the entrance to make sure patients traveled to the service quickly by offering a referral service. Patients were told they could bypass self-registration and go directly to the registration desk. Both patients and their proxies were allowed to use the self-registration tools. Data were collected during a 20-day period in each center. Random days were chosen for the use of kiosks and smartphones. At a given time, only one digital tool was evaluated to direct the patient flow. For example, when kiosks were evaluated, the signs with QR codes were removed from the entrance.

In each center, assistants (N=4) were recruited to work at the self-service area to assist patients for self-registration. All of the assistants had a background in qualitative research, and they were trained on how to handle technical issues related to self-registration that could result in triage interruptions [34]. Their observations were documented at the end of each day. Two authors (TL and LY) with expertise in informatics, human factors, quality and safety, and qualitative research served as coders and reviewers. These authors worked with the assistants for coding. Once coding was complete, thematic analysis [35] was used to group codes. Discrepancies were discussed by both the coders and the assistants and reconciled by consensus prior to final analysis.

To evaluate timeliness and usability, medical students (N=210) were recruited to simulate ED arrivals. They received no training and were asked to arrive randomly. Upon arrival, the timestamp (T_{arrive}) was recorded. When they received an acuity result from triage staff, the timestamp, or T_{end}, was recorded. The interval (T_{end}–T_{arrive}) was used to denote pretriage waiting times. For usability evaluation, the After-Scenario Questionnaire (ASQ) [36] was used, which is a standard questionnaire with three questions: “ease of task completion,” “satisfaction with completion time,” and “satisfaction with support.” The ASQ has been validated and is commonly used in studies related to mobile health [37]; this tool is particularly suitable in scenarios where a user might finish a task despite not successfully completing the task. Scale options were set according to a range of 1 to 7, with higher scores representing a higher degree of satisfaction. Two additional assistants were recruited to work in certain posttriage areas to administer paper-based ASQs. An unanswered question was treated in the same manner as a “not applicable” (NA) question. Since the study was designed to evaluate self-services, most participants might complete a session without any help, leaving the question of “satisfaction with support” unanswered. However, since “satisfaction with support” was designed to measure the level of self-service received, these “NA” answers were treated as the highest score in this study. For “ease of task completion” and “satisfaction with completion time,” records with “NA” were treated as invalid feedback.

During the evaluation, triage nurses (N=30) were recruited to work on a shift in each group and two nurses were assigned to the triage unit on each shift. The Net Promoter Score (NPS) [38] was used to solicit the nurses’ opinions in using the tool to handle patient flow, including questions such as “On a scale from 0 to 10, how likely are you to recommend this tool to ED managers to deal with pretriage patient flow?” Participants scoring 9 or 10 were classified as “promoters,” those providing a rating of 7 or 8 were classified as “passives,” and those providing a rating from 0 to 6 were classified as “detractors.” The final NPS was calculated by subtracting the percentage of detractors from the percentage of promoters (excluding the passives). The result could range between –100% and +100%, and the performance was marked as “good” for scores above 50% [39].

Statistical Analysis

Data analysis was performed using SPSS software (version 27.0). The χ^2 test was used to analyze proportion data. All analyses were based on a two-sided P value, with $P<.05$ considered statistically significant.

Ethical Considerations

According to regulations of the Shanghai Ethics Committee for Clinical Research [40], the requirement for ethical approval was exempt since the hospital only exports deidentified data for study purposes. Participants were informed about the study orally. Individual and privacy-related data were not used in this study.

Results

Primary Results

The recruitment flow of real patients is displayed in Figure 3 and the participant characteristics are summarized in Table 3. Within the study time frame, 5928 of 8575 patients (69.13%) performed self-registration on kiosks and 7330 of 8532 patients (85.91%) checked in on their smartphones, representing a significant difference ($P<.001$). There was also a statistically significant difference in the percentage of patients referred to kiosks and smartphone self-registration (Table 3).

Timeliness and usability were evaluated using simulated arrivals (N=210) in each group. Compared to kiosks, pretriage waiting times were significantly reduced in the smartphone group, whereas the smartphone group scored significantly higher in the usability items “ease of task completion,” “satisfaction with completion time,” and “satisfaction with support” (Table 3).

The NPS was calculated based on feedback obtained from triage nurses (N=30) in each group. According to their scores, there were 14 promoters, 6 passives, and 10 detractors in the kiosk group, whereas there were 28 promoters, 2 passives, and 0 detractors in the smartphone group. The use of smartphones significantly improved the final NPS compared to the use of kiosks (Table 3).

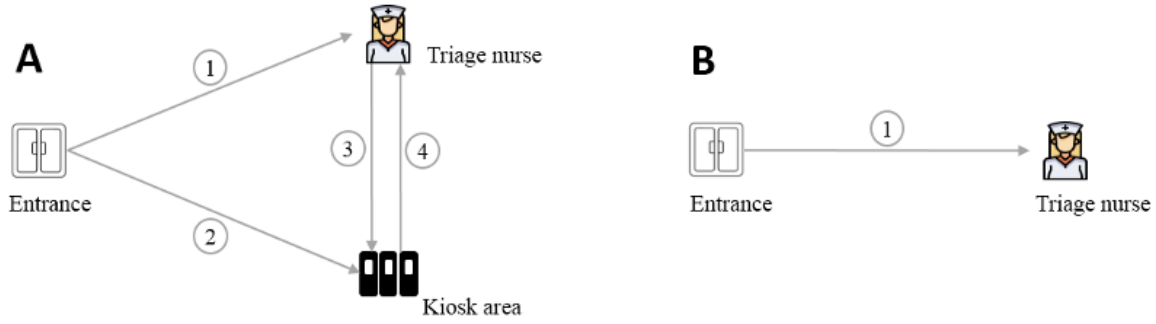
Patient Flow

While kiosk users competed with each other while waiting in lines (Figure 2C) for check-in, smartphone users encircled (Figure 2D) a posted QR symbol to start using the tool. After scanning, smartphone users quickly dispersed around the ED to use their devices privately; thus, no queues were formed in the smartphone group. As illustrated in Figure 4, there were 4 paths in the kiosk group: (1) patients skipped self-registration and walked directly to triage staff, (2) patients walked to the kiosk area for self-registration, (3) patients left the kiosk area to see triage staff, and (4) patients switched to the self-registration line after arriving at the traditional registration desk. By comparison, there was only 1 path in the smartphone group: all patients followed the same path for self-registration and triage.

Figure 4. Paths in the pretriage flow. (A) Patient flow in the kiosk group. (B) Patient flow in the smartphone group.



Reach

Compared to the kiosk area, the posted QR symbols appeared to be easily seen by arrivals and then resulted in followers. Assistant B4 described that "It is good for patients to find and follow, especially posted outside." By contrast, in relation to kiosks, the assistant indicated that "the roadmap seems not working that well."

Although patients waited to be triaged in no particular order, the crowded situation in front of the registration desk could be seen from a distance. In the kiosk area, patients had to wait in order of their arrival, and the lines were also easily seen from the triage area. The two endpoints attracted patients and sometimes resulted in extra traffic of switching. Assistant A2 commented: "It is fine but I have a concern for patient safety when these two lines compete for patients." This concern was not found in the smartphone group.

Patient proxies were allowed to perform the actual data entry. However, in the kiosk group, the proxy often stepped into the line for the kiosk with the patient, resulting in a more crowded area. Although this is helpful for conversation-based data entry, it definitely increased the density of the self-service area. Indeed, assistant B2 advocated that "queue discipline is a must for kiosks." For smartphones, the proxy simply went ahead with scanning the QR code and then returned to the patient in an open area for collaborative data entry. The assistant then concluded, "the queue disappeared and it's privacy-friendly."

A kiosk might break down at any time. When this occurs, the clinical staff should be notified in a timely manner so that an "under repair" sign can be set up. However, this was not often the case in practice; instead, as described by assistant C3, "some patients just switched to another line or simply quit." In the case of smartphones, most interruptions were related to a low battery or bad signal. A smartphone failure would not cause a delay for other patients.

Initiate

Kiosks can be used not only for self-registration but also for other purposes [33], and each case requires its own launching icon on the homepage. Patients faced burdens with respect to page navigation and language switching. For example, the previous session might not end as expected, which would prevent appropriately resetting the screen to the homepage.

Card swiping was considered to be convenient but was also associated with intermittent failures such as an inability to read the card or swiping on the wrong side. Manual input was provided in case of any failure. However, this required some cognition effort, as described by assistant A1: "some patients spent too much time on trying." Patients who forgot their cards could also use the manual input option; however, this caused some issues, as described by assistant B3: "some patients blocked the line and stood too much time in front of a kiosk for searching."

By comparison, it was more straightforward for smartphone users to get started. After scanning, the page showed up right away without requiring any additional information to be input such as a password.

Input

During data entry, a kiosk failure was so disruptive that the entire line was impacted. Assistant C2 logged the following: "the entire line was moved to another." No failures were logged for smartphones in this step.

Print

After data entry was complete, the record was materialized as a proof. Namely, kiosks generated a paper document and smartphones used a QR code. With this proof, patients could confirm with the triage nurse that self-registration had been completed. However, patients had to spend some time to tear the paper document carefully from the printer. In some cases, the workflow was paused due to jammed paper, partially torn paper, or the printer being out of paper or ink. These delays were disruptive, as reported by assistant C1: "it really takes time to recover and most patients cannot wait." By contrast, printing QR codes on smartphones was instant and no failures were reported.

Submit

As mentioned above, patients needed to tear off the paper document from the printer before leaving the kiosk area. However, there were some cases in which more than one document was left in the printer. Consequently, some patients took the wrong record for submission, as logged by assistant A3: "Today, a record was marked with a wrong acuity level. It turned out that the patient took a wrong document." Such an out-of-sequence issue was never found in the smartphone group.

In the kiosk group, some printouts were occasionally found to be left on the floor. No such data privacy issues were observed in the smartphone group.

Discussion

Principal Findings

ED overcrowding is an unresolved issue worldwide [5,41], which threatens patient safety and public health [42]. Therefore, it is an urgent need to address the long pretriage waiting time, as it is associated with an increased level of morbidity and mortality [7,8]. Patient registration becomes a bottleneck when data entry is completed by triage nurses. With SSTs, triage nurses can focus on higher-order tasks [10,43] and enable rapid assessment [44] in EDs.

Unlike outpatients, registration is not a prerequisite for ED patients. This study thus contributes to improving ED self-registration in two ways. The first is related to the actual device provider. Instead of using in-house devices for registration, patients can use their own smartphones with advantages of flexibility and scalability. The second contribution is related to improved digital interaction. "Scan-to-process" should be easy for nurses, as this is already a ubiquitous technique in medical settings (eg, barcode-based medication administration) [45]. During COVID-19, QR codes were widely used for contact tracing [46,47]. Therefore, visitors are now familiar with the rule of "scan to enter" before stepping into public buildings. Accordingly, we applied this concept for patients to adapt to the new workflow of ED check-in.

EDs are space-constrained areas [48] and thus patient flow occurs in an often crowded setting. In addition to the registration desk, the use of a self-registration kiosk introduces another point of convergence. Kiosks cannot be positioned too close together in the case of a sudden increase in arrivals. Theoretically, one flow will start at the ED entrance, pass through to the kiosks, and finally meet up with triage nurses, while the other flow is directly from the entrance to the triage area. In reality, there may be a third path in which patients might return to the kiosk area for registration from the line formed at the registration desk to see a human after balancing out the potential waiting times. Passing through kiosks is helpful for reducing triage burden, but the increased movement within the ED and midway congestion might be detrimental to patient safety [49], especially for patients with potential critical illnesses. Smartphones barely have an impact on the incoming flow. Outside the entrance, scanning takes only a few seconds, and then patients can walk into the ED and complete registration while waiting to be triaged in front of nurses. In this way, experienced nurses could have a better chance of quickly scanning the patients to determine who should be treated first, even if the registration is not complete.

Although there was not a substantial difference in terms of completion time, using smartphones for self-registration could completely eliminate the prominent waiting issue caused by limited resources in EDs, as it enables an infinite-server queueing model [50]. Thus, serviceability and scalability could be refined from a different lens.

Usability is a key factor for users' continuance intention. Some patients who have experienced kiosk malfunctions or delayed help may not use the kiosk area the next time they have to visit the ED. This can explain the low number of participants in the kiosk group. In China, WeChat and QR technologies are frequently used [20]; therefore, patients will be familiar with a QR-based interaction when approaching the ED entrance. Smartphone users also encounter few failures during the process, which might enhance their willingness to continue using the mobile check-in service.

Indeed, the triage nurses gave the smartphones a higher usability score than the kiosks. There could be several reasons for this difference. First, kiosks generate more interruptions than smartphones, which is supported by the ASQ results and observations. Triage staff have to pause their work to handle any kiosk-related interruptions. Second, the overall observation could have an impact, as arrivals are directed in a flow for self-registration and triage. Third, with respect to the signage, the kiosk area is more challenging as a prerequisite for registration compared to the ED entrance, resulting in high referring effort. Finally, smartphones could cause less delay for patient identification than kiosks.

Smartphones increase hospitality in the pretriage flow [51]. First, compared to public screens, smartphones honor patient privacy. Second, the use of personal devices ensures hygiene and cleanliness, which are more difficult to maintain when using shared kiosk touchscreens. Third, social distancing is important in the ED, which could pose a challenge when lining up at kiosks to compete for timely identification. Finally, smartphones are more user-friendly in multilingual scenarios.

Although smartphones have numerous benefits, a computer-literate arrival can still choose to use a kiosk when a smartphone is not at hand. In addition, those who are not comfortable with SSTs can still register at the human-based line. Thus, providing numerous options in EDs can help to improve triage efficiency, especially during peak hours.

Limitations

Our study has limitations. First, this study was performed in three metropolitan ED centers in Shanghai; hence, our findings do not represent other disparate geographical areas with different ED volumes. For example, scanning QR codes might not be a common behavior adopted by patients in other countries. Second, due to the limited time frame of observation, some issues might not have been disclosed. Third, the smartphone-based tool was developed for the purpose of this evaluation and more features should be added in the future, such as integrating the tool with mobile sensors and using algorithms to predict triage results for decision-making. The lack of such features may have affected the usability results but could also serve as a basis to measure future enhancements.

Conclusions

EDs are overcrowded with long waiting times for registration and triage. Patient registration is managed in a single thread when completed by a triage team. Therefore, using SSTs would ease the burden on triage nurses and allow them to focus on higher-order tasks. Compared to kiosks, smartphones seem to be more convenient and suitable as a pretriage SST. However, it is recommended to offer multiple options of self-registration services in EDs.

Abstract

Background: Patient-reported outcome and experience measures can play a critical role in providing patient-centered and value-based health care to a growing population of patients who are chronically ill. Value-based telemedicine platforms such as the Naveta initiative may facilitate the effective integration of these tools into health care systems.

Objective: This study aims to evaluate the response rate to electronic patient-reported outcome measures (ePROMs) and electronic patient-reported experience measures (ePREMs) among patients participating in the Naveta telemedicine initiative and its correlations with sociodemographic and clinical characteristics, as well as the evolution of the response rates over time.

Methods: Between January 1, 2021, and June 30, 2023, a total of 53,364 ePREMs and ePROMs for 20 chronic conditions were administered through the Naveta-Phemium platform. Descriptive statistics were used to summarize continuous and categorical variables. Differences in response rates within each sociodemographic variable were analyzed using logistic regression models, with significance assessed via chi-square and post hoc Tukey tests. Two-way ANOVA was used to examine the interaction between time interval and disease type on response rate evolution.

Results: A total of 3372 patients with severe chronic diseases from 64 public hospitals in Spain participated in the Naveta health questionnaire project. The overall response rate to ePROMs and ePREMs during the first 2.5 years of the Naveta initiative was

46.12% (24,704/53,364), with a baseline rate of 53.33% (7198/13,496). Several sociodemographic factors correlated with lower response rates, including male gender, older age, lower education level, frequent alcohol use, being a student, and not being physically active. There were also significant variations in response rates among different types of chronic conditions ($P<.001$), with the highest rates being for respiratory (433/606, 71.5%), oncologic (200/319, 62.7%), digestive (2247/3601, 62.4%), and rheumatic diseases (7506/12,982, 57.82%) and the lowest being for HIV infection (7473/22,695, 32.93%). During the first 6 months of follow-up, the response rates decreased in all disease types, except in the case of the group of patients with oncologic disease, among whom the response rate increased up to 100% (6/6). Subsequently, the overall response rate approached baseline levels.

Conclusions: Recognizing the influence of sociodemographic factors on response rates is critical to identifying barriers to participation in telemonitoring programs and ensuring inclusiveness in patient-centered health care practices. The observed decline in response rates at follow-up may be due to survey fatigue, highlighting the need for strategies to mitigate this effect. In addition, the variation in response rates across chronic conditions emphasizes the importance of tailoring telemonitoring approaches to specific patient populations.

Introduction

Background

Health care systems and institutions worldwide are undergoing transformation to meet the demands of an aging population, implement new health care standards, and integrate advancements in digital technology [1-4]. Increased life expectancy and improvements in medicine have led to a growing number of people living with chronic conditions [5-7]. This growth represents a major challenge for health care systems, which must provide efficient care for patients with chronic conditions while wisely allocating limited resources [3,8]. To address these complex challenges, governments, health organizations, and health care providers are increasingly recognizing the need to transition toward more personalized and patient-centered care models, aligned with the concept of value-based health care (VBHC) [9-12]. In this new paradigm, value is defined as health outcomes that matter to patients in comparison to the cost of achieving these outcomes [9].

To carry out these changes, health care services and systems need tools to guide the transition [11,13]. Measuring, reporting, and comparing outcomes is essential to assess the value of care provided to patients [9,14,15]. Patient-reported measures are the fundamental tools used to guide health systems and providers in implementing person-centered health care and achieving outcomes that matter to patients [16,17]. Patient-reported measures are administered in the form of questionnaires and include patient-reported outcome measures (PROMs) and patient-reported experience measures (PREMs). PROMs can assess a variety of outcomes, such as physical performance, social functioning, psychological well-being, symptom severity, disability, and impairment, from the perspective of the patient, whereas PREMs focus on the patient's experience of care [18]. These measures can be used to support diagnosis, monitor treatment and patient progress, improve communication between patient and health care professionals, and facilitate shared decision-making [17,19]. Despite their potential value and some examples of successful health system–level PREM and PROM programs, such as the National Health Service PROMs program in the United Kingdom and the Danish patient-reported outcome (PRO) system, their routine use in health systems is not widespread in other countries [11,13,16,18,20-22].

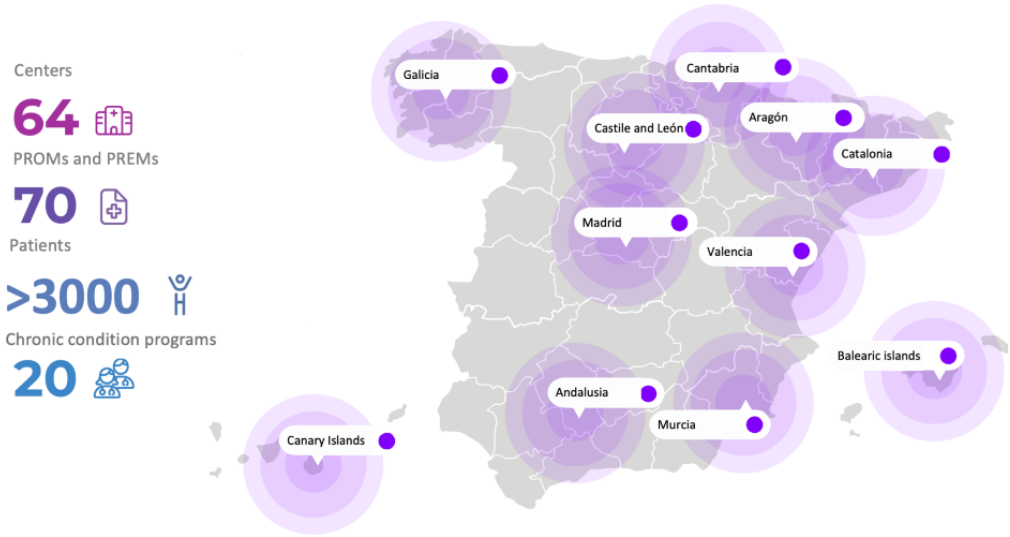
The Naveta Value-Based Telemedicine Initiative

Digital transformation and the integration of eHealth tools and value-based IT platforms in health care settings are critical for achieving the systematic delivery of standardized PREMs and PROMs in clinical practice [11,23,24]. The COVID-19 pandemic has sparked a revolution in digital health technologies that can pave the way for this transformation [4,25]. In this context, the Naveta initiative [26] has emerged as a scientific community that aims to promote VBHC for patients with serious chronic conditions by implementing processes and strategies related to the electronic delivery of PROMs and PREMs and the use of telemedicine tools.

Naveta was created by the Association of Pharmacists of Outpatient Departments of the Balearic Islands (FARUPEIB) with the participation of BiblioPRO, a web-based library of PRO questionnaires in Spanish [27,28]. The technological infrastructure that supports Naveta activities is provided by Phemium [29], a software platform specialized in telemedicine projects. The scientific committee of Naveta is currently composed of physicians, hospital pharmacists, nurses, psychologists, members of BiblioPRO, and experts in eHealth and innovation. The committee's responsibilities include selecting PROM standard sets, determining the frequency and timing of questionnaire administration, evaluating and improving the efficiency of the platform and standard sets, promoting VBHC, mentoring and advising health care professionals and researchers, and fostering new technological developments within the Naveta ecosystem. To date, specific and generic PROM standard sets have been selected for 20 chronic diseases. These measures can assess, among other outcomes, health status, disease activity, impact on quality of life, treatment satisfaction, and productivity from the patient's perspective.

One of the goals of the Naveta initiative is to provide state-of-the-art PROM and PREM tools that enable health care managers and professionals to obtain accurate and valuable information directly from patients to be incorporated into the decision-making process. Another goal of the initiative is to build a body of knowledge on the appropriate use of PROMs, considering both disease type and sociodemographic data, in line with initiatives such as Patient-Reported Outcomes Tools: Engaging Users and Stakeholders (PROTEUS) and the International Consortium for Health Outcomes Measurement (ICHOM) [30,31]. Recognized recently by different Spanish associations as an outstanding innovation project, Naveta is one of the most widespread value-based telemedicine initiatives in Spain [32] and has been widely implemented at hospitals and institutions in different Spanish regions (Figure 1). Furthermore, several observational studies on patients with various chronic diseases are currently being conducted using the Naveta VBHC approach.

Figure 1. Distribution of Spanish hospitals participating in the Naveta initiative. PREM: patient-reported experience measure; PROM: patient-reported outcome measure.



Goal of the Study

Here, we present our experience in implementing the Naveta value-based telemedicine initiative at different hospitals in Spain, which involved the administration of 53,634 electronic PROMs (ePROMs) and electronic PREMs (ePREMs) to 3372 patients with severe chronic conditions over the last 2.5 years.

The primary objective of this study was to assess the response rate to electronic questionnaires among patients who were chronically ill registered in Naveta and to examine its correlation with various sociodemographic characteristics. In addition, this study aimed to track the evolution of response rates over time, specifically among patients with different types of chronic diseases. The purpose of this analysis was to identify potential biases in the collection of information that might have prevented the comprehensive monitoring of the maximum number of patients.

Methods

Study Design and Sample Selection

This study was carried out in the context of routine clinical practice in which patients were receiving dual care (on-site plus telematic care with the Naveta platform). We conducted an observational retrospective multicenter study involving patients with severe chronic diseases. These patients were regularly receiving hospital-only medicines at pharmacy outpatient clinics of 64 public hospitals in different regions of Spain (Figure 1). Patients were enrolled at the time of starting or changing their prescribed outpatient medication and registered for ≥1 chronic condition programs based on their diagnosis. The study covered the period from January 1, 2021, to June 30, 2023.

All patients met the following criteria: aged ≥18 years, diagnosed with ≥1 chronic diseases (psoriasis, psoriatic arthritis, rheumatoid arthritis, asthma, cancer, ulcerative colitis, atopic dermatitis, Crohn disease, multiple sclerosis, ankylosing spondylitis, hidradenitis suppurativa, urticaria, and HIV infection, among others), and agreed to participate in a telemedicine project linked to health questionnaires through the Naveta-Phemium platform.

Selection of Patient-Reported Measures

The questionnaires included in each disease standard set, selected by Naveta's scientific committee, are specified in Figure 2. The color code in the figure indicates the type of medical condition: rheumatic diseases, gastrointestinal diseases, neurological diseases, skin diseases, oncologic diseases, respiratory diseases, HIV infection, and other diseases.

Figure 2. Naveta's standard sets of patient-reported measures for 20 chronic conditions. The scientific committee that selects Naveta's standard sets of PROMs for each pathology is composed of physicians, hospital pharmacists, psychologists, members of BiblioPRO, and eHealth experts.

Their decisions are informed by the study of literature reviews and recommendations from authoritative sources such as the Patient-Reported Outcomes Measurement Information System (PROMIS) [33], the ICHOM initiative [34], and the Patient-Reported Indicator Surveys initiative of the Organisation for Economic Co-operation and Development [35]. The questionnaires used are the validated Spanish versions and meet licensing requirements. The platform mainly included PROMS for a variety of chronic conditions (67), and only a few PREMs were administered, including the Person-Centered Coordinated Care Experience Questionnaire (P3CEQ), which is designed to assess person-centered coordinated care from the perspective of people with long-term conditions [36,37]. Other PREMs included the Self-Injection Assessment Questionnaire (SIAQ)

[38,39] and a Likert scale survey to assess satisfaction with the dual follow-up (on-site and telematic care; administered annually).

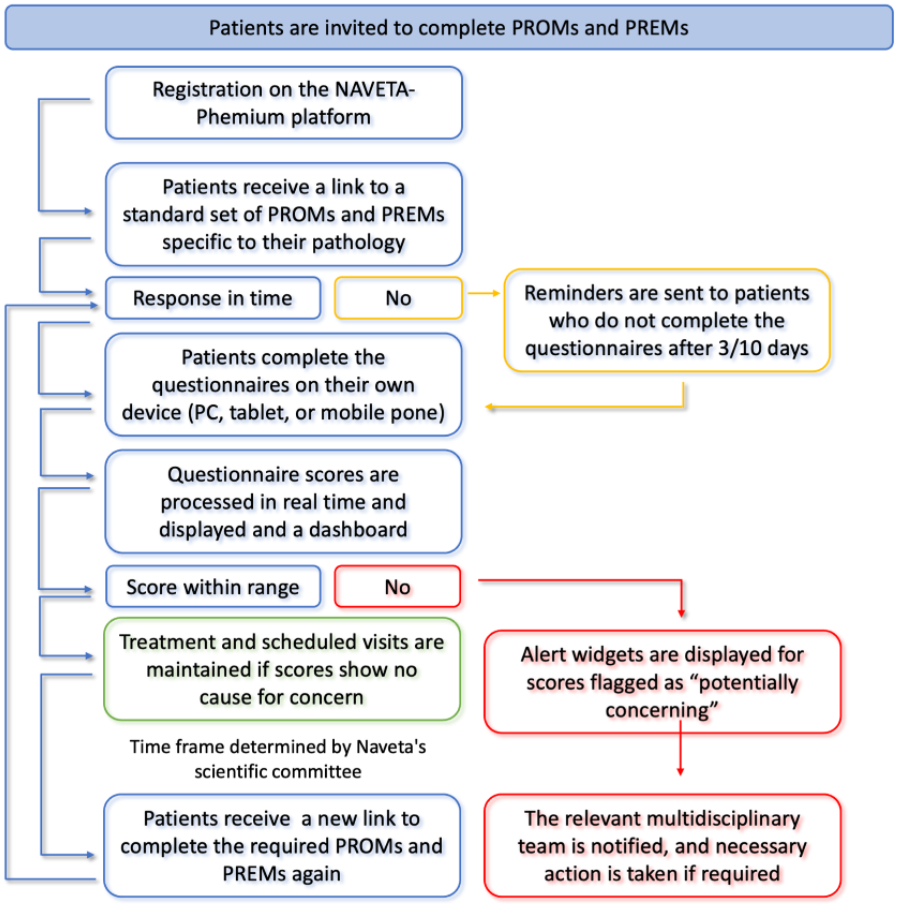
Data Collection Procedures

Patients who provided informed consent (refer to the Ethical Considerations subsection for details) received a link to access the electronic questionnaires, which they could complete on their own device (PC, tablet, or mobile phone). Each patient was provided with a standard set of PROMs tailored to their specific chronic disease. Participants were also asked to complete a sociodemographic questionnaire that included questions about their level of education, employment status, smoking habit and alcohol consumption, BMI, and physical activity. The BMI parameter was categorized according to the World Health Organization classification: underweight (<18.5 kg/m^2), healthy weight (18.5-24.9 kg/m^2), overweight (25.0-29.9 kg/m^2), and obese (≥30 kg/m^2) [40]. After 1 year of follow-up with the Naveta telemedicine program, patients were administered a 10-point Likert scale questionnaire to assess their satisfaction, and this survey was repeated annually.

The process of delivering and collecting PROMs and PREMs through the Naveta-Phemium platform is illustrated in Figure 3. The system automatically generates and sends reminders (via SMS text messaging and email) to patients who do not complete the questionnaires 7 and 15 days after receiving the link. It also generates alert widgets for potentially concerning scores and enables users to specify the score categories that should be flagged for each PROM (eg, scores indicating moderate to severe impairment). These alerts, along with other data from the patient's medical record, are used to make clinical decisions about medication changes, specialist referrals, lifestyle recommendations, and more. The patients were requested to complete the relevant standard set of questionnaires at the start of each pharmacological treatment or at each medication change (baseline collection). The periodicity of the follow-up questionnaires was determined by the Naveta scientific committee according to the specific chronic conditions and the outcome measured.

The team at each center was responsible for seeking permission to use the questionnaires through the Naveta initiative.

Figure 3. Process of delivering and collecting patient-reported measures through the Naveta-Phemium platform. PREM: patient-reported experience measure; PROM: patient-reported outcome measure.



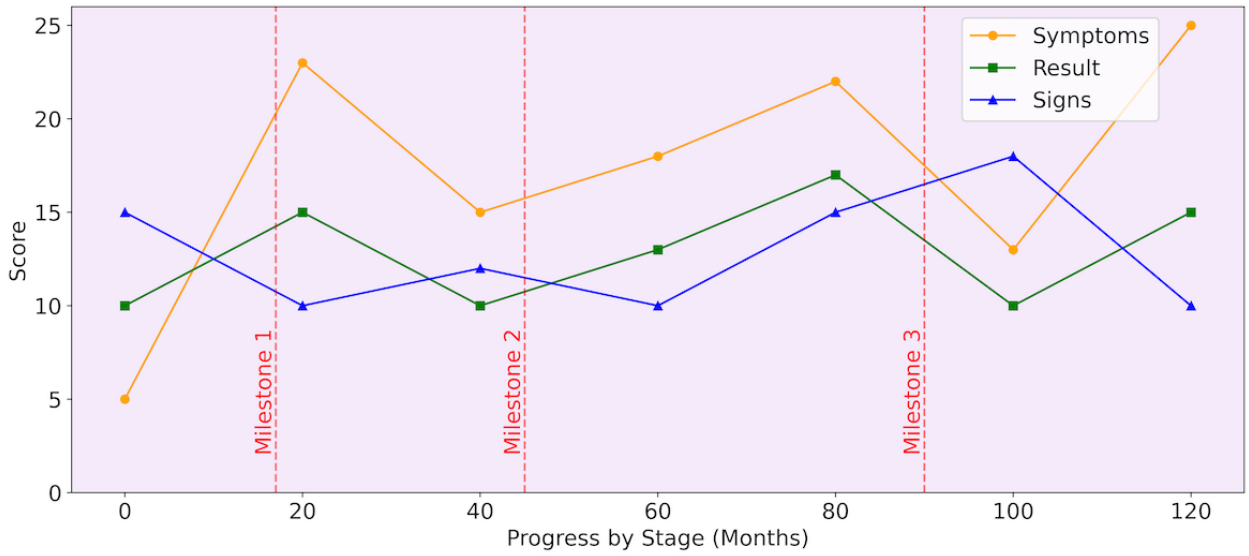
Technology Infrastructure

The Naveta initiative is supported by Phemium [29], a technological multiplatform specialized in the design and implementation of telemedicine projects. This platform has >2000 active professional users in different countries (Spain, Poland, the Czech Republic, Germany, Chile, Peru, Mexico, and Nigeria), with >2 million health care interactions per year globally. It complies with the requirements of a high standard

of data protection, level 3, according to the European General Data Protection Regulation and Spanish Organic Law 3/December 5, 2018, regarding the protection of personal data and the guarantee of digital rights.

The platform facilitates effective communication between health care professionals and patients. To systematize the delivery and interpretation of PROMs and PREMs in health care practice, the system performs the parameterization and customization of protocols. Each PROM is labeled for ≥1 specific conditions or as a generic questionnaire. The system interprets patient responses according to the score intervals of each questionnaire. Responses that do not meet the conditions required for a particular questionnaire are automatically discarded. The results of the questionnaires are processed in real time and presented graphically on a dashboard (Figure 4). This allows health care professionals (nurses, hospital pharmacists, and physicians) to immediately monitor patient outcomes and compare their progress with that of other patients and to monitor the evolution of an individual patient in a clinical context. The system also allows global analysis within groups for each pathology and compares individual and global results. In addition, patients can access their results on their dashboard.

Figure 4. Psoriasis Symptoms and Signs Diary: an example of a patient-reported outcome measure dashboard. This dashboard monitors 3 distinct metrics—symptoms, results, and signs—over a 120-month time frame. Notably, it features milestone markers at roughly 17, 45, and 90 months, with dashed vertical lines denoting significant events in the management of the condition, such as weight loss, changes in alcohol consumption, or alterations in treatment, among potential examples.



Statistical Analysis

Descriptive statistics were used to summarize continuous variables as means and SDs and categorical variables as frequencies and percentages. For results analysis, chronic conditions were categorized based on their respective disease type (Figure 2). To assess the response rates over time, the number of completed questionnaires at distinct intervals was calculated. Differences in response rates among categories within each sociodemographic variable were analyzed using logistic regression models. Their significance was evaluated with chi-square and post hoc Tukey tests (using the *glht* function from the *multcomp* R package). A 2-way ANOVA was used to study the interaction effect between time interval and disease type on response rate evolution. All statistical procedures were performed using R software (version 4.2.2; R Foundation for Statistical Computing) [40], and a significance level of $P \leq .05$ was set for all tests.

Ethical Considerations

Ethics approval was obtained from the research ethics committee of the Balearic Islands (Comitè d'ètica de la investigació de les Illes Balears; IB 5117/23 EOm). This study was conducted in accordance with the principles of the Declaration of Helsinki and its subsequent revisions. The informed consent form and other patient information were reviewed and approved by the clinical research ethics committee and the independent ethics committee of Balearic Islands (Palma de Mallorca, Spain).

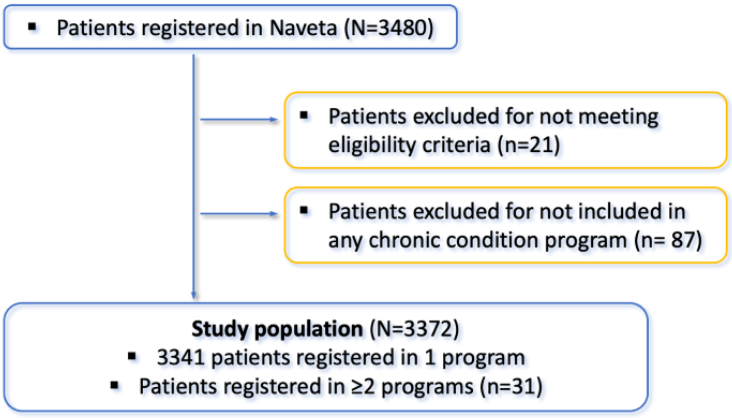
Before enrollment in the Naveta project, all patients received detailed information and provided written informed consent.

Results

Descriptive Analysis of the Sample

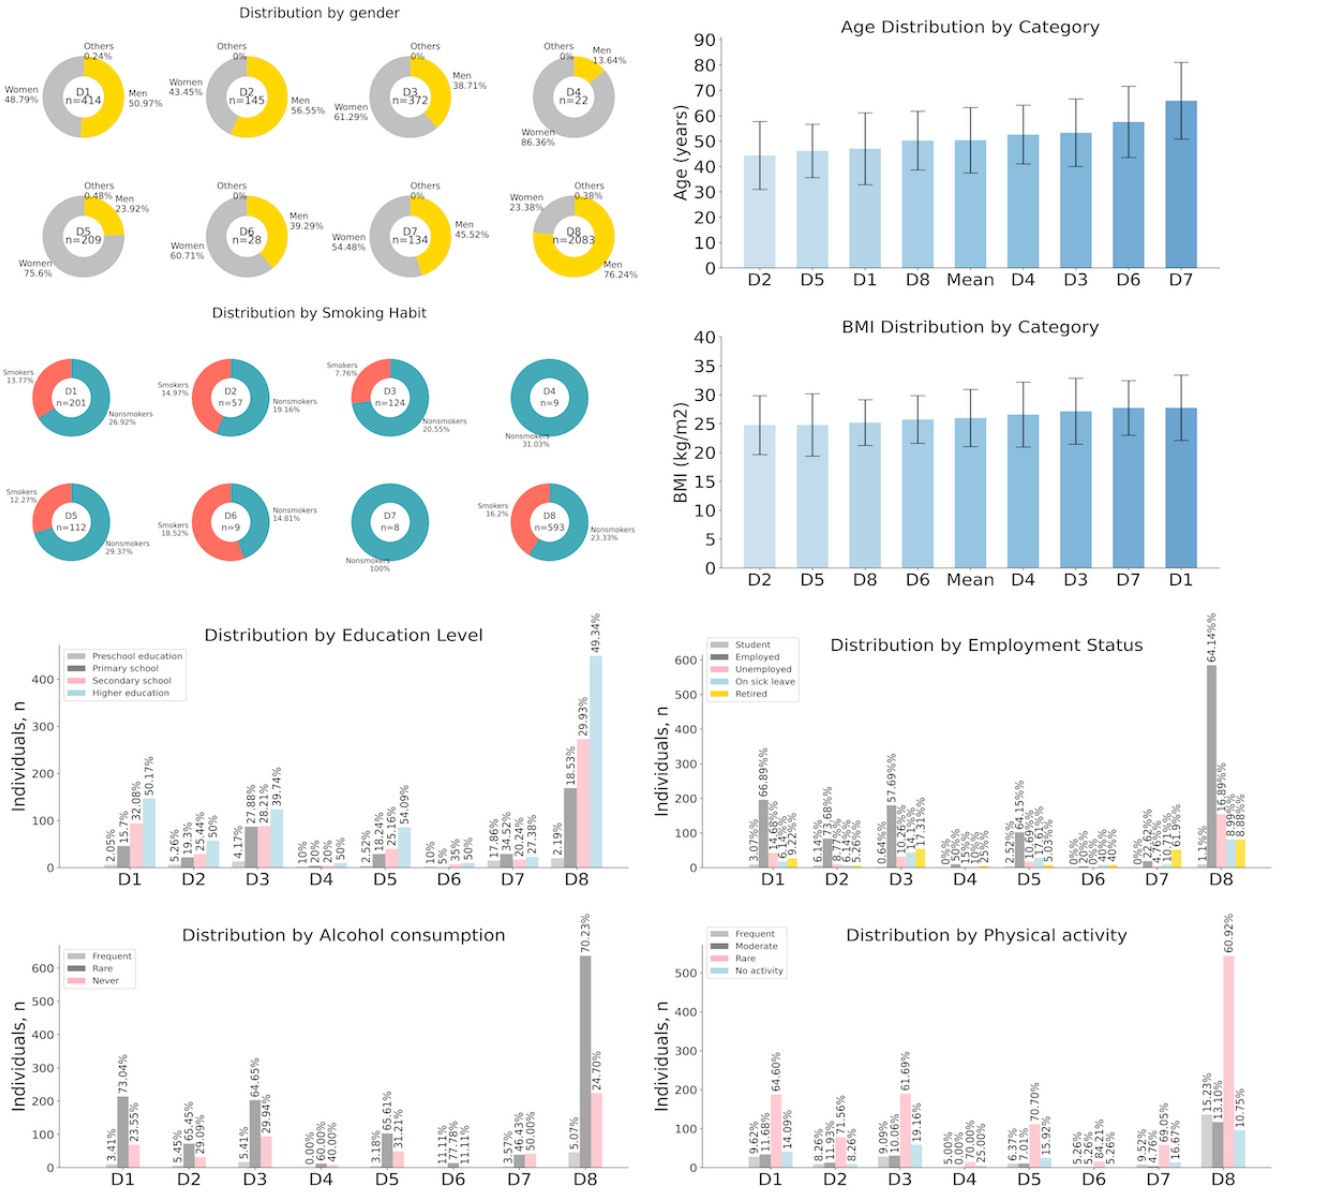
In total, 3372 patients diagnosed with at least 1 chronic condition were registered on the Naveta-Phemium platform: 2128 (63.11%) men, 1234 (36.6%) women, and 10 (0.3%) people who self-identified as *other gender*. Of the 3372 patients, 3341 (99.08%) were registered in only 1 chronic condition program, while 31 (0.92%) had multiple diagnoses and were registered in ≥2 chronic condition programs (n=28, 90% were registered in 2 programs; n=2, 6% in 3 programs; and n=1, 3% in 4 programs; Figure 5). The mean age of the whole cohort was 50.36 (SD 12.91) years.

Figure 5. Flowchart for participant recruitment.



The HIV disease program had the highest number of registered patients (2083/3372, 61.77%), whereas the breast cancer (17/3372, 0.5%), prostate cancer (9/3372, 0.27%) and lung cancer (2/3372, 0.06%) programs had the lowest number of registered patients (Table S1 in Multimedia Appendix 1). Within the disease type categories, the largest group was Naveta HIV (2083/3372, 61.77%), followed by Naveta Derma (414/3372, 12.28%), Naveta Rheuma (372/3372, 11.03%), Naveta Miscellaneous (134/3372, 3.97%), Naveta Neuro (209/3372, 6.2%), Naveta Digest (145/3372, 4.3%), Naveta Onco (28/3372, 0.83%), and finally Naveta Respir (22/3372, 0.65%). Figure 6 and Table S2 in Multimedia Appendix 1 present the main sociodemographic characteristics of the study participants by type of disease.

Figure 6. Sociodemographic characteristics of study participants by disease type (a comprehensive analysis of demographic distribution and health habits across different disease categories). The charts illustrate the distribution—among individuals with dermatological, digestive, respiratory, neurological, oncologic, HIV-related, and miscellaneous conditions—by (A-D) gender, age, BMI, and smoking habits; and (E-H) education level, employment status, alcohol consumption, and physical activity. D1: dermatological diseases; D2: digestive diseases; D3: rheumatological diseases; D4: respiratory diseases; D5: neurological diseases; D6: oncological diseases; D7: miscellaneous diseases; D8; HIV.



Descriptive Analysis of the Questionnaires

A total of 53,364 questionnaires were sent out for all disease categories, and 24,704 (46.12%) were completed. The response rates (percentage of completed questionnaires out of the total number of questionnaires sent) at specific time intervals were as follows: 53.33% (7198/13,496) at baseline, 41.5% (9131/22,000) from baseline to 6 months, 43.7% (4474/10,239) from 6 months to 1 year, and 51.13% (3901/7629) from 1 year to 2.5 years (Figure 7; Table S3 in Multimedia Appendix 1).

The analysis revealed a significant interaction effect between time interval and disease type on response rate evolution over time (P<.001). In all disease categories, the response rate decreased after 6 months, except in the category of oncologic diseases, where the response rate increased up to 100% (6/6). In the following intervals, the evolution of the response rate did not show a homogeneous trend in the different disease categories. It should be noted that the number of questionnaires sent to patients for completion differed based on the type of disease (Figure 8).

Figure 7. Evolution of response rate by disease program.

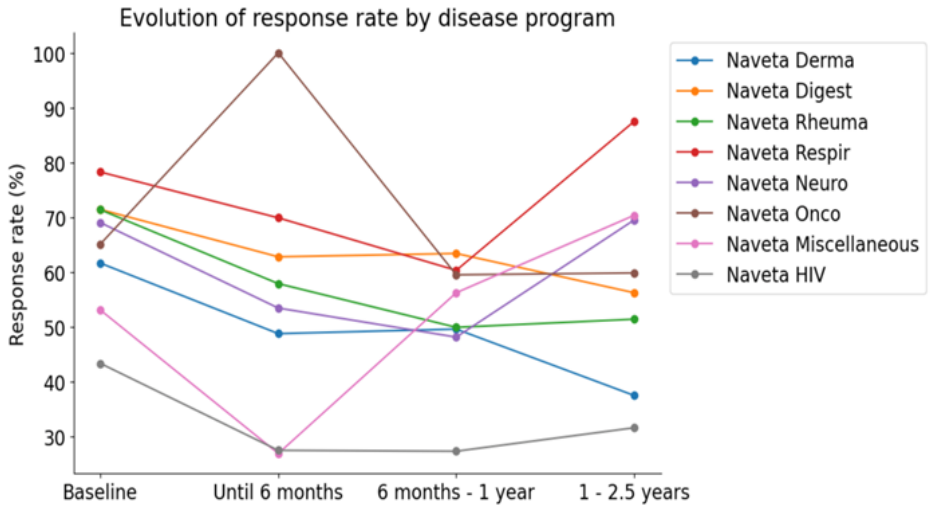


Figure 8. Number of questionnaires sent out by disease program.

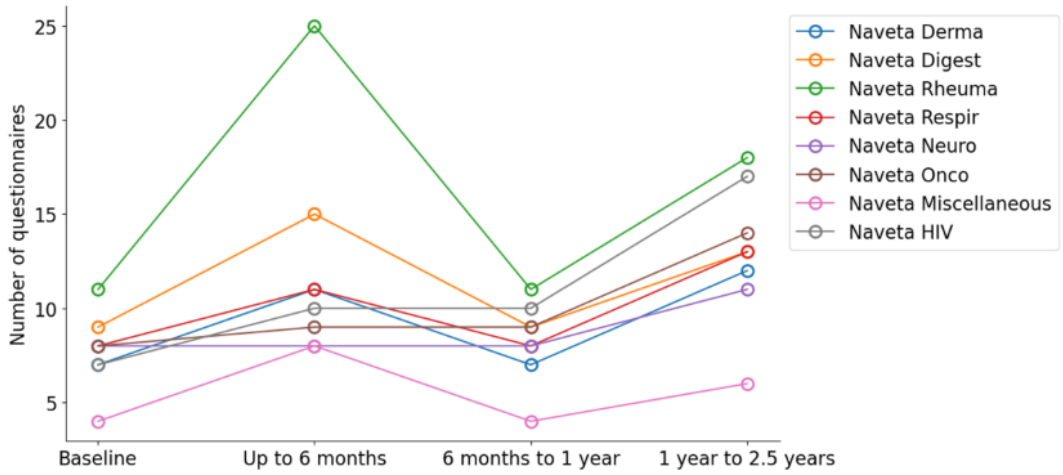
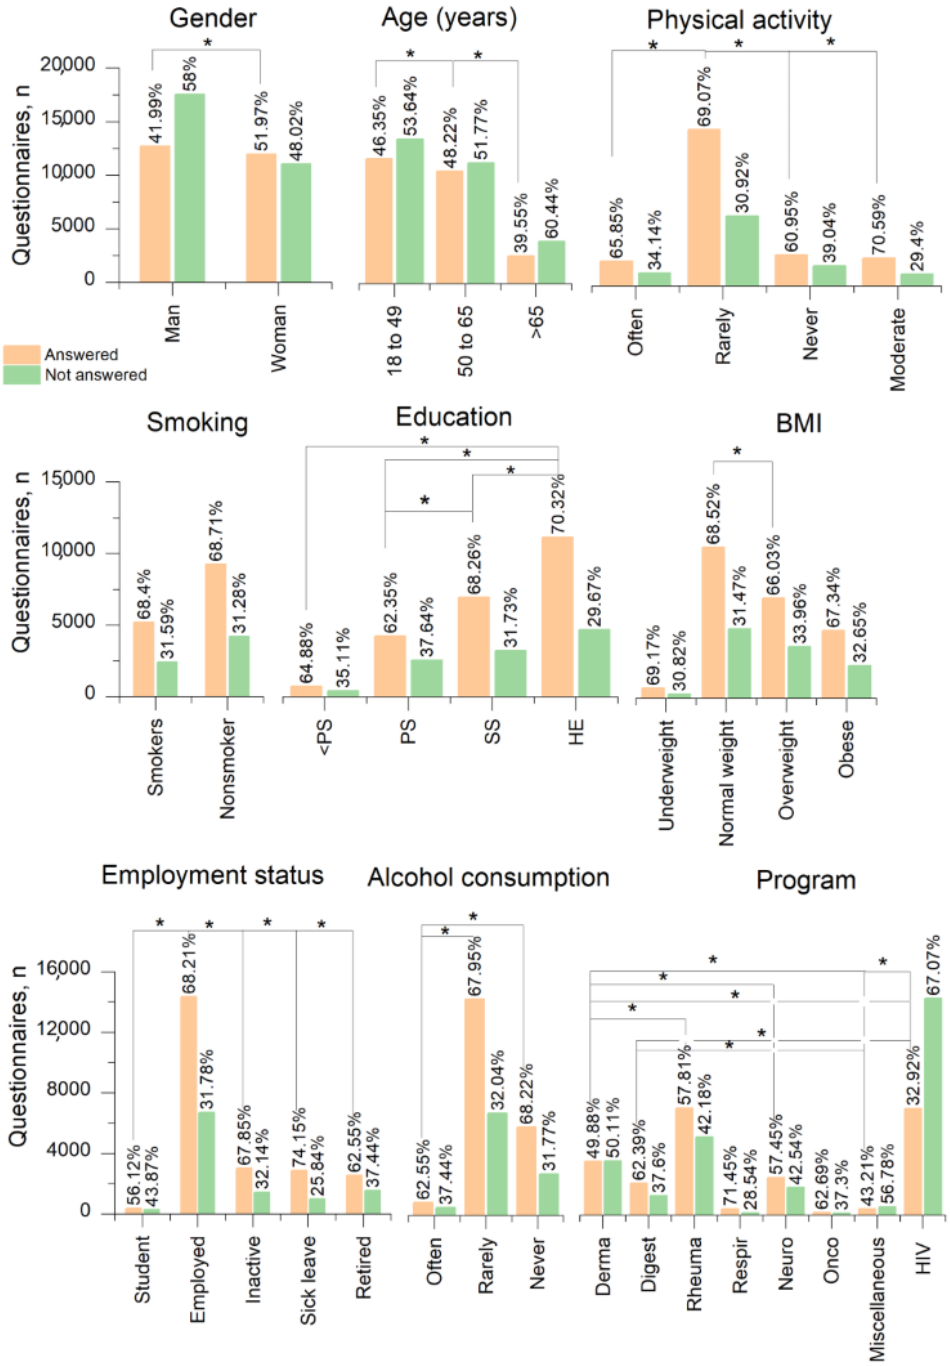


Significant differences were found for gender, age, education level, employment status, alcohol consumption, and physical activity. Women were more likely to complete questionnaires than men (P<.001), and patients aged >65 years had a lower response rate than younger patients (P<.001). Higher education correlated with a higher frequency of completed questionnaires compared to the categories of preschool education (P<.001), primary school education (P<.001), and secondary school education (P=.002). Regarding employment status, patients on sick leave had the highest response rate (P<.001), and students had the lowest response rate (P<.001) compared to the other categories. Finally, when comparing the categories of alcohol consumption and physical activity, a lower frequency of completed questionnaires was found for frequent alcohol consumption (P<.001) and no physical activity (P<.001; Figure 9).

Figure 9. Frequencies of answered and unanswered questionnaires compared across different sociodemographic factors. *At post hoc level, the difference in the means is significant, *P*<.05. HE: higher education; PS: primary school; SS: secondary school.



For disease type, significant differences among the categories were observed (Figure 9; Table S4 in Multimedia Appendix 1; refer to Table S5 in Multimedia Appendix 1 for frequencies of answered and unanswered questionnaires by disease program). The highest response rates were found for Naveta Respir, Naveta Digest, Naveta Rheuma, and Naveta Onco; and the lowest response rates were associated with the patients who had tested positive for HIV infection and those included in Naveta Miscellaneous.

In terms of satisfaction with the telemonitoring program via Naveta, 87.7% (381/434) of the patients rated their experience with scores between 7 and 10 (n=197, 45.4% provided a rating of 9 or 10; and n=184, 42.3% provided a rating of 7 or 8). The analysis in the different clinical sets did not show significant differences among them in the level of satisfaction (*P*=.63). A third of the most satisfied patients (61/197, 30.9%; rating of 9 or 10) belonged to the group categorized as Naveta Rheuma.

Discussion

Principal Findings

The Naveta initiative aims to promote the principles of VBHC and improve the quality of care for people with chronic diseases through the systematic integration of ePROMs and ePREMs

into clinical practice settings and a continuous learning process based on result analysis. The routine collection of PROMs and PREMs enables health care providers to assess treatment effectiveness, identify unrecognized issues, and positively impact patient management and satisfaction [41-43]. High response rates to PROMs have been associated with better health outcomes and are important to ensure that the information collected is representative [21,44]. The overall response rate to ePROMs and ePREMs during the first 2.5 years of Naveta was 46.12% (24,704/53,364), with a baseline rate of 53.33% (7198/13,496). In countries with a long tradition of systematic PROM collection, such as the United Kingdom, Denmark, and the United States, response rates might range from 50% to 80% or higher [45-49]. However, comparing response rates among studies is challenging due to the lack of a standardized calculation formula [44,48]. Understanding the variables that influence these rates is fundamental to developing effective strategies to improve patient engagement. We consider that with the publication of similar studies and with the implementation of these systems in more regions, comparable data will be available, and cutoff points could be established. The association of response rate with common clinical surrogate markers would also be necessary.

These data could also be useful in future studies to assess the adequacy of PROMs and PREMs for different profiles of patients and their usefulness in clinical practice and future integration in health services databases.

Our study identified several sociodemographic factors that seemed to negatively impact response rates, including male gender, older age, lower education level, frequent alcohol consumption, being a student, and no physical activity. Women in our cohort exhibited higher response rates than men, a pattern already observed in other studies, although not consistently [44,50]. Further investigation is warranted to confirm this observation and to determine why men may be less motivated to answer health questionnaires. Older age was also significantly associated with lower response rates compared to younger age, and this is a common pattern in previous studies [44,50,51]. Possible reasons for this association include lower levels of digital confidence and skills as well as language and literacy skills, visual impairment, and health problems [50,51]. The higher response rates observed among individuals with higher levels of education in our study align with those in other studies examining barriers to completing ePROMs [52,53].

Lower education levels are often associated with lower health literacy and digital skills [52]. To the best of our knowledge, limited research has been conducted on the impact of employment status, physical activity, and alcohol consumption on PREM and PROM response rates [54,55].

The potential for bias in response rates associated with certain sociodemographic characteristics should be given due consideration and thoroughly examined to implement appropriate compensatory measures. To make the use of PROMs more accessible to a wider range of people, particularly to older and less educated patients, it could be necessary to offer some assistance (from a nurse, data manager, family members, or caregiver). This assistance could help, for example, to complete electronic questionnaires and promote a better understanding of the associated benefits [19,53].

It should be noted that, according to the study by Eriksen et al [21], PROMS equip patients with an improved understanding of their conditions, treatment, and health and increase their awareness of psychosocial issues and symptoms by encouraging disease-related reflections. However, in some cases, particularly patients with some complex conditions, the anxiety stemming from reporting symptoms or being reminded of their deteriorating health status can be a reason for not participating in such health-related survey [56].

Patients' increased access to, and accumulation of, knowledge through digital platforms allow mobilizing and empowering them and might affect their expectations and their political engagement related to the quality of health care [57].

Naveta's scientific committee has so far selected 20 standard sets for different chronic diseases, comprising 70 different PROMs and PREMs. Significant variations in response rates have been observed among different types of chronic conditions, with the highest rates being for respiratory, digestive, rheumatic, and oncologic diseases and the lowest rates being for HIV infection. Studies comparing response rates to ePROMs across different chronic diseases, especially when using condition-specific standard sets of questionnaires, are scarce. In a study describing the implementation of the WestChronic PRO system in Denmark, which included 22 PRO projects for 18 chronic diseases, the highest response rates were observed in patients with epilepsy and prostate cancer, whereas the lowest rates were observed in patients with stroke [58]. A review of response rates available in clinical quality registries and databases that collect PROMs for all types of health conditions found that patients with chronic conditions and cancer have the highest response rates at baseline [48]. The differences observed in response rates in our study may be related to the nature of the specific conditions. However, it would be necessary to determine the role of disease-specific PROMs and other factors such as the severity of symptoms and the presence of comorbidities [59,60]. Further research is necessary to fully understand these differences and to implement strategies to improve response rates across pathologies.

During the first 6 months of follow-up, response rates declined across all disease types, except in the case of the group of patients with oncologic disease, where a notable increase was observed. Subsequently, the overall response rate increased and approached baseline levels, and the response rate pattern in the group of patients with oncologic disease became comparable to the response rate patterns in the other groups. It should be noted that the number of questionnaires that patients were requested to complete varied over time in each group. This initial increase in response rates in patients with oncologic disease has not been described in other studies and should be investigated in a larger cohort to elucidate potential underlying causes [49,61,62]. One possible explanation is the support provided by the cancer functional units, which include multidisciplinary professionals such as oncologists, surgeons, pharmacists, nurses, psychologists, nutritionists, and physiotherapists; nurses, in particular, play an important role

in motivating patients to respond to PROMs. However, as side effects become more pronounced or accumulate over time, patient motivation may diminish.

The overall decline in response rates at follow-up is a common tendency in numerous studies, with only a few exceptions [44,48,49,58,60,63,64]. This decline has been attributed to survey fatigue, which is associated with factors such as response burden, questionnaire length, perceived item irrelevance, older age, disease severity, and the presence of comorbidities [59,64,65]. When selecting standard sets and the frequency of questionnaire administration for each pathology, it is crucial to balance the need to obtain comprehensive information with the potential burden on patients if they have to complete numerous questionnaires. To address survey fatigue and enhance response rates, Naveta's scientific committee is currently exploring new strategies inspired by the PROMIS Computer Adaptive Tests and the studies that have investigated patient burden [59,65-67]. These strategies include reducing the number of PROMs in standard sets; labeling some of them as optional; using shorter questionnaires; and reducing, delaying, or spreading over time the administration of questionnaires.

Unlike the traditional use of PROMs in clinical practice as a supplement to the patient's follow-up, PROM-based follow-up with AmbuFlex and Naveta platforms represents a new model of service delivery where PROMs are used as the basis for outpatient follow-up [68].

Implementing the routine collection of PROMs and PREMs in clinical settings involves integrating technological systems for electronic questionnaire administration [69]. The advantages of ePROMs and ePREMs over paper questionnaires include reduced data entry errors, shorter completion times, real-time results, improved symptom management, the prioritization of clinical visits, and cost reduction [19,70]. In addition, automated alerts enable health care professionals to promptly address serious complications, reducing symptom burden and the risk of hospital readmissions [19]. Challenges associated with electronic questionnaires include privacy concerns, a higher initial investment in infrastructure, and potential bias due to patients' lack of digital literacy [19].

Positive feedback from patients regarding PROM monitoring via the Naveta system was demonstrated by the results of the satisfaction questionnaire. Aligned to our commitment to improve the health and well-being of patients with chronic diseases and guided by the principles of VBHC and right care [8,9], our initiative aims to ensure that digitalization goes hand in hand with humanization. Examples of this approach include health care professionals personally contacting patients in response to flagged alerts identified through questionnaire results or establishing communication channels for consultations. Recently, to help bridge the digital gap, data managers have been introduced to contact patients who do not complete questionnaires. Their role involves understanding the reasons for noncompletion, clarifying doubts, emphasizing the benefits of completing PROMs, and offering assistance to respond if desired. These actions reinforce our commitment to a patient-centered model that embraces technology while reaffirming the human connection.

Moreover, we believe that it is important to involve patients in the design of health technology. Effective patient engagement can profoundly change how patient-centered research is conceptualized and conducted, resulting in better patient-centered care, management, and measurement [71]. In our case, the feedback obtained in the satisfaction surveys is taken into consideration for making improvements to the Naveta platform. While, currently, the perspective of patients is indirectly obtained through contacts with patients' associations, we plan in the future to include patient representatives in the meetings of the scientific committee.

Strengths and Limitations

This study provides empirical evidence on the implementation of a telemonitoring system for patients who are chronically ill through electronic questionnaires at different hospitals and in different regions in Spain. Our comprehensive examination of multiple sociodemographic factors that influence the response rate to ePROMs and ePREMs provides valuables insights into existing literature. This study is one of the few that has compared response rates to ePROMs across different types of chronic diseases when specific standard sets of questionnaires were administered for each disease. Our findings contribute to the current understanding of the strategies needed to implement the systematic collection of ePROMs and ePREMs for patients with chronic conditions in clinical practice according to the principles of value-based care. We present a feasible model of telemedicine, which allows the remote clinical follow-up of a high number of patients with chronic conditions, helped by real-time patient-reported measures, that could substantially change the basis of current clinical management and facilitate shared decision-making, with substantial improvements in comparison with traditional on-site care.

However, 2 limitations should be noted. First, the sample size in certain disease categories (eg, oncologic diseases) was relatively small due to the recent introduction and limited adoption of the Naveta initiative in certain settings. The low number of patients in certain disease groups and the high number of missing values in certain sociodemographic categories reduced the statistical power of the study and did not allow us to perform more specific statistical analysis. Second, the retrospective design of the observational study meant that certain variables, such as the total number of questionnaires and variations in the frequency of questionnaire administration, were not systematically controlled in the analysis of the effect of different diseases on response rates and their evolution.

Conclusions

In conclusion, the overall response rate to the questionnaires during the first 2.5 years of the Naveta initiative was 46.12% (24,704/53,364), with several sociodemographic factors associated with lower response rates. There was a general trend of decreasing rates in the first 6 months, possibly indicating survey fatigue. Recognizing the impact of sociodemographic and clinical factors on response rates may help identify barriers for certain patient groups to participate in telemonitoring programs, suggesting the need to tailor telemonitoring approaches according to patient populations.

Abstract

Background: Hypertension is one of the most important cardiovascular disease risk factors and affects >100 million American adults. Hypertension-related health inequities are abundant in Black communities as Black individuals are more likely to use the emergency department (ED) for chronic disease–related ambulatory care, which is strongly linked to lower blood pressure (BP) control, diminished awareness of hypertension, and adverse cardiovascular events. To reduce hypertension-related health disparities, we developed MI-BP, a culturally tailored multibehavior mobile health intervention that targeted behaviors of BP self-monitoring, physical activity, sodium intake, and medication adherence in Black individuals with uncontrolled hypertension recruited from ED and community-based settings.

Objective: We sought to determine the effect of MI-BP on BP as well as secondary outcomes of physical activity, sodium intake, medication adherence, and BP control compared to enhanced usual care control at 1-year follow-up.

Methods: We conducted a 1-year, 2-group randomized controlled trial of the MI-BP intervention compared to an enhanced usual care control group where participants aged 25 to 70 years received a BP cuff and hypertension-related educational materials. Participants were recruited from EDs and other community-based settings in Detroit, Michigan, where they were screened for initial eligibility and enrolled. Baseline data collection and randomization occurred approximately 2 and 4 weeks after enrollment to ensure that participants had uncontrolled hypertension and were willing to take part. Data collection visits occurred at 13, 26,

39, and 52 weeks. Outcomes of interest included BP (primary outcome) and physical activity, sodium intake, medication adherence, and BP control (secondary outcomes).

Results: We obtained consent from and enrolled 869 participants in this study yet ultimately randomized 162 (18.6%) participants. At 1 year, compared to the baseline, both groups showed significant decreases in systolic BP (MI-BP group: 22.5 mm Hg decrease in average systolic BP and $P<.001$; control group: 24.1 mm Hg decrease and $P<.001$) adjusted for age and sex, with no significant differences between the groups (time-by-arm interaction: $P=.99$). Similar patterns where improvements were noted in both groups yet no differences were found between the groups were observed for diastolic BP, physical activity, sodium intake, medication adherence, and BP control. Large dropout rates were observed in both groups (approximately 60%).

Conclusions: Overall, participants randomized to both the enhanced usual care control and MI-BP conditions experienced significant improvements in BP and other outcomes; however, differences between groups were not detected, speaking to the general benefit of proactive outreach and engagement focused on cardiometabolic risk reduction in urban-dwelling, low-socioeconomic-status Black populations. High dropout rates were found and are likely to be expected when working with similar populations. Future work is needed to better understand engagement with mobile health interventions, particularly in this population.

Introduction

Background

Hypertension affects >100 million American adults, which is nearly half of individuals aged ≥20 years [1]. Hypertension is also one of the most important cardiovascular disease risk factors, and when uncontrolled, it can cause adverse health outcomes such as myocardial infarction, stroke, heart failure, and chronic kidney disease [2-6]. Despite the importance of maintaining adequate blood pressure (BP) control, the American Heart Association has reported that only approximately 21.6% of those with hypertension have their BP controlled within age-adjusted criteria. Furthermore, 38.8% are unaware of their condition [1]. Hypertension-related health inequities are abundant in Black communities. Compared to White individuals, Black individuals have a greater prevalence of hypertension, hypertension-associated disease severity, and younger age of onset, making uncontrolled hypertension a significant problem in this population [7]. Moreover, Black individuals are more likely to use the emergency department (ED) for chronic disease–related ambulatory care, which is strongly linked to lower BP control, diminished awareness of hypertension, and adverse cardiovascular events [8-10].

Although uncontrolled hypertension is linked to a host of adverse outcomes, BP can typically be well controlled through lifestyle and behavior changes. Recommendations for managing hypertension have been consistent for decades and center on positive health behaviors such as maintaining a healthy weight, reducing daily sodium intake, increasing physical activity, and adhering to prescribed antihypertensive therapies [11]; however, engaging in these behaviors is difficult for many individuals, and this is especially true in Black individuals, who are less likely than White individuals to report adherence to preventive behaviors [1]. With the increasing national conversation focused on health inequities and social determinants of health [12], population-specific interventions are needed to intervene in communities where the burden of hypertension is disproportionately high.

Objectives

Mobile health (mHealth) for chronic disease self-management is increasing in use, and based on this, as well as on the high penetration of smartphone ownership among Black individuals (currently approximately 83%) [13], we sought to develop and test an mHealth intervention (MI-BP). The MI-BP intervention was developed with the intention of educating and supporting self-monitoring of multiple health behaviors to reduce BP among Black individuals with uncontrolled hypertension recruited from urban EDs and community-based settings. Our goal was to determine the effect of MI-BP on the primary outcome of BP and secondary outcomes of physical activity, sodium intake, medication adherence, and BP control compared to enhanced usual care in a 1-year randomized controlled trial (RCT). We hypothesized that (1) mean systolic BP (SBP) would be significantly lower in the MI-BP arm than in the control group after 1 year (hypothesis 1) and (2) measures of physical activity, sodium intake, medication adherence, and BP control would be significantly better in the MI-BP arm than in the control arm after 1 year (hypothesis 2).

Methods

Overview

This study was a 1-year, 2-group RCT of the MI-BP intervention compared to enhanced usual care. The study was overseen by our Data and Safety Monitoring Board (DSMB). Details on the full study protocol have been previously published [14], but a summary of those procedures follows.

Clinical Setting and Recruitment

All recruitment occurred in Detroit, Michigan, and was primarily conducted at the Detroit Medical Center in the EDs of Detroit Receiving Hospital and Sinai-Grace Hospital. Potentially eligible participants were screened by trained volunteers or by study staff members. Once a potentially eligible participant was identified according to clinical criteria, a research staff member spoke with the treating physician to determine whether they were a good candidate for participation. If so, individuals were informed of the study, screened further, and then consented and enrolled if they were interested and met the eligibility criteria. Additional recruitment occurred at community events where BP screening was conducted, such as mobile health unit visits, health fairs, and other health-related community events. Procedures for these potential participants were the same except for not checking with treating physicians to determine whether our staff should proceed with screening and enrollment.

Eligibility Screening and Consent

Inclusion Criteria

To be eligible to participate in this trial, individuals were required to be Black, between the ages of 25 and 70 years, previously diagnosed with hypertension, have a smartphone compatible with the MI-BP intervention, and have uncontrolled BP (SBP >135 mm Hg) at triage and on repeat measurement using a BpTRU BPM-200 device (Smiths Medical PM, Inc) or Omron HEM 907XL IntelliSense (Omron Healthcare, Inc) at least 1 hour after triage vitals were taken.

Exclusion Criteria

Individuals were excluded from this trial if they were pregnant; had serious existing medical conditions that may make BP control difficult or necessitate frequent hospitalization (ie, previous diagnosis of resistant hypertension, steroid-dependent asthma or emphysema, cirrhosis or hepatic failure, stage-C or stage-D chronic heart failure, stage-IV or stage-V chronic kidney disease, and terminal cancer or ongoing active chemotherapy or radiation therapy); had a history of other serious medical conditions (eg, stroke, dementia, myocardial infarction, or known coronary artery disease); or had a history of alcohol or drug abuse as determined using the Cut down, Annoyed, Guilty, and Eye-opener Adapted to Include Drugs questionnaire (excluded if score was ≥2).

Study Procedures

Baseline Data Collection Visit

After consent and enrollment, participants were scheduled for a return visit 1 to 2 weeks later for baseline data collection at a nearby university building. Transportation to all study visits via taxi or ride-sharing service was offered to anyone requiring transportation assistance. At the baseline visit, a secondary BP screening was conducted to ensure that we were only retaining participants with persistent uncontrolled hypertension in the study. At this time, participants who had an SBP of <130 mm Hg were deemed ineligible and excluded from the study. Next, baseline data were collected. To control response fatigue in the baseline data collection survey, we created 6 different permutations, each with a different order of instruments, which were also balanced within blocks. At this time, participants were also given a prescription for antihypertensive therapy. If needed, referrals to primary care were made by study physicians. In the event that a participant was already taking antihypertensive medications prescribed through a preexisting relationship with a primary care provider (PCP), we contacted their PCP to inform them of our algorithm-based approach to antihypertensive therapy and coordinated with them when medication adjustments were indicated.

Medication Titration and Randomization Visit

At 2 weeks after the baseline visit, participants were assessed for medication titration, the process of adjusting antihypertensive medication dosages to ensure appropriate and optimal treatment. At this time, participants were randomized into 1 of the 2 study arms in the trial. In total, it took approximately 4 weeks for an enrolled participant to be randomized into the study. This month-long de facto washout period was designed to ensure that we were truly reaching individuals with uncontrolled hypertension and who were not just temporarily presenting with elevated BP in the ED. Moreover, our previous experiences conducting work in this setting demonstrated high levels of attrition between ED recruitment and initial follow-up. Delaying randomization also helped ensure identification of individuals who did not intend to fully participate at the outset, increasing the likelihood of randomized participant retention. Trial randomization was stratified by sex in blocks of equal size. Study staff responsible for arm allocation were blinded to block size to prevent contamination. After randomization, all study materials, including any equipment, were distributed to the participants according to the treatment arm. A second titration visit was conducted 6 weeks after randomization, and the need for titration was assessed at each subsequent follow-up visit.

Quarterly Follow-Up Visits

Data collection assessments were conducted at weeks 0, 13, 26, 39, and 52 using a consistent set of study measures. In addition to survey measures, patients were instructed to bring their hypertension medications with them so pill counts could be conducted. As electronic health record data were not available to our study team, all medication data, including prescribed medication names and doses, were self-reported or captured from pill bottles. We also monitored for any potentially harmful renal or metabolic issues at baseline and weeks 26 and 52 and adjusted medications accordingly. To measure sodium intake (a secondary outcome measure of interest), at weeks 0, 26, and 52, participants were given supplies to collect 24-hour urine for sodium measurement. Study staff collected these specimens directly from the participants at their home to improve adherence. All medication titration and study follow-up visits were free; however, participants were responsible for the cost of medications, PCP visits, or copays, as applicable.

Impact of COVID-19 on Study Procedures

In March 2020, the MI-BP trial was closed to new enrollments and in-person data collection due to the COVID-19 pandemic. This necessitated protocol changes in the following weeks and months in an effort to maximize data collection from participants who were enrolled in the study before the pandemic. To

summarize these changes, we pivoted to remote data collection for follow-up assessments via phone or videoconference. This meant that home-monitored BP measurements using study-issued cuffs served as the final outcome measures for participants completing their trial participation between March 2020 and April 2021. In addition, as all in-person participant interaction had been suspended, all laboratory measures were discontinued during the COVID-19 pandemic, and survey-based assessments were conducted verbally by phone or videoconference out of concern for literacy levels among participants. We also removed several instruments from interim follow-up assessments in weeks 13 and 39. Finally, anthropometric assessments, including weight, height, and waist circumference measurements, were self-reported by participants using their own home scales and tape measures. Given the increased reliance on home-based, self-reported data, the chance of missing data from follow-up assessments was greater.

Trial Arms

Participants in this trial were randomized equally to 1 of the 2 treatment arms, which included an enhanced usual care control arm and the MI-BP intervention arm.

Enhanced Usual Care (Control Arm)

Participants in the enhanced usual care group were given a prescription for antihypertensive medications, printed educational materials on hypertension, and a BP monitor for daily use. Participants assigned to the enhanced usual care control group received no further intervention; however, they were asked to take part in all study-specific follow-up visits. The decision to provide home BP cuffs to control participants, above and beyond true usual care, was made to reflect the fact that home BP monitoring is widely accepted as a guideline-based standard of care for individuals being treated for hypertension [6], making it appropriate to include in the usual care arm. We acknowledge that this active control represents a departure from true usual care; however, it does represent an ideal usual care scenario based on current hypertension management guidelines.

MI-BP (Treatment Arm)

Participants randomized to receive the MI-BP intervention were given a prescription for antihypertensive medication, a Bluetooth-enabled pedometer (Fitbit Zip), a BP cuff, and access to the MI-BP mobile app. Participants were asked to use the MI-BP mobile app and related peripheral devices for 12 months.

MI-BP Intervention

Overview

MI-BP is a comprehensive, multicomponent intervention that targets multiple behaviors for managing hypertension via smartphone app, including BP self-monitoring, physical activity tracking, sodium intake tracking, goal setting, educational and motivational messaging, and medication adherence reminders. The MI-BP app was developed by Vibrent Health, a digital health company. Vibrent Health designed the app, study staff web-based portal, and server platforms necessary to support this trial. The MI-BP app was previously described in detail but is summarized in this section [14].

BP Monitoring

To support BP self-monitoring, participants who could use a standard BP cuff (suitable for an arm circumference between 23 and 45 cm) were provided with a Bluetooth-enabled BP cuff (A&D UA-651BLE) that could sync to the MI-BP app. The MI-BP app showed different visualizations of BP over time, including both graph and log form. In the event that a participant required a larger cuff size (between 42 and 60 cm), we provided an extra-large arm monitor (A&D LifeSource UA-789), which was not Bluetooth enabled and required manual data entry. Participants were instructed to measure and sync (or manually enter) their BP to the MI-BP app at home using a commonly accepted home BP-monitoring protocol for a minimum of 3 days per week; however, daily self-monitoring and syncing were encouraged. If participants self-monitored an SBP reading of >180 or <100 mm Hg or a diastolic BP (DBP) reading of >110 mm Hg, they were instructed by the study staff at baseline, as well as by automated notifications within the app at the time of the elevated reading, to check their BP again. If it was still elevated after 3 days, participants were instructed to call the study staff. Participants were also instructed to report to the ED and follow up afterward with a call to the research staff if they were experiencing symptoms of dizziness, chest pain, severe headache, vision changes, or numbness or weakness in the face or extremities.

Physical Activity Monitoring and Tracking

To support physical activity self-monitoring, participants were provided with a Fitbit Zip pedometer that could sync to the MI-BP app, which showed different visualizations (graph and log form) of physical activity data over time. Participants were instructed to wear their Fitbit daily and sync the device at least once per week.

Sodium Intake Monitoring and Tracking

To support sodium intake monitoring, the MI-BP app used a logging approach that encouraged participants to identify their intake of high-sodium foods using a checklist-type log available within the MI-BP app. The checklist comprised 7 categories with 3 to 8 items per category and represented the most common types of high-sodium foods that contribute to high-sodium diets. Although we encouraged users to track their intake of high-sodium foods daily, users were instructed to engage at a minimum in highly focused, 3-day consecutive bouts of logging that were prompted within the MI-BP app.

Goal Setting

Participants received weekly step count goals that were displayed in the MI-BP app and were also delivered via push notifications. On the basis of previous work from our team [15-19], step count goals were gradually incremented and were based on an average of 7 consecutive days of data, during which at least 5 of the days needed to be considered valid. A valid day was defined as >200 steps per day. As we gradually incremented weekly goals, calculated goals never exceeded 600 additional steps over the previous goal. This gradual increment in weekly step count goals was made in an effort to reduce potential adverse events (AEs).

Goal setting for sodium intake was also conducted every 2 to 4 weeks after an intensive 1-week baseline self-monitoring period that was used to calculate the initial goal for each participant. Sodium intake goals were displayed within the app and were also sent via push notifications. Participants were instructed to log their intake of high-sodium foods for a 3-day period approximately 2 weeks after receiving their initial sodium intake goal that limited the number of high-sodium foods to be consumed. When sodium goals were met during a logging period, a new lower sodium intake goal was issued, and participants were asked to log their intake of high-sodium foods 4 weeks later. If the goal was not met, participants were asked to try again in 2 weeks. Additional details on our sodium logging and goal-setting protocols have been published previously [14].

Messaging

MI-BP provided users with 4 different types of messages, which were sent via push notifications and in-app messaging. These included educational messaging focused on hypertension, physical activity, sodium intake, and tips for behavior change and overcoming barriers to behavior change; motivational messaging; tailored messaging, including tips for overcoming specific self-reported barriers to behavior change and daily medication reminders as well as tailored feedback responsive to whether participants were meeting their set goals; and customizable daily medication reminders. In addition to the customizable daily medication reminders, MI-BP sent approximately 7 messages per week. Message content, frequency, and timing were varied and tailored wherever possible to maximize user engagement.

Measures

We collected a variety of measures throughout this study. Full details of our study measures have been published previously [14]; however, those discussed in this paper are described in this section. Data were collected at baseline; medication titration visits at weeks 2 and 8; and planned follow-up assessments at weeks 13, 26, 39, and 52. Although most measures were collected at all time points, some were collected less frequently due to participant burden and cost of administration. The primary outcome measure of BP was collected at the clinic (or at home with study issued BP cuffs during the COVID-19 pandemic) and was assessed at every study visit by a trained study staff member using a BpTRU BPM-200 or Omron HEM 907XL IntelliSense BP-monitoring device. Secondary outcome measures included the following: physical activity as measured using the International Physical Activity Questionnaire–Short Form (IPAQ-SF) [20]; sodium intake as measured using the Block Sodium Screener (BSS) [21] as well as a 24-hour urine sodium test; self-reported medication adherence using the Adherence to Refills and Medication Scale (ARMS-14) [22]; and self-efficacy for changing targeted behaviors, including physical activity via the Self-Efficacy for Exercise Behaviors (SEEB) scale [23] and medication adherence via the Medication Adherence Self-Efficacy Scale (MASES) [24], as well as diet using an investigator-developed 11-item instrument assessing confidence in reducing sodium consumption, avoiding high-fat foods, avoiding sugar-sweetened beverages, and improving vegetable and legume intake. Additional measures included hypertension knowledge measured by the Hypertension Evaluation of Lifestyle and Management (HELM) scale [25]; health literacy measured by the Rapid Assessment of Adult Literacy in Medicine–Short Form (REALM-SF) [26]; patient activation measured by the Patient Activation Measure (PAM) [27], and health-related quality of life measured by the Short Form–12 (SF-12) [28]. In addition to instruments assessing physical activity, sodium intake, and clinic-measured BP, we analyzed related study data from MI-BP treatment arm participants collected in the app.

Statistical Analysis

Sample Size

As stated in our study protocol [14], our sample size was initially developed with 2 co–primary outcomes: SBP measured continuously and SBP control (defined dichotomously as either above or below the SBP target of 130 mm Hg), which is a more conservative measure. After experiencing sustained challenges with recruitment, the more conservative dichotomous BP control measure was dropped as a co–primary outcome. This necessitated a recalculation in sample size based solely on continuously measured SBP [29]. Due to a lack of similar studies available at the time, we estimated a drop of 10 and 17 mm Hg points in SBP in the usual care and MI-BP arms, respectively, at the end of the trial, based on estimates derived from our own previous work [30]. A constant between-subject SD of 10 mm Hg was assumed, along with an intrasubject correlation of 0.5 [31]. With 121 participants per arm, these estimates would allow us to detect a group-by-time interaction with power of >95% at a 5% level of significance. Allowing for 20% attrition, we sought to recruit 152 participants per study arm for a total of 304 participants.

Analysis Plan

Descriptive statistics were calculated for demographic variables and baseline measures. To ensure balance across study arms, these measures were compared using 2-tailed *t* tests, Wilcoxon rank sum tests, or chi-square tests, as appropriate. Linear mixed models were used to investigate differences in change in the outcomes between study arms, with time, study arm, and their interaction as primary covariates. For all outcomes, time was entered as a categorical covariate. The models were further adjusted for age and sex. For the BP outcomes (SBP and DBP), a second set of models was explored, where time was entered as a linear term to capture the rate of change in the outcomes. All models included a random intercept to account for intrasubject correlation. Square root transformations were used for the IPAQ-SF and BSS, and a log transformation was applied to the ARMS-14 before running the linear mixed models to better meet model assumptions.

To investigate whether dropout was associated with any covariates, a time-to-dropout analysis was carried out using a Cox regression model. As this study was partially conducted during the COVID-19 pandemic, we wanted to consider the impact of COVID-19 on dropout. To that end, we defined a new variable, *COVID group*, for each individual at each time point. If the event time (eg, week 13) of individual assessments was before 3 PM on March 16, 2020, we considered these

records as *Before COVID-19*. Otherwise, we considered the records as *During COVID-19*. Thus, the COVID-19 group was modeled as a time-dependent covariate in the Cox model. All statistical analyses were carried out in SAS (version 9.4; SAS Institute).

Ethical Considerations

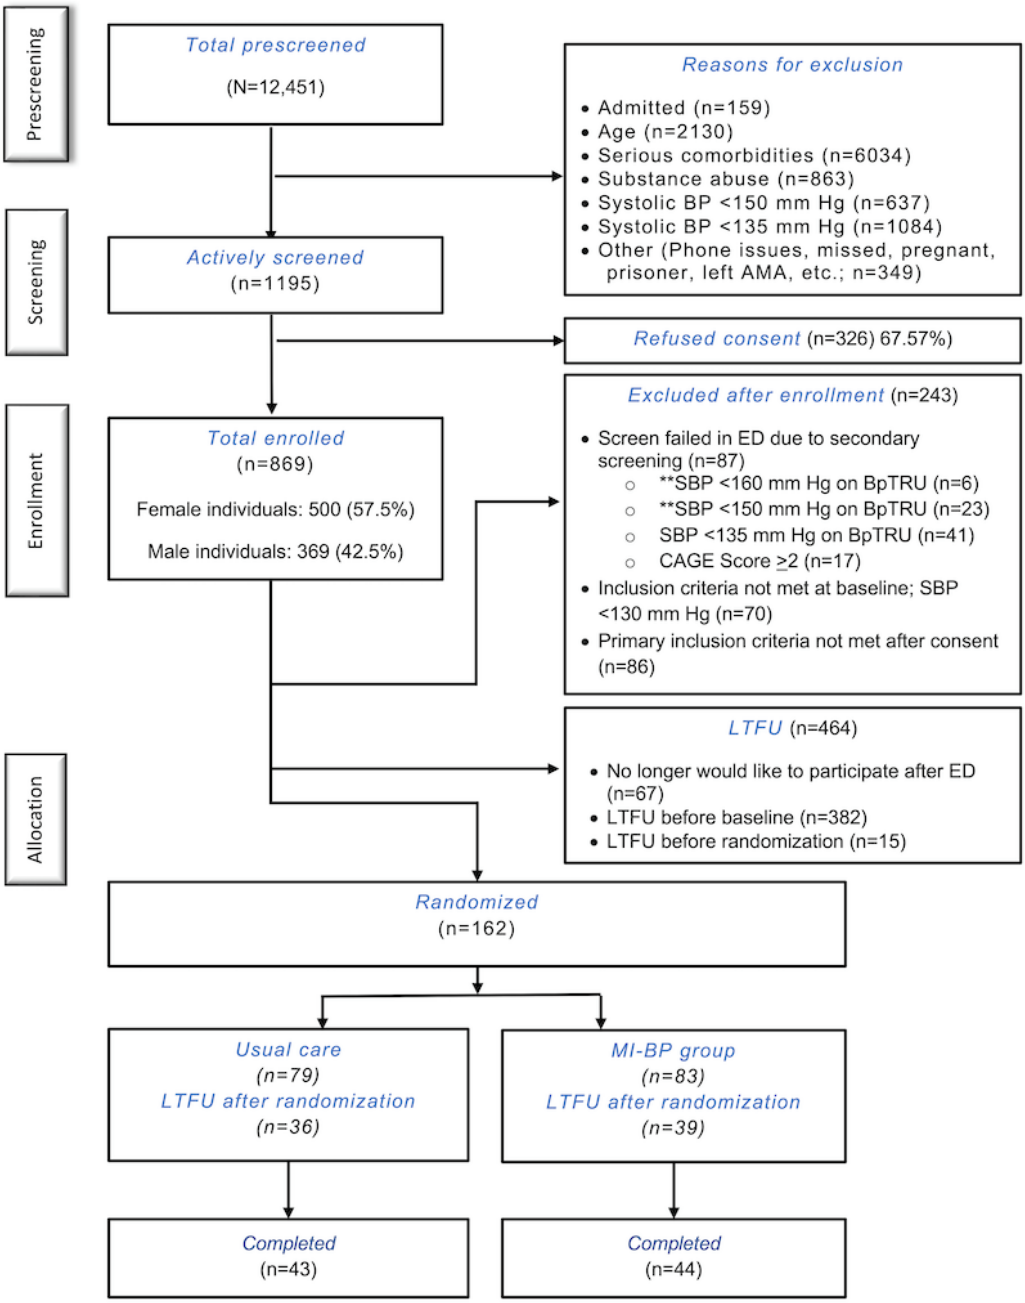
The methods for this study were approved by the institutional review boards (IRBs) at both Wayne State University (WSU; IRB 040416M1F) and the University of Michigan (HUM00114202). All participants provided written informed consent before enrollment. Participants received financial incentives to take part in this study, with each visit individually incentivized, and could earn up to US $275 over the course of 1 year. To protect the privacy and confidentiality of participants, all data are reported in the aggregate and no identifiable information is presented here.

Results

Trial Recruitment

In total, we prescreened 12,451 individuals, predominantly in ED settings (n=12,089, 97.09% in EDs; n=169, 1.36% from community events; and n=193, 1.55% from mobile health units), of whom 1195 (9.6%) were preliminarily eligible for participation. Of those 1195 participants, 869 (72.72%) were consented and enrolled in this study. Most enrolled participants were excluded after enrollment (before randomization) for failing the secondary screening in the ED, not meeting the inclusion criteria at baseline, or not meeting the primary inclusion criteria after consent (243/869, 28%); lost to follow-up before randomization (416/869, 47.9%); or scheduled for baseline or randomization visits that were halted due to the COVID-19 pandemic (48/869, 5.5%). Figure 1 shows the CONSORT (Consolidated Standards of Reporting Trials) diagram of participant flow through the trial. Due to the COVID-19 pandemic, in March 2020, ED recruitment for the trial was suspended precluding new enrollments from the ED. While we were able to eventually transition to community-based recruitment using mobile health units under an IRB-approved protocol amendment within 9 months of this, screening was severely reduced, and no new randomizations occurred. These considerations, combined with the challenge of keeping participants engaged using remote follow-up, prompted a decision by the study team, made in conjunction with our DSMB, to end recruitment for this study in January 2022. Ultimately, we randomized 162 participants to the MI-BP trial.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) diagram showing participant recruitment and retention. **Reflects secondary blood pressure (BP) criteria in the previous protocol. AMA: against medical advice; CAGE: Cut down, Annoyed, Guilty, and Eye-opener; ED: emergency department; LTFU: lost to follow-up; mHealth: mobile health; SBP: systolic blood pressure.



Participant Characteristics

The 162 participants randomized to this trial (n=79, 48.8% to usual care and n=83, 51.2% to the MI-BP intervention) were predominantly female (n=97, 59.9%) and were, on average, aged 48.3 (SD 9.3; range 29-68) years. As race was an inclusion criterion, 100% (162/162) of our participants were Black individuals. Participants were characterized by being single (86/162, 53.1%) and employed (97/162, 59.9%) and having a high school education or lower (90/162, 55.6%) and an average household income of <US $25,000 (73/162, 45.1%). Table 1 shows participant characteristics as well as summary baseline measures stratified by study arm.

Effect of MI-BP on Outcomes

BP Outcome

For our primary outcome of SBP, sex- and age-adjusted average baseline SBP was comparable between the groups (MI-BP group mean 153.92 mm Hg, SD 2.10; enhanced usual care group mean 153.96 mm Hg, SD 2.15; *P*=.99). Both groups saw a mostly steady and similar decline in SBP over the 12-month intervention (unadjusted means shown in Figure 2A). Table 2 shows a model-based assessment of pairwise differences in adjusted mean SBP for each study arm. At week 52, compared to baseline, the MI-BP group exhibited a 22.5 mm Hg decrease (SE 3.35 mm Hg; *P*<.001), and the control group exhibited a 24.12 mm Hg decrease (SE 3.25 mm Hg; *P*<.001) in average estimated SBP adjusted for age and sex. The average declines were not significantly different between the groups (time-by-arm interaction: *P*=.99). A regression model with a linear time term estimated the rate of decline in the MI-BP group to be 0.3 mm Hg per week (SE 0.05 mm Hg/wk; *P*<.001) and 0.34 mm Hg per week (SE 0.05 mm Hg/wk; *P*<.001) in the control group adjusted for age and sex. Again, these rates were not significantly different between the groups (interaction: *P*=.60; Table S1 in Multimedia Appendix 1). At week 52, overall 58% (19/33) of participants in the intervention group had controlled BP (secondary outcome, defined as SBP <130 mm Hg), whereas 53% (18/34) of participants in the nonintervention group achieved BP control. This difference was not statistically significant (*P*=.89).

Figure 2. Unadjusted mean trajectories (with 95% confidence interval) for (A) systolic blood pressure (SBP) and (B) diastolic blood pressure (DBP) by study arm.

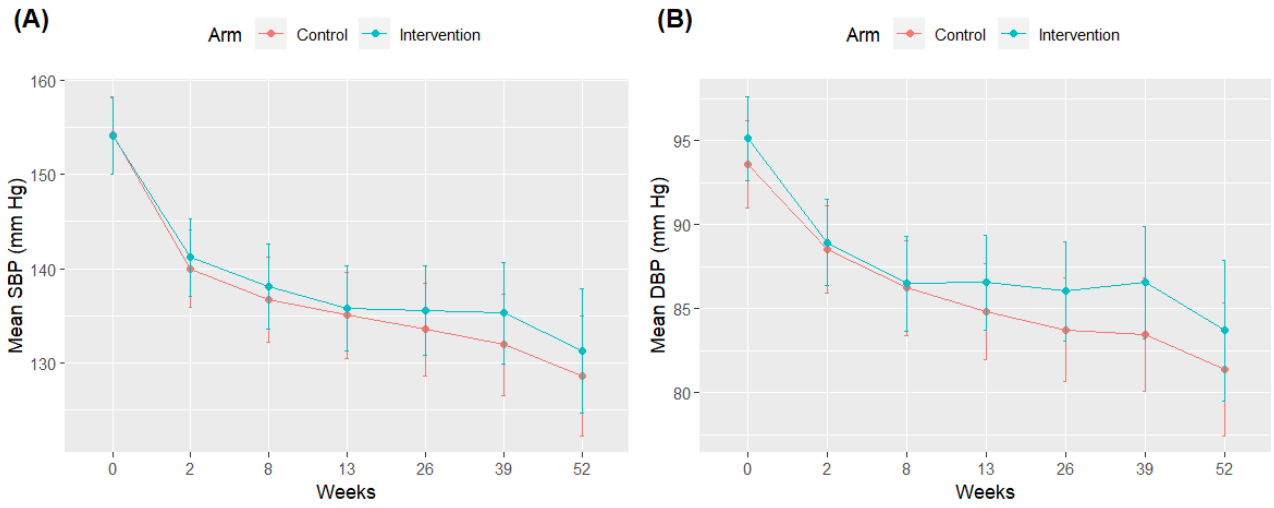

Table 2. Estimated pairwise mean differences and SEs across time for systolic blood pressure by study arm.

Comparison	Intervention		Control

39 vs 52 weeks	–5.1723 (3.6255)	.15	–2.8721 (3.5034)	.41

DBP exhibited a very similar pattern to that of SBP (Figure 2B), with the MI-BP and control arms experiencing significant reductions in DBP from baseline to 52 weeks with a 10.20 mm Hg (SE 1.82 mm Hg; *P*<.001) and 11.44 mm Hg (SE 1.75 mm Hg; *P*<.001) estimated average decrease, respectively (Table 3). However, no significant differences were found between the groups (time-by-arm interaction: *P*=.79). Model-based rates of decline were observed in the MI-BP (estimate=0.13 mm Hg/wk; SE 0.03 mm Hg/wk; *P*<.001) and control (estimate=0.17 mm Hg/wk; SE 0.03 mm Hg/wk; *P*<.001; Table S1 in Multimedia Appendix 1) groups. Again, none of these changes were statistically significantly different between the groups (*P*=.21).

Table 3. Estimated pairwise mean differences and SEs across time for diastolic blood pressure by study arm.

Physical Activity

Slight improvements in physical activity over the course of the trial were found for both the MI-BP and enhanced usual care groups as measured using the iPAQ-SF, although the improvements were not statistically significant in general. In the MI-BP group, the age- and sex-adjusted average IPAQ-SF score (after square root transformation) increased by 10.25 metabolic equivalent of task (MET) minutes per week (SE 6.37 MET min/wk; *P*=.11) at 52 weeks, whereas the increase was 10.57 MET minutes per week in the control group (SE 5.87 MET min/wk; *P*=.07; Table S2 in Multimedia Appendix 1). Both groups exhibited fluctuations in the change pattern, where the up-and-down behavior was more prominent in the MI-BP arm (Figure S1 in Multimedia Appendix 2). However, there were no significant differences in the change pattern across the groups (time-by-group interaction: *P*=.93).

Sodium Intake

Figure S2 in Multimedia Appendix 2 shows that mean sodium intake measured using the BSS declined fairly steadily in the MI-BP arm, whereas in the enhanced usual care group, there was a fluctuating pattern in the mean trajectories. However, both arms experienced significant improvements when comparing the baseline with the 52-week values. In the MI-BP group, the average decrease in the adjusted (square root–transformed) BSS score was 0.36 (SE 0.19; *P*=.06), whereas the average decrease in the control arm was 0.60 (SE 0.18; *P*=.001; Table S3 in Multimedia Appendix 1). No significant time-by-group interaction was observed (*P*=.19). We successfully obtained 24-hour urine sodium samples from 136 participants at baseline and 32 participants at 52-week follow-up. In contrast to BSS results, no differential improvements in sodium concentration in 24-hour urine sodium samples were found across arms (time-by-group interaction, *P*=.56).

Medication Adherence

Both treatment groups experienced significant improvements in medication adherence as measured using the ARMS-14 over 1 year (Figure S3 in Multimedia Appendix 2). The average estimated decrease at 52 weeks compared to the baseline in the log-transformed ARMS-14 score in the MI-BP group was 0.20 (SE 0.04; *P*<.001), whereas the corresponding decrease in the control arm was 0.15 (SE 0.04; *P*<.001; Table S4 in Multimedia Appendix 1). No significant difference in the pattern of change was observed (time-by-group interaction: *P*=.30).

Self-Efficacy

Self-efficacies were measured in 4 different ways related to attitude and habits of exercise, medication adherence, and eating habits. Figures S4A and S4B in Multimedia Appendix 2 show

that the trajectories of exercise self-efficacy as measured using 2 subscales of the Self-Efficacy for Exercise Behaviors scale (Sticking to It and Making Time for Exercise) were similar in both study arms. However, in neither arm did the average scores change significantly. In the MI-BP arm, the average estimated decrease in the Sticking to It subscale score at week 52 from the baseline was 0.11 (SE 0.20; *P*=.59), whereas the corresponding decrease in the control arm was 0.01 (SE 0.18; *P*=.94). For the Making Time for Exercise subscale score, the adjusted mean decrease was 0.09 (SE 0.22; *P*=.69) in the MI-BP arm and 0.11 (SE 0.20; *P*=.58) in the control arm (Tables S5 and S6 in Multimedia Appendix 1). As with other outcomes, no significant time-by-group interactions were found (*P*=.88 and *P*=.94 for Sticking to It and Making Time for Exercise, respectively).

For medication adherence self-efficacy (MASES), statistically significant improvements were observed in both arms as the trajectories seemed to follow similar patterns (Figure S4C Multimedia Appendix 2). The increase in the estimated average MASES score in the MI-BP arm was 0.38 (SE 0.16; *P*=.02), and the corresponding increase in the control arm was 0.37 (SE 0.15; *P*=.02; Table S7 in Multimedia Appendix 1). No significant time-by-arm interaction was observed, suggesting no differences in the pattern of change between the groups (overall time-by-group interaction: *P*=.47).

Self-efficacy for eating behaviors showed worse values compared to the baseline (estimated mean 43.95) in the intervention group at week 52 as the estimated mean decreased from a baseline value of 43.95 to 40.04 at week 52 (estimated mean reduction 3.91; SE 1.47; *P*=.008). In contrast, in the control arm, the score increased slightly from baseline (mean 41.64) to week 52 (mean 43.69), although this improvement was not statistically significant (estimated mean improvement 2.05; SE 1.4; *P*=.14; Table S8 in Multimedia Appendix 1; Figure S4D in Multimedia Appendix 2). This was the only outcome for which a significant time-by-group interaction was observed (*P*=.04), albeit in the unintended direction.

Trial Retention

Over the course of the 12-month RCT, we saw steady rates of participant dropout, and only 67 participants (n=33, 49% in the intervention group and n=34, 51% in the control group) remained at the end of the 1-year study (retention rate=67/162, 41.4%). The greatest dropout rates were observed early in the trial between the week 2 and week 8 visits, followed by the periods later in the trial between the week 26 and week 39 visits and between the week 39 and week 52 visits.

Dropout Analysis and Effect of COVID-19

Steady dropout was observed in both treatment arms over the study period, amounting to 60% (50/83) and 57% (45/79) dropout in the MI-BP and control arms, respectively, at the end of study. These dropout patterns were very similar in both study arms (Figure 3). In the time-to-dropout analysis, marital status and COVID-19 group turned out to be statistically significant at the 5% level, with the post–COVID-19 phase showing a strong propensity (Table 4) for dropout (hazard ratio=2.12; SE 0.23; *P*=.001).

Figure 3. Dropout history over the course of the trial by study arm.

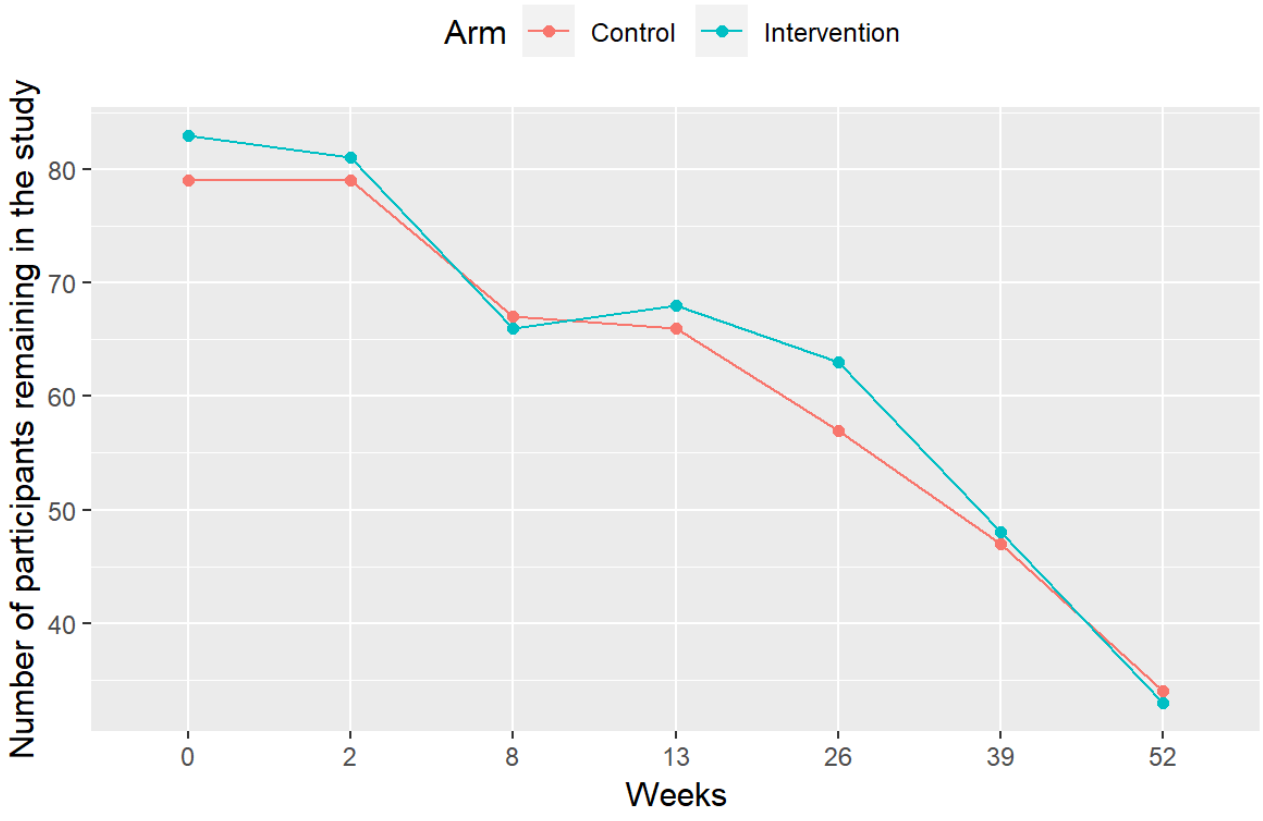

Table 4. Time-to-dropout results based on Cox regression model.

Variable	Hazard ratio (95% CI)	*P* value
COVID-19 group (reference: before COVID-19)	2.120 (1.353-3.322)	.001
Age	0.983 (0.959-1.008)	.18
Marital status (reference: divorced, widowed, or separated)		
Married or cohabitating	1.998 (1.049-3.802)	.04
Single or never been married	1.820 (1.021-3.247)	.04
Sex (reference: male)	0.912 (0.604-1.379)	.66

AE Reporting

AEs for this trial were all determined to be cardiovascular in nature. A total of 15 AEs of SBP>180 were reported. All were determined to be unrelated to the study, and all were reported to both the WSU IRB and the study DSMB. In addition, during the course of this trial, 3 serious AEs (SAEs) were reported by research participants. All 3 SAEs were determined to be unexpected and unrelated to the MI-BP intervention, and all 3 patients recovered with treatment. SAEs reported in this trial included 2 instances of non–ST-elevation myocardial infarction and 1 instance of cerebral visual impairment. All SAEs were reported to both the WSU IRB and the study DSMB.

Discussion

Principal Findings

Results from this study suggest that, compared to our enhanced usual care control group, the MI-BP intervention did not have any significant effects on participants in this study, including the primary outcome measure of BP or the secondary outcome measures of physical activity, sodium intake, medication adherence, and BP control. Even though the trial was underpowered to detect differences due to stopping recruitment early because of the COVID-19 pandemic, trends to suggest that MI-BP had an effect on these outcomes compared to enhanced usual care were not evident. However, it is important to note that, despite a high overall dropout rate, participants in both groups experienced significant reductions in SBP, DBP, and sodium intake, as well as significant increases in physical activity and medication adherence, from baseline to 1 year. This speaks to the general benefit of proactive outreach and engagement focused on cardiometabolic risk reduction in urban-dwelling, low-socioeconomic-status Black populations.

Our findings are similar to those of the recent work by Pletcher et al [32], who found no benefit in terms of SBP reduction for BP self-monitoring using a connected smartphone app compared to standard BP self-monitoring over 6 months. As in our trial, Pletcher et al [32] found that in a sample of 2101 patients with uncontrolled BP, at 6 months, both the intervention and control arms experienced comparable and significant decreases in SBP (–10.8, SD 18 mm Hg vs –10.6, SD 18 mm Hg in the enhanced vs standard group, respectively) with no significant differences between the groups. While our findings and those of Pletcher et al [32] stand in contrast to those of other work suggesting benefit of mHealth apps in reducing BP [14], it should be noted that the evidence base for app-supported self-monitoring of BP is often plagued by short duration and follow-up, small sample sizes, and inconsistent comparison groups, which undermines the quality of research in this area. Moreover, it is important to remember that our control group was not assigned to usual care alone; rather, we used an active control condition where control group participants received a home BP monitor in addition to antihypertensive medication and standard educational materials. This may have led to greater reduction in BP than may have been experienced with standard usual care alone.

The high dropout rate (95/162, 58.6%) among enrolled and randomized participants warrants further mention. While this dropout rate is higher than those in other studies that involved similar digital interventions for monitoring and controlling BP or other study populations [33-35], high dropout rates in studies that deploy digital health interventions are quite common in the mHealth domain and range upward of 80% attrition, with approximately 49% attrition in observational studies and 40% attrition in RCTs. In his seminal piece, Eysenbach [36] described the law of attrition for eHealth interventions, which constitutes the phenomenon of participants dropping out of a research trial before completion or stopping their use of the trial intervention before the study is over. This phenomenon has been described time and time again in the digital health literature and has been specifically evident for mHealth interventions focused on physical activity [37,38], diet [39], and medication adherence (all targeted behaviors in the MI-BP intervention) [40]. Recent studies have demonstrated that a higher dropout rate is even more common for digital health intervention studies involving Black participants [41]. For instance, Jonassaint et al [42] suggested that it may be important to develop a digital intervention system that is culturally tailored to historically marginalized groups. However, our intervention was culturally tailored to the Black community, suggesting room for other explanations for the high dropout rate. We did include a wash-out period to screen out individuals who did not truly have uncontrolled hypertension and identify those who were not fully vested in trial participation, but neither of these is a culture-specific approach. Michaud et al [43] suggested that a high-incentive program may be effective in decreasing the attrition rate for digital health interventions for increasing physical activity in Black women. Although we incorporated a distributed incentive system, which rewarded participants for each visit completion, this was not sufficient to prevent the high dropout rates that echoed those in similar digital intervention studies. It should be mentioned that, particularly when working with historically excluded and underresourced communities, the notion of providing higher incentives to encourage

participation is a hotly contested topic as some believe that it may be considered coercive; however, study incentives are meant to acknowledge participant burden, such as loss of time, and differentially incentivizing study participants based on level of advantage introduces its own host of ethical conundrums.

Our findings, coupled with the high dropout rates found in similar studies, suggest that these types of mHealth behavior change interventions may not be a complete solution that can promote behavior change and improve health outcomes in this population. Rather, mHealth may have the greatest potential as part of a suite of approaches available to health care professionals and patients. It is clear that mHealth solutions are here to stay, but the goal of future research should be to identify the use cases and implementation strategies and factors that contribute to optimization. Moreover, the expectation of high dropout rates for mHealth interventions, especially when working with challenging populations with considerable barriers caused by social determinants of health, should be assumed and addressed at the outset. This is important as underpowered samples compromise the quality of research studies and the evidence base; however, review panels for different funding mechanisms often look unfavorably on proposed research studies that anticipate very high dropout rates. This may cause researchers to intentionally underestimate attrition, which may compromise the research study as a whole.

Limitations

As with all research, this study was not without limitations. Perhaps the largest limitation was the undeniable negative impact of the COVID-19 pandemic, which caused us to stop study recruitment early and likely had significant effects on trial participation for those who were already randomized to the study. Combined with a high dropout rate, early study termination led to an underpowered study, which may have caused us to be unable to find significant differences between the groups. That said, data trends across our participants suggest that both groups experienced significant improvement in both primary and secondary outcomes, and if there really was a benefit of the MI-BP intervention, it was likely much smaller than our initially projected effect size. Given the absence of an indication of differential improvements, future efforts would be better served simply focusing on scalable outreach and engagement programs that facilitate better care of Black patients with uncontrolled hypertension.

We should also note that, although we consented and enrolled 869 individuals in the ED and other community-based settings, 464 (53.4%) were considered lost to follow-up before randomization. Most of this loss to follow-up occurred before the baseline visit (Figure 1). Although we cannot say for certain why there was such tremendous loss to follow-up before randomization, our de facto wash-out period helped remove individuals who were not fully committed to participation in the trial. Given the large loss to follow-up before randomization, we most certainly had some degree of selection bias in our randomized sample. In addition to our loss to follow-up before randomization, as discussed, we experienced high dropout rates in our trial arms, which serves as a potential threat to the validity and generalizability of our findings. We also note that our quarterly follow-up assessments may have helped some participants stay engaged with the intervention and trial, masking even further attrition that may have been experienced without frequent contact. As suggested previously, very high rates of attrition are not uncommon in mHealth studies, and our trial was no exception. More research on how to best engage participants in these types of interventions and trials is desperately needed as the mechanisms that drive engagement are poorly understood. Moreover, our work was met with additional challenges as we are positioned in a community where social determinants of health play an enormous role in the daily lives of our participants. These additional challenges are sure to have contributed to our high attrition rates. While attrition may serve as a threat to the validity of our findings, it is important to remember that this is often the reality of working with populations of individuals who experience health inequity. Rather than shying away from work in this area due to methodological and statistical concerns, we must continue to conduct research with populations of individuals with great need to address inequities.

Conclusions

Although we did not find increased improvement in outcomes for participants using MI-BP compared to enhanced usual care, we are encouraged to see that proactive outreach in a sample of Black individuals with uncontrolled hypertension recruited from EDs and other community-based settings had a significant effect in improving hypertension-related outcomes regardless of treatment group. Given that mHealth approaches for chronic disease self-management are becoming more commonplace, continued work is needed to understand how to better engage and retain users as well as how to better position these types of interventions within a suite of treatment options available to patients. Moreover, participant dropout in mHealth interventions remains high in many studies, including ours, and this phenomenon must be further explored before optimal mHealth use can be achieved.

Acknowledgments

This study was funded by the National Heart, Lung, and Blood Institute at the National Institutes of Health (1R01HL127215-01A1). The authors of this study wish to thank Drs John Flack, MD; Richard Sinert, DO; and Philip Boonstra, PhD, for their service on the MI-BP trial Data Safety and Monitoring Board. Their support of this trial and their guidance were unparalleled and much appreciated. The authors also wish to thank Dr Paula Einhorn, the program officer at the National Heart, Lung, and Blood Institute, for her support. Additional thanks go to Leah Huang and Alexandria Degner for editing assistance as well as Lilly Pritula and Judy Connelly for administrative and grant management support.

Abstract

Background: The use of digital interventions by patients for remote monitoring and management of health and disease is increasing. This observational study examined the feasibility, use, and safety of a digital smartphone app for routine monitoring of blood pressure (BP), medication, and symptoms of COVID-19 during the COVID-19 pandemic.

Objective: The objective of this study was to deploy and test electronic data recording using a smartphone app developed for routine monitoring of BP in patients with primary hypertension. We tested the app for ease of data entry in BP management and tracking symptoms of new-onset COVID-19 to determine if participants found this app approach useful and sustainable.

Methods: This remote, decentralized, 12-week, prospective, observational study was conducted in a community setting within the United States. Participants were approached and recruited from affiliated sites where they were enrolled in an ongoing remote decentralized study (CURE-19) of participants experiencing the COVID-19 pandemic. Potential participants were asked to complete a digital screener to determine eligibility and given informed consent forms to read and consent to using the Curebase digital platform. Following enrollment, participants downloaded the digital app to their smartphones for all data collection. Participants recorded daily BP, associated medication use, and emergent symptoms associated with SARS-CoV-2 infection. In addition, usability (adherence, acceptability, and user experience) was assessed using standard survey questions. Adverse events were collected based on participant self-report. Compliance and engagement were determined from user data entry rates. Feasibility and participant feedback were assessed upon study completion using the User Experience Questionnaire.

Results: Of the 389 participants who enrolled in and completed the study, 380 (98%) participants downloaded and entered BP routines in week 1. App engagement remained high; 239 (62.9%) of the 380 participants remained in the study for the full 12-week observation period, and 201 (84.1%) of the 239 participants entered full BP routines into the digital app 80% or more of the time. The smartphone app scored an overall positive evaluation as assessed by the User Experience Questionnaire and was benchmarked as “excellent” for domains of perspicuity, efficiency, and dependability and “above average” for domains of attractiveness and stimulation. Highly adherent participants with hypertension demonstrated well-controlled BP, with no significant changes in average systolic or diastolic BP between week 1 and week 12 (all $P>.05$). Participants were able to record BP medications and symptoms of SARS-CoV-2 infection. No adverse events attributable to the use of the smartphone app were reported during the observational period.

Conclusions: The high retention, engagement and acceptability and positive feedback in this study demonstrates that routine monitoring of BP and medications using a smartphone app is feasible for patients with hypertension in a community setting. Remote monitoring of BP and data collection could be coupled with hypertensive medication in a combination product (drug+digital) for precision management of hypertension.

Introduction

Hypertension is the leading preventable cause of premature death worldwide [1]. Prevalence of hypertension in the United States is 44% to 49% with an estimated 116 million having the disease [2]. Physician inertia (inadequate up-titration of treatment, especially from monotherapy) and poor patient adherence to treatment (especially when based on multiple pills) are now recognized as major factors contributing to poor blood pressure (BP) control [1,3,4].

During the COVID-19 pandemic, social distancing was a priority measure to limit infection in the general population. This measure alongside the redeployment of clinicians to frontline medicine restricted the medical management of hypertension. In turn, this led to the desire to move as much medical management as possible to arms-length support. To meet this need, health care providers rapidly moved to remote monitoring and patient engagement tools where possible. This trend gained momentum, and as a result, over the past 3 years, a 38-fold increase in the use of remote communication technology to deliver health care services (telehealth) in the United States has been observed [5]. This, alongside a strong patient preference to use telehealth services for ordering medications, clinical visit preparation, and receiving educational material and test results, suggests that widespread adoption of telehealth services by health care providers, insurance companies, and patients will continue [6]. Digitization and automation of these services not only can increase patient access to health services but can also build efficiencies within the health care system.

These recent changes have occurred against a backdrop of longer-term technical developments, allowing the delivery of personalized drug treatment to an individual to get much closer to being feasible. This; the use of electronic diaries; and eventually, as more data are collected over time, decision support by mobile apps, could make that a reality. Our team (Closed Loop Medicine Ltd [CLM]) has expertise in the design and development of electronic apps to develop patient treatment solutions that allow combinations of drug and nondrug therapies. One such solution is a smartphone app created by CLM and coproduced by patients through patient engagement and user testing. This prototype app allows patients' BP diary entries, collection of hypertensive adverse drug reactions, and other patient-reported data to be routed to a study database for analysis and surveillance.

When the full scale of the COVID-19 pandemic became apparent, we responded by adapting the prototype app to collect COVID-19 symptoms and hypertension drug regimen information, using the existing patient experience and data collection technology. This corresponded to our early design thinking for a general-purpose platform. The app was made available to study participants through Google and Apple app stores. This allowed deployment of the app into the community setting within the United States in an observational study facilitated by our study partner Curebase. Additional data collection and integration components and a financial reconciliation program were developed to facilitate the study's operational aspects.

The information gained from this study regarding BP measurements, type of drug taken and symptom data, and the learnings and experience of delivering this study will inform future product development plans and future iterations of the hypertension platform to best meet the needs of health care providers and patients. Furthermore, the information gained will provide evidence that digitization of health care is feasible and a valid means of remote management of hypertension within the existing health care system.

Therefore, the observational study aimed to rapidly modify, deploy, and test a digital smartphone app for routine monitoring of BP, BP-associated medications, and symptoms of SARS-CoV-2 infection in the community setting during the COVID-19 pandemic. This testing would provide valuable information for further development of the app before use in future interventional clinical trials. Alongside this, we examined core interactions and use of the app by patients with hypertension, assessed by participant engagement, compliance, and a User Experience Questionnaire (UEQ) [7]. From a clinical point of view, we assessed BP control in a community setting within the United States and whether BP drug use or level of BP control affected the risk of SAR-CoV-2 infection. We also assessed the safety of participants using the app. In addition, this study established a well-defined cohort of patients ready for recruitment into an interventional trial, should we, or other research groups, need this on account of new insights into COVID-19 and the requirement for rapid study execution.

Methods

Personalized Electronic Record Development and Deployment

A mobile app was created for use in this observational study setting. The app was developed as a data collection interface and modified to additionally collect COVID-19 symptoms as well as current antihypertensive medications, based on a curated set of hypertension drugs and doses that were identified as potentially impacting COVID-19 symptoms. These modifications, along with the existing prototype app experience and an incentives scheme rewarding patient adherence, were used to promote patient engagement in the data collection process. Table 1 lists the standard behavior change techniques [8] and the corresponding participant engagement features used to encourage data entry in the study. Some of the corresponding

user interfaces used in the study are shown in Multimedia Appendix 1.

As shown in the system diagram (Multimedia Appendix 2), the mobile app was supported by several shared backend services hosted in Amazon Web Services. These were extended to support storage of the new data and to allow the data to be shared with CLM's study partner Curebase. A financial reconciliation service was used, where payment eligibility was calculated on the basis of study participation level, then passed on to Curebase in support of a regularly scheduled payment process.

New Google and Apple app store entries were created and configured so that patients in the United States were able to install and run the app. Patient study enrollment was managed using a previously established approach based on a unique patient identifier and an enrollment code shared with the patient, which was then linked to their mobile device. A new set of patient identifiers and enrollment codes was generated and shared with Curebase, which integrated these into their patient training and onboarding process.

Table 1. Participant engagement features.

Behavior changes technique taxonomy [8]	Participant engagement features
Self-monitoring of behavior: Establish a method for the person to monitor and record their behaviors as part of a behavior change strategy.	• Blood pressure monitoring: Enable participants to enter their blood pressure readings into the app. • COVID-19 symptom monitoring: Enable participants to enter any COVID-19 symptoms they experience. • Hypertension medication monitoring: Enable participants to maintain a list of their current hypertensive medications.
Demonstration of the behavior: Provide an observable sample of the performance of the behavior, directly in person or indirectly, for example, through film, pictures, for the person to aspire to or imitate.	• Blood pressure measurement demonstration: Educate participants on the correct way to take consistent blood pressure readings.
Instruction on how to perform a behavior: Advise or agree on how to perform the behavior.	• COVID-19 symptom information: Provide participants with clear information about COVID-19 symptoms so they can correctly identify any symptoms they are experiencing.
Habit formation: Prompt rehearsal and repetition of the behavior in the same context repeatedly so that the context elicits the behavior.	• Morning and evening routine management: Enable consistent routine formation by providing a morning and evening data entry ritual.
Prompts or cues: Introduce or define environmental or social stimulus with the purpose of prompting or cueing the behavior. The prompt or cue would normally occur at the time or place of performance.	• Smartphone reminders: Enable participants to set routine reminders to enter data into the app.
Feedback on outcome of behavior: Monitor and provide feedback on the outcome of performance of the behavior.	• Data history: Provide participants with clear diagrams of previous blood pressure and COVID-19 symptom entries.
Incentive (outcome): Inform that a reward will be delivered if and only if there has been effort or progress in achieving the behavioral outcome.	• Participant incentives: Participants who downloaded the app successfully were given US $10 and then an additional US $10 each week for 12 weeks if all study activities were completed. Participants could continue using the app after the 12 weeks but were not compensated for completion of activities.

Study Design

This remote, decentralized, 12-week, prospective, observational study was conducted in the community with no participant visits to investigational sites during the COVID-19 pandemic. The study consisted of an observational period of 12 weeks, with an optional 12-week extension. Participants recorded daily BP (morning and evening) and associated medication use, as well as any emergent symptoms indicative of SARS-CoV-2 infection.

Participants

Participants were aged 18 years and older with hypertension, defined as receiving prescription drug treatment (minimum of 1 drug) to reduce BP. To take part, participants had to be willing to provide informed consent; be able to speak, read, and comprehend English; and possess a suitable home BP monitoring device (as a BP monitor would not be provided to participants) and a suitable smartphone (to support iOS versions 10.0 [Apple Inc] and newer or Android versions 5.0 [Google] and newer; minimum storage space required to install the digital app) that they could independently use. Main exclusions included any known or suspected COVID-19 symptoms at enrollment, comorbidities incompatible with study participation (ie, that would inhibit completion of daily smartphone app entries), and limited or no understanding of spoken or written English.

Participants were recruited to the study through internet-based recruitment to a larger study called CURE-19 being undertaken by Curebase (contract research organization [CRO]). Study personnel at clinical sites affiliated with the CRO approached and recruited participants from their patient population. Those who were interested in taking part of the study were then screened for eligibility, and if deemed eligible, they continued to the enrollment phase. Digital recruitment methods including

recruitment campaigns through social media and internet advertisement were also used. Potential participants who encountered recruitment information through social media or on the internet expressed interest by clicking on the content, which led them to a study landing page website. To assess eligibility, a digital screener containing relevant questions was used, asking potential participants questions to determine their eligibility. All participants who submitted screeners were asked to provide their email address in order to create an account. Screening responses were automatically analyzed and an outcome for the patient was generated, either eligible or ineligible. If eligible, patients were given informed consent forms to read and were consented using the CRO's digital platform, either remotely on their own personal device or in the presence of study personnel. Electronic signatures were captured and stored electronically in the Curebase platform.

Study Procedures

Following consent, participants were given instructions through the CRO's remote onboarding system to download the digital smartphone app from the app store on their personal smartphone and complete the baseline data entry in the app. In some instances, remote onboarding also included telephone calls as well as emails sent to the participants. Participants were then asked to enter routine daily recordings of BP (morning and evening), BP medication use, and emergent symptoms of SAR-CoV-2 infection for 12 weeks. Following the initial 12-week observational period, participants could continue to an additional optional 12-week extension period. Demographic and adverse event information was collected from participants by self-report and electronic medical records by an electronic case report form. Participants received internet-based surveys to complete in order to collect self-reported data. At the completion of 12 weeks or 24 weeks, the UEQ was sent to the participants as a Google Form to allow participants to give their evaluation of the smartphone app they used during the study.

Outcomes

The main objective of this study was to deploy and test a personalized electronic record in the form of a digital smartphone app to participants with primary hypertension for routine monitoring of BP in a community setting within the United States. We used this app to assess daily BP control within this population. We also assessed interactions with the app over the 12-week observational period, including compliance to BP monitoring routines (percentage of patients entering a BP diary entry on 80% or more occasions) and patient feedback and satisfaction using the smartphone app as assessed by the UEQ. Other outcomes of interest included assessment of antihypertensive medication use and emergent symptoms of SARS-CoV-2 infection including cough, fever, and shortness of breath. The safety of participants in relation to the use of the app was assessed through self-reporting of adverse events (AEs) and serious adverse events (SAEs). Exploratory outcomes included analysis of associations of BP antihypertensive drug use as well as BP level with the incidence of SARS-CoV-2 infection and the severity of COVID-19 outcomes, to determine if antihypertensive drug use or the level of BP control can affect severity of COVID-19 illness or pneumonia.

Statistical Analysis

This study's exploratory nature made finding a specific sample size impractical. Given this study's low risk, there was no cap on enrollment and the intent was to enroll as many participants as possible within the recruitment time period. As this was an observational study, analyses included basic descriptive statistics and statistical tests to assess differences between groups. Analysis groups were defined based on compliance with BP data capture. We planned to analyze patient outcomes, but due to the lack of disease outcomes observed in the study, this was not done. Adherence to BP monitoring routines was assessed by calculating the percentage of patients completing a full BP diary routine entry on 80% or more occasions (a full routine consisted of 3 BP measurements and routines were twice daily—morning and evening). Complete adherence to the digital diary was defined in terms of full routines consisting of morning BP in triplicate with medications summary, or an evening BP triplicate along with a symptoms report.

Ethical Considerations

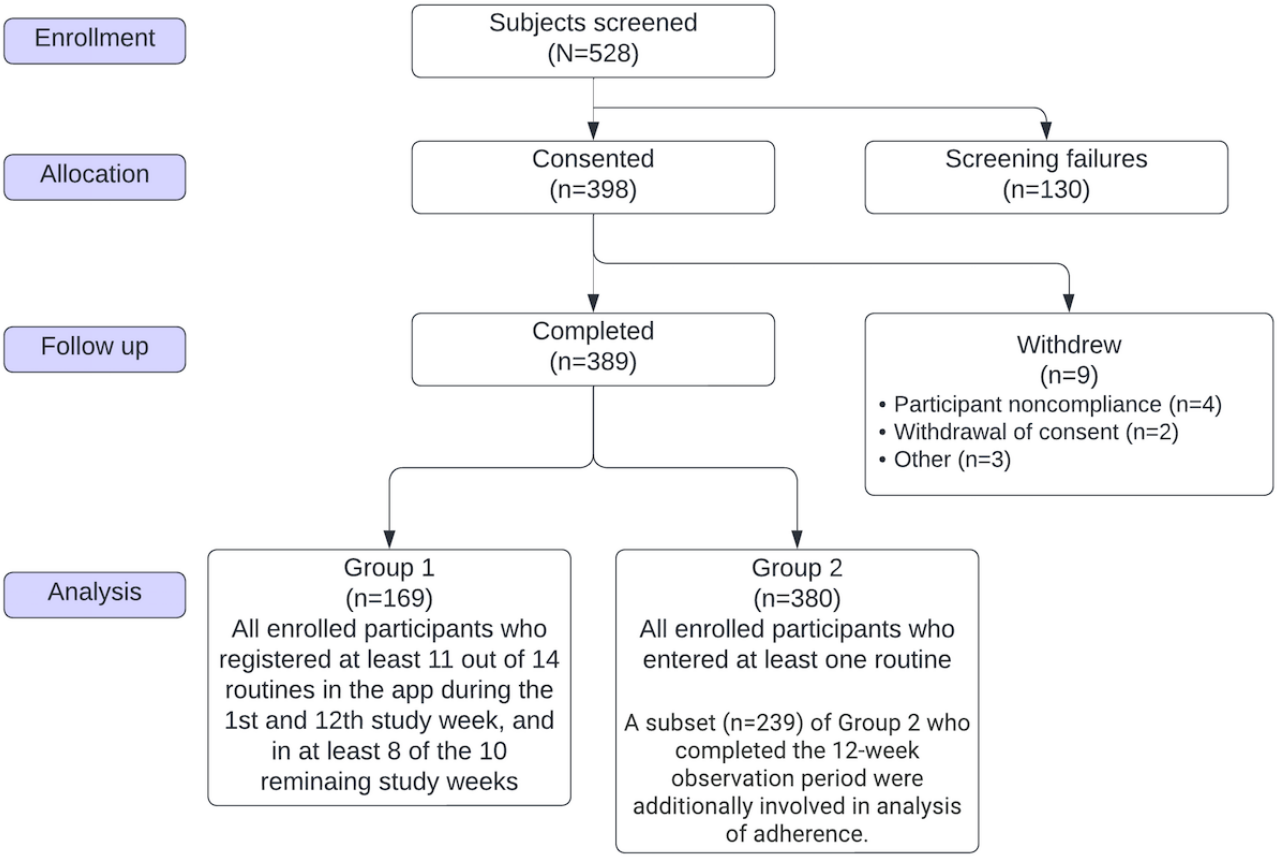
This study was reviewed and approved by IntegReview Institutional Review Board (later became Advarra), which provided a favorable opinion to conduct this study in the United States. Participants who were deemed eligible and after submitting their screeners and signed informed consent forms using electronic signature had their forms stored in the Curebase platform. Participants were able to withdraw from the study at any time. They were able to withdraw consent as well as have all archived clinical data discarded. All information was confidential and data were pseudonymized. Institutional review board–approved small pro rata payments were offered to participants as compensation for participation based on the amount of time in the study and the number of data entry routines completed (US $10 for successfully downloading the app and an additional US $10 for each week of participation up to 12 weeks total).

Results

Overview of Study, Procedures, and Patient Population

A total of 528 participants were screened for entry into the study (Figure 1). From August 2020 to November 2020, a total of 398 patients with hypertension were enrolled, with 389 (98%) participants completing the study. The last participant completed follow-up in February 2021, with 9 participants being lost to follow up. A summary of participant disposition is shown in Figure 1. Participants were analyzed in 2 main groups, with group 1 consisting of 169 participants who were highly compliant at data entry into the smartphone app (participants who registered at least 11 of 14 routines in the app during the 1st and 12th study week, and in at least 8 of the 10 remaining study weeks). At least 80% of routine entries was considered to be the benchmark in this study based on Haynes and colleagues' [9] definition of sufficient adherence of individuals taking antihypertensive medication being ≥80%.

Figure 1. Details of enrollment into the trial.



The other main group, group 2, consisted of 380 participants (overall study population), which included all participants who had entered 1 or more routines into the app. There were 9 participants who did not enter any routines. A subset of group 2 was defined for the purpose of adherence consisting of 239 (62.9%) participants who remained in the study until the end of the 12-week observation period.

A summary of demographic data of all participants is presented in Table 2. The average age of the population was 58.1 (SD 9.9) years in group 1 and 54.1 (SD 12.1) years in group 2. More female participants were present in group 1 (109/169, 64.5%) and group 2 (260/380, 68.4%) than male participants in the study. The average BMI of participants was 33.9 (SD 10.2) kg/m² for group 1 and 34.9 (SD 9.6) kg/m² for group 2. A mix of races and ethnicities were represented, with the majority of participants being White (128/169, 75.7% in group 1 and 283/380, 74.5% in group 2).

[a]Includes all participants who registered at least 11 of 14 routines in the app during the 1st and 12th study week, and in at least 8 of the 10 remaining study weeks.

[b]Includes all enrolled participants who completed the study and entered any routines (9 enrolled participants did not enter any routines).

[c]Participants who identified as 2 or more races and ethnicities.

Adherence and Participant Satisfaction

Central to examining the core participant interactions with the app was the adherence of participants to record their daily routines (Table 3). Out of all 380 enrolled participants (group 2), a total of 248 (65.3%) participants recorded full BP routines 80% or more over the 12-week period and 322 (84.7%) participants recorded any data on 80% or more of the days over the 12-week period. Out of the 239 participants who remained in the study for the full 12-week observation period, 201 (84.1%) participants recorded full BP routines 80% or more over the 12-week period, and 227 (95%) participants of patients recorded any data on 80% or more of the days over the 12-week period. The number of study participants decreased from 380 at week 1 to 239 (62.9%) at week 12. Participants also had the option to continue for an additional 12 weeks resulting in an observational period of up to 23 weeks. The adherence to entry of routines for up to an additional 12 weeks was assessed (Multimedia Appendix 3), which looked at the total number of participants listed for each week, including only those participants who entered routines for the week. Of the 239 participants who completed the 12-week study period, 234 progressed to the optional 12-week extension period and started a 13th week. Furthermore, 155 participants progressed to week 14 and 99 participants continued to week 15. At this point, the number of participants dropped to 57 at week 16 and less than 10% of enrollees (30/380, 7.9% of participants) continued to enter data after week 17. However, it should be noted that the length of participation in the study was also dependent on the remaining time for recruitment and overall study completion;

thus, some participants did not have the opportunity to participate in the extension period or could only participate in a time limited portion.

Participant feedback and satisfaction using the digital diary to record BP routines was assessed using the UEQ. The UEQ uses 26 questions, which are presented as a scale from 1 to 7 with a positive term and a negative term on each end of the scale (eg, annoying=1 to enjoyable=7). The 26 questions are grouped into 6 domains, which are attractiveness, perspicuity, efficiency, dependability, simulation, and novelty. A mean score for each domain is presented, whereby mean values for the domains can range from –3 to +3. Mean values between –0.8 and +0.8 are considered neutral, mean values above 0.8 are considered a positive evaluation, and mean values less than –0.8 are considered a negative evaluation. However, it should be noted that question number 26 from the UEQ that asks if users found the app to be "conservative or innovative" was missing from the dataset. Therefore, there are not any data present for this question, and it does not contribute toward the mean scores for the domain it belonged to (novelty).

Table 3. Participant compliance with remote data collection (number of routines[a] recorded).

Analysis group	Full routine[a]	Full BP[b] routine[c]	Any entry within a day
Group 2 [d] (n=380)			
Over 80% adherence, n (%)	241 (63.4)	248 (65.3)	322 (84.7)
Median adherence (%), median (IQR)	87.1 (69.3-97)	88 (70.3-97)	100 (92.5-100)
Participants who completed 12-week observation period (subset of group 2 [d], n=239)			
Over 80% adherence, n (%)	196 (82)	201 (84.1)	227 (95)
Median adherence (%), median (IQR)	92.8 (83.9-97.6)	94 (84.4-98.2)	100 (98.8-100)

[a]A full routine consists of morning BP in triplicate along with medication summary, or evening BP in triplicate along with a symptom report.

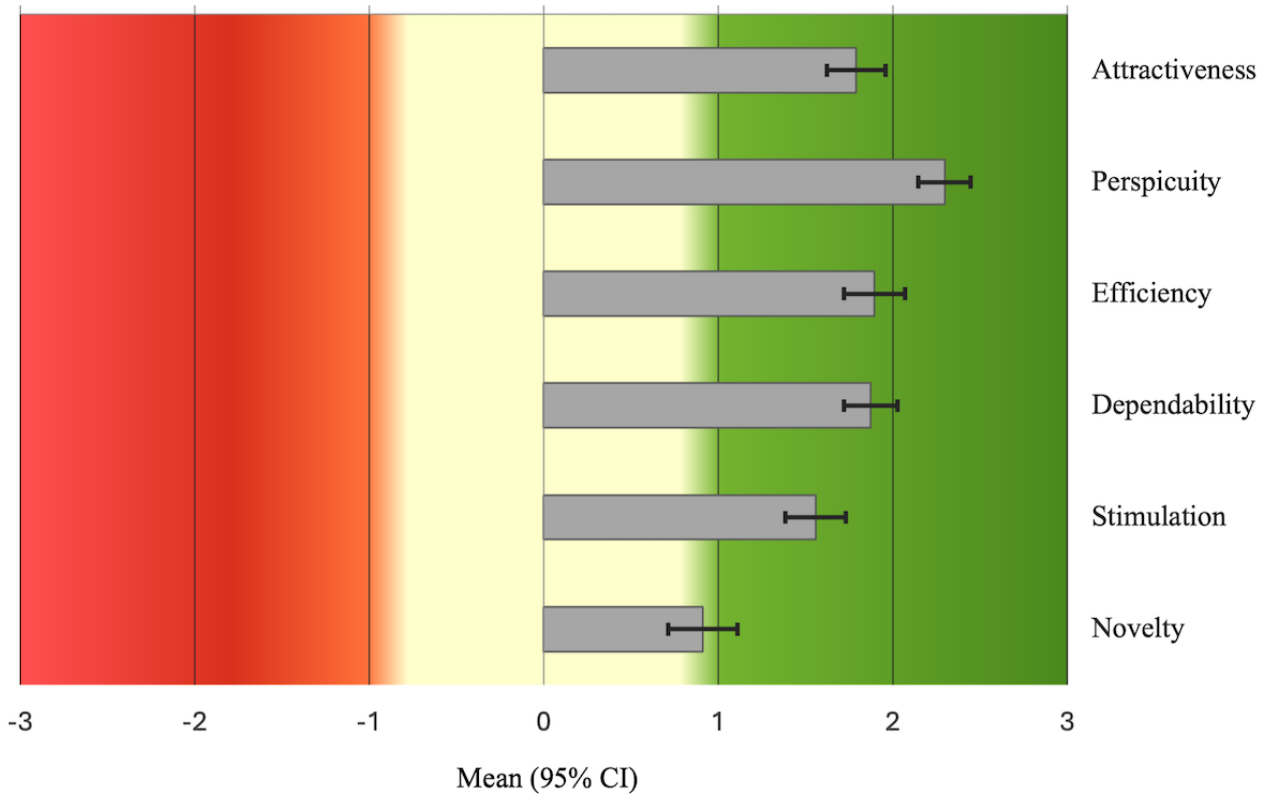
[b]BP: blood pressure.

[c]A full BP routine consists of morning blood pressure in triplicate or evening blood pressure in triplicate.

[d]Includes all enrolled participants who completed the study and entered any routines (9 enrolled participants did not enter any routines).

Almost all single-scored items of the UEQ averaged a positive evaluation (>0.8; only inventive to conventional scored lower [mean score 0.5]), with the majority scoring a very good evaluation (1.5 or above). Figure 2 shows the analysis of the 6 domains representing groups of single items within the UEQ. These results revealed very good to excellent evaluations for attractiveness (mean 1.79, SD 1.29), perspicuity (mean 2.30, SD 1.03), efficiency (mean 1.90, SD 1.43), dependability (mean 1.87, SD 1.09), and stimulation (mean 1.56, SD 1.41). The score for novelty was slightly lower (mean 0.91, SD 1.83) but was still a positive evaluation. The UEQ can be used to benchmark products against other apps, web pages, software, and social networks, with data coming from 21,175 persons involved in 468 studies regarding different products [7]. The digital app in this study was benchmarked as "excellent" (top 10% best results) for perspicuity, efficiency, and dependability and as "good" (10% of results are better and 75% of results are worse) for attractiveness and stimulation. Novelty scored an "above average" UEQ benchmark (25% of results are better and 50% of results are worse).

Figure 2. User Experience Questionnaire scores (all enrolled participants).



BP Control

Changes in self-reported average systolic BP (SBP) and diastolic BP (DBP) during the observational period for group 1 and subgroups within this population are shown in Table 4. No significant changes in average SBP (mean –0.9, SD 10.7 mm Hg; *P*=.30) or DBP (mean –1.0, SD 7.9 mm Hg; *P*=.10) were detected between week 1 and week 12. Subgroup analysis by age (≥65 y and <65 y) and sex also showed no significant changes in BP during the 12-week period (all *P*>.05). Average levels for SBP (week 1: mean 129.5, SD 13.4 mm Hg; week 12: 128.6, SD 13.6 mm Hg) and DBP (week 1: 79.2, SD 9.9 mm Hg; week 12: 78.2, SD 10.8 mm Hg) were below UK and US hypertensive diagnostic thresholds.

Comparison of BP levels measured at week 1 and week 12 by race for group 1 showed no significant changes in SBP or DBP for Black participants or in SBP for White participants (all *P*>.05). A statistically significant change in average DBP between baseline and 12 weeks was observed for White participants (mean –1.6, SD 7.6 mm Hg; *P*=.02). No significant changes in SBP or DBP for participant groupings based on current antihypertensive medication (angiotensin-converting enzyme inhibitor [ACEi] or angiotensin receptor blocker [ARB], β-blockers, or calcium channel blockers [CCB]) between week 1 and week 12 were observed (all *P*>.05), except for a minor decrease in DBP (mean –2.1, SD 6.6 mm Hg; *P*=.01) observed in participants currently taking β-blockers.

Subgroupings of group 1 derived from hypertensive diagnostic thresholds (135/85 mm Hg and 140/90 mm Hg) revealed significant reductions at week 12 in comparison with week 1 in SBP (BP≥135/85 mm Hg group: mean –6.8, SD 10.3 mm Hg, *P*<.001; BP≥140/90 mm Hg group: –9.0, SD 10.8 mm Hg, *P*<.001) and DBP (BP≥135/85 mm Hg group: mean –3.8, SD 10.0 mm Hg, *P*=.02; BP≥140/90 mm Hg group: mean –5.4, SD 9.2 mm Hg, *P*=.008) for participants entering the study with BP equal to or higher that these thresholds. No changes in SBP or DBP over the 12-week period were observed in participants with average BP levels lower than these thresholds, except for a minor increase (mean 2, SD 9.8 mm Hg; *P*=.03) in SBP in participants joining the study with BP<135/85 mm Hg.

Table 4. Change in blood pressure by subgroup (group 1[a]).

Subgroup	Systolic BP[b]					Diastolic BP				
	Participants, n	Week 1, mean (SD)	Week 12, mean (SD)	Week 1-12 change, mean (SD)	*P* value	Participants, n	Week 1, mean (SD)	Week 12, mean (SD)	Week 1-12 change, mean (SD)	*P* value

[a]Includes all participants who registered at least 11 of 14 routines in the app during the 1st and 12th study week, and in at least 8 of the 10 remaining study weeks.

[b]BP: blood pressure.

[c]HBP: home blood pressure.

[d]ACE: angiotensin-converting enzyme.

[e]AR: angiotensin receptor.

Antihypertensive Medication Use

Antihypertensive medication use was examined for participants analyzed in group 1 (which includes all participants who registered at least 11 of 14 routines in the app during the 1st and 12th study week, and in at least 8 of the 10 remaining study weeks). No statistically significant differences in average SBP and DBP were seen for participants grouped by their antihypertensive medications (ACEi or ARB, β-blockers, and CCBs; all $P>.05$; Figures 3 and 4). Over the 12-week observational period, a significant but minor reduction in DBP (mean –2.1, SD 6.6 mm Hg; $P=.01$) in those participants

currently taking β-blockers was observed (Table 3). ACEi or ARB were the most common antihypertensive medication taken (n=116), with smaller numbers of participants taking β-blockers (n=70), CCBs (n=55), or thiazide-type diuretics (n=6; Figure 3).

Further categorization of these participants by current antihypertensive medication revealed no statistically significant differences in average SBP and DBP (Figures 5 and 6). The most commonly taken antihypertensive medications in this population included lisinopril (ACEi; n=55), amlodipine (CCB; n=55), losartan (ARB; n=49), and metoprolol (β-blocker; n=38).

Figure 3. Average systolic blood pressure for each drug combination group (group 1 population). ACEi: angiotensin-converting enzyme inhibitor; ARB: angiotensin receptor blocker; CCB: calcium channel blocker.

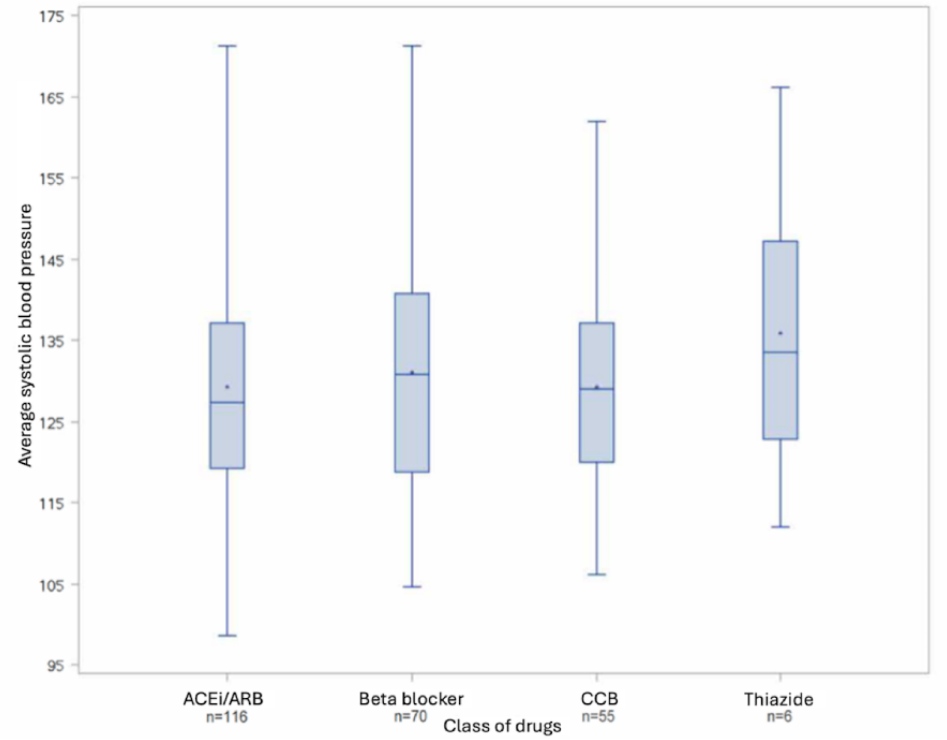

Figure 4. Average diastolic blood pressure for each drug combination group (group 1 population). ACEi: angiotensin-converting enzyme inhibitor; ARB: angiotensin receptor blocker; CCB: calcium channel blocker.

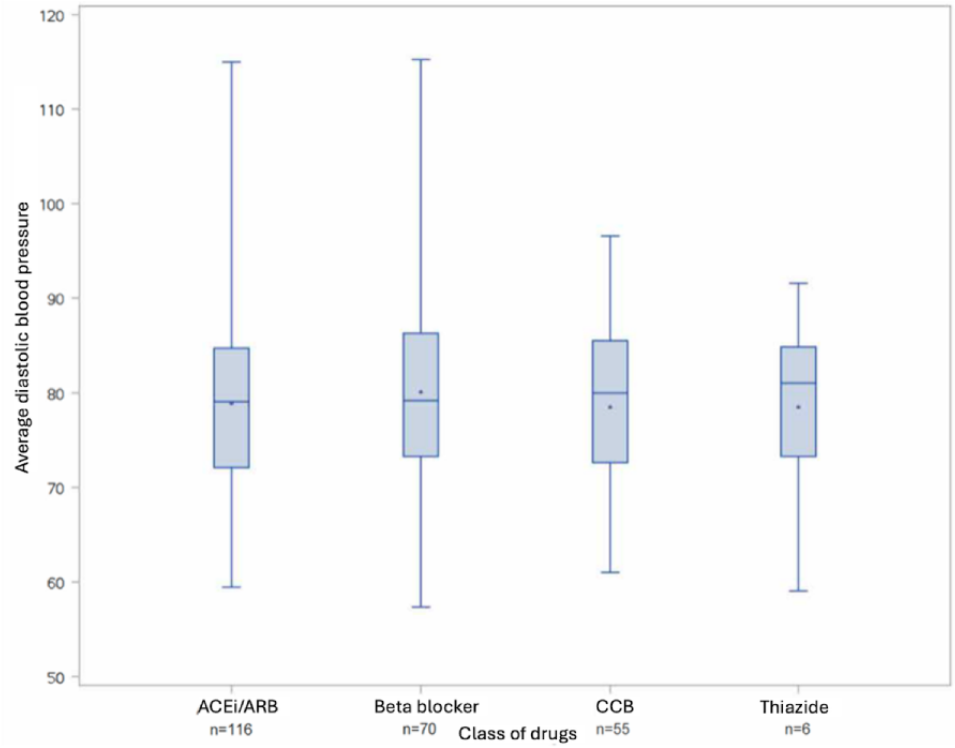

Figure 5. Average systolic blood pressure for each drug (group 1 population). ACEi: angiotensin-converting enzyme inhibitor; ARB: angiotensin receptor blocker; CCB: calcium channel blocker; freq: frequency.

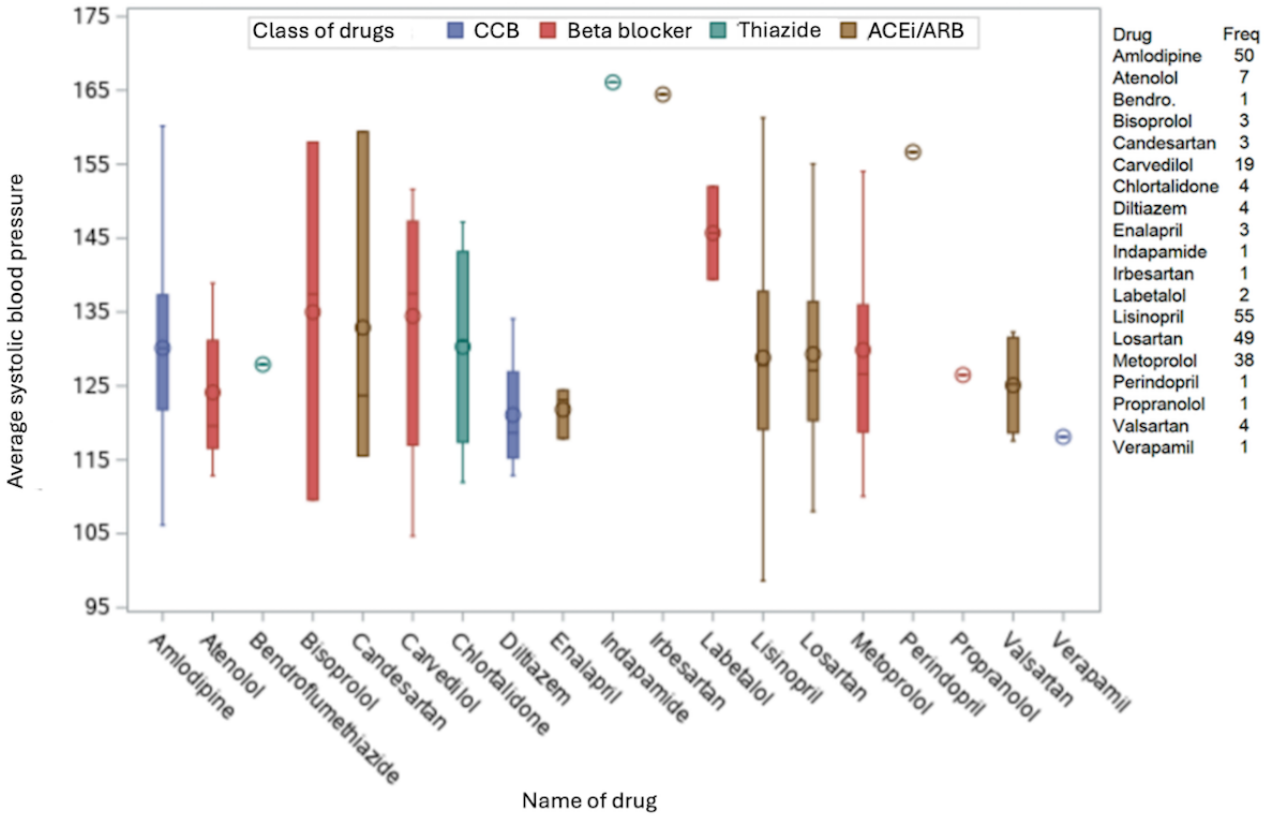

Figure 6. Average diastolic blood pressure for each drug (group 1 population). ACEi: angiotensin-converting enzyme inhibitor; ARB: angiotensin receptor blocker; CCB: calcium channel blocker; freq: frequency.

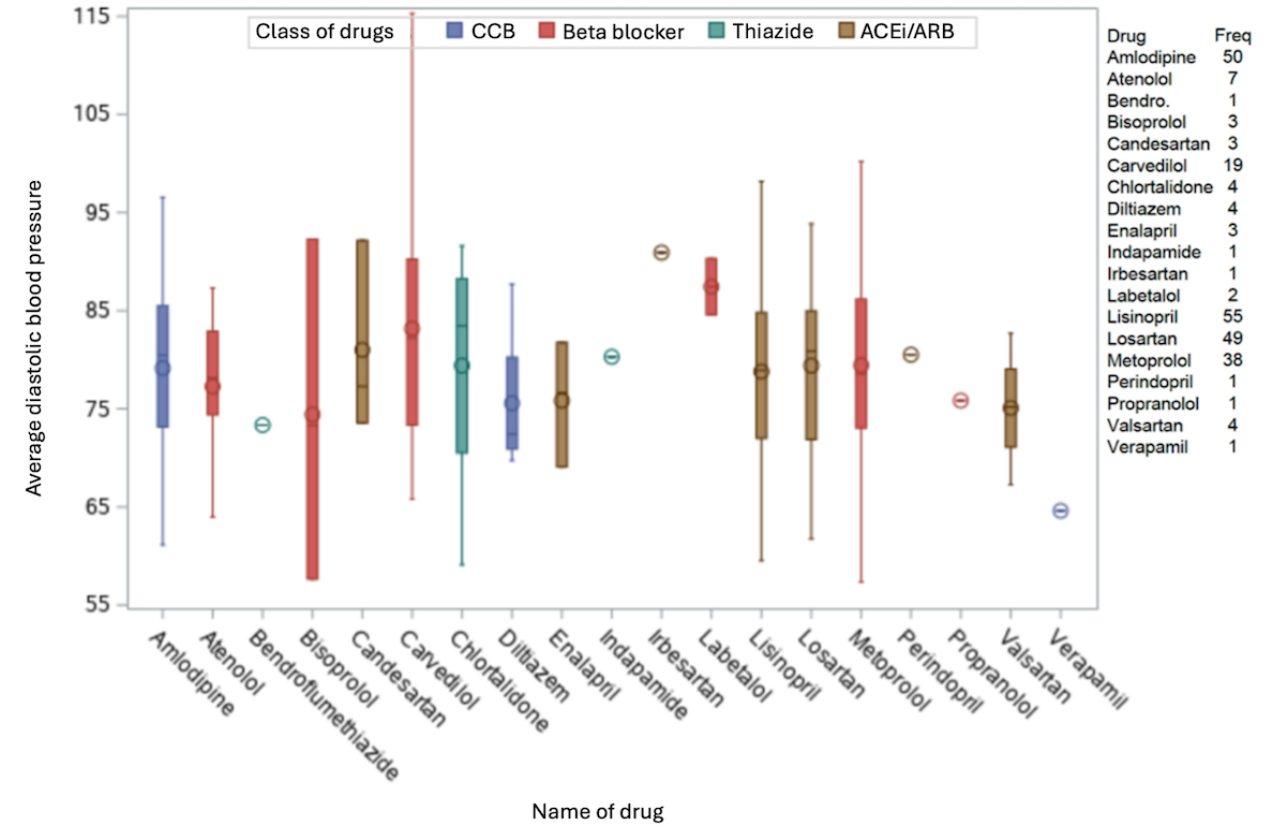

COVID-19 Symptoms

An analysis of emergent symptoms of SARS-CoV-2 infection, including but not limited to fatigue, high temperature, persistent dry cough, chest pain, and shortness of breath, in all enrolled participants was performed. This revealed very low levels of symptoms related to infection with COVID-19, with only 3 participants experiencing these symptoms. Due to insufficient numbers of participants experiencing COVID-19 symptoms, associations between BP medication and BP level with SARS-CoV-2 infection and COVID-19 outcomes could not be assessed.

Adverse Events

All enrolled participants (n=398) were included in the safety population. There were no AEs attributable to the smartphone app, SAEs, or deaths recorded in this study.

Discussion

Principal Findings

Our study successfully deployed a smartphone app used for monitoring daily BP, medication, and side effects in a community setting within the United States, and almost all participants (380/389, 98%) downloaded and entered BP routines in week 1. A high proportion of participants remained in the study for the full 12-week observation period and entered full BP routines into the digital app 80% or more of the time. Participants reported their experience of using the smartphone app using the UEQ, giving an overall positive evaluation, whereby the app was benchmarked “excellent” and “above average” for almost all domains. Highly adherent participants with hypertension demonstrated well-controlled BP, with no significant changes in average SBP or DBP between week 1 and week 12. Participants were able to record BP medications and symptoms of SARS-CoV-2 infection. No AEs attributable to use of the smartphone app were reported during the observational period.

The study population had a broad age range, between 24 and 87 (mean 54.1) years. There were more female than male participants enrolled (260/380, 68.4%), and analysis of race and ethnicity showed the population consisted of 74.5% (283/380) White participants, 14.7% (56/380) Black participants, 7.4% (28/380) participants who reported “other” for their race and ethnicity, and 2.9% (11/380) participants who reported their race and ethnicity as “2 or more.” Any participant who did not report as being White, Black, or having 2 or more races or ethnicities were required to enter their ethnicity as “other.”

According to the 2020 US decennial census, out of 331,449,281 people, there were 204,277,273 (61.6%) White (alone) individuals; 41,104,200 (12.4%) Black individuals; and 33,848,942 (10.2%) individuals who reported “2 or more” for their race and ethnicity [10]. In comparison with the reported demographics of the Unites States, we observed a higher percentage of White and Black participants enrolled into the study. However, a recent report describing racial and ethnic demographics of adults with hypertension in the United States reported 79,910,050 individuals with hypertension, of which 66.4% (51,03,185) were White and 14.4% (11,061,686) were Black [11]. The percentage of Black participants in our study is representative of the proportion of Black patients with hypertension in the United States; however, we observed a higher proportion of White participants than the proportion of White patients with hypertension in the United States. Our study observed 28 (7.4%) out of 380 participants who reported their race and ethnicity as “other,” which included any individuals did not identify as Black, White, or having “2 or more” races and ethnicities; so, we did not focus on other racial and ethnic groups specifically. The average BMI of the study population was 34.9 kg/m^2. These results indicate that, on average, the population was clinically obese, which are consistent with levels of obesity reported for US-based adults with hypertension [11].

CLM successfully modified an existing app and deployed it for use in the study. The patient experience and data collection components that had been developed as part of an early platform concept proved straightforward to adapt and extend for this study, building confidence that the goal of rapidly developing an adaptable multitherapeutic technology for patient data collection and treatment is viable. During pandemic conditions, the ability to quickly respond with digital patient support and assessment tools is critical [12]. Symptom collection proved straightforward by reusing user interface components from the early platform that allowed patients to rate their symptoms using a visual analog scale (VAS). The symptom component was designed to present a configurable and customizable list of symptoms to the patient, which allows the data to be collected, stored, and presented. A similar approach was taken with the hypertension drug list. The patient experience component required only simple adaptation as it was directly suitable for adoption in this study. The changes were simple, such as updating the app name or contact information presented to patients. This provided reassuring evidence that a common set of user interaction components, supported by an underlying platform, can be viable in a digital health care setting involving mobile devices.

In this study, we used the smartphone app to record daily BP measurements in patients with hypertension. Telemonitoring is another method that is used for routine BP monitoring in hypertension [13]. Industry standards and other clinical studies have shown that 39% to 72% of patients report their BP 80% or more of the time using this method [14-17]. In our study, 248 (65.3%) out of 380 participants (group 2) showed high compliance for entering daily BP routines into the CLM digital diary (entering full BP routines on 80% or more of days). Compliance to entering daily BP routines was even higher in the 239 who completed the full 12 weeks, with 201 (84.1%) entering full BP routines over 80% of the time. While overall adherence levels may have been affected by the daily requirement to enter 2 routines (morning and evening) within a limited time window, recording morning and evening routines each day reflects best practice. Nonetheless, these results demonstrate that our test smartphone app meets industry norms for adherence to routine BP self-monitoring. It should be noted that the digital app development deployed in this study was not designed for high engagement and still achieved these industry standards. Future work will focus on refinement and

incorporation of engagement enhancing features as part of product development.

Participant satisfaction of the CLM smartphone app for remote BP monitoring was assessed using the validated UEQ. The app scored an overall positive evaluation. Analysis of UEQ domains consisting of several questionnaire items, revealed that the app scored an excellent evaluation for perspicuity and very good evaluations for attractiveness, dependability, efficiency, and stimulation. A lower but still positive evaluation was given for novelty. Data from another hypertension study, PERSONAL-COVIDBP, in the United Kingdom has shown similar outcomes for user experience [18,19]. Overall, these results suggest very high levels of participant satisfaction of this smartphone app for daily monitoring of BP.

The UEQ can be used to benchmark products against other apps, web pages, software, and social networks, with data coming from 21,175 persons involved in 468 studies regarding different products [7]. Here, we show that our smartphone app for monitoring BP benchmarked "excellent" for domains of perspicuity, efficiency, and dependability and "good" for domains of attractiveness and stimulation. Novelty was benchmarked at "above average." Again, these results indicate that despite the app being a prototype, a very high level of participant satisfaction was observed. Further app development work at CLM will include a particular focus on novelty, attractiveness, and stimulation.

Clinical Outcomes

Through remote BP monitoring, we demonstrated that in a population of people with hypertension, self-reported BP in study completers was stable over a 3-month period with no significant changes in average BP (129.5/79.2 mm Hg at baseline, 128.6/78.2 mm Hg at week 12). These levels are below the established hypertensive diagnostic thresholds (United Kingdom: 135/85 mm Hg [20] and United States: 130/80 mm Hg [21]). These thresholds represent treatment targets for BP and as such, demonstrate that BP levels in this study population on average are being effectively managed. Although we do acknowledge that these results are based on self-reported data and that direct measurement might have resulted in higher BP data.

Although subgroup analysis showed that there was no difference in our BP outcomes across age and sex, significant reductions in SBP and DBP were observed for those participants who entered this study with baseline BP levels higher than the established hypertensive diagnostic thresholds for the United States and United Kingdom (Table 4). As this was an observational study with no drug intervention, these findings may have in part been a result of remote BP monitoring having a positive impact on BP control, when used in conjunction with standard of care antihypertensive medications. However, it is possible that a lowering of BP during the observational period could be due to other factors such as the Hawthorne Effect or regression to the mean, and in some cases, perhaps patients were at the early stages of their antihypertensive treatment. Nonetheless, our results are in line with the demonstrated effectiveness of BP self-monitoring, combined with other interventions, to lower BP in patients with high BP levels [22-24]. Self-monitoring of BP is thought to be advantageous as it can provide better estimation of underlying BP, increase adherence to medications, and reduce the need for clinic monitoring. In the future, remote BP monitoring would facilitate drug optimization through the development of more sophisticated electronic mobile apps.

According to American College of Cardiology and American Heart Association treatment guidelines for high BP, the first-line antihypertensives used to treat hypertension include ACEi, ARBs, CCBs, and thiazide-type diuretics [21]. After the Joint National Committee guidelines 8 in 2014, β-blockers have been considered secondary agents. Accordingly, this population of hypertensive patients based in the United States were seen taking 1 or more of these antihypertensive medications. Analysis of BP levels with respect to participant-reported antihypertensive drugs revealed no difference in levels of SBP and DBP reported for the participants taking thiazide-type diuretics, CCBs, ACEi, or ARBs. Similar results were seen for analyses of single antihypertensive drugs. We did however observe a minor decrease in DBP (mean 2.1, SD 6.6 mm Hg; P=.01) in those participants currently taking β-blockers at week 12.

Strengths and Limitations

The strengths of this study were the rapid set up of a decentralized study during the COVID-19 pandemic, which involved the rapid modification and deployment of a smartphone app for monitoring BP, BP medication use, and symptoms of SARS-CoV-2 infection. Another strength of this research includes the large sample size and the accurate representation of Black participants in our study against the proportion of Black patients with hypertension in the United States. The low dropout rates also eliminated the need to correct for missing data. However, a limitation is that the study did not specifically look at Hispanic or Latino as well as Asian patients who have been reported under the "other" category of race and ethnicity; therefore, analysis specifically on these groups could not be performed.

Another limitation of this study was that data entry, adherence, and participant engagement rates may have been influenced by (1) participants being incentivized for entry of data into the smartphone app and (2) lockdown social distancing measures, which meant that patients with hypertension were at home without other activities occupying their time. Thus, study routines would have been less interrupted, possibly resulting in enhanced habit formation. Incentives were kept to a minimum, with the monetary value low to temper this limitation. As part of the UEQ, question-26 data were missing, which asked whether users considered the app to be "conservative or innovative." As these data are missing and could have affected the mean score for the novelty domain in a positive or negative manner, it is a further limitation of the study.

Low incidence of symptoms of COVID-19 in the hypertensive study population was another limitation to this study. This meant that we were unable to examine associations between BP levels or BP antihypertensive drug use and the incidence of SARS-CoV-2 infection and severity of COVID-19 outcomes.

In our study, we evaluated changes in BP in a cohort compliant with BP data capture so we could accurately assess their BP levels. It is possible that those who were not as compliant with BP data capture may be different in some ways to this adherent population; however, as it would be less reliable to analyze BP in those with low BP data capture, it would be hard to make that assessment.

Conclusions

We successfully deployed and tested a personalized electronic record in the form of a smartphone app in participants with primary hypertension for routine monitoring of BP in a community setting within the United States. The patient population engaged with the app and provided highly positive feedback. However, novelty features and additional engagement features beyond data monitoring should be considered to bolster patient adherence. This study also demonstrated no safety implications regarding the use of the smartphone app. These are important components for the provision of individualized and targeted treatment for hypertension.

Abstract

Background: Smartphone-based monitoring in natural settings provides opportunities to monitor mental health behaviors, including suicidal thoughts and behaviors. To date, most suicidal thoughts and behaviors research using smartphones has primarily relied on collecting so-called “active” data, requiring participants to engage by completing surveys. Data collected passively from smartphone sensors and logs may offer an objectively measured representation of an individual’s behavior, including smartphone screen time.

Objective: This study aims to present methods for identifying screen-on bouts and deriving screen time characteristics from passively collected smartphone state logs and to estimate daily smartphone screen time in people with suicidal thinking, providing a more reliable alternative to traditional self-report.

Methods: Participants (N=126; median age 22, IQR 16-33 years) installed the Beiwe app (Harvard University) on their smartphones, which passively collected phone state logs for up to 6 months after discharge from an inpatient psychiatric unit (adolescents) or emergency department visit (adults). We derived daily screen time measures from these logs, including screen-on time, screen-on bout duration, screen-off bout duration, and screen-on bout count. We estimated the mean of these measures across age subgroups (adults and adolescents), phone operating systems (Android and iOS), and monitoring stages after the discharge (first 4 weeks vs subsequent weeks). We evaluated the sensitivity of daily screen time measures to changes in the parameters of the screen-on bout identification method. Additionally, we estimated the impact of a daylight time change on minute-level screen time using function-on-scalar generalized linear mixed-effects regression.

Results: The median monitoring period was 169 (IQR 42 - 169) days. For adolescents and adults, mean daily screen-on time was 254.6 (95% CI 231.4-277.7) and 271.0 (95% CI 252.2-289.8) minutes, mean daily screen-on bout duration was 4.233 (95% CI 3.565-4.902) and 4.998 (95% CI 4.455-5.541) minutes, mean daily screen-off bout duration was 25.90 (95% CI 20.09-31.71) and 26.90 (95% CI 22.18-31.66) minutes, and mean daily screen-on bout count (natural logarithm transformed) was 4.192 (95% CI 4.041-4.343) and 4.090 (95% CI 3.968-4.213), respectively; there were no significant differences between smartphone operating systems (all *P* values were >.05). The daily measures were not significantly different for the first 4 weeks compared to the fifth week onward (all *P* values were >.05), except average screen-on bout in adults (*P* value = .018). Our sensitivity analysis indicated that in the screen-on bout identification method, the cap on an individual screen-on bout duration has a substantial effect on the resulting daily screen time measures. We observed time windows with a statistically significant effect of daylight time change on screen-on time (based on 95% joint confidence intervals bands), plausibly attributable to sleep time adjustments related to clock changes.

Conclusions: Passively collected phone logs offer an alternative to self-report measures for studying smartphone screen time characteristics in people with suicidal thinking. Our work demonstrates the feasibility of this approach, opening doors for further research on the associations between daily screen time, mental health, and other factors.

Introduction

The widespread use of smartphones has created new opportunities for capturing social, behavioral, and cognitive phenotypes in free-living settings [1]. The ability to collect data from individuals in their natural environments, rather than in controlled laboratory settings, allows for a more complete ascertainment of an individual's behavior. In addition, the use of smartphones allows for near-continuous data collection, enabling a more detailed and dynamic view of an individual's behavior over time. This approach is well suited to study mental health disorders that are often characterized by a fluctuating and recurrent course [2].

Suicide is a complex mental health problem that is characterized as an "act of intentionally ending one's own life" [3]. According to the National Institute of Mental Health, in 2021, more than 48,000 people died by suicide in the United States [4]. Suicide is often triggered by one or a combination of factors, including mental illness, substance use disorders, traumatic life events, and social isolation [3].

To date, in suicidal thoughts and behaviors (STB) research, smartphone-based monitoring has been primarily used to collect "active" data, which requires a participant to actively engage by contributing data entries via surveys. For example, smartphones can be used to collect ecological momentary assessment (EMA) data, which are frequent surveys on an individual's thoughts, feelings, and behaviors in their natural environment [5,6]. EMA deployed through a smartphone app has been successfully used to understand potential risk factors for STB and characterize dynamics in suicidal ideation over time [7-13]. Importantly, the ability to deploy active data collection via smartphones and access EMA outcomes in real time has given rise to ethical and safety concerns, including when and how to intervene if a participant's responses indicate an elevated risk during the course of the study [14].

The use of smartphone "passive" data, that is, data collected from smartphone sensors and logs without any active engagement from a participant, is less common in STB research. Existing studies have mostly relied on proprietary mobile apps and analytic methods [15]. Using smartphone log data to obtain detailed characteristics of an individual's screen time is a potentially compelling application in STB studies due to the growing research focus on the association between screen time and mental health. Indeed, existing studies have demonstrated a link between increased levels of anxiety and depression and high smartphone screen time, measured either objectively or via a self-report [16,17]. In addition, objectively measured excessive screen time on mobile devices has been linked with a decreased quantity of sleep, which can further exacerbate mental health issues [18]. Interestingly, Rozgonjuk et al [19] reported that in a sample of 101 undergraduate university students, depression and anxiety symptom severity negatively correlated with the frequency of phone screen unlocking but were not related to total screen time; this finding suggests that not only screen-on total duration time but also screen-on use patterns are potentially relevant.

Data missingness is a common issue in digital health studies [20,21]. For smartphone passive data, Kiang et al [22] estimated missingness due to sensor noncollection rates to be 19% for accelerometer data and 27% for GPS data across 6 digital phenotyping studies. Sensor noncollection has been attributed to users' behavior (eg, forgetting to charge a phone, disabling the GPS, and uninstalling the study app) and technological factors (the phone operating system restricting data collection). If the expected data volume or temporal coverage is fixed by study design (as was the case in these studies), one can identify smartphone sensor noncollection by comparing the expected versus observed data volume or temporal coverage. Determining missing data in the context of estimating smartphone screen time from phone state logs is more complicated, and without identifying the missingness, results may be biased. To the best of our knowledge, to date, no systematic approach has been proposed to determine the missingness status of smartphone state logs.

In this paper, we present methods for identifying and characterizing smartphone screen-on bouts, which we define as periods of consecutive smartphone use, in smartphone state logs. These methods were applied to a sample of adolescents (n=50) and adults (n=76) with suicidal thinking. Data were collected for up to 6 months from participants' personal Android and iOS phones using the Beiwe smartphone app (Harvard University) [23]. Our methodological contributions are as follows. First, we present a method for preprocessing raw smartphone state logs into discrete screen-on bouts, capturing the duration and timing of each screen interaction, and handling missingness due to sensor non-collection; additionally, we performed multiple sensitivity analyses for preprocessing of raw logs. Second, we extracted several day-level metrics from the preprocessed bouts, including total screen time volume and fragmentation metrics that quantify the temporal distribution of screen use. Third, we compared screen time measures from early versus later stages of monitoring (which starts after the presentation of suicidal thinking) to identify use pattern shifts potentially associated with recent suicidal thoughts. Finally, we demonstrated how functional data analysis regression techniques

can be used to analyze complex minute-level screen time outcomes. We estimated a time-varying effect of a daylight saving time (DST) change on the outcome using the natural experiment this event creates. The code for all preprocessing and analysis steps is openly available on GitHub [24].

Methods

Ethical Considerations

This study was conducted ethically and in accordance with relevant guidelines and regulations. Institutional review board approval from Harvard University (IRB18-1749) was obtained before the study began. All data collection and maintenance followed university, hospital, state, and national policies and regulations. Participants gave informed consent before taking part in any study procedures. All identifying information, such as names, initials, or hospital numbers, has been omitted from the data used in this analysis to protect participant privacy.

Study Design and Population

The study recruited 2 samples of participants: adults from Massachusetts General Hospital's Acute Psychiatry Service and children or adolescents (and their parents or guardians) from Franciscan Children's psychiatric inpatient unit. Adult participants were eligible if they were 18 years or older, with other criteria including owning a smartphone and presenting to the emergency department with suicidal thoughts. Children and adolescents aged 12 - 19 years were recruited from Franciscan Children's, with eligibility criteria including smartphone ownership, parental consent for minors, child or adolescent assent, and presenting problems that included suicidal thoughts. The recruitment process involved initial identification and informed consent, and it was conducted via both an in-person manner and a remote manner (but fully remote during heightened periods of the COVID-19 pandemic). The recruitment process was designed to promote diversity among participants, without restrictions based on diagnosis or clinical history.

Phone State Logs

Phone state logs were collected with the Beiwe smartphone app, the front end of the open-source Beiwe high-throughput digital phenotyping platform [23]. The Beiwe platform consists of smartphone apps for Android and iOS, a web-based platform for study administration, and a cloud-based back-end system for data storage and processing. Participants were assigned a Beiwe participant ID and had the Beiwe app installed during enrollment, which defined a study start date (Multimedia Appendix 1). The phone state logs were recorded with millisecond-level timestamps. iOS and Android phones report state logs differently (Table S1 in Multimedia Appendix 1). For Android, the logs capture "screen turned on" and "screen turned off" events; for iOS, the logs capture "locked" and unlocked" events. For iOS, the log also includes an event for each 1% change (positive or negative) in battery charge level.

Screen Time Estimation

We define a "screen-on bout" for a smartphone as a period of consecutive screen use and a "screen-off bout" as a period of consecutive screen nonuse. Each screen-on bout is followed by a screen-off bout, and vice versa. To estimate the timing and duration of screen-on bouts for iOS, we used the time intervals between consecutive "unlocked" and "locked" event timestamps, while for Android, we used the time intervals between consecutive "screen turned on" and "screen turned off" event timestamps. During preprocessing, we imputed missing logs, removed bouts attributed to notification arrivals (for Android only), and capped screen-on bouts that lasted longer than 30 minutes (which corresponds to approximately the 97th percentile). A detailed description of our methods is provided in Multimedia Appendix 1. Our preprocessing steps closely resemble those previously presented by Kristensen et al [25]. For comparison, we also estimated timing and duration of screen-on bouts using three comparator approaches: (1) imputing missing logs and capping screen-on bout duration at 6 hours (instead of 30 minutes); (2) not imputing missing logs, that is, only considering consecutive pairs of matching events ("unlocked" and "locked" for iOS and "screen turned on" and "screen turned off" for Android), and not capping screen-on bout duration (ie, minimal preprocessing); and (3) not imputing missing logs with screen-on bout duration capped at 30 minutes.

Daily Measures of Screen Time

To obtain daily measures of smartphone screen time, we used the estimated screen-on bouts and calculated 4 metrics: total screen-on time, average screen-on bout duration, average screen-off bout duration, and screen-on bout count. We defined a day as the period from midnight to midnight in the Coordinated Universal Time (UTC) time zone. The smartphone state logs were originally recorded in UTC, and we assumed the time zone choice would have no impact on the statistical analyses. The total screen-on time and screen-on bout count metrics capture the volume of screen time, while the average bout duration metrics reflect screen-on time accumulation patterns.

Missing Data Labeling

A heuristic was developed to identify periods of missing phone state logs for iOS based on changes in battery charge level log events. Our approach assumes that the battery charge level is in one of four states: (1) decreasing, (2) increasing (when the phone is being charged), (3) constant at 0% (when the phone battery is fully depleted), and (4) constant at 100% (when the phone battery is fully charged and the charger is plugged in). First, we defined a minute of the monitoring time as "valid" based on either of two criteria: (1) phone's battery level was changing at least 1% per hour (decreasing or increasing) or (2) the phone had been recently charged to 100% and not depleted battery for a period of at most 12 hours (likely having a charger plugged in). Minutes that did not meet these criteria were labeled as invalid. A "valid day" was defined as one with at least 1080 valid minutes (18 hours). Unlike for iOS, we were unable to define "valid minutes" for Android due to the absence of phone battery level change logs. Therefore, we only defined "valid days" for Android data as those consisting of at least 8 distinct hours that contained at least 1 screen-on bout. Only valid days were included in the statistical analyses.

Statistical Data Analysis

The data analysis sample consisted of participants who provided at least 28 valid days of data. A day was considered valid if it belonged to a 28-day period with at least 14 valid days. We computed the number of days in the study observation period and the number of valid days of phone state logs for each participant and characterized these measures using the median and range, separately for adolescents, adults, and the combined sample.

To visualize daily measures over time, we aggregated the measures (median, 25th, 75th, 10th, and 90th percentile) across participants for each relative day since the discharge, separately for adolescents and adults. We used a 7-day moving average to smooth the sample statistics and improve readability.

To quantify population-level daily measures of screen time, we considered 4 different linear mixed-effects models (LMMs). Each model had a participant-specific daily measure as the outcome. The LMMs had different fixed-effect coefficients: model 1 had a fixed effect for an age group (adolescents, adults); model 2 had a fixed effect for an age group, operating system (Android, iOS), and their interaction; model 3 had a fixed effect for an age group, monitoring period (one of: the first four weeks after discharge period, from the fifth week up to 6 months period), and their interaction; and model 4 had a fixed effect for an age group, study monitoring period (one of: the first four weeks after discharge period, from the fifth week up to 6 months period), and their interaction. Each LMM included a participant-specific random intercept. Additionally, models 3 and 4 also had a subject-specific random slope for a study period. We fitted each of these 4 different LMMs separately for each of the 4 daily measures: total screen-on time, average screen-on bout duration, average screen-off bout duration, and screen-on bout count (natural logarithm-transformed), yielding a total of 4×4=16 model fits. Using these models, least squares means of daily measures were estimated across age groups, operating systems, and study periods of interest. We also quantified the contrasts of interest: the difference between age groups from model 1, the difference between operating systems across age groups from model 2, and the difference between (differently defined) study periods across age groups from models 3 and 4. The statistical significance of the contrasts of interest was evaluated using a significance level of α=.05.

We calculated screen-on time for each minute of each participant day using the timing and duration of screen-on bouts. The function-on-scalar generalized LMM (FoS-GLMM) was used to estimate the time-varying effect of daylight saving time (DST) on the probability of screen-on time at the minute level. We chose to study the effect of DST changes because they create a natural experiment that allows us to assess the feasibility of our method. Specifically, these changes provide a sudden and exogenous shift in the timing of daylight hours, which can impact individuals' daily routines and phone use patterns. By examining the minute-level screen time outcome around these time changes, we explore whether our method captures changes in phone use.

In our FoS-GLMM, the outcome was a participant- and day-specific functional observation recorded on a minute-level discrete grid, with a value of 1 if any screen-on time was recorded for that minute and 0 otherwise. To quantify the effect of DST, we included a time-varying fixed-effect indicator for the change effect (1 if the functional observation was from a time period after the DST change and 0 otherwise) and a time-varying participant-specific intercept. The model was estimated separately at the start and end of DST (March and November of 2019 - 2022, respectively) using data from ±14 days from the time change, and we performed a sensitivity analysis using data from ±7-day and ±28-day windows. We estimated FoS-GLMMs using the fast inference approach for longitudinal functional models proposed by Cui et al [26], and we made inferences about the time-varying fixed effect based on 95% joint confidence bands.

Results

Sample Characteristics

In total, 297 participants had the Beiwe app installed during enrollment. Of those, 247 participants had at least 1 valid day of data. The final analysis sample consisted of 126 participants (Table 1). The median age of the combined sample (adolescents and adults) was 22 (IQR 12-69) years, with adolescents having a median age of 15 (IQR 12-18) years and adults having a median age of 30 (IQR 18-69) years. The sample was predominantly female (n=81, 64.3%) and self-identified as White (n=101, 80.2%). Most participants (n=75, 59.5%) used smartphones with iOS, but the proportion of iOS users differed between the 2 subsamples, with 84% (42/50) in adolescents and 43.4% (33/76) in adults. The study observation period had a median duration of 169 (IQR 42-169) days, and participants had a median of 94 (IQR 29-167) days of valid smartphone state logs.

Table . Baseline demographic and observation period metadata characteristics of the analysis sample.[a]

Characteristic (statistic)	Statistic value

iOS	42 (84)	33 (43.4)	75 (59.5)
Android	8 (16)	43 (56.6)	51 (40.5)
Observation period metadata, median (IQR)			
Days in observation period	169 (51-169)	169 (42-169)	169 (42-169)
Smartphone state logs (valid data days)	103 (34-158)	86 (29-167)	94 (29-167)

[a]The number of valid data days of smartphone state logs was determined differently for iOS and Android operating systems due to the differences in the type of smartphone state logs recorded.

[b]pron: gender pronouns use.

Daily Measures of Screen Time

Table 2 summarizes the estimated population-level mean daily smartphone screen time. Adults had a mean total screen-on time of 271.0 minutes (4.52 hours), while adolescents had a mean 254.6 minutes (4.24 hours). Adults showed slightly higher average screen-on bout duration (mean 4.998 vs 4.233 minutes), slightly higher average screen-off bout duration (mean 26.90 vs 25.90 minutes), and slightly lower average screen-on bout count (natural logarithm transformed; mean 4.090 vs 4.192) compared to adolescents. None of these differences were statistically significant (Table S3 in Multimedia Appendix 1, rows 1 - 4). Mean daily smartphone screen time measures across different phone operating systems and age groups (adults and adolescents) are shown in Table S2 in Multimedia Appendix 1 (rows 9 - 24). There were no statistically significant differences in any of the 4 screen time measures across phone operating systems within any age group (Table S3 in Multimedia Appendix 1, rows 5 - 12).

Table . Mean daily screen time measures separately for age groups (adolescents and adults).

Daily measure and age group		Daily measure mean (95% CI)
Total screen-on time (minutes)		
	Adolescent	254.6 (231.4-277.7)
	Adult	271.0 (252.2-289.8)
Average screen-on bout (minutes)		
	Adolescent	4.233 (3.565-4.902)
	Adult	4.998 (4.455-5.541)
Average screen-off bout (minutes)		
	Adolescent	25.90 (20.09-31.71)
	Adult	26.90 (22.18-31.62)
Log [a] (screen-on bout count)		
	Adolescent	4.192 (4.041-4.343)
	Adult	4.090 (3.968-4.213)

[a]log(): natural logarithm transformation.

Figure 1 displays heat maps of minute-level smartphone screen time for 4 participants. Screen time per minute is shown across minutes of a day for each day of the participant's observation period. The figure highlights various between- and within-participant screen time patterns. Participant ID 48 (plot A) has a relatively low average total screen-on time (mean 166.7 minutes across the monitoring days) and short average screen-on bouts (mean 0.9 minutes), whereas participant ID 92 (plot B) has a relatively high average total screen-on time (mean 351.0 minutes) and a moderate average screen-on bout duration (mean 4.3 minutes). Participant ID 20 and ID 102 (plots C andD) have similar total screen-on times (mean 253.6 and 266.7 minutes, respectively), but different accumulation patterns, as measured with average screen-on bout durations (mean 2.5 and 8.8 minutes, respectively) and average screen-off bout durations (mean 12.2 and 42.8 minutes, respectively). Participant ID 48 experiences a decline in daily total screen-on time around their 50th day relative to the study start. Participant ID 92 exhibits a pattern of waking up at the same time across many of the 5-day long periods of time (for 15th-80th relative days: waking up at 10:30 AM UTC, ie, 6:30 AM in their current Eastern Daylight Time [EDT] time zone; and for 80th-180th relative days: waking up at 11:30 AM UTC, ie, 6:30 AM in their current EST time zone). Participant ID 102 appears to have very irregular sleep and wake-up time and has screen-on time bouts scattered across the Eastern Time nighttime on multiple days.

Figure 2 displays the median, 25th-75th percentile bounds, and 10th-90th percentile bounds of the screen time daily measures aggregated across participants for each day relative to the study start, separately for adolescents and adults. Although some day-to-day variability is evident, we did not observe any specific patterns during the early versus later monitoring period, which is consistent with the results of our LMMs. Our analysis did not identify any statistically significant differences in population-level daily measures between the first 4 weeks and week 5 and onward nor between the first week and week 5 and onward after the discharge, except for 2 cases: in the adult subsample, the average screen-on bout duration was significantly lower during the first 4 weeks than week 5 and onward; and in the adolescent subsample, the average screen-off bout duration was significantly higher during the first 4 weeks than week 5 and onward. Please refer to Table S2 in Multimedia Appendix 1 for daily measure means across different treatment periods by age group (rows 25 - 56) and to Table S3 in Multimedia Appendix 1 for difference between treatment periods by age group (rows 13 - 28).

In addition to our proposed approach, we estimated the timing and duration of screen-on bouts using 3 comparator methods. Figure S1 illustratesin Multimedia Appendix 1 illustrates the differences in daily measures of total screen-on time and average screen-on bout duration among participants. Comparators 1 and 2 produced substantially higher estimates for daily total screen-on time, with mean differences of −106.1 (range −502.6 to −1.3) minutes and −133.5 (range −666.4 to −2.4) minutes, respectively. These methods used either a generous cap of 6 hours on an individual screen-on bout duration (comparator 1) or no cap at all (comparator 2). In contrast, comparator 3 (no imputation, capping screen-on bout duration at 30 minutes) yielded results similar to our proposed approach, with an average difference of −0.2 (range −11.8 to 7.3) minutes.

Figure 1. Characteristics of minute-level smartphone screen time for 4 participants. Screen time per minute is shown (color-coded; expressed in seconds) across minutes of the day (y-axis; UTC time) for each day of participant's monitoring period relatively to the study start (x-axis). Days labeled as invalid data days are shadowed in gray. Plot A: ID 48 (iOS, adolescent) with the following means of daily measures: total screen-on time=166.7 minutes, average screen-on bout=0.9 minutes, and average screen-off bout=8.4 minutes. Plot B: ID 92 (iOS, adolescent): total screen-on time=351.0 minutes, average screen-on bout=4.3 minutes, and average screen-off bout=13.8 minutes. Plot C: ID 20 (iOS, adolescent): total screen-on time=253.6 minutes, average screen-on bout=2.5 minutes, and average screen-off bout=12.2 minutes. Plot D: ID 102 (iOS, adolescent): total screen-on time=266.7 minutes, average screen-on bout=8.8 minutes, and average screen-off bout=43.8 minutes. UTC: Coordinated Universal Time.

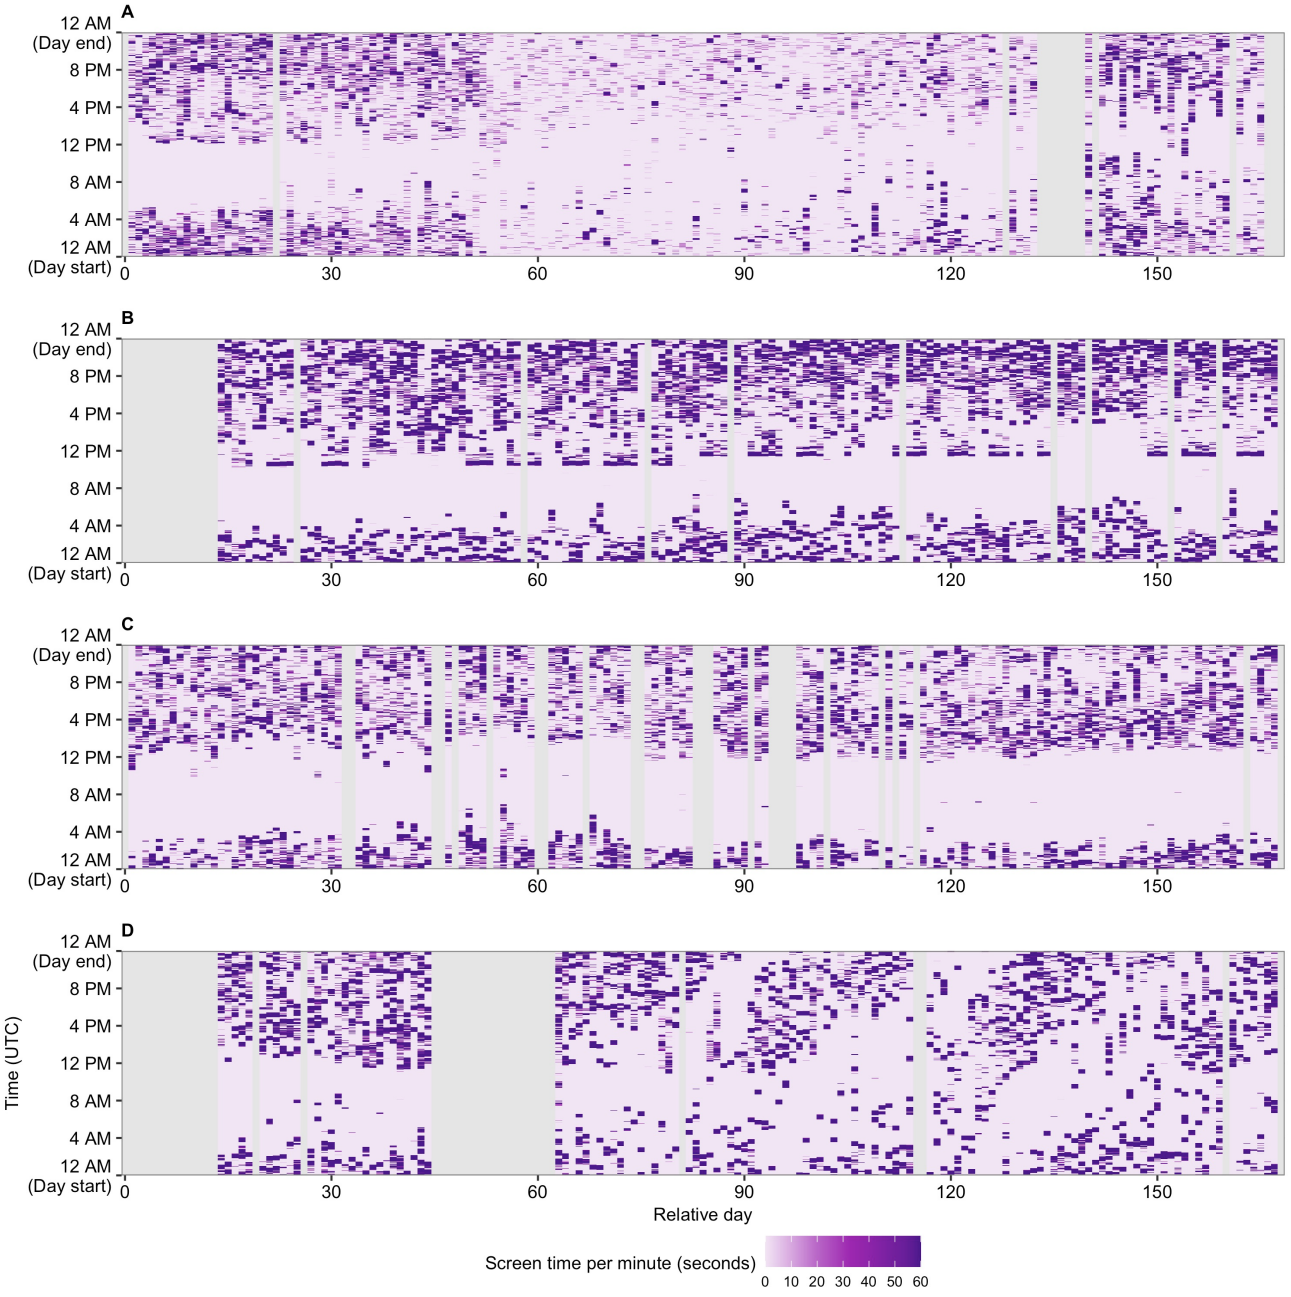

Figure 2. Characteristics of daily screen time measures across time relative from study start. Plots A-H show sample median (black line), 25th-75th percentile bounds (darker color ribbon), and 10th-90th percentile bounds (lighter color ribbon) of day-level measures: total screen-on time (in minutes; plots A and B), average screen-on bout duration (in minutes; plots C and D), average screen-off bout duration (in minutes; plots E and F), and screen-on bout count (plots G and H). Plots I and J show the number of participants contributing a valid day of phone state logs data on a given day relative from the study start.

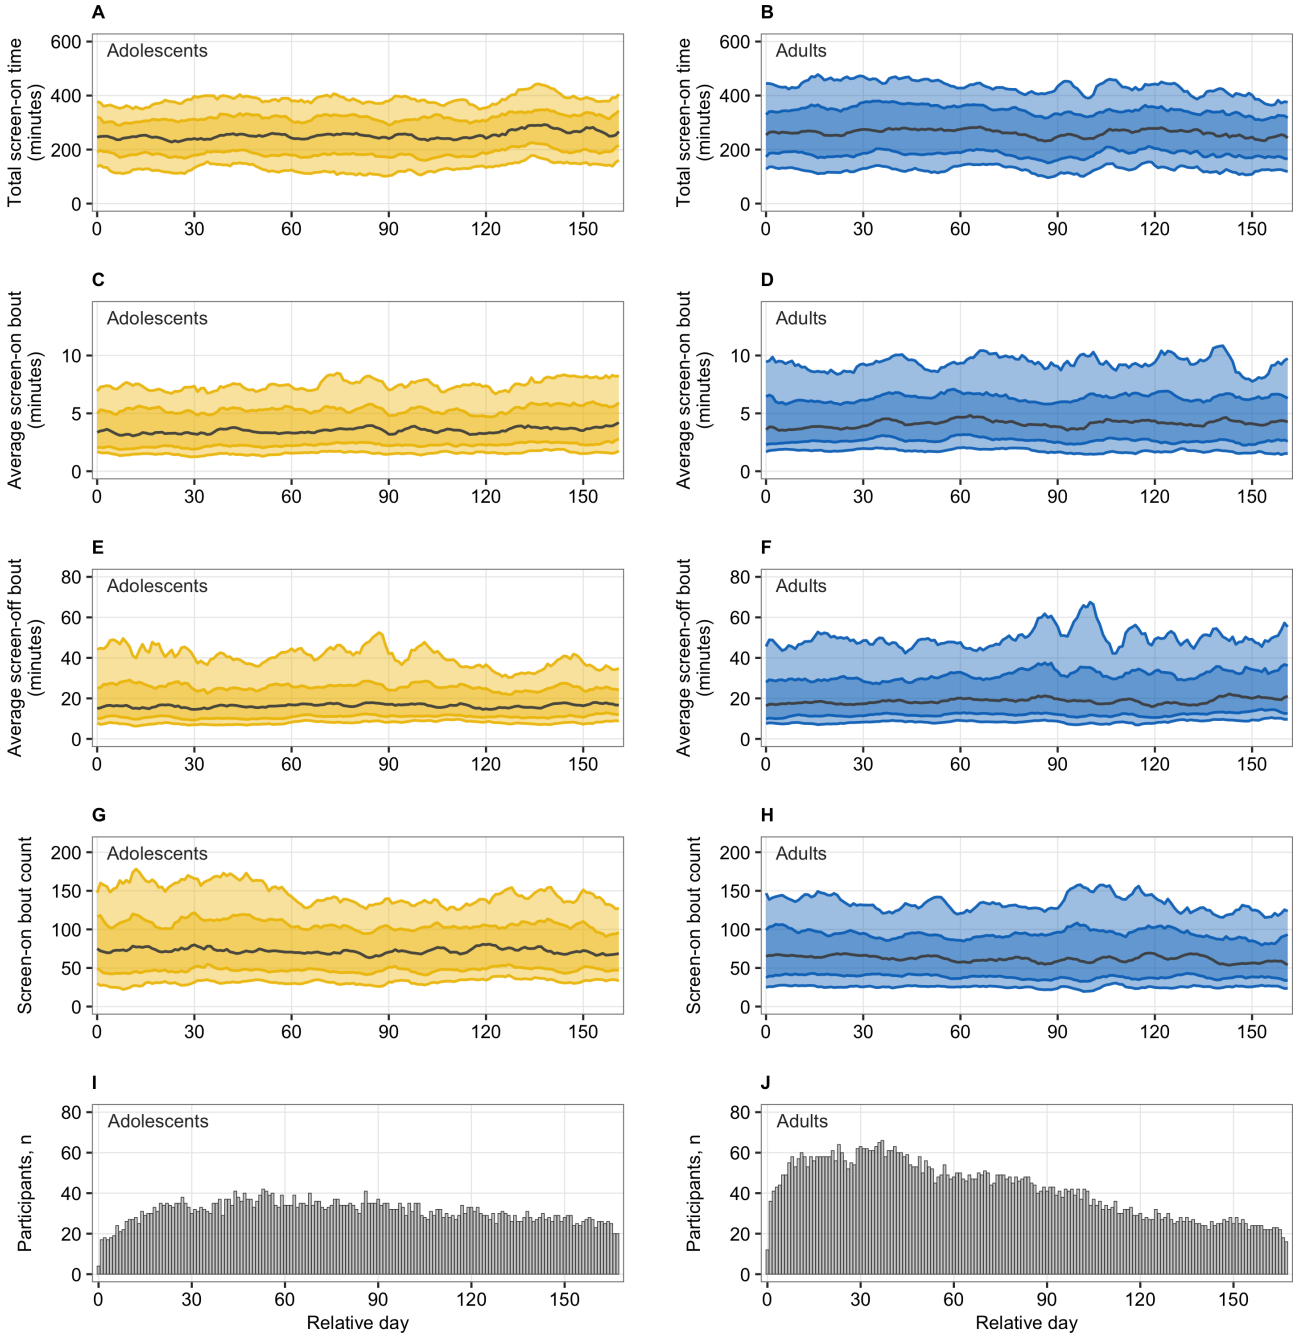
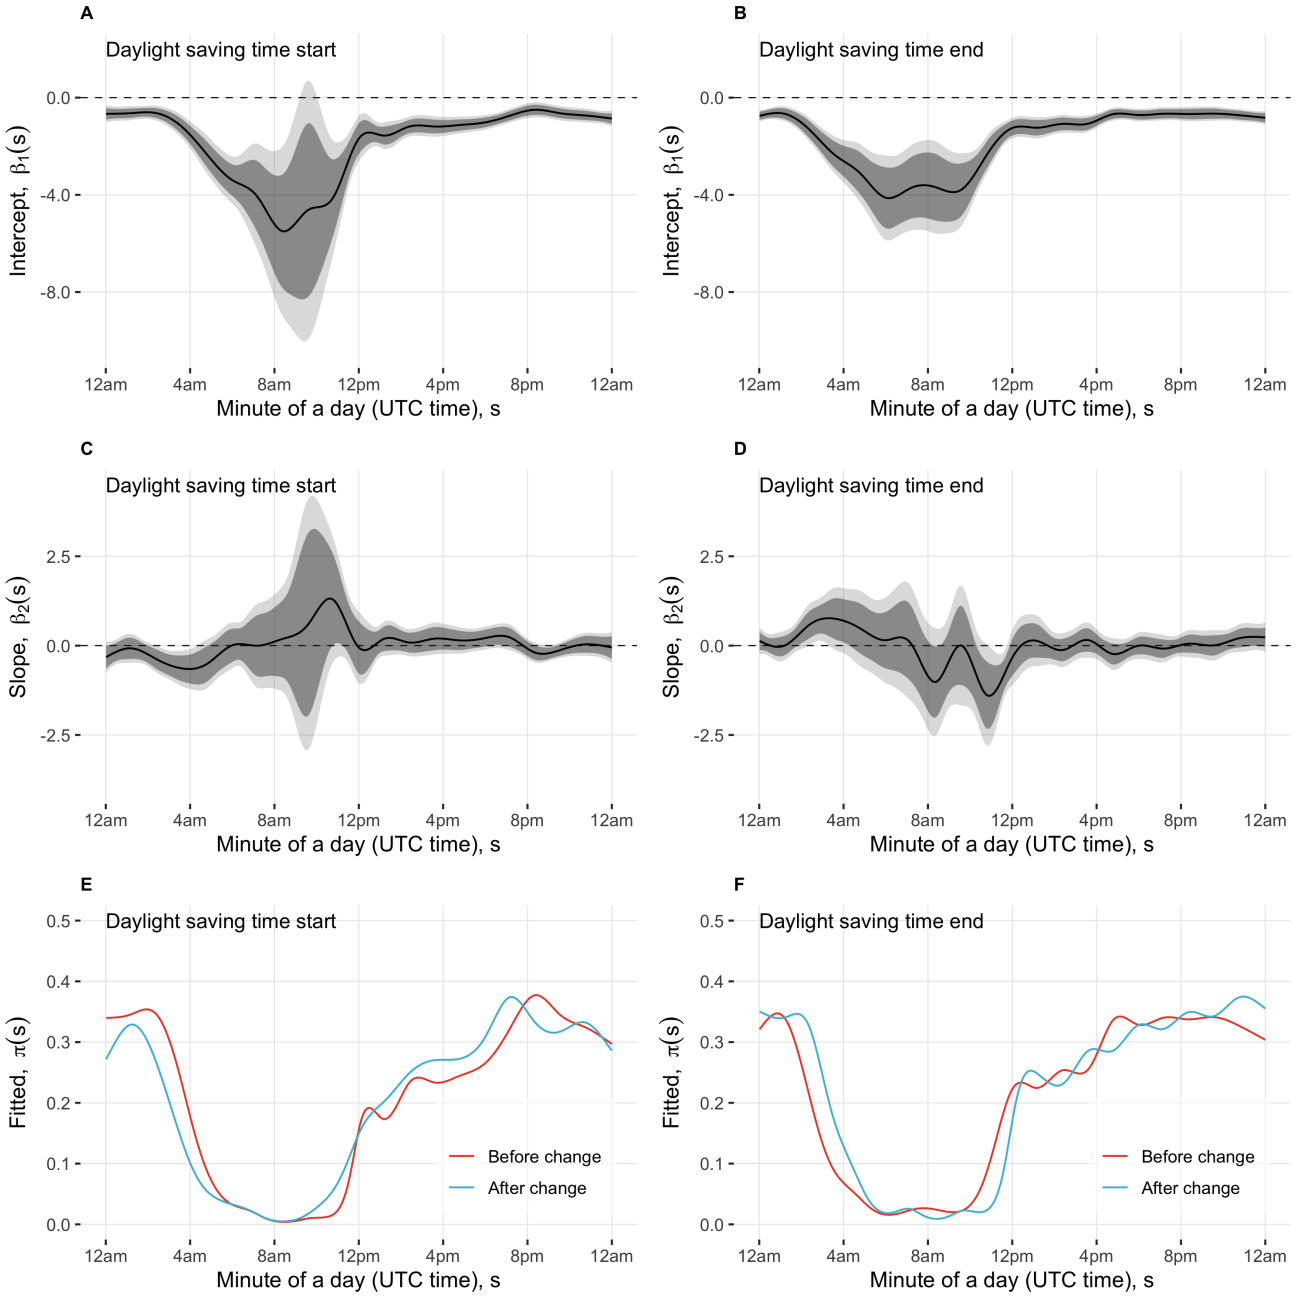


Time-Varying Effect of a Daylight Time Change on Minute-Level Screen Time

We used FoS-GLMM to estimate a time-varying effect of a daylight time change on the probability of screen-on time at the minute level. Figure 3 shows estimates of a functional intercept and a functional slope for the fixed-effect covariate (1=after and 0=before DST change; plots A-D) as well as fitted probabilities of screen time (plots E and F) in a given minute across the functional domain of a day.

Figure 3. Estimates of functional intercept and slope for daylight saving time (plots A-D) and fitted probabilities of screen time (plots E and F) in a given minute across the minute-level functional domain of a day. Logistic function-on-scalar mixed-effects regression was used to estimate the time-varying effect of the covariate (1=after and 0=before daylight saving time change) on the functional outcome (1=any screen time and 0=no screen time). In rows 1 - 2 (plots A-D), functional coefficient estimates (solid black line), 95% point-wise CIs (dark gray shaded area), and 95% joint CIs (light gray shaded area) are presented. In row 3 (plots E and F), fitted probabilities for before and after the change are shown, with vertical dashed lines indicating the time window with a statistically significant effect based on joint CIs. Separate models were fitted for the start (column 1; plots A, C, and E) and end (column 2; plots B, D, and F) of daylight saving time, each using a ±14-day window of data relative to the change night. UTC: Coordinated Universal Time.



With the start of the DST model, we observed statistically significant negative effects (based on 95% joint confidence bands) on the probability of screen-on time after the time change during the period from 2:24 AM UTC to 4:19 AM UTC (equivalent to 9:24 PM EST to 11:19 PM EST before the time change). In this timeframe, the functional coefficient estimate had an average value −0.57 (range −0.65 to −0.38). This estimate suggests that the odds of phone use after the time change were 0.56 times lower compared to the odds before the time change. The average probabilities of phone use in a given minute were 0.26 and 0.17 for before and after the change in that period, respectively, as depicted by the blue and red lines in Figure 3E, respectively (located between the dashed vertical lines).

With the end of the DST model, we observed statistically significant positive effects (based on 95% joint confidence bands) on the probability of screen-on time after the time change from 2:22 AM UTC to 3:19 AM UTC (10:24 PM EDT to 11:19 PM EDT before the change) and statistically significant negative effects (based on 95% joint confidence bands) during the time window from 10:52 AM UTC to 11:44 AM UTC (6:52 AM EDT to 7:44 AM EDT before the change). In the time window of positive effect significance, the functional coefficient estimate

had an average value 0.71 (range 0.58-0.77), corresponding to the odds of phone use after the time change being 2.03 times the odds before the change, and average probabilities of phone use in a given minute 0.15 and 0.27 for before and after the change, respectively (Figure 3E). In the time window of negative effect significance, the functional coefficient estimate had an average value −1.13 (range −1.40 to −0.66), corresponding to odds of phone use after the time change being 0.32 times the odds before the change, and average probabilities of phone use in a given minute 0.15 and 0.06 for before and after the change, respectively (Figure 3E).

Based on sensitivity analysis results (Figure S2 in Multimedia Appendix 1), the inference was very similar for cases of using ±14 days (main analysis) and ±28 days, whereas for the ±7-day model, the 95% joint confidence bands do overlap with 0 value for the functional coefficient in the DST end model.

Taken together, these results suggest that the effects on screen-on time during these time windows are plausibly attributable to sleep time adjustments related to clocks going 1 hour forward (“we sleep less”) or 1 hour backward (“we sleep more”).

Discussion

Screen Time Data in STB Studies

Digital phenotyping entails the collection and analysis of various types of data from personal digital devices in naturalistic settings; it has applications both within and outside mental health. The focus of our paper is the development of a simple method to enable investigators to use moment-by-moment screen time metrics when studying adolescents and adults with STB. We emphasize that in our approach, the data are collected in naturalistic settings and arise as a byproduct of how participants use their phones, which makes the approach scalable.

In the digital phenotyping literature in mental health, there is surprisingly little existing research on the intersection of STB and screen time. For example, a recent literature review only briefly mentions STB and does not discuss screen time [27]. Another paper focusing on stress, anxiety, and mild depression carried out a systematic review of 40 studies [28]; 7 studies with “student participants” and 2 studies with “adult participants” used screen time data (screen on or off, phone lock or unlock, and similar metrics), but none of the reviewed studies dealt with STB. Finally, a recent narrative review of digital phenotyping for differential diagnosis of major depressive disorder reviewed 74 papers dealing with “digital tools”; 4 of the papers focused on STB, but none were reported to discuss screen time [29].

Principal Findings

We investigated the smartphone screen time characteristics in 126 adolescents and adults with suicidal thinking. Passively collected smartphone state logs data for a median of 169 (IQR 42 - 169) days provided objective measurements of screen time. Our analysis showed that study participants spent an average of 254.6 and 271.0 minutes per day on their smartphones for adolescents and adults, respectively. The means of participants’ average screen-on bout duration were 4.2 and 5.0 minutes, average screen-off bout duration were 25.9 and 26.9 minutes, and screen-on bout count (natural logarithm transformed) were 4.2 and 4.1 for adolescents and adults, respectively.

The daily measures remained relatively constant across the monitoring period. The near constancy of the measures at the daily level could be perceived as a favorable result. First, nearly all methods that attempt to detect changes in temporal data, such as anomaly detection and change-point detection methods, need to establish an underlying trend of the measure over time. Substantial variation in the daily measures of screen time could complicate the detection of changes potentially due to STB episodes. With that, there were very few suicide attempts in this cohort during the monitoring period (data not reported in this paper), highlighting the clinical team’s effectiveness in ensuring participant safety. Finally, the crucial question of the longitudinal association between screen time and STB, as well as the identification of STB episodes, will be addressed in future work, with this paper laying the groundwork by introducing the necessary method.

Another finding was the significant impact of DST changes on screen use behavior. When DST started, a decrease in screen-on time probability was observed between 2:24 AM and 4:19 AM UTC, with average probabilities dropping from 0.26 to 0.17. Conversely, when DST ended, an increase in screen-on time probability occurred between 2:22 AM and 3:19 AM UTC, with average probabilities rising from 0.15 to 0.27. A further decrease was observed between 10:52 AM and 11:44 AM UTC, with average screen-on probabilities dropping from 0.15 to 0.06. These findings suggest that sleep adjustments related to DST shifts do influence screen use behaviors.

Our study highlights the advantages of phone log–derived measures of screen time compared to traditional self-report surveys. As noted by Harris et al [30-33], self-report scales often lack internal consistency and test-retest reliability, rely on the participant’s memory, and may result in both over- and underestimation of screen time. In contrast, phone logs provide an objectively measured representation of an individual’s smartphone screen time, making them particularly useful for identifying trends or patterns in screen time, especially in longitudinal studies and free-living settings.

Our framework derives 4 daily measures of screen time: total screen-on time, average screen-on bout duration, average screen-off bout duration, and screen-on bout count to enable us to characterize a phone use behavior. The framework allows adaptation for different time resolutions, allowing researchers to explore subday-level (including minute-level) use patterns. For instance, they can investigate diurnal variations in screen time, identify atypical use periods, or study the impact of specific events on phone interactions. In future work, we propose to use sudden deviations from a participant’s routine of phone use (and screen time in particular) to identify potential STB episodes, with the goal of ultimately developing clinical interventions.

Finally, to the best of our knowledge, this is the first presentation of freely available code for preprocessing and analysis of raw phone state logs [24]. Using open-source software and sharing publicly the analysis code are essential for ensuring transparency

and replicability of the results, promoting accountability, and building trust in the research process.

Limitations

The primary limitation is the lack of a gold standard for identifying missing smartphone state logs. Though related mental health research often fails to report data quality, accounting for missingness is crucial for accurate screen time estimates and valid comparisons [16]. We proposed a heuristic for iOS to identify missingness at the minute level based on battery level changes and a method for both platforms to label data quality by day. Additionally, we evaluated the sensitivity of screen time measures to missing log imputation and, inherently related, the choice of maximum screen-on bout duration threshold (Figure S1 in Multimedia Appendix 1). Results showed substantial variability in participants' mean total screen-on time and screen-on bout duration based on the chosen screen-on duration cap. Given the lack of a principled approach for selecting an optimal cap, researchers should be mindful that this choice can substantially influence measure estimates. We do not have a definitive reason for choosing the 30-minute threshold instead of other options. However, we believe this choice strikes a good balance by indicating when a long screen time session has likely occurred while minimizing the impact of outliers on our daily estimates. Our code is openly available for transparency.

We acknowledge the potential for differences in daily measures resulting from difference in how we identified on-screen bouts for iOS versus Android devices. In additional analyses (Tables S2 and S3 in Multimedia Appendix 1), we quantified the differences in daily measures between Android versus iOS across age groups (adolescents and adults). However, the observed difference sizes were relatively small, and no statistical significance between iOSs was found. It is important to note that the absence of statistical significance does not necessarily imply the absence of a true effect. Nevertheless, given the substantial sample size, we deemed the results sufficient for our analysis.

In the sensitivity analysis for time-varying effect of a daylight time change on minute-level screen time (Figure S2 in Multimedia Appendix 1), for the ±7-day model, the 95% joint confidence bands do overlap with 0 value for the functional coefficient in the DST end model. We note that the ±7-day model's insignificant results might be due to either small sample size or using conservative 95% joint confidence bands to make inferences about the subset of the whole functional domain. Future studies could consider joint confidence bands for a prespecified restricted subset of the functional domain to increase power.

Conclusions

Passively collected smartphone logs allowed us to estimate daily measures of screen time characteristics in a large sample of adolescents and adults with suicidal thinking over a half year–long monitoring period. Our work demonstrates the feasibility of this approach, opening doors for further research on the associations between daily screen time, mental health, and other factors.

Acknowledgments

The authors would like to thank the participants and their parents and guardians who devoted their time to participate in the study. The authors thank Peter Lund Kristensen for providing us with further explanation and engaging in the discussion of the details of his paper, which we relied on in this work. The authors thank Eli Jones for his assistance in determining the characteristics of smartphone state logs across phone operating systems. This research was supported by the National Institute of Mental Health (grant U01MH116928) and by the Fuss Family Research Fund. RGF is supported by the National Institute of Mental Health (grant K23MH132766). KLZ is supported by the National Institute of Mental Health (K23MH120439). KHB is supported by the National Institute of Mental Health (K23MH120436).

Data Availability

A project repository with all data preprocessing and analysis code is publicly available on GitHub (onnela-lab/stb-beiwe-screen-time).

Authors' Contributions

MK contributed to the study concept and design, conducted data preprocessing and analysis, and wrote the first manuscript draft. DH contributed to the study concept and design and the data preprocessing and analysis concept. ZC managed operations related to data access and processing infrastructure. AJM was involved in the concept and design and provided a critical review of the manuscript. EMK, KHB, KLZ, RGF, DD, AH, AD, RJB, SAB, and JWS contributed to data collection and provided a critical review of the manuscript. MKN provided funding, contributed to the study concept and design, and provided a critical review of the manuscript. JPO contributed to the study concept and design and the data preprocessing and analysis concept and provided major edits to the manuscript draft. All authors reviewed the final manuscript.

Conflicts of Interest

MKN receives publication royalties from Macmillan, Pearson, and UpToDate. He has been a paid consultant in the past 3 years for Apple, Microsoft, and COMPASS Pathways and for legal cases regarding a death by suicide. He has stock options in Cerebral

Inc. He is an unpaid scientific advisor for Empatica, Koko, and TalkLife. JWS is a member of the Scientific Advisory Board of Sensorium Therapeutics (with equity) and has received grant support from Biogen, Inc. DD is the founder and CEO of Apoth. Other authors report no conflicts of interest.

Multimedia Appendix 1
Supplementary material containing further data on smartphone state log characteristics, estimated daily measures, screen-on time and bouts, the effect of daylight saving time, and additional details regarding our methodology.

Abstract

Background: Obesity is a rapidly increasing health problem in China, causing massive economic and health losses annually. Many techniques have emerged to help people with obesity better adhere to intervention programs and achieve their weight loss goals, including food replacement and internet-delivered weight loss consultations. Most studies on weight loss interventions mainly focused on the change in body weight or BMI; however, body fat, especially visceral fat mass, is considered the main pathogenic factor in obesity. In China, more reliable evidence is required on this topic. Moreover, it is unclear whether an integrated weight loss program combining food replacement products, mobile app-based platforms, and daily body composition monitoring using a wireless scale is useful and practical in China.

Objective: In this 2-arm, parallel-designed, randomized study, we explored the effectiveness and safety of the Metawell (Weijian Technologies Inc) weight loss program in China, which combines prepackaged biscuits, a wireless scale, and a mobile app.

Methods: Participants in the intervention group were guided to use food replacement products and a scale for weight loss and monitoring, whereas participants in the control group received printed material with a sample diet and face-to-face education on weight loss at enrollment. The intervention lasted for 3 months, and follow-up visits were conducted at months 3 and 6 after enrollment. Dual-energy x-ray absorptiometry and quantitative computed tomography were used to assess body fat. A multilevel model for repeated measurements was used to compare differences between the 2 groups.

Results: In total, 220 patients were randomly assigned to intervention (n=110) and control (n=110) groups. Participants in the intervention group had significantly greater decreases in BMI, total body fat, visceral adipose area, and subcutaneous adipose area (all P<.001) than those in the control group. However, the rate of change in lean mass was not significantly different between the 2 groups (P=.62). Further, 35 participants in the intervention group reported adverse events. Constipation was the most frequently reported adverse event (11/110), followed by dizziness (6/110), hypoglycemia (4/110), fatigue (3/110), and gastritis (3/35).

Conclusions: The Metawell program was effective for weight loss. After the intervention, participants in the intervention group lost more body weight and body fat while retaining muscle mass than those in the control group.

Introduction

In China, the prevalence of obesity has increased rapidly from 3.1% in 2004 to 8.1% in 2018 [1]. Obesity is closely related to a series of diseases such as cardiovascular diseases, diabetes, and hypertension and leads to physical impairments and a decrease in the quality of life [2]. The economic losses caused by overweight and obesity in China are estimated to be US $12.97 billion [3]. Moreover, an elevated BMI was estimated to be the seventh highest risk factor for death in China, equating to nearly 0.7 million deaths in 2017 [4].

Nutrition therapy is considered to be the foundation of obesity management [5]. Meal replacement products provide an easy way for participants to follow a weight loss program, and rapid weight loss during the initial stage of the intervention can help to build the confidence of participants, thus leading to greater weight loss. The Doctor Referral of Overweight People to Low Energy Total Diet Replacement Treatment (DROPLET) study revealed that total meal replacement programs provided by general practitioners are effective for weight loss [6], and a meta-analysis showed that partial or total meal replacements were associated with greater weight loss [7,8].

The delivery of lifestyle intervention programs may also have an impact on their effectiveness in weight loss. Whether the use of the internet or a mobile app platform to deliver the intervention will lead to greater weight loss is controversial. A meta-analysis showed that the use of mobile apps can improve the effect of weight loss interventions [9], whereas other studies did not find a statistically significant effect for mobile apps [10].

Most studies of weight loss interventions focused on the change in body weight or BMI; however, body fat, especially visceral fat mass, is considered the main pathogenic factor in obesity [11]. We found 1 randomized study focused on the change in body composition during a weight loss intervention in China [12]. However, the sample size was limited, and the body composition results are not sufficiently accurate considering their measuring method; therefore, we still need more reliable evidence on this topic. Furthermore, it is unknown whether an integrated weight loss program combining food replacement products, a mobile app-based platform, and daily monitoring of body composition using a wireless scale would be useful and practical in China. Thus, we performed this study to evaluate the safety and efficacy of the Metawell program, a weight loss program using prepackaged biscuits, a Bluetooth body composition scale, and a mobile app for uploading body composition data and delivering meal guidance from health care professionals daily for weight loss and changes in body composition and body fat distribution.

Methods

Study Design

This was a single-center, open-label, 2-arm, parallel-designed, randomized controlled trial; all participants were recruited from Chengdu City via social media platforms and face-to-face visits, and assessments will take place at enrollment and at 3 and 6 months after enrollment. The trial started on April 11, 2019. Participants were randomly assigned to the intervention and control groups at a ratio of 1:1. This trial was registered in the Chinese Clinical Trial Registry (ChiCTR1900021630). After our trial started, several participants older than 65 years showed a strong willingness to participate; after discussion, we decided to raise the upper limit of the participant aged from 65 to 75 years.

Ethical Considerations

This trial was approved by the ethics committee of the Hospital of Chengdu Office of People's Government of the Tibetan Autonomous Region (2019-No.01). All participants have signed the informed consent; all data are anonymized. All participants will be informed that they will receive ¥200 (a currency exchange rate of ¥6.92=US $1 is applicable) compensation for each follow-up visit they attend.

Eligibility Criteria

The inclusion criteria were those aged between 18 and 75 years with a BMI ≥25 and <40 kg/m^2 and one or more of the following: a history of hypertension or either systolic blood pressure >120 mm Hg or diastolic blood pressure >80 mm Hg, abdominal circumference >96 cm (90 cm for women), fasting triglyceride level >1.69 mmol/L, a history of type 2 diabetes mellitus managed with lifestyle (not on insulin or oral medications) or fasting blood glucose level >5.6 mmol/L, and high-density lipoprotein cholesterol level <1.04 mmol/L (1.3 mmol/L for women).

Participants with one or more of the following conditions were excluded: a history of coronary artery disease; diabetes mellitus managed with insulin or any oral hypoglycemic pill for diabetes; glucose intolerance or fasting glucose level ≥8 mmol/L; congestive heart failure; familial hypercholesterolemia, including familial hypertriglyceridemia, fasting low-density lipoprotein cholesterol level >4.2 mmol/L, fasting triglyceride level >6.8 mmol/L, and current use of lipid-lowering agents; a past medical history of hypothyroidism, Cushing syndrome, eating disorders, gout in the past 6 months, confirmed episodes of hypoglycemia, pregnancy, advanced liver disease, renal insufficiency, or any other major chronic medical condition; and smokers who planned to quit smoking in the following 12 months. Participants with hypertension were included only if they were taking fewer than 3 antihypertensive medications, did not have changes in the dose of their blood pressure medications in the last month, and had systolic blood pressure

<160 mm Hg and diastolic blood pressure <100 mm Hg. Finally, people who could not use smartphones were excluded.

Randomization, Masking, and Blinding

The list of random numbers was generated using R with a certain random seed, the results of which were sequentially sealed in opaque envelopes and were unsealed while participants signed the consent and finished eligibility screening. This study was an open-label study; patients and researchers were not blinded.

Interventions

Details of the interventions had been described in our previously published protocol [13]. In general, participants in the intervention group would download a mobile app and be guided to use food replacement products and a scale for weight loss and monitoring. Their diet, body composition, and urine ketone will be monitored every day, and trained instructors will guide them remotely. During the weight loss stage (0 - 3 months), participants will be guided to take food replacement biscuits along with a selection of healthy recipes (such as seaweed soup, skimmed milk, spiced beef, grains, vegetables) and advised to take multivitamin tablets daily. Detailed nutritional information on diet replacement biscuits is listed in Table S1 in Multimedia Appendix 1, and the overall intake of energy for the intervention group was restricted to 800 - 1200 kcal/day; the instructor will guide participants to adjust their recipe based on their health condition and the speed of weight loss. During the weight maintenance stage (3 - 6 months), participants will stop using the biscuit, and they will be told to monitor their weight and upload data. When noticeable weight regain is detected, the practitioner will initiate a 2 - to 3-day weight loss intervention using the same protocol as that used in the weight loss stage to maintain the participant's body weight. Based on obesity management guidelines, a calorie intake of 800 - 1200 is generally safe. Furthermore, on analyzing the data of over 250,000 Chinese using this program for weight loss, we found no significant safety concerns.

Meanwhile, participants in the control group would receive printed material with a sample diet, as well as face-to-face education on weight loss at enrollment. The printed sample diet used for the control group included a daily energy intake of 1500 kcal for men and 1200 kcal for women. Doctors and the dietician in our research group (XW, L Zhong, and YW) were responsible for monitoring participants' safety.

Outcomes

The primary outcome was weight loss as a result of the intervention, defined as the reduction in BMI after 6 months. The following two secondary outcomes were also analyzed: (1) the proportion of participants achieving a body weight reduction of greater or equal to 10% of baseline body weight and (2) the change in body fat mass and lean mass, as well as changes in the distribution of adipose tissue.

Assessment and Follow-Up

Participants were followed up at 3 and 6 months after enrollment. During each follow-up assessment, body weight was measured using an ultrasonic height-weight scale (DHM-200, Dinghengkeji), and physical activity was assessed using the International Physical Activity Questionnaire long form. Dual-energy x-ray absorptiometry (DXA) was used to assess the body composition of the participants using a GE Lunar Prodigy scanner (GE Healthcare). A 16-slice computed tomography (CT) scanner (Aquilion 16; TOSHIBA) was used to perform abdominal scanning, and the distribution of adipose tissue was analyzed with QCTPRO software (Mindways Software) using a slice between L2 and L3. DXA and CT were performed only at baseline and at the 6-month follow-up.

Sample Size

According to the DROPLET study [6], we hypothesized that the average absolute difference in weight loss between the trial and control groups would be at least 4 kg in weight, with an SD of 9 kg. Therefore, 100 participants per group will provide more than 90% power to detect this difference, with an α error of .05. The sample size would be 110 participants per group considering an estimated 10% attrition rate.

Statistical Analysis

The intention-to-treat dataset was used to analyze the primary and secondary outcomes. The normality of data was tested using Kolmogorov-Smirnov test. All of our continuous data had nonnormality according to test results, so they are presented as median (IQR). Categorical data are presented as count (%). Baseline information was compared between the 2 groups, Mann-Whitney *U* test and chi-square test were used for continuous and categorical variables, respectively. A multilevel model for repeated measurements was used to test the interaction of the intervention and time against BMI as the primary outcome and fat mass, lean mass, visceral adipose area, and subcutaneous adipose area as the secondary outcomes. Variants of different individuals were treated as the first level and different follow-up times were treated as the second level. After reviewing previous studies such as he DROPLET study and incorporating with clinical experience of clinicians in our group, baseline body weight, physical activity, sex, and age were adjusted. The rate of missing data was relatively low in this study; therefore, missing data were not considered in the analysis.

We performed a post hoc subgroup analysis to determine whether there were any differences among participants of different age and sex groups. Baseline characteristics were compared using SPSS (version 24.0; IBM Corp), and multilevel model analysis was performed using MLwiN (version 2.30; Centre for Multilevel Modelling, University of Bristol). *P* values <.05 were considered statistically significant.

Results

Overview

Participants were recruited between April 2019 and January 2020. A total of 329 participants were registered for screening and 220 were randomly assigned to the intervention and control groups (n=110 each; Figure 1). The median age of the participants was 33 (IQR 28-41) years and 57.8% (n=125) were women. The median BMI was 27.9 (IQR 4) kg/m^2. There were no differences in any of the baseline characteristics between the 2 groups (Table 1). At the 6-month follow-up, we followed 103

participants in the intervention group and 94 in the control group (Figure 1).

Figure 1. Flowchart of this study.

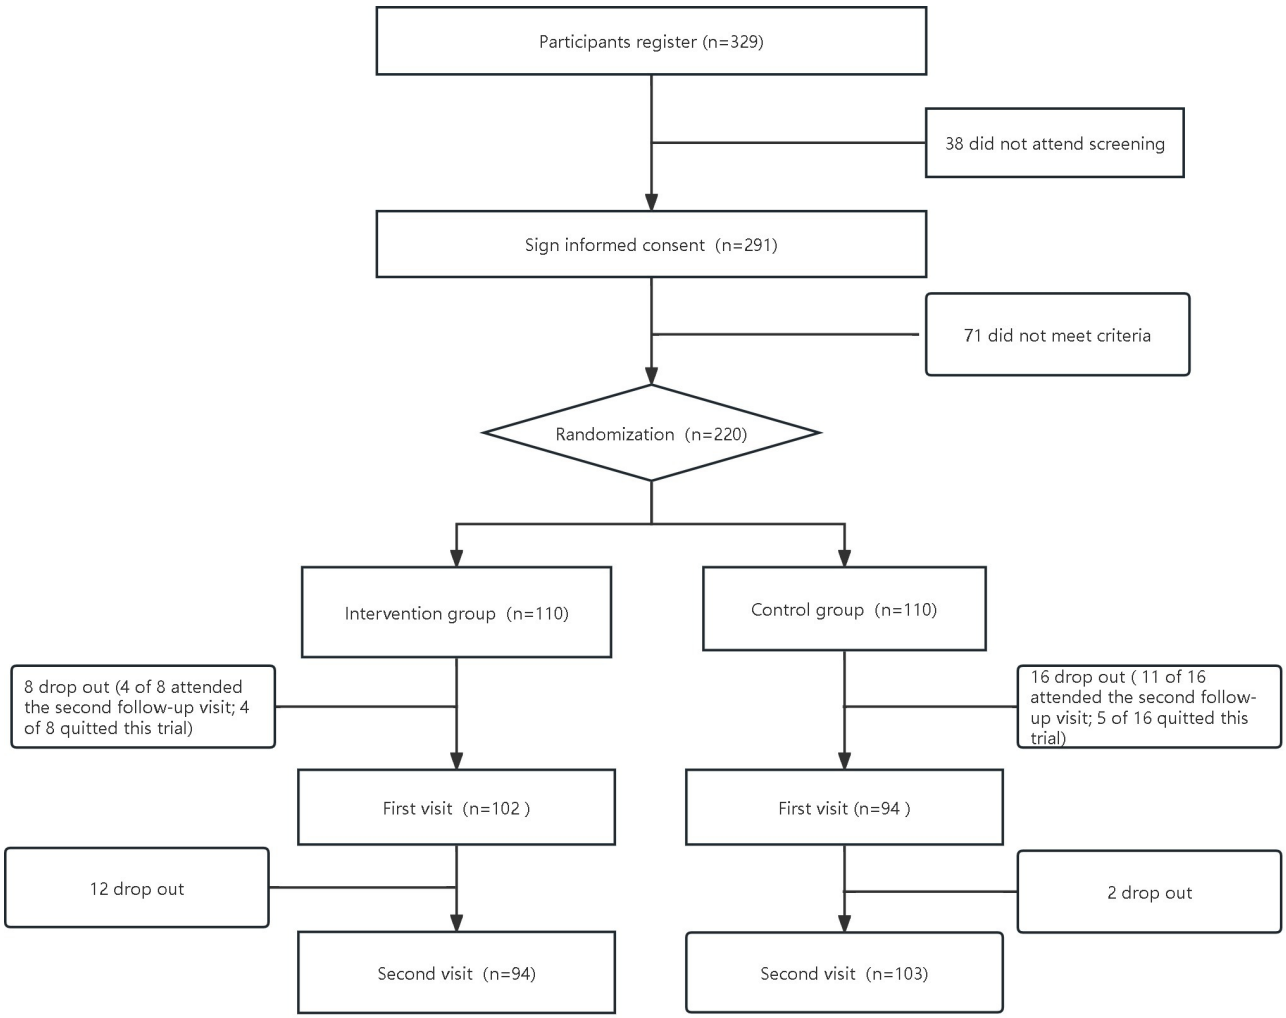

Table . Baseline information of the participants.

	Overall (n=220)	Intervention group (n=110)	Control group (n=110)	*P* value
Sex, n (%)				.63
Male	95 (42.22)	48 (44.86)	47 (41.59)	
Female	125 (57.78)	59 (55.14)	66 (58.41)	
Age (years), median (IQR)	33 (28-41)	32 (28- 39)	33 (28-41)	.48
Height (cm), median (IQR)	164.5 (158.0-171.0)	165.0 (159.0-170.5)	164 (158.0-171.0)	.85
Weight (kg), median (IQR)	76.4 (68.9-86.1)	77.4 (70.1-85.3)	75.2 (67.8-86.2)	.49
BMI (kg/m^2), median (IQR)	27.9 (26.2-29.9)	28.2 (26.3-30.9)	27.7 (26.0-29.7)	.39
Waist circumference (cm), median (IQR)	97.4 (92.4-102.8)	97.7 (93.0-102.5)	97.1 (92.1-102.9)	.57
Hip circumference (cm), median (IQR)	105.4 (101.3-110.0)	105.5 (100.2-109.8)	106.4 (102.1-110.0)	.18
Subcutaneous adipose (cm^2), median (IQR)	201.5(158.7-271.1)	208.8 (167.5-275.7)	196.9 (155.1-267.8)	.33
Visceral adipose (cm^2), median (IQR)	167.9 (123.2-230.7)	171.6 (127.4-215.4)	163.3 (120.5-237.1)	.54
Total fat mass (kg), median (IQR)	29.4 (25.1-34.9)	29.8 (25.6-34.7)	29.35 (24.6-35.6)	.96
Total lean mass (kg), median (IQR)	46.1 (39.1-55.0)	47.5 (39.1-54.9)	43.83 (39.1-55.1)	.67
Physical activity (METs[a]/week), median (IQR)	1062.5 (258.0-2715.0)	1284 (346.5-2806.0)	928.5 (102.5-2331.0)	.33

[a]MET: metabolic equivalent of task.

Primary Outcome

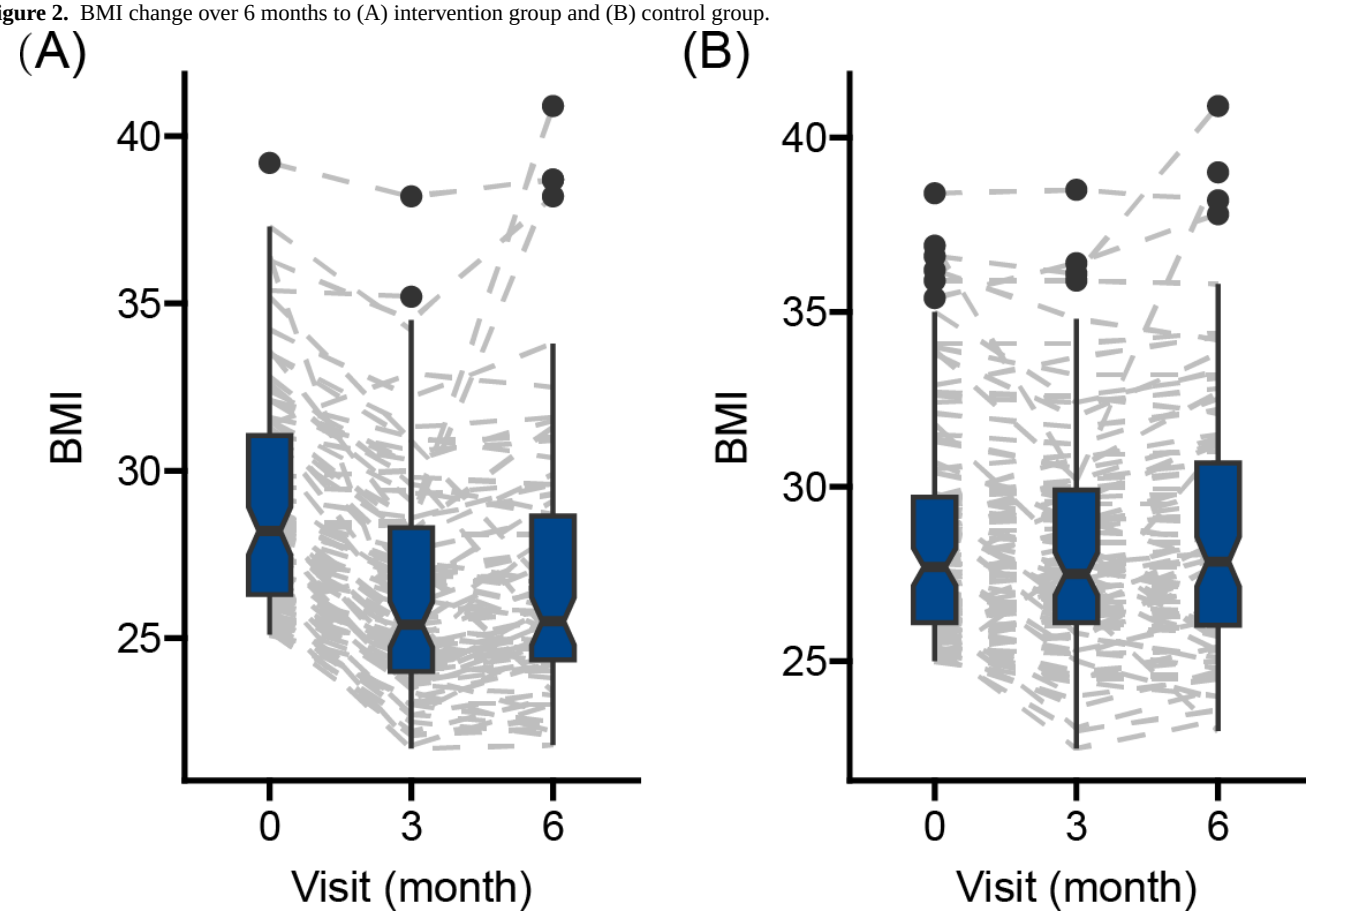
At 6 months, 31 (28%) and 3 (3%) participants in the intervention and control groups, respectively, achieved a weight loss of at least 10% compared with their baseline weight. The median change in BMI was –1.90 (IQR –0.8 to –3.2) kg/m^2 for the intervention group and –0.03 (IQR –0.9 to –0.4) kg/m^2 for the control group (Table 2).

Table . Primary and secondary outcomes by group.

Outcomes	Intervention group	Control group
3 months		
BMI change (kg/m^2), median (IQR)	–2.3 (–3.2 to –1.3)	–0.2 (–0.9 to 0.4)
At least 10% weight lost, n (%)	37 (33.63)	5 (4.54)
6 months		
BMI change (kg/m^2), median (IQR)	–1.9 (–0.8 to –3.2)	–0.03 (–0.9 to 0.4)
At least 10% weight lost, n (%)	31 (28.18)	3 (2.72)
Body fat mass change (kg), median (IQR)	–3.9 (–7.3 to –1.3)	0.1 (–1.9 to 2.6)
Body lean mass change (kg), median (IQR)	–0.8 (–2.1 to 0.2)	–0.4 (–1.7 to 0.6)
Subcutaneous adipose change (cm^2), median (IQR)	–37.6 (–71.4 to –10.4)	–11.2 (–34.9 to 18.8)
Visceral adipose change (cm^2), median (IQR)	–15.1 (-44.3 to 2.4)	7.8 (–12.6 to 37.9)

The change in BMI was different between the 2 groups before ($\beta_{group\times time}$=–1.214, *P*<.001) and after ($\beta_{group\times time}$=–1.238, *P*<.001) adjustment for sex, age, baseline body weight, and baseline physical activity level (Figure 2; Table S2 in Multimedia Appendix 2).

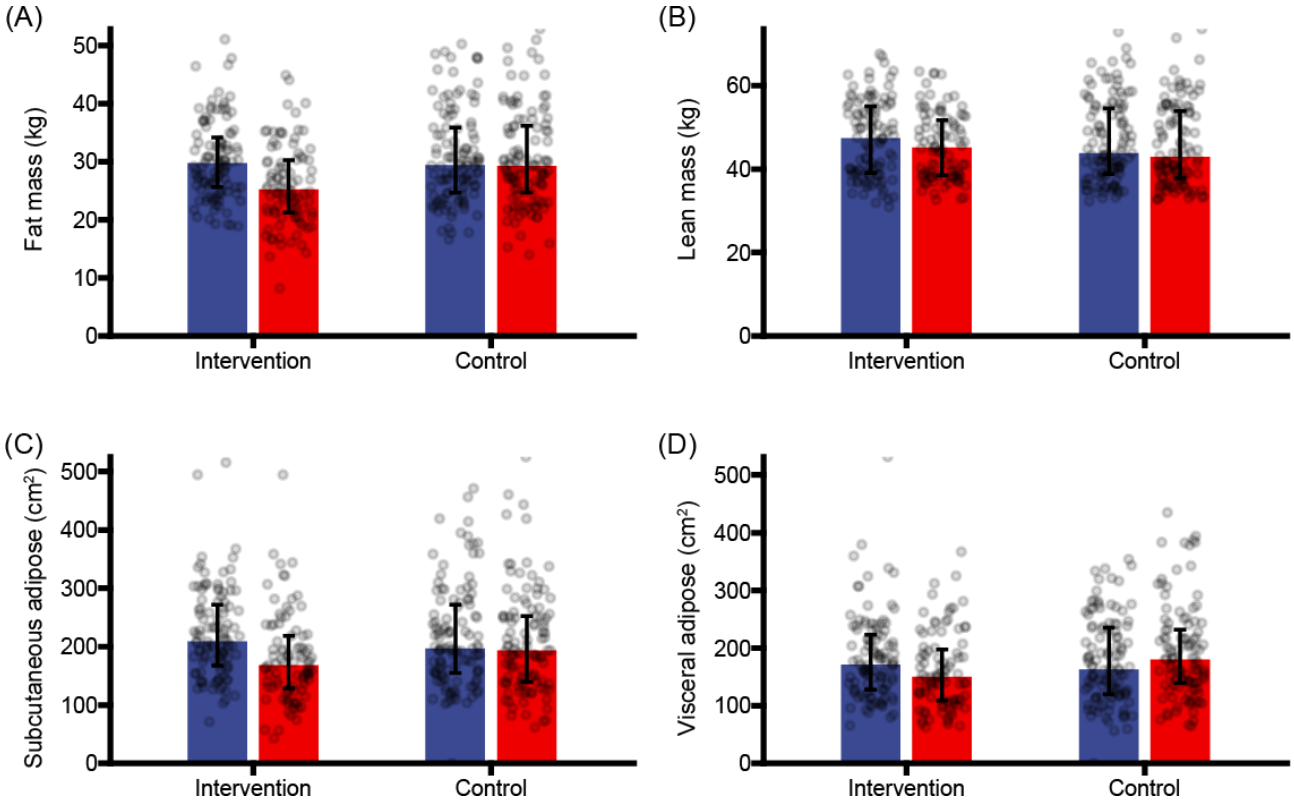
Figure 2. BMI change over 6 months to (A) intervention group and (B) control group.



Secondary Outcomes

After the intervention, the total body fat mass decreased by 5.07 kg and the total body lean mass decreased by 3.13 kg in the intervention group. In the control group, body fat mass increased by 0.06 kg, and body lean mass decreased by 0.27 kg (Figure 3). The change rate of body fat mass between the 2 groups was statistically significant ($\beta_{group\times time}$=–4.127, P<.001), whereas that of total muscle mass was not significant ($\beta_{group\times time}$=–0.177, P=.62; Table S2 in the Multimedia Appendix 2).

Figure 3. Change in body composition before (blue) and after (red) the intervention in different groups: (A) total body fat mass, (B) total lean mass, (C) subcutaneous adipose area, and (D) visceral adipose area.



Subcutaneous and visceral adipose areas decreased by 53 and 31 cm^2, respectively, in the intervention group (Figure 3). In the control group, subcutaneous adipose area decreased by 1 cm^2 and visceral adipose area increased by 19 cm^2. The rates of change in subcutaneous adipose area ($\beta_{group\times time}$=–40.898, P<.001) and visceral adipose area ($\beta_{group\times time}$=–40.409, P<.001) were different between the 2 groups (Table S3 in Multimedia Appendix 3).

Subgroup Analysis

Subgroup analyses were performed to determine whether the intervention was effective in the different sex and age groups. The decrease rate in BMI was greater in the intervention group in both male and female participants ($\beta_{group\times time}$=–1.781 for male sex and $\beta_{group\times time}$=–0.833 for female sex; Table S4 in Multimedia Appendix 4). Furthermore, for participants in all age groups, the rate of decrease in BMI was greater in the intervention group ($\beta_{group\times time}$=–0.754 for age ≤30 years, $\beta_{group\times time}$=–0.833 for age 31 - 40 years, and $\beta_{group\times time}$=–2.055 for age ≥41 years; Table S4 in Multimedia Appendix 4).

Adverse Events

In the control group, only 2 participants reported 4 adverse events (AEs) during the follow-up visits, whereas 35 participants reported AEs in the intervention group (Table 3). The most common AE in the intervention group was constipation (11/110); 10% of the participants in the intervention group reported varying degrees of constipation during the follow-up visits. Other common AEs were dizziness (6/35), hypoglycemia (4/110), fatigue (3/110), and gastritis (3/110). All AEs were classified as mild to moderate, none of these participants were hospitalized because of AEs.

Table . Numbers of participants reporting adverse events.

	Intervention group, n	Control group, n	Total, n
Constipation	11	1	12
Hypoglycemia	4	0	4
Diarrhea	1	1	2
Fatigue	3	1	4
Dizziness	6	1	7
Sour regurgitation	1	0	1
Hair loss	1	0	1
Flustered	1	0	1
Rhinitis	2	0	2
Gastritis	3	0	3
Menstrual disorder	1	0	1
Elevated urinary ketones	1	0	1

Discussion

Principal Results

This investigation demonstrated that the implementation of a weight loss program combining food replacement products, remote guidance by practitioners, and daily monitoring of body composition is effective for weight loss and reducing fat mass, especially visceral fat, without significant muscle loss in people with overweight and obesity in China.

Comparison With Prior Work

According to previous investigations, more than half of patients with obesity were not motivated to adhere to weight loss interventions; the most frequently reported barrier was a lack of accessibility to weight loss diets and a lack of support and external control [14]. Furthermore, the need for intensive follow-up with motivational interviews was highlighted. In our program, a series of methods were used to address these barriers, including using food replacement products, intensive guidance delivered via a mobile app, and a wireless scale provided to participants for their daily monitoring of body composition. Food replacement products can be a useful tool in weight loss programs, providing an easy way for participants to adhere to the diet intervention [14]. Mobile apps enable frequent interactions between health care professionals and patients and allow intensive motivational interviews. Additionally, more frequent body composition monitoring is closely associated with better adherence. Several studies have revealed that the use of food replacement products, mobile apps, and wireless scales can lead to greater weight loss [7,15-17]. Our study confirms that the combination of these techniques can lead to greater weight loss than traditional educational materials.

Although BMI is a good marker for obesity screening, the threshold varies among different ethnic and age groups. Moreover, considering that most comorbidities of obesity are mediated by excess fat, endocrine and immune responses of adipose tissue are distributed throughout different organs [18,19]. Hence, BMI is not suitable to reflect the complexity of obesity. In recent years, some studies on weight loss interventions have investigated the change in body composition and adipose tissue distribution; however, most used bioelectrical impedance analysis for the measurements, which is less accurate than DXA or CT [20]. In our study, we used DXA and quantitative CT for a more accurate assessment of body composition changes, and we confirmed that the intervention program could reduce the amount of total fat, visceral fat, and subcutaneous fat compared with the control program. Therefore, we can be more confident that patients with obesity can achieve health benefits through the loss of body fat by adhering to this intervention program.

We also found that the change rate in lean mass was not statistically significant (P=.62) between the 2 groups. In contrast, previous studies suggested that severe calorie-restricting interventions would lead to a greater loss of lean mass [21]. The use of a food replacement product might be a reason why the participants in the intervention group did not experience a significant loss of lean mass, despite having a restricted intake of calories. A systematic review by Coleman et al [22] indicated that food replacement products can minimize the loss of lean mass by reducing the variety of foods. Furthermore, our intervention provided a relatively high protein intake level while restricting calorie intake. Increasing the daily intake of protein can prevent muscle loss while decreasing the amount of body fat [23].

The safety of food replacement products is a concern for health care professionals, and their use is not recommended by most guidelines because of the lack of data on safety and effectiveness. Our study demonstrated that, although the risk was slightly higher in the intervention group, the side effects of this product were mild to moderate. The most common AE was constipation, which is consistent with a previous study on total food replacement products and low-carbohydrate diets [6]. To assess the safety of our intervention program, we also analyzed the change in spinal bone mineral density (BMD), we found the BMD decreased by about 2% (from mean 1.11, SD 0.10 g/cm^2 to mean 1.09, SD 0.09 g/cm^2, P<.01) in the

intervention group (data not shown). However, considering that the least significant change of our DXA measurement was 5.3%, which is much higher than the decreasing rate we found in our study, we believe that this change was not clinically significant. Therefore, food replacement programs are relatively safe for weight loss in healthy individuals.

The follow-up of some participants was delayed owing to the COVID-19 pandemic and the lockdown in Chengdu City; however, considering that our participants did not have access to our weight loss intervention during the lockdown and according to relevant studies [24,25], we expected their body weight to increase, resulting in the underestimation of the effect size; therefore, we did not treat this situation.

Limitations and Strengths

To the best of our knowledge, this is the first study using DXA and quantitative CT to accurately and systematically evaluate change in body fat, visceral adipose tissue, and subcutaneous adipose tissue during weight loss intervention, which is more relative to participants' health than BMI [26,27]. This is the main highlight of our study.

The main limitation of our study is that the follow-up period was relatively short to observe the long-term effects of this intervention. Meanwhile, we found a statistically significant (although without clinical significance) decrease in BMD in the intervention group, it remains unclear whether there would be any lasting impact on BMD after the intervention ended. Therefore, an extended follow-up will be performed to investigate whether participants will regain their body weight and whether their BMD will continue to decrease. Furthermore, we only explored the effectiveness of this weight loss program without performing a cost-effectiveness analysis. We will collect and analyze related data in the following study. Moreover, this study's results should be treated as exploratory outcomes, and further studies are required to verify them.

Conclusions

The Metawell program was effective for weight loss. After the intervention, participants in the intervention group lost more body weight and body fat while retaining muscle mass than those in the control group.

Acknowledgments

We would like to present our special thanks to Dr Francisco Lopez-Jimenez, Dr Lilach O Lerman, and Dr Amir Lerman for their help in the designation of our study, and Miss Li Qiuyue for helping us in recruiting participants. Abstract

Background: The increasing prevalence of sedentary lifestyles has prompted the development of innovative public health interventions, such as smartphone apps that deliver personalized exercise programs. The widespread availability of mobile technologies (eg, smartphone apps and wearable activity trackers) provides a cost-effective, scalable way to remotely deliver personalized exercise programs to users. Using machine learning (ML), specifically reinforcement learning (RL), may enhance user engagement and effectiveness of these programs by tailoring them to individual preferences and needs.

Objective: The primary aim was to investigate the impact of the Samsung-developed i80 BPM app, implementing ML for exercise prescription, on user satisfaction and exercise intensity among the general population. The secondary objective was to assess the effectiveness of ML-generated exercise programs for remote prescription of exercise to members of the public.

Methods: Participants were randomized to complete 3 exercise sessions per week for 12 weeks using the i80 BPM mobile app, crossing over weekly between intervention and control conditions. The intervention condition involved individualizing exercise sessions using RL, based on user preferences such as exercise difficulty, selection, and intensity, whereas under the control condition, exercise sessions were not individualized. Exercise intensity (measured by the 10-item Borg scale) and user satisfaction (measured by the 8-item version of the Physical Activity Enjoyment Scale) were recorded after the session.

Results: In total, 62 participants (27 male and 42 female participants; mean age 43, SD 13 years) completed 559 exercise sessions over 12 weeks (9 sessions per participant). Generalized estimating equations showed that participants were more likely to exercise at a higher intensity (intervention: mean intensity 5.82, 95% CI 5.59 - 6.05 and control: mean intensity 5.19, 95% CI 4.97 - 5.41) and report higher satisfaction (RL: mean satisfaction 4, 95% CI 3.9-4.1 and baseline: mean satisfaction 3.73, 95% CI 3.6-3.8) in the RL model condition.

Conclusions: The findings suggest that RL can effectively increase both the intensity with which people exercise and their enjoyment of the sessions, highlighting the potential of ML to enhance remote exercise interventions. This study underscores the benefits of personalized exercise prescriptions in increasing adherence and satisfaction, which are crucial for the long-term effectiveness of fitness programs. Further research is warranted to explore the long-term impacts and potential scalability of RL-enhanced exercise apps in diverse populations. This study contributes to the understanding of digital health interventions in exercise science, suggesting that personalized, app-based exercise prescriptions may be more effective than traditional, nonpersonalized methods. The integration of RL into exercise apps could significantly impact public health, particularly in enhancing engagement and reducing the global burden of physical inactivity.

Trial Registration: ClinicalTrials.gov NCT06653049; https://clinicaltrials.gov/study/NCT06653049

Introduction

Every year, hundreds of randomized controlled trials evaluating the effects of exercise in diverse population groups are published. This research has demonstrated the medicinal capacities of exercise for numerous chronic diseases [1]. Consequently, exercise is considered an essential component in the management plans of many health care interventions [1-3]. Regular exercise has also been shown to have wide-ranging health benefits for nonpathological groups; for instance, there is evidence to suggest that a sedentary lifestyle may be an even stronger predictor of mortality than smoking, hypertension, and diabetes [4]. National and international campaigns, advertisements, and public health guidelines have been developed to increase public awareness of the benefits of exercise [5,6]. Despite this, inactivity (and the increased risk of morbidity and mortality associated with it) remains a significant public health concern [7,8]. This raises the question: if people know that regular physical activity and exercise are good for them, why are so many inactive?

Even in randomized controlled trials, low levels of adherence to exercise sometimes belie the treatment effect to such an extent that results in comparison to a nonexercising control group are statistically insignificant [9,10]. Adherence to exercise, which is defined as the degree to which the target intensity and volume are achieved [11,12], is likely to be worse among the general population, who are not enthusiastic volunteers in a research study and who are being closely supervised by a research team [13].

Many theories and models have been proposed to explain why adherence to exercise is suboptimal [14,15]. A recent umbrella review identified a number of key factors for improving adherence to exercise [16]. Among the 14 factors that were identified, individualizing the exercise program, making sure that it integrates easily into participants' daily living schedules, continually monitoring and providing feedback on progress (and adapting the exercise program accordingly), ensuring that users have an active role in goal setting, and using technology to deliver the exercise intervention were deemed to be important in improving adherence [16]. Patient education was also considered crucial to increase self-efficacy, enhancing the knowledge about what they can do and what they can change to improve their overall health [17-19].

Mobile technologies (eg, smartphone apps and wearable activity trackers) are a cost-effective, scalable way of delivering exercise programs to users that incorporate these factors. Over 60% of adults worldwide own a smartphone, with worldwide penetration rates highest in the United States (where >80% of the population uses a smartphone) [20]. In addition to being able to deliver interventions through wireless internet and messaging connectivity, smartphones have in-built tools like global positioning systems, inertial measurement units, and cameras that can objectively measure several exercise parameters [21-23]. Smartphones also have powerful computation and communication capabilities that enable the use of machine learning (ML) and artificial intelligence to individualize each user's exercise program.

Reinforcement learning (RL) represents a compelling method within ML for tailoring and adapting exercise programs to individual users. In RL, a decision-making agent performs actions that lead to preferred states within its environment. Each action transitions the environment to a new state, following which the agent receives feedback—either positive or negative reinforcement. This feedback helps to refine the agent's "policy," which is essentially a strategy that maps states to actions aimed at maximizing cumulative rewards over time.

For instance, consider the use of RL within a smartphone app designed for exercise prescription. Here, the agent could consider variables such as user satisfaction or perceived exertion (ie, the session's intensity) as states. The agent's actions could involve adjusting various exercise parameters, such as the number of sets, repetitions, or rest periods in a training session, or altering the types of recommended exercises. The reward function would assess the degree of user satisfaction or exertion, aiming to minimize discrepancies and optimize user experience.

RL is particularly well-suited to the sequential decision-making required in exercise prescription. It operates in a cycle where the agent proposes an exercise session, the user completes it and provides feedback, and the agent uses this information to tailor future sessions. Although several frameworks exist for automating exercise prescription based on user demographics, fitness levels, engagement behaviors, and preferences [24-27], comprehensive studies evaluating the effectiveness of fully computerized, app-based exercise prescription remain limited [28-31]. This gap underscores the need for further research to validate and optimize RL apps in this field.

Therefore, the aim of this study was to test a smartphone app that generates adaptive exercise regimes, incorporating RL to personalize the composition of exercises within sessions based on user satisfaction. We compared user satisfaction between sessions generated by the RL system to a control condition that administered a generic exercise to the user, irrespective of their preferences. The primary outcome for this aim was users' satisfaction with exercise, which was defined by an abbreviated 8-item version of the Physical Activity Enjoyment Scale (PACES-8) [32,33].

Our primary hypotheses were that users would report higher satisfaction and demonstrate greater adherence to exercise programs generated using RL compared with sessions that are generated randomly or using predefined (ie, nonpersonalized) templates. Our secondary hypothesis was that users would demonstrate higher levels of exertion, measured using Borg's rate of perceived exertion (RPE) scale, during sessions generated with an RL approach.

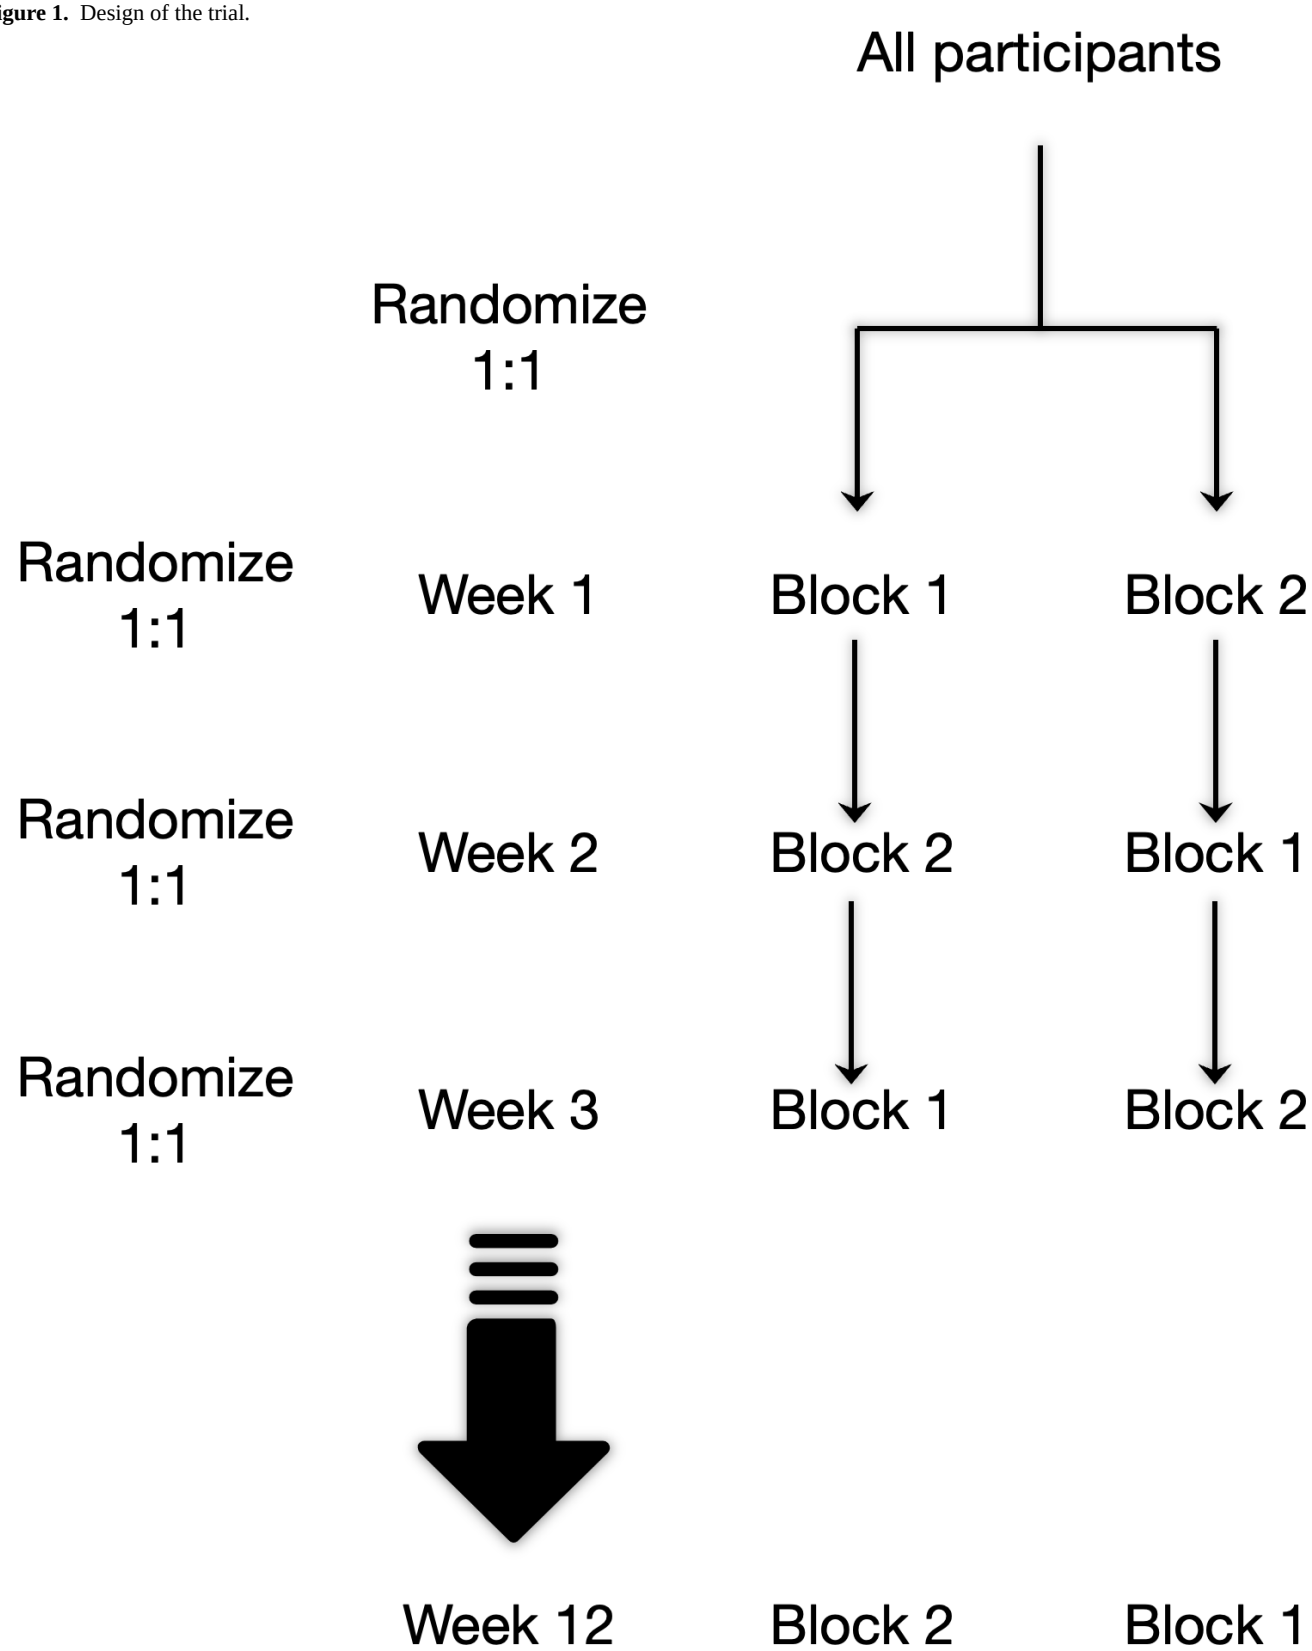
Methods

Study Design

The protocol for this study was developed using the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) checklist [34] The design was a 12-week, assessor-blinded, randomized crossover trial, with the primary end point being user satisfaction after each exercise session. However, unlike a typical crossover trial, participants

transitioned “back and forth” between experimental conditions. Specifically, each participant alternated between the intervention and control conditions at the end of each 1-week cycle. The order in which participants completed each condition (RL condition and control condition) was altered on a weekly basis; each participant was administered condition-generated exercise sessions for 1 week. Each of these 1-week cycles was comprised of 3 workout sessions of approximately 20 minutes in duration, containing >30 exercises (each exercise lasted <30 seconds). The only difference between the workout sessions within each condition was the specific exercises that were recommended (and the order in which they were completed); all other parameters of exercise were held consistent. After a 1-week cycle had elapsed, each cluster of participants completing the protocol under each of the 2 conditions crossed over to the opposing condition, with each crossover marking the start of a new 1-week cycle, regardless of whether participants actually completed the sessions within that cluster. This design is illustrated in Figure 1.

Figure 1. Design of the trial.



Ethical Considerations

The University College Dublin Human Research Ethics Committee approved this study (LS-21 - 34-Tragos-Lawlor). Written informed consent was obtained, and health screening was conducted for all participants before they enrolled in the trial. The trial was not prospectively registered. Recruitment was conducted between July 6, 2022, and August 29, 2022, and the trial was completed on November 16, 2022. During data collection, each participant was given a participant ID number when they registered with the app. The data were stored using these ID numbers. The key to the code that matched participants' full name to their ID number was saved in an electronic password-protected file, which was stored on an encrypted drive.

The authorship team had sole access rights to these key codes and ID numbers during the trial. Data acquired via the smartphone app were stored on a password-protected University College Dublin server. After data collection, data were anonymized by permanently deleting the file with the participants' identification key. Participants were not compensated for their participation.

Population

Participants were recruited from Dublin, Ireland, and its environs via word of mouth and social media. Male and female participants aged 18 to 65 years were recruited. To be eligible for inclusion, participants were required to be healthy, recreationally active adults. This was defined as having engaged in aerobic activity for a total of 80 minutes at moderate intensity, less than or equal to twice per week. Prior to randomization, participants were screened for eligibility by the "exercise preparticipation health screening questionnaire for exercise professionals." Exclusion criteria included an inability to exercise due to physical disability or motor impairment, having a severe cognitive impairment, or an inability to read and write in English.

Blinding

Participants were blinded to their allocation throughout the course of the trial. The researcher conducting data analysis was also blinded to knowledge of the intervention.

Procedure

Upon expressing interest, potential participants received detailed information about the trial along with a health screening questionnaire. After completing the health screening, participants attended an information session via Zoom (Zoom Video Communications), where they were shown how to use the app and its various functions and also instructed on downloading it to their mobile devices. At this session, informed consent was obtained. Each participant was issued a Samsung Galaxy Fit 2 smartwatch (Samsung Electronics Co, Ltd) to use during the exercise sessions for recording heart rate data. Several studies have demonstrated the accuracy of the Samsung Gear Fit for heart rate measurement during a variety of activity types, making it a suitable choice for this study [35-37]. Participants were allowed to keep the fitness tracker after the trial concluded. Immediately following randomization, baseline data collection was carried out through the app.

Interventions

Participants were asked to complete 3 exercise sessions weekly over 12 weeks using the i80 BPM smartphone app developed by Samsung Electronics Co, Ltd. This app offers video-guided exercise programs and includes a library of 161 exercises. Using RL, i80 BPM customizes and adapts exercise sessions to suit the user's preferences and abilities. The duration of these sessions, ranging from 10 to 30 minutes, was selected by the user. Users could create personalized session plans varying from 1 to 12 weeks and choose between aerobic and muscle-strengthening exercises, targeting specific muscle groups. The RL model selected exercises for each session based on these preferences, ensuring a diverse range of possible sessions.

Aside from the RL model's app, all other parameters remained constant across both the intervention and control conditions. These included the exercises available, the app's interface, and options for session duration and focus (aerobic vs muscle strengthening). The key difference was the individualization of exercise sessions using the RL model in the intervention condition, whereas the control condition used generic, nonpersonalized sessions. Further details on the RL model are discussed elsewhere [38], but in summary, the model used within the i80 BPM app aimed to optimize user satisfaction by personalizing the exercise sequence based on user feedback and evolving preferences. The app's RL framework used a decision-making agent within an environment shaped by user interactions and fitness profiles. The model was trained to maximize expected rewards, which incorporated metrics of performance and user feedback. In this framework, "actions" referred to the selection of exercises from the app's database. The "state" included information such as the user's fitness level and exercise preferences along with session specifics like previously recommended exercises and user feedback. The "reward function" balanced various elements including exercise diversity, suitability to the user's fitness level, and feedback after each session to ensure that the recommendations met the user's goals and responses to past workout sessions. The RL model used a neural network to map states to action probabilities, optimizing the sequence of recommended exercises to maximize cumulative rewards—reflecting both user satisfaction and session effectiveness [38].

RL Intervention

The RL intervention used the app's full functionality, meaning that exercise sessions were tailored to the user by the RL model, as outlined earlier.

Baseline Control Condition

The control condition used the same i80 BPM app as described earlier; however, the RL model was not applied. Instead, generic exercise sessions were provided for the user, irrespective of their preferences.

Crossover Design

As crossover design was used in this trial, participants transitioned between the intervention and control conditions. At the end of each 1-week cycle, participants transitioned to the opposing condition regardless of how many sessions they had completed. Therefore, each participant could complete exercise sessions that were adapted by the RL model (intervention) as well as sessions that were not adapted (control). This design was chosen to maximize the amount of data captured for each condition in anticipation of a high number of dropouts or waning adherence as the trial progressed.

Outcome Measures

Our primary outcome, user satisfaction, was determined after each session and was collected via the smartphone app. Satisfaction was measured using an abbreviated PACES-8 [32,33].

Our secondary outcome was perceived exertion, measured using the Borg scale, which was administered via the smartphone app

at the end of each session; participants were cued to "rate your perceived exertion on a scale from 2 to 10, where 2 means 'really easy' and 10 means 'maximal exertion.'" Additionally, heart rate data were collected using the Galaxy Fit 2 smartwatch provided to each participant [37]. This device uses photoplethysmography to measure heart rate continuously during the exercise sessions. The heart rate data captured by the smartwatch were automatically relayed to the i80 BPM app, which was used to record and analyze these measurements as part of the session data. See Table 1 for all outcomes and questionnaires.

Table . Outcome measures.

		Baseline	Weekly	During each session	After each session
Satisfaction					
	Physical Activity Enjoyment Scale-8				✓
	Rating of perceived exertion				✓
	Heart rate			✓	
	Exercise skipped			✓	
Behavioral engagement					
	Exercise altered			✓	
	Total time spent on the app		✓		
	Number of sessions completed		✓		
User profiling					
	Demographics (eg, age and sex)	✓			
	International Physical Activity Questionnaire	✓			

Public Involvement

During an initial feasibility trial, members of the public worked with us to evaluate the sessions generated by the RL system and the mobile app user interface and were asked to assess the burden and time commitment of the study as part of a user-centered design approach [19]. During this feasibility study, participants also completed a web-based survey to establish their current activity levels, their experience with different health and fitness smartphone apps, how they currently exercise, and their self-efficacy. Participants were then asked to use the app over an 8-week period (between June and October 2021) and were asked to provide feedback on their experience. Analysis of participants' feedback and the app use logs was undertaken by the project team, and the app was further iterated based on this feedback. The version of the app that was used in this study (which took place between June and October 2022) integrated all participants' feedback from this initial feasibility trial.

Power Calculations and Sample Size

A sample size of minimum 40 participants was estimated based on the following factors: the sample size recruited as part of the initial feasibility study (we previously recruited 36 participants over an 8-week trial period), an estimated mean difference of 8 on the PACES-8 scale based on previous work for 80% power, and the rule of thumb of at least 10 events for variable (or measures of user satisfaction and behavioral and physiological engagement) [39]. Controlling for 15% dropout, we aimed to recruit a total of 42 participants.

Data Management and Statistical Analysis

Overview

All collected data were anonymized before analysis, with each participant assigned a unique identification code that was used in place of personal identifiers. Data were stored on secure, encrypted servers accessible only to authorized personnel involved in the study. All electronic communications and data transmissions involving participant information were encrypted. Participant consent forms and other sensitive documents were stored separately from the study data, in locked cabinets within secure facilities.

Baseline Characteristics

Descriptive statistics were used to summarize user demographics and scores on the questionnaires.

Primary and Secondary Hypotheses

The primary outcome measure, user satisfaction, was assessed using the PACES-8 questionnaire, while the secondary outcome, perceived exertion, was measured using the Borg scale. Both outcomes were evaluated at the session level, meaning each exercise session contributed to the analysis rather than summarizing data at the participant level.

To account for the repeated measures design and the correlation of observations within participants, generalized estimating equations (GEEs) were used to assess differences between the RL and control conditions for both primary and secondary outcomes. The dependent variables in the models were PACES satisfaction scores and Borg perceived exertion scores. The independent variables included condition (RL vs control) and trial week (treated as a continuous variable to account for time effects). Covariates adjusted for in the models included age, gender, and baseline physical activity level (categorized as low, moderate, or high). User ID was included as a subject effect to account for within-subject correlation. An independent working correlation matrix was specified for the GEE models, with an identity link function used for both models. Normal distribution was assumed for the outcomes. Model fit was assessed using the quasi-likelihood under independence model criterion and the corrected quasi-likelihood under independence model criterion, with lower values indicating better model fit. The main effects of condition and trial week were estimated, and their significance was assessed using Wald chi-square tests. All statistical analyses were performed using SPSS Statistics software (version 29; IBM Corp).

Results

In total, 69 participants were initially recruited for the study (27 male and 42 female participants); however, only 62 (24 male and 38 female participants) completed at least 1 exercise session. The mean age of participants was 42.8 (SD 13.3) years, with an average height of 1.7 (SD 2.4) m, body mass of 75.7 (SD 21.1) kg, and BMI of 25.8 (SD 7.8) kg/m^2. These 62 participants completed 559 exercise sessions between them (9 sessions per participant). A total of 16% (n=11) adhered to at least 50% (n=18) of the sessions they were assigned to complete (ie, 18 of 36), while 34% (n=23) adhered to at least 25% (n=9) of sessions. In total, 268 sessions were completed that were comprised of exercises generated by the RL model, while 291 sessions were completed that were comprised of exercises generated by the baseline model.

The PACES-8 GEE estimated a main effect for condition. An analysis of the parameter estimates revealed that participants were more satisfied with exercise sessions generated by the RL model (RL condition: mean satisfaction 4, 95% CI 3.9-4.1 and baseline condition: mean satisfaction 3.73, 95% CI 3.6-3.8). The main effect for condition was significant (P=.02), with a parameter estimate of B=−0.261 (SE 0.109), indicating a modest but meaningful difference in satisfaction scores. The 95% CI for this estimate ranged from −0.475 to −0.047.

The intensity GEE estimated significant main effects for condition (P<.01) and trial week (P=.048). The intensity was significantly higher in sessions generated by the RL model compared to the baseline model (RL condition: mean intensity 5.82, 95% CI 5.59 - 6.05 and baseline condition: mean intensity 5.19, 95% CI 4.97 - 5.41). Analysis of the parameter estimates indicated that participants exercised at higher intensities during RL sessions (B=−0.633, SE 0.179; P<.01).

We conducted an exploratory analysis of the separate questions from the PACES-8 questionnaire. Specifically, separate GEEs assessed differences in responses to individual items on the PACES-8 questionnaire. Significant main effects for condition were found for items related to pleasure (item #1), invigoration (item #4), gratification (item #5), exhilaration (item #6), stimulation (item #7), and how refreshing each session was (item #8; P=.02 for each). Summary statistics for the primary outcome measures of satisfaction, difficulty, heart rate, the number of exercises completed, and the duration for exercise sessions generated by the baseline and RL models are presented in Table 2.

Table . Summary statistics for overall satisfaction and heart rate for the baseline and reinforcement learning (RL) models and the average scores for the individual PACES-8[a] items.

Outcome	Baseline, mean (95% CI)	RL model, mean (95% CI)	*P* value
PACES-8	3.73 (3.6-3.8)	4 (3.9-4.1)	.02
Heart rate	106.81 (105-107)	107.24 (106-108)	—[b]
Intensity	5.19 (4.97-5.41)	5.82 (5.59-6.05)	<.01
Duration (minutes)	17 (17-18)	20 (20-21)	—
PACES-8_pleasure[c]	3.66 (3.6-3.7)	3.88 (3.8-4.0)	.047
PACES-8_fun[d]	3.53 (3.4-3.6)	3.72 (3.6-3.8)	.08
PACES-8_pleasant[e]	3.53 (3.4-3.6)	3.71 (3.6-3.8)	.05
PACES-8_invigorating[f]	3.75 (3.7-3.8)	4.15 (4.1-4.2)	<.01
PACES-8_gratifying[g]	3.84 (3.7-3.9)	4.17 (4.1-4.3)	<.01
PACES-8_exhilarating[h]	3.74 (3.6-3.8)	4.04 (3.9-4.1)	.02
PACES-8_stimulating[i]	3.85 (3.7-3.9)	4.13 (4.0-4.2)	.02

[a]PACES-8: 8-item version of the Physical Activity Enjoyment Scale.

[b]Not available.

[c]PACES-8_pleasure: item related to the pleasure derived from the exercise.

[d]PACES-8_fun: item related to the fun experienced during the exercise session.

[e]PACES-8_pleasant: item related to how pleasant the exercise session felt.

[f]PACES-8_invigorating: item related to the invigorating nature of the exercise session.

[g]PACES-8_gratifying: item related to the gratification from the exercise session.

[h]PACES-8_exhilarating: item related to the exhilaration felt during the exercise session.

[i]PACES-8_stimulating: item related to how stimulating the exercise session was.

[j]PACES-8_refreshing: item related to how refreshing the exercise session felt.

Discussion

Principal Findings

The aim of this randomized crossover trial was to investigate whether exercise sessions generated using RL were associated with better user satisfaction compared with a control condition. In this trial, exercise recommendations were delivered via the same smartphone app over the course of a 12-week “back and forth” crossover period, in which participants were subjected to each experimental condition in a 1-week cycle, each comprising 3 exercise sessions of 20 minutes in duration. Whether participants actually completed the sessions within a cycle did not affect their weekly crossover to an alternative condition. The primary outcome of user satisfaction was determined using the PACES-8 questionnaire, which has been previously used in diverse population groups [32,33,40,41] and as part of smartphone app testing protocols [42]. The secondary outcome, perceived exertion, was determined after each exercise session using the Borg scale.

During the trial, 62 (62% female) participants completed 559 exercise sessions (approximately 9 sessions per participant). Our results showed that participants were more satisfied with exercise sessions generated by the RL model (RL condition: mean satisfaction 4, 95% CI 3.9-4.1 and baseline condition: mean satisfaction 3.73, 95% CI 3.6-3.8). By incorporating trial week as a covariate in our analysis, we were able to show that participants were generally more satisfied with exercise sessions generated by the RL model compared to the control condition. Additionally, participants reported exercising at a higher intensity during sessions generated using the RL model (RL condition: mean intensity 5.82, 95% CI 5.59 - 6.05 and baseline condition: mean intensity 5.19, 95% CI 4.97 - 5.41).

Comparison to Prior Work

Our findings have import practical implications. Despite the well-known benefits of regular physical activity, many individuals struggle to stick to an exercise routine over the long term [43,44]. This is often due to a lack of motivation or a mismatch between the exercise program and the individual’s personal preferences and abilities [45-47]. RL-generated sessions, however, make it possible to personalize exercise programs, tailoring them to an individual’s unique preferences, abilities, and goals. This could potentially improve motivation and adherence to the exercise routine, ultimately leading to better health outcomes.

In particular, the ubiquity of smartphones means that app-based exercise prescription, enabled by RL algorithms, has the potential to greatly improve public health by increasing motivation and adherence to exercise routines. RL is a type of

artificial intelligence that involves training a model to make decisions that maximize a reward. This is typically done through a process of trial and error, where the model receives a reward for taking certain actions and a penalty for others. Over time, the model learns to make the decisions that are most likely to result in the maximum reward. The process of RL is similar to how animals and humans learn to perform tasks, and it has been used to solve a wide range of problems in fields such as robotics, gaming, and finance [48,49]. The key advantage of RL is its ability to learn from experience and adapt to new situations without needing to be explicitly programmed. This makes it an effective approach for solving complex, dynamic problems such as how to devise an exercise program.

The use of ML methods, including RL, to generate is a burgeoning research area. Previous research has demonstrated the effectiveness of using ML for tailoring interventions in these apps. For instance, Aguilera et al [50] observed a significant improvement in step count among individuals with diabetes and depression over the short term when ML was used to tailor SMS text messages within a self-management app. Additionally, RL has been successfully applied to enhance adherence to exercise in patients with diabetes through the distribution of individualized service messages that encourage physical activity [51]. The application of ML has even shown promise in the general population, with personalized daily step goals leading to increased physical activity compared to static step goals [52].

Our trial is the first known study to use an RL model specifically for personalizing exercise sessions and assessing its impact on participant satisfaction. While prior studies have used RL to promote exercise adherence through personalized messaging, the outcomes were mostly centered around physical activity measures such as step count [52,53]. Although our study and these previous studies differ in design and primary outcomes, a common thread can be observed regarding the potential of RL to encourage physical activity and exercise, despite the challenges inherent in smartphone app delivery. Furthermore, there is a relative scarcity of evidence concerning the use of RL specifically for exercise, as opposed to physical activity. RL has found utility in wider health care contexts, such as individualizing the difficulty level in a virtual reality rehabilitation game [54], aiding in weight loss maintenance [55], and even selecting and delivering drugs [56-58].

These studies, alongside the findings from our trial, reinforce the emerging potential of RL in health-related behaviors and outcomes. The results of this crossover trial contribute to our understanding of the potential for adaptive exercise interventions to improve adherence to an exercise intervention. Our hypothesis that users would be more satisfied with sessions generated by the RL system was confirmed. The effect size, calculated as the mean difference normalized by the SD (Cohen *d*), was approximately 0.24. This represents a small to moderate effect size, suggesting that while the RL model led to higher satisfaction, the magnitude of this difference, though statistically significant, might not be substantial in practical terms. These findings underscore the importance of considering both statistical and practical significance in evaluating the efficacy of health interventions. The practical implications suggest that while the RL model enhances satisfaction, efforts to refine the model to maximize its impact on user engagement and satisfaction should continue. Future research should focus on identifying and integrating additional predictors of satisfaction into the RL model, potentially increasing the effect size and thereby the practical impact of the technology. This research could also inform the development of RL systems for exercise prescription in patient populations (such as those with cardiovascular or metabolic diseases). This could lead to better health outcomes and reduced health care costs, as regular physical activity and exercise are known to prevent a wide range of chronic diseases [59]. Additionally, app-based exercise prescription has the potential to be more accessible and convenient than traditional forms of exercise prescription, making it easier for individuals to incorporate physical activity into their daily lives. On this basis, RL in smartphone app–based exercise prescription has the potential to greatly benefit public health; this study is the first step in setting the empirical foundation for follow-on research to investigate and establish the potential of RL-based exercise prescription in larger and more diverse populations.

Typically, in exercise science research investigating the use of mobile technologies to deliver the exercise intervention, participants are randomized to either an intervention group or a control group [60,61]. These groups are subsequently monitored for a predefined period as they use the app and are measured at the end of the intervention period to determine the health benefits of the exercise intervention, for example, based on a decrease in body weight or BMI, an increase in fat-free mass, or alterations in certain blood biomarkers [62,63]. However, the health benefits of exercise in diverse population groups are now well established. This is one of the primary reasons why we adopted a session-focused, “back and forth” crossover design (which was more robust to reducing levels of participation over the course of the trial), with satisfaction as our primary outcome. By cycling between each intervention condition on a weekly basis, participants acted as their own controls and ensured that we have a representative dataset for both the RL and control conditions. Rather than user-associated outcomes such as body weight at the start and conclusion of the intervention period being the primary experimental end point then, we focused on session-level outcomes like satisfaction and RPE. Specifically, each exercise session was characterized by the aggregated statistics of satisfaction and RPE for our entire cohort. This allowed us to build a profile for each session and evaluate how profiles are altered for each experimental condition under which the sessions are completed (and also to provide continuous input for the RL system).

However, despite its novelty and the strength of its methodological design, this study is not without limitations. Ours was a relatively small sample of homogenous participants; therefore, our findings may not be generalizable to other populations. It is also important to note the potential for selection bias in our recruitment strategy. Participants were recruited through word of mouth and social media, which might not provide a fully representative sample of the target population. This approach could attract individuals who are more technologically savvy, potentially more health-conscious, or with specific demographic characteristics that are

overrepresented in social media networks. Consequently, our findings might not be generalizable to all segments of the population. While the crossover study design was statistically efficient, it meant that we were unable to compare 2 separate groups in the long term for our primary and secondary outcomes. It was also not possible to follow a double-blind design, as researchers needed to be aware of participants' group allocation throughout the intervention period to manage follow-up and ensure that participants did not have any issues using the app; the researchers and technical personnel had to monitor our server for troubleshooting throughout the trial. Finally, we observed that participants completed an average of 9 sessions over the 12-week trial period, equating to less than 1 session per week. This level of engagement is notably lower than the intended 3 sessions per week per participant outlined in the study protocol. Several factors could contribute to this lower-than-expected adherence rate, including potential barriers faced by participants such as time constraints, lack of motivation, or the possibility that the app did not fully engage users as anticipated. Understanding and addressing these factors are crucial for the future development of app-based exercise prescriptions, as enhanced user engagement is key to achieving the health benefits of regular physical activity. The insights gained could also inform the broader field of digital health interventions aimed at improving lifestyle behaviors.

Conclusions

This randomized crossover trial evaluated the utility of a type of artificial intelligence called RL for devising an app-based system for exercise prescription. Our findings demonstrated that exercise sessions generated using RL were associated with higher satisfaction. Additionally, our participants completed sessions in the RL condition at a higher intensity than in the control condition. Taken together, our results suggest that there is significant scope for using RL algorithms to train a model to recommend exercises that are tailored to an individual's unique goals, preferences, and abilities. Further research should investigate the potential for exercise prescription using RL to empower the general population to be healthier by providing personalized and engaging exercise programs that are tailored to an individual's unique goals, preferences, and abilities. Such an approach may help individuals take control of their own health and fitness and provide them with the tools and support they need to maintain a regular exercise routine. By making exercise more accessible, engaging, and personalized, RL has the potential to improve public health by encouraging more individuals to incorporate physical activity into their daily lives.

Editorial Notice

This randomized study was only retrospectively registered. The editor granted an exception from ICMJE rules mandating prospective registration of randomized trials, because the risk of bias appears low and the study was considered formative, guiding the development of the application. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness, as retrospective registration does not prevent authors from changing their outcome measures retrospectively.

Abstract

Background: Perceived stress in the United States has drastically increased since the COVID-19 pandemic and is associated with negative mental health outcomes such as depression and anxiety. Digital mental health (DMH) interventions are efficacious tools to address negative mental health outcomes and have helped reduce the severity of psychological symptoms, such as anxiety, depression, and perceived stress, compared to waitlist controls. Although DMH tools have been studied in controlled settings, less is known about the real-world evidence of such interventions.

Objective: This study aimed to (1) characterize patterns in baseline perceived stress and changes in perceived stress among Headspace members with moderate and severe baseline perceived stress and (2) examine associations between engagement with Headspace content and changes in perceived stress (ie, evaluate whether there is a dose-response relationship).

Methods: We evaluated real-world perceived stress and engagement data at 2 time points among Headspace app members with baseline moderate and severe perceived stress. Perceived stress was measured using the Perceived Stress Scale (PSS-10) and engagement using active days and active minutes engaged with Headspace as well as the number of user sessions. Descriptive statistics were computed for all variables. Correlations between baseline and follow-up scores, percent change in PSS-10 scores, days between PSS-10 use, active days, active days per week, active minutes, active minutes per day, sessions, and sessions per week were evaluated. We used *t* tests to investigate differences in the abovementioned parameters between (1) participants who did and those who did not see improvements in PSS-10 scores (yes vs no improvement) and (2) participants who saw ≥30% improvement versus those who saw a <30% improvement in PSS-10 scores.

Results: Overall, 21,088 Headspace members were included in these analyses. On average, members saw a 23.52% decrease in PSS-10 scores from baseline to follow-up. On average, members had 2.42 (SD 1.76) active days per week and 25.89 (SD 33.40) active minutes per day, and completed 7.11 (SD 8.34) sessions per week. *t* tests suggest that members who saw improvements in PSS-10 scores from baseline to follow-up had significantly higher baseline PSS-10 scores (Cohen *d*=0.56), more active days per week (Cohen *d*=0.33), and more sessions per week (Cohen *d*=0.27) than those who did not see improvements in PSS-10 scores (all *P*<.001). Additional *t* tests suggest that members with ≥30% improvement in PSS-10 scores had significantly higher baseline PSS-10 scores (Cohen *d*=0.35), more active days per week (Cohen *d*=0.36), and more sessions per week (Cohen *d*=0.31) than those with a >30% improvement (all *P*<.001).

Conclusions: Real-world use of Headspace is associated with decreased perceived stress. Furthermore, data suggest that more engagement, specifically weekly active days and sessions, is associated with a greater likelihood of stress reduction.

Introduction

Stress in the United States has increased, with significant impacts from the COVID-19 pandemic. While the pandemic itself caused a drastic increase in stress from 2019 to 2020 [1], stress levels still remain high and continue to impact the majority of Americans [2]. Higher perceived stress is associated with poorer mental health outcomes such as depression and anxiety [3]. Further meta-analytic research indicates small to medium effects of the relationship between perceived stress and mental health outcomes, suggesting that peoples' appraisal of stressful situations in their lives might be a predictor of mental health outcomes [4,5]. Higher perceived stress also has economic costs, and studies have estimated that perceived stress, primarily

work-related perceived stress, accounts for US $221 million to US $187 billion in both direct (eg, medical) and indirect costs (eg, absenteeism, burnout, and decreased productivity) [6]. This is important in the larger context of mental health costs and outcomes and how people manage stressors daily in their lives. Digital mental health (DMH) interventions may provide an accessible, scalable way to mitigate perceived stress.

DMH interventions are scalable and accessible; incorporate evidence-based practices (ie, mindfulness meditation and cognitive behavioral therapy techniques); are efficacious for a range of mental health concerns including anxiety, depression, and posttraumatic stress disorder [3]; and have shown to be effective in a wide range of populations with all levels of mental health concerns (ie, mild, moderate, and severe), including college students, employees, graduate trainees, and rural communities [7-9]. Studies suggest that digital mindfulness-based interventions significantly reduce perceived stress [10-12]. Specifically, a randomized controlled trial evaluated an app-based mindfulness tool among individuals with moderate and severe baseline perceived stress and suggested a 30.12% decrease in perceived stress from baseline to 8 weeks (intervention completion), with these reductions retained at 12-week follow-up (a 31.24% decrease) [12]. In addition to randomized controlled trials, current meta-analytic and systematic review data suggest medium effect sizes for DMH interventions for perceived stress from baseline to post intervention [4,5]. Beyond clinical outcomes, DMH interventions improve access to mental health care and provide individuals with effective, cost-effective care readily available via a mobile app or website.

While DMH interventions in clinical trials have been shown to be effective, less is known about their use in real-world settings. Real-world evidence builds upon clinical trials to improve our understanding of an intervention's efficacy in a person's daily functioning, providing data on the effectiveness and accessibility of DMH products as well as the external validity of interventions. As DMH interventions are delivered via a mobile device or computer to use within one's own environments, real-world evidence highlights intervention effectiveness outside of controlled settings. As such, there is an increasing need to understand the real-world effectiveness of widely used commercial apps and DMH interventions that help improve mental health outcomes for the overall population.

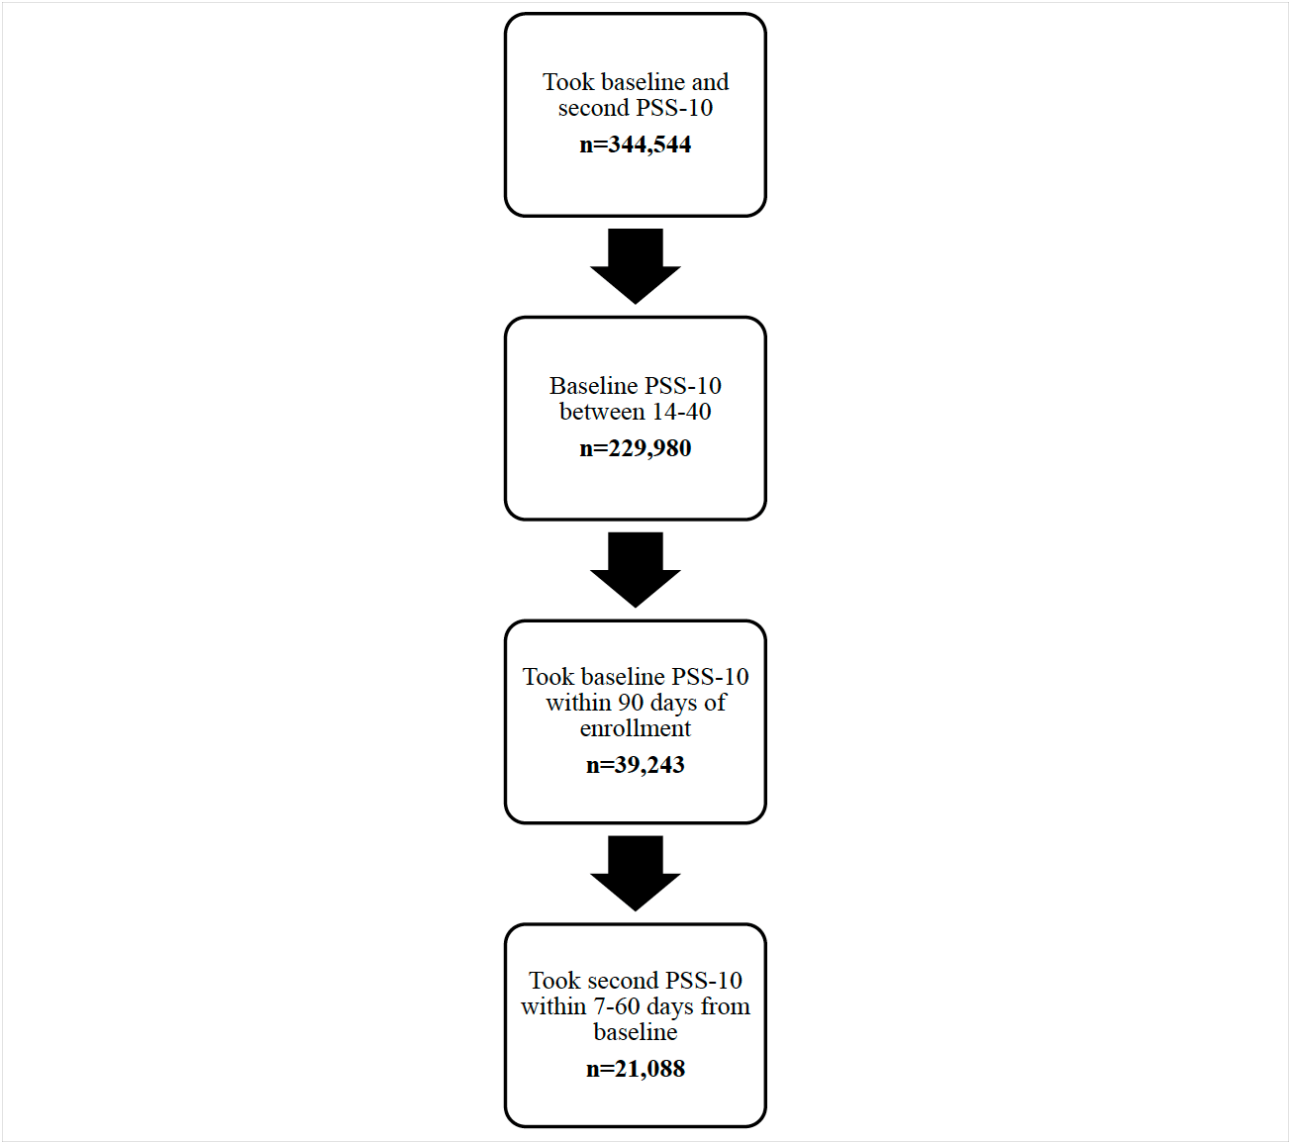
Headspace is a popular and evidence-based DMH platform with over 100 million downloads and supported by >50 published peer-reviewed studies. The Headspace app offers a range of services, most notably to this study, mindfulness and meditation-based content that teaches coping strategies to manage daily stressors. Previous clinical trials on the efficacy of the Headspace app show evidence of improved mindfulness, focus, stress, sleep quality, burnout, resilience, anxiety, depression, and quality of life. Given the reach and scale of Headspace's membership, there is an opportunity to better understand real-world outcomes beyond clinical trials. As such, this study aims to use real-world data to evaluate perceived stress among Headspace members. To accomplish this goal, this study's aims are to (1) characterize patterns in baseline perceived stress and changes in perceived stress among Headspace members with moderate and severe baseline perceived stress and (2) examine associations between engagement with Headspace content and changes in perceived stress (ie, to evaluate if there is a dose-response relationship).

Methods

Study Design and Participants

This real-world observational study examined perceived stress among Headspace members. This study followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) framework for reporting observational studies [13]. Individuals were included in this study if they enrolled on Headspace between March 2020 and January 2023, completed a baseline and follow-up perceived stress questionnaire (the Perceived Stress Scale [PSS-10]), completed the baseline PSS-10 within 90 days of enrollment, completed the follow-up PSS-10 at >7 and <60 days from the baseline, and reported moderate or severe perceived stress levels at baseline (Figure 1).

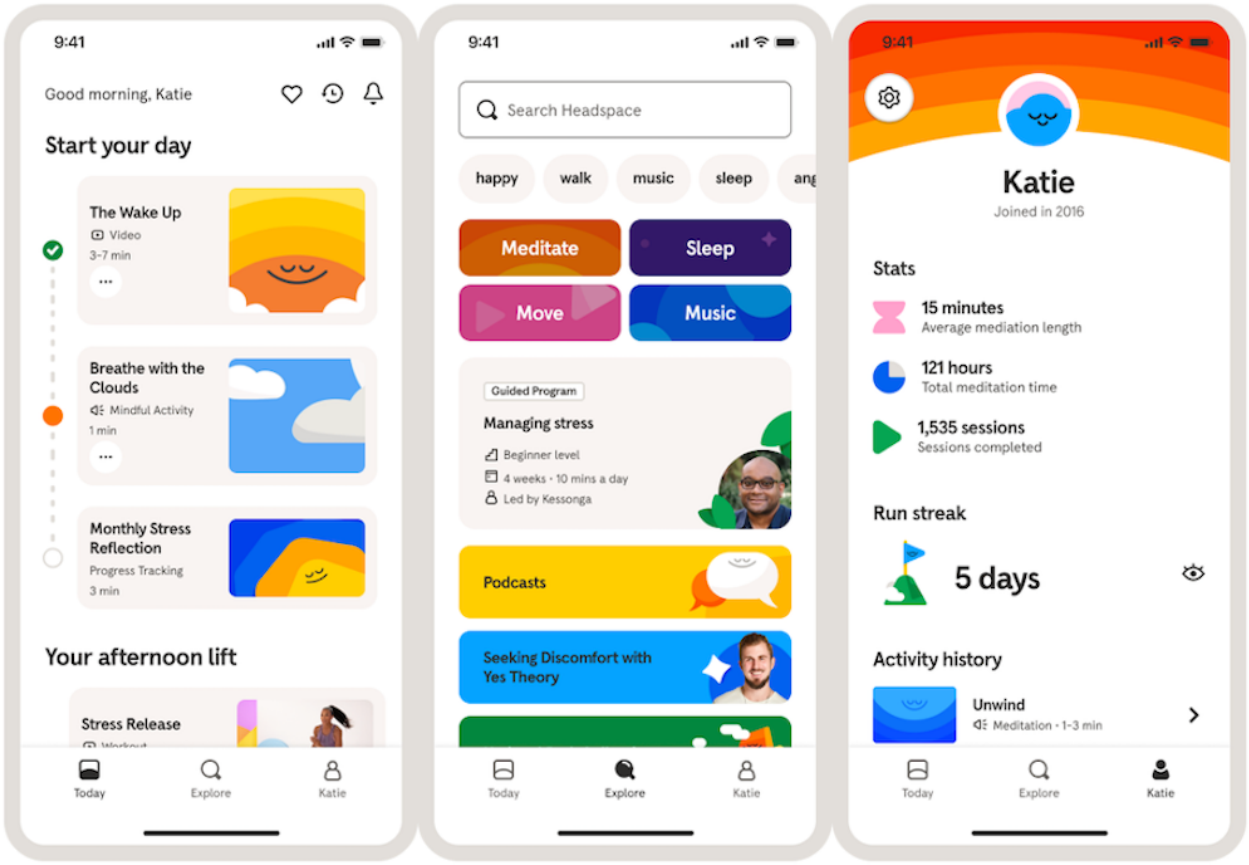
Figure 1. Sample size filter for the current study. PSS-10: Perceived Stress Scale.



The Headspace App

Study participants had access to all Headspace app offerings and used the app at their own discretion. The Headspace app includes evidence-based, expert-led content including guided mindfulness, meditation with animated guided videos, progressive muscle relaxation, psychoeducation, and gratitude exercises. Mindfulness content ranges from content for general self-care to that specific to mental health disorders such as anxiety, stress, and sleep disorders. When participants open the Headspace app, they are first directed to the "Today" tab, which contains personalized, daily content recommendations to encourage health habit formation throughout the day. Content on the "Today" tab includes a breathing exercise, educational video, and 3 meditations (1 each for the morning, afternoon, and evening). All other content can be found in the "Explore" tab, which includes a search bar; content organized into large categories of meditate, sleep, move, and music at the top; and as they scroll further, more specific categories and courses such as Beginning Meditation, Mindfulness at Work, Mindful Eating, etc. Finally, all participants have a personalized "Profile" tab, which tracks activity history and overall app statistics (minutes meditated, sessions completed, and days in a row of content engagement). Study participants had access to all Headspace app offerings and navigated the app to choose their own content (Figure 2).

Figure 2. The "Today," "Explore," and "Profile" tabs in the Headspace app shown from left to right.



Ethical Considerations

This study represents a secondary analysis of preexisting deidentified data [14]. The study team does not have access to the participants' identifying information and will not contact the participants. Therefore, in accordance with the US Department of Health and Human Services' regulations (45 CRF 46.104), this study is deemed exempt from institutional review board oversight and informed consent. Participants are notified through the Headspace terms of service that their deidentified data may be used for research.

Measures

Perceived stress was measured using the PSS-10 [15]. Participants were prompted to complete the PSS-10 through the Headspace app and answered 10 questions about their perceived feelings and thoughts regarding stress with a 5-point Likert scale (0=never to 4=very often). Scores range from 0 - 40, with higher scores indicating higher perceived stress. The scale has high test-retest reliability (Cronbach α=.85). PSS-10 scores were categorized to indicate low (<14), moderate (14-26), and high (27-40) levels of perceived stress [15]. Those with low levels of perceived stress at baseline were excluded from this study. Study participants completed a baseline and follow-up PSS-10. Total scores for each time point were reported, along with the raw change in PSS-10 score and percent change in PSS-10 score. Participants completed the PSS-10 within the Headspace app, and final scores were extracted directly from the app. Scores were calculated and extracted only for those who completed all questions on the PSS-10 (ie, incomplete data were excluded from this study).

Engagement was assessed using active days and minutes engaged with Headspace as well as the number of sessions started. Additionally, ratios for active days per week, active minutes per day, and sessions per week were calculated to further define engagement. Engagement data are tracked for all members within the Headspace app and were extracted directly from the app.

Statistical Analysis

Means, SDs, medians, and 95% CIs were computed for baseline and follow-up PSS-10 scores, raw change in PSS-10 score, percent change in PSS-10 score, days between PSS-10 assessments, active days, active days per week, active minutes, active minutes per day, sessions, and sessions per week. Frequencies and percentages were computed for baseline and follow-up PSS-10 scores (moderate vs high).

Mean percent change in PSS-10 scores was segmented out by active days per week, active minutes per day, and sessions per week to delineate the relationship between app engagement and percent change in PSS-10 score. Correlations between baseline and follow-up PSS-10 scores, percent change in PSS-10 score, days between PSS-10 assessments, active days, active days per week, active minutes, active minutes per day, sessions, and sessions per week were evaluated.

We used *t* tests to evaluate the differences in baseline PSS-10 scores, follow-up PSS-10 scores, percent change in PSS-10

score, active days, active days per week, active minutes, active minutes per day, sessions, and sessions per week between (1) those who saw and those who did not see improvements in PSS-10 scores (yes vs no improvement) and (2) those who saw a ≥30% improvement versus those who saw a <30% improvement. A 30% improvement threshold was chosen to coincide with a clinically meaningful change in perceived stress [16]. *P* values of <.05 were considered significant, and effect sizes were reported using the Cohen *d* to determine the magnitude of significance.

Results

Sample and Perceived Stress Descriptives

Overall, 344,544 Headspace members completed 2 PSS-10s between March 2020 and January 2023. Of them, 21,088 met this study's inclusion criteria and were included as study participants (Figure 1).

At baseline, 15,127 (71.73%) participants reported moderate levels of perceived stress and 5961 (28.27%) reported severe levels of perceived stress with a mean baseline PSS-10 score of 23.14 (SD 5.69). On average, members completed their follow-up PSS-10 33.25 (SD 11.17) days after their first PSS-10 with a mean follow-up PSS-10 score of 20.41 (SD 6.47). At follow-up, 2878 (13.56%) participants reported mild to moderate levels of perceived stress, 14,376 (68.17%) reported moderate levels, and 3834 (18.18%) reported high levels. On average, members saw a 23.52% decrease in PSS-10 scores from baseline to follow-up, and 13,692 (64.93%) participants saw a decrease in their PSS-10 score (Table 1).

Table . Descriptive statistics for engagement and primary outcomes.

Parameters		Mean (SD)	Median	95% CI
PSS-10[a]				
	Baseline	23.14 (5.69)	23	23.06 to 23.21
	Follow-up	20.41 (6.47)	20	20.33 to 20.50
	Raw change in the PSS-10 score	–2.72 (6.06)	–3	–2.80 to –2.64
	Percent change in the PSS-10 score	–23.52 (62.60)	–13.04	–24.37 to –22.68
	Days between PSS-10 assessments	33.25 (11.17)	31	33.10 to 33.40
Engagement metrics				
	Active days	18.04 (11.42)	17	17.89 to 18.20
	Active days per week	2.42 (1.76)	2.01	2.39 to 2.44
	Active minutes	547.4 (1004.81)	281.95	533.83 to 560.96
	Active minutes per day	25.89 (33.40)	16.68	25.44 to 26.34
	Sessions	49.73 (48.14)	35	49.08 to 50.38
	Sessions per week	7.11 (8.34)	4.33	7.00 to 7.23

[a]PSS-10: Perceived Stress Scale.

Engagement

On average, members engaged with Headspace content for 18.08 (SD 11.42) days and 547.40 (SD 1004.81) minutes and started 49.73 (SD 48.14) sessions. On average, members had 2.42 (SD 1.76) active days per week, 25.89 (SD 33.40) active minutes per day, and completed 7.11 (SD 8.34) sessions per week (Table 1). The percent change in PSS-10 score by active days per week, active minutes per day, and sessions per week are presented in Table 2, with data suggesting peak changes in PSS-10 scores at 7 active days per week, 11 - 15 active minutes per day, and 19 - 20 sessions per week.

Table . Mean percent change in PSS-10[a] scores by active days per week, active minutes per day, and sessions per week.

		Mean percent change in PSS-10 score
Active days per week

	>20	–25.39

[a]PSS-10: Perceived Stress Scale.

Engagement and Perceived Stress

Correlations between engagement and perceived stress are reported in Table 3. The results of *t* tests investigating the association between engagement and perceived stress are reported in Table 4. Participants who demonstrated an improvement in perceived stress had significantly higher baseline PSS-10 scores ($t_{16,575}$=–40.08; *P*<.001; Cohen *d*=0.56) and significantly more active days ($t_{14,774}$=–9.00; *P*<.001; Cohen *d*=0.13), active days per week ($t_{17,152}$=–24.18; *P*<.001; Cohen *d*=0.33), sessions ($t_{16,515}$=–11.18; *P*<.001; Cohen *d*=0.16), and sessions per week ($t_{19,025}$=–20.53; *P*<.001; Cohen *d*=0.27) than those who did not demonstrate an improvement.

Participants with a ≥30% improvement in perceived stress had significantly higher baseline PSS-10 scores ($t_{12,794}$=–23.52 *P*<.001; Cohen *d*=0.35), more active days per week ($t_{11,401}$=–23.10; *P*<.001; Cohen *d*=0.36), and more sessions per week ($t_{10,150}$=–18.87; *P*<.001; Cohen *d*=0.31) than those with a <30% improvement. Although effect sizes suggest smaller relationships, *t* tests also suggest that participants with a ≥30% improvement in PSS-10 scores had significantly more active days ($t_{12,984}$=–12.02; *P*<.001; Cohen *d*=0.17), more active minutes ($t_{13,569}$=–2.61; *P*<.001; Cohen *d*=0.04), and more sessions ($t_{11,539}$=–12.68; *P*<.001; Cohen *d*=0.19) than those with a <30% improvement in PSS-10 score.

[a]PSS-10: Perceived Stress Scale.

[b]Italicized values are significant at $P<.05$.

Discussion

This study focused on using real-world data from Headspace members to evaluate changes in perceived stress and its association with app engagement. Our findings suggest that participants experienced a significant reduction in perceived stress scores and those who used Headspace more frequently experienced greater reductions in perceived stress. This study builds on prior clinical trials and provides real-world evidence supporting the use of Headspace to improve perceived stress.

On average, participants experienced a 23.52% reduction in perceived stress scores from baseline to the follow-up assessment (ie, approximately a 30-day period). Furthermore, 64.93% of participants saw a reduction in their PSS-10 scores from baseline to follow-up, suggesting that Headspace improved perceived stress for a majority of individuals. Shifts in perceived stress levels also provide evidence supporting the use of Headspace, as 10% of members who reported high levels of perceived stress at baseline no longer met those criteria at follow-up (ie, reported moderate or mild levels of perceived stress at follow-up). These shifts in individual perceived stress are important for self-management behaviors (eg, mindfulness or self-regulation) that are associated with improved patient well-being and mental health outcomes [17]. Thus, it is likely that shifts in perceived stress might be an important predictor of patients' mental health outcomes. These findings are consistent with previous clinical research examining the impact of DMH interventions to improve perceived stress [10,18,19] and provide additional real-world evidence to support those claims.

We also identified relationships between app engagement and changes in perceived stress. Specifically, correlations suggest that active days per week and active sessions per week were associated with a higher percent change in PSS-10 scores. App-based mindfulness interventions of longer duration, such as those from 4 to 12 weeks, have shown improvements in not only mindfulness and perceived stress but also depression, anxiety, and overall well-being [11,20,21]. Few app-based mindfulness interventions are less than 4 weeks in duration, supporting the use of longer interventions. While this study revealed that a higher number of active days (total and per week) is associated with larger improvements in perceived stress, our

data did not reveal a relationship between active minutes (total and per week) and percent change in perceived stress. These data support the findings of a previous study comparing 10 and 30 minutes of daily mindfulness, which reported no difference in mindfulness or psychological distress between the dosage groups [22]. This study's findings, in addition to those of previous studies investigating mindfulness dosage, may suggest that active days are more important than total time spent practicing mindfulness or engaging with the app. Future research is necessary to further understand these relationships to more accurately suggest mindfulness dosage for clinical practice and research.

Identifying changes in perceived stress by active days per week, active minutes per day, and sessions per week provide more nuanced data informing the duration and dosage of mindfulness interventions. The largest percent change in perceived stress occurred with 7 active days per week; however, data show a sizable increase at 4 active days per week with a leveling off in those active for more days. We also note peak percent change in PSS-10 score at 11 - 15 active minutes per day and 19 - 20 sessions per week. These data indicate that consistent Headspace use results in more prominent improvements in perceived stress. Previous research has reported that the psychological status of approximately 25% of patients improved after 1 psychotherapy session, with steadier improvements occurring over 8 weeks [23]. This study's findings indicate a similar pattern that emphasizes a shift in perceived stress from baseline to the second administration of the PSS-10 during the first 3 weeks of engaging with the Headspace platform.

Higher engagement, specifically more active days and sessions, was significantly associated with a higher likelihood of improving stress (both overall and ≥30%), suggesting that frequent engagement with the Headspace app might be related to improved outcomes. This is an important finding given the breadth of research on increased patient engagement with psychotherapy and improved mental health outcomes [24]. In particular, the effect sizes for active days per week and sessions per week of –0.33 and 0.27 in the group that saw improvements in perceived stress and the group that did not see an improvement and 0.36 and 0.31 in the group that saw a ≥30% improvement in perceived stress and the group that saw a <30% improvement are notable. These results build on previously reported correlations, suggesting that higher engagement days and a higher number of sessions are associated with a higher percent change in PSS-10 scores and provide further support for the intervention dosage, suggesting multiple bouts of mindfulness each day [22]. Previous research highlights positive mental health outcomes for people who establish consistent health behaviors. In light of higher costs and access to mental health care, these preliminary findings suggest that consistently engaging with Headspace may decrease perceived stress, thus supporting the use of DMH in real-world settings to accessibly improve outcomes.

Strengths, Limitations, and Future Research

This study has several limitations and strengths. As this study was the first real-world study investigating the Headspace app, our data are largely focused on descriptive and group mean differences. While this information is important to establish overall benchmarks for this study, we are limited in the types of questions (eg, prospective) we can ask with this study's format and recognize that the current statistical approach does not allow for causal inferences. Additionally, these data did not include the demographic information of Headspace members; therefore, we were unable to investigate the impact of demographics on the study outcomes. Future research should examine longitudinal data and changes in perceived stress, while accounting for the demographic characteristics of Headspace members and engagement factors. As a real-world evidence study, we were unable to identify specific programming used by members; we focused only on overall engagement outcomes. Future studies should include more in-depth engagement outcomes to better understand how certain programming is used and impacts perceived stress. Finally, data for this study were collected during the COVID-19 pandemic (March 2020 and January 2023). As noted, stress greatly increased among individuals in the United States during this time, which may have impacted PSS-10 scores (ie, increased scores). However, members were only included if they completed their 2 PSS-10s between 7 and 60 days, and the average number of days between PSS-10 assessments was approximately 1 month, suggesting that if members completed their baseline PSS-10 at the beginning of the pandemic, when stress levels were higher nationwide, they would have completed their follow-up at a similar time period within the pandemic.

A primary strength of the study is the methodology incorporated to understand changes in perceived stress and engagement on the platform. The use of a real-world evidence methodology often helps researchers and clinicians to observe the feasibility and generalizability of interventions in daily functioning. Given the current sample size, which is over 20,000 participants, it is evident that the Headspace platform provides benefits to people who frequently engage with the platform. Furthermore, this study's large sample size also offers strong evidence for the generalizability of our findings in the real world. The large sample size coupled with the current methodology also allowed us to establish reliable findings for our current platform; therefore, establishing a foundational understanding of how much change is possible on the platform while understanding overall engagement trends.

Conclusions

Our findings suggest that members using Headspace experienced significant reductions in perceived stress in a real-world setting. Furthermore, data suggest that members who engaged with the platform more regularly were more likely to experience improvements in perceived stress. This study is the first to provide real-world evidence of the DMH Headspace platform aimed to reduce participants' perceived stress. Our results have implications for clinical practice, which include incorporating mediation and mental health psychoeducation as an adjunct to psychotherapy or as a preventive intervention to reduce stress.

Authors' Contributions

CC contributed to the study design, data analysis, manuscript writing, and manuscript review. JK contributed to the study design, manuscript writing, and manuscript review. EH contributed to the study design, data analysis, manuscript writing, and manuscript review. LT contributed to the data analysis and manuscript review. SK contributed to the study design, data analysis, manuscript writing, and manuscript review.

Conflicts of Interest

CC, LT, and SK are currently employed by Headspace. JK and EH were employed by Headspace at the time of data collection.

Abstract

Background: Older Chinese immigrants constitute the largest older Asian ethnic population in New Zealand. Aging in a foreign land can be complex, presenting increasing challenges for gerontology scholars, practitioners, and policy makers. Older Chinese immigrants are more susceptible to experiencing loneliness and social isolation compared to native older people, primarily due to language, transportation, and cultural barriers. These factors subsequently impact their physical and mental health. With advancements in robotic technology, aged care robots are being applied to support older people with their daily living needs. However, studies on using robots with older immigrants living in the community are sparse. Their preferences for the appearance and function of aged care robots are unclear, which impacts the acceptance and usability of robots, highlighting the need for a user-centered design approach.

Objective: This study aims to explore older Chinese immigrants' needs and preferences toward the appearance and function of aged care robots and to examine their relationships with the demographic characteristics of participants.

Methods: A cross-sectional design was used in this study, which was undertaken between March and May 2020. A total of 103 participants completed a web-based survey.

Results: The average age of participants was 68.7 (SD 5.5) years. The results suggest that 41.7% (n=43) of the 103 participants preferred a humanlike adult appearance, while 32% (n=33) suggested an animallike appearance. These participants reported higher scores in both rigorousness and friendliness compared to others who preferred different robot appearances. Participants expressed a greater preference for the functions of housework assistance (n=86, 83.5%), language translation (n=79, 76.7%), health monitoring (n=78, 75.7%), facial expressions (n=77, 74.8%), news reading (n=66, 64.1%), and security monitoring (n=65, 63.1%). These preferences were found to be significantly associated with marital status, financial status, and duration of immigration.

Conclusions: To support immigrant populations to age well in a foreign country and address the growing shortage of health and social professionals, it is important to develop reliable robotic technology services that are tailored based on the needs and preferences of individuals. We collected and compared the perspectives of immigrant and nonimmigrant participants on using robots to support aging in place. The results on users' needs and preferences inform robotic technology services, indicating a need to prioritize older Chinese immigrants' preference toward aged care robots that perform housework assistance, language translation, and health and safety monitoring, and robots with humanlike features.

Introduction

Older Chinese immigrants are more prone to experiencing loneliness and social isolation than native older people due to language, transportation, and cultural barriers, which subsequently impact their physical and mental health [1]. In 2017, 11 million people emigrated from China to their destination countries [2]. New Zealand is one of the most popular host countries for Chinese immigrants, and as a result, it faces the growing needs of an increasingly diverse aging population. According to the New Zealand Census results in 2018, there were 247,770 Chinese immigrants 45 years or older, with 23,625 (9.5%) of them 65 years or older [3]. Compared to the statistics from the 2013 census, there was an increase of 76,359 (44.5%) Chinese immigrants [4]. Older Chinese immigrants are the largest older Asian ethnic population in New Zealand [3].

Aging in a foreign land can be complex, posing increasing challenges for gerontology scholars, practitioners, and policy makers. Self-supported aging in place has been reported as a benefit for enhancing older people's health and quality of life, as it supports the continuity of the environment and promotes independent living within the community [5]. However, a large and rapidly growing social and health workforce shortage in New Zealand has been unable to meet the increasing needs of older Chinese immigrants to access social and care services in the community [6]. With innovations and advancements in computer systems, robotic technology and information and communication technologies have been applied to support older people with their daily living needs.

In a New Zealand study, a daily care robot was used at home to assist older community-dwelling adults who had different aging-related health needs. The robot's purpose was to remind them of daily activities, and it showed promising potential in old age care, especially in providing reminders for taking medication [5]. Most existing studies on using robots to support older people have focused on dementia care and cognitive training, and have been undertaken in dementia care units. For example, a recent study in Italy reported that a humanoid robot called NAO effectively supported memory training among 24 patients with mild cognitive impairment, enhancing their therapeutic compliance and reducing symptoms of depression [7]. The study reported significant changes in prose memory and verbal fluency measures [7]. Additionally, the social robot Paro (an animal seal robot) was tested in Taiwan with 20 older adults in a long-term care facility for 8 weeks using a single-group pre-post quasi-experimental design and showed a statistical decrease in depression and loneliness and an increase in quality of life among the participants [8]. Our pilot study in Hong Kong has reported good feasibility and acceptance of using a humanoid social robot called KaKa among older Chinese adults and their family caregivers in their homes [9]. However, studies of using robots among older immigrants living in the community are sparse. Their preferences for the appearance and function of aged care robots are unclear, which impact the acceptance and usability of robots, and therefore, a user-centered design is required. It is imperative to understand users' needs and preferences before designing and developing a robot to meet their specific care needs [10].

Aged care robots, including health care assistive robots and socially assistive robots, should be tailored for older people to be easy to use, flexible, and able to support natural older people–robot interaction [10]. In particular, the design should consider those people with less experience in using technological devices [10]. Gaseiger and colleagues [5] reported that older people living alone at home accepted a robot as a companion, and the functions of an aged care robot should be more personalized to meet older people's health and social needs. A cross-sectional survey among middle-aged and older Taiwanese living in the community revealed that female participants preferred an animallike robot, while male participants favored a humanlike robot [11]. The most popular functions of a robot recommended by those participants included dancing, singing, storytelling, and news reading [11]. Moreover, the New Zealand study indicated that older Chinese immigrants were more likely to accept the companionship of robots when they were feeling lonely, yet more evidence is needed regarding their preferences for robot features [12]. Therefore, this study aimed to explore older Chinese immigrants' needs and preferences toward the appearance and function of aged care robots. Additionally, it sought to examine the relationships between these needs and preferences and the demographic characteristics of participants.

Methods

Participants

Adults 60 years or older, as defined by the World Health Organization [13], who self-identified their ethnicity as Chinese; held a permanent resident visa in New Zealand or were New Zealand citizens; were able to read, write, and understand traditional or simplified Chinese; were able to access the internet; and had completed the web-based survey were eligible to participate. There were no specific exclusion criteria. We screened each participant's eligibility through their individual demographic information.

Instrument

We used a web-based survey design tool, SurveyCake, to create a structured anonymous survey written in the traditional Chinese language. A simplified Chinese version was also made available as an alternative option. At the beginning of the survey, there was a 5-minute video using images from various online sources that was made for research purposes only. The video introduced different types of aged care robots, including health care assistive robots and socially assistive robots, each with a variety of appearances and features. The content of the video was presented in Mandarin with traditional Chinese subtitles, providing participants with a general idea about the types of robots and their capabilities. Following the video, participants were asked to complete the survey, which included four sections: (1) demographic information, (2) five personality traits, (3) eHealth literacy, and (4) preference for robot appearance and functions. Screenshots of the video are shown in 1-3.

Figure 1. Screenshot of a video depicting an older adult chatting with a robot.

Figure 2. Screenshot of a video depicting a robot's companionship role for an older lonely adult.

Figure 3. Screenshot of a video depicting a humanlike infant robot.

Participants were asked 18 questions regarding demographic information, including age, gender, education level, etc. The 15-item International Personality Item Pool, Five Personality Scale (extroversion, friendliness, rigorousness, emotional stability, and intelligence/imagination) was used [14]. The eHealth literacy of participants (ie, the internet use and search skills, ability to find reliable web-based content, and confidence in their abilities to search the internet) was assessed by the eHealth Literacy Scale [15]. Participants' preferred or favorite appearance (ie, animallike, humanlike infant, humanlike adult, or another form) and functions of the robots (eg, assisting with housework, health monitoring, and instant language translation) were collected. The survey was developed based on our previous study in Taiwan on middle-aged and older Chinese adults [11].

Ethical Considerations

The study protocol was approved by the institutional review board of the affiliated university (No. A-ER-105-509). Before participating in the web-based survey, each participant had to provide informed consent. They were introduced to the aims and content of the study, potential risks and benefits, and the right to withdraw from the study at any time. Each participant was asked to click a box to confirm their willingness to proceed. All respondents in this study have ticked this box, and their responses were anonymous.

Procedure

The study was undertaken between March and May 2020 using a cross-sectional design. The recruitment was supported by a local social service organization for older people in Auckland and several Chinese community groups from different regions of Auckland. Following the ethics approval, an electronic version of the flyer (in both traditional and simplified Chinese), advertising the study and linking to the web-based survey, was circulated by social workers and community group leaders via word of mouth, WeChat groups, and WhatsApp groups. No incentives were offered for participation in this web-based survey study. The completeness check was done by two team members after the questionnaire had been submitted.

Data Analysis

Descriptive analyses and inferential statistics were performed on R (version 4.1.1; R Foundation for Statistical Computing). Descriptive statistics were used for analyzing the demographic information, five personalities, eHealth literacy, and preference for robot appearance and functions. For each item, we calculated descriptive statistics as appropriate (eg, mean and SD or frequency and percentage). ANOVA and χ^2 test were adopted to analyze the correlations between demographic factors and preferences for robot functions.

Results

Demographic Information

A total of 103 older Chinese immigrants completed the survey, resulting in a response rate of 89.6% (103/115). Among the participants, the minimum age was 60 years, and the maximum age was 87 years, with an average age of 68.7 (SD 5.5) years. Of the participants, 74 were female and 29 were male. Most of the 103 participants attained a bachelor's degree or above (n=72, 70%), and had a good self-reported financial status (mean 22.7, SD 4.7). Most of the participants were married or had a partner (n=88, 85.4%) and lived with family or others (n=90, 87.4%). Most of them immigrated to New Zealand to reunite with family (n=83, 80.6%), and about half of them had lived in this country for more than 10 years. Participants reported higher scores in

rigorousness and friendliness than other personalities. Details on the data distribution are shown in Table 1.

Table . Demographic information of participants (N=103).

Demographic variables		Values
Age (years), mean (SD)		68.7 (5.5)
Gender, n (%)		
	Female	74 (71.8)
	Male	29 (28.2)
Level of education, n (%)		
	Under bachelor's degree	31 (30.1)
	Bachelor's degree or above	72 (69.9)
Marital status, n (%)		
	Married or have a partner	88 (85.4)
	Unmarried, widowed, or no partner	15 (14.6)
Live alone, n (%)		
	Yes	13 (12.6)

Participants' Preferences for Appearance of Aged Care Robots

Table 2 shows that most of the 103 participants, both female and male, preferred a humanlike adult appearance (n=43, 41.7%), and their second preference was an animallike appearance (n=33, 32%). The remaining participants reported their preferences for a humanlike infant appearance (n=20, 19.4%) and other forms (n=6, 5.8%). Participants who preferred humanlike adult or infant and animallike appearances reported higher scores in rigorousness and friendliness than other personalities. Participants who desired other appearances, rather than animal and humanlike appearances, were more likely to report high scores in extroversion, friendliness, rigorousness, and emotional stability as well as in eHealth literacy. Participants who were married or had a partner were more likely to choose humanlike adult and animallike appearances.

Table . Participants' preference for the appearance of a robot (N=103).

		Preference for robot's appearance[a]			
		Animallike	Humanlike infant	Humanlike adult	Other forms
Participants, n (%)		33 (32.0)	20 (19.4)	43 (41.7)	6 (5.8)
Gender, n (%)					
	Female (n=74)	25 (33.8)	17 (23.0)	28 (37.8)	4 (5.4)
	Male (n=29)	8 (27.6)	3 (10.3)	15 (51.7)	2 (6.9)
Personality (range 0-15), mean (SD)					
	Extroversion	10.5 (2.2)	10.8 (2.0)	9.9 (2.2)	12.3 (2.0)
	Friendliness	11.2 (2.4)	11.3 (1.7)	11.0 (2.0)	12.3 (2.0)
	Rigorousness	11.4 (2.1)	11.1 (1.9)	11.2 (2.1)	12.5 (1.9)

[a]Participants could provide multiple answers to this question.

Participants' Most Preferred Functions of Aged Care Robots

Participants' most preferred functions of aged care robots were housework assistance, language translation, health monitoring, facial expressions, news reading, and security monitoring. By analyzing the correlations between the demographic factors and the preferred functions of a robot, participants who were married or had a partner were more likely to choose functions of facial expressions (71/88, 81%; *P*=.002), news reading (61/88, 69%; *P*=.02), and security monitoring (60/88, 68%; *P*=.02) than their counterparts. High financial status showed a significant correlation with the function of facial expressions (mean 3.7, SD 0.7; *P*=.001). Participants who had immigrated for fewer than 10 years were more likely to use the function of facial expressions (43/51, 84%; *P*=.05) than people who had immigrated for 10 years or more. Detailed information is shown in Table 3.

Table . Participants' most preferred six functions of robots (N=103).[a]

		Preference for robot functions[b]					
		Housework assistance	Language translation	Health monitor	Facial expressions	News reading	Security monitor
Participants, n (%)		86 (83.5)	79 (76.7)	78 (75.7)	77 (74.8)	66 (64.1)	65 (63.1)
Marital status, n (%)							
	Married or have partner (n=88)	72 (81.8)	70 (79.5)	69 (78.4)	71 (80.7)	61 (69.3)	60 (68.2)
	Unmarried, widowed, or no partner (n=15)	14 (93.3)	9 (60.0)	9 (60.0)	6 (40.0)	5 (33.3)	5 (33.3)

Discussion

Principal Findings

With the advancement of robotic technology, care robots are being used to assist older adults with their daily living needs. However, there is a lack of research on the use of robots with older immigrants residing in the community and their preferences regarding the appearance and functionality of aged care robots. Therefore, this study aimed to investigate the needs and preferences of older Chinese immigrants toward the appearance and function of aged care robots, and examine the relationship between these preferences and the demographic characteristics of the participants. The findings revealed that older Chinese immigrants favored a humanlike adult appearance for the robots. Additionally, participants with different marital status, financial status, and duration of immigration had varying needs for the robot's functionalities.

Robot Appearance

In this study, the most popular appearance of a robot rated by older Chinese immigrants were those with a humanlike adult appearance, where no difference was identified between female and male participants. Our findings are consistent with Chiu et al's [11] study that the favorite appearance of robots among middle-aged and older Taiwanese people was a humanlike adult appearance, but the correlation to marital status was less significant. Prakash and Rogers [16] reported distinctive differences in preferences for a robot appearance between young and older adults, whereas older adults had a higher preference for humanlike robots. The authors suggested that the differences might be attributed to their experiences with robots [16], and older adults felt comfortable talking with robots with human traits such as eyes and a mouth [17]. Moreover, a rural study in China reported that older adults perceived small-sized robots as more friendly, and steel machinelike robots were less preferred [18].

According to the research on human-robot interaction, the appearance and morphology of a robot are known to be important in increasing the acceptance and use of and interaction with a robot among older adults [19]. However, there is less evidence showing that robots were developed based on the characteristics of older adults. This study uniquely found that older Chinese immigrants who preferred humanlike adult or infant appearances reported higher scores in rigorousness and friendliness. This knowledge may help inform future robot designs for older adults from a morphological perspective [19].

User Needs and Preferences

Results of the study showed that participants with different marital status, financial status, and duration of immigration had different needs for robot functions. Designing robot services to support older people must be based on individually collected information [20]. In this study, older Chinese immigrants mostly desired family service functions (ie, housework assistance), language translation, health monitoring, facial expressions, news reading, and security monitoring. The findings were different from the reported results among middle-aged and older Taiwanese, where the most preferred functions were the skill and recreation functions, followed by family services (ie, housework) and then health status monitoring [11]. The difference might be explained by the immigrant context of individual circumstances and the purpose of immigration. In

this study, over 80% of the participants immigrated to reunite with their adult children, which is aligned with Zhao et al's [21] study that found that most Chinese late-life immigrants relocated to New Zealand to share house chores with their adult children or look after their grandchildren. The burden of housework adversely impacted their health and became a risk factor for their experiences of loneliness and social isolation [1,12,21]. The same issue was also observed among other Asian immigrant groups due to the value of filial piety [22]. Assistive functions of robots were required by participants to relieve their workload and address the language barrier in a host country.

The evidence of this study found that the safety- and health-monitoring functions of the robot were regarded as essential for participants to meet their health and well-being needs, and our data supports Chiu et al's [11] findings that different ages were significantly related to the preference for the safety-monitoring function of the robot. Most of our participants lived independently and expected to maintain their independence, which is consistent with Park et al's [20] study that early detection of emergencies by using robot technology to assist with community-dwelling older adults' daily living is necessary. Moreover, living with others was significantly correlated to participants' preference for the health-monitoring robot function, which might be justified by several studies in New Zealand on Asian immigrant groups that have barriers to access health services due to their language, culture, and transportation barriers, and they intended to stay healthy and avoid becoming a burden to their family [1,21,23].

Moreover, participants who were married or had a partner, had good financial status, and had immigrated fewer than 10 years ago were more likely to choose the function of facial expressions. The finding is consistent with the previous study that older adults with lower technology acceptance preferred friendly and familiar robot designs with humanlike facial features [19]. However, the needs of those who were single with lower education levels might be underreported in this study, as the majority of our participants had higher education levels and were married or had a partner.

Limitations and Future Work

This study recognizes several limitations. First, due to the web-based survey, we might have excluded potential participants without access to the internet, computer, cellphone, etc, or who were not able to answer the survey on the web. Second, it is possible that the responses of participants were biased due to the self-reported data. Third, the data collection was undertaken in Auckland. The generalizability of the study results for the whole of New Zealand and other destination countries is limited. In the future, larger representative samples are needed to further investigate the needs and preferences of using robots in the later phase of life and to generalize the relationships between demographic factors, characteristics of older adults, and preferences for robots among immigrant populations. Mixed methods and co-design research methods are recommended to gain in-depth insights into end users' needs and preferences for robots to support their functions and independence in old age.

Conclusion

To support immigrant populations to age well in a foreign country and to fill the gaps of increasing shortages in the health and social workforce, it is important to develop reliable robotic technology services that are tailored based on the needs and preferences of individuals. We collected and compared the opinions on using robots to support aging in place among immigrant and nonimmigrant groups. The results of users' needs and preferences would inform robotic technology services to prioritize older Chinese immigrants' preference toward housework assistance, language translation, health and safety monitoring, and robots with humanlike features.

Abstract

Background: Low-intensity cognitive behavioral therapy (LICBT) has been implemented by the Improving Access to Psychological Therapies services across England to manage excessive worry associated with generalized anxiety disorder and support emotional well-being. However, barriers to access limit scalability. A solution has been to incorporate LICBT techniques derived from an evidence-based protocol within the Iona Mind Well-being app for Worry management (IMWW) with support provided through an algorithmically driven conversational agent.

Objective: This study aims to examine engagement with a mobile phone app to support worry management with specific attention directed toward interaction with specific LICBT techniques and examine the potential to reduce symptoms of anxiety.

Methods: Log data were examined with respect to a sample of "engaged" users who had completed at least 1 lesson related to the Worry Time and Problem Solving in-app modules that represented the "minimum dose." Paired sample 2-tailed *t* tests were undertaken to examine the potential for IMWW to reduce worry and anxiety, with multivariate linear regressions examining the extent to which completion of each of the techniques led to reductions in worry and anxiety.

Results: There was good engagement with the range of specific LICBT techniques included within IMWW. The vast majority of engaged users were able to interact with the cognitive behavioral therapy model and successfully record types of worry. When working through Problem Solving, the conversational agent was successfully used to support the user with lower levels of engagement. Several users engaged with Worry Time outside of the app. Forgetting to use the app was the most common reason for lack of engagement, with features of the app such as completion of routine outcome measures and weekly reflections having lower levels of engagement. Despite difficulties in the collection of end point data, there was a significant reduction in severity for both anxiety (t_{53}=5.5; *P*<.001; 95% CI 2.4-5.2) and low mood (t_{53}=2.3; *P*=.03; 95% CI 0.2-3.3). A statistically significant linear model was also fitted to the Generalized Anxiety Disorder–7 ($F_{2,51}$=6.73; *P*<.001), while the model predicting changes in the Patient Health Questionnaire–8 did not reach significance ($F_{2,51}$=2.33; *P*=.11). This indicates that the reduction in these measures was affected by in-app engagement with Worry Time and Problem Solving.

Conclusions: Engaged users were able to successfully interact with the LICBT-specific techniques informed by an evidence-based protocol although there were lower completion rates of routine outcome measures and weekly reflections. Successful interaction

with the specific techniques potentially contributes to promising data, indicating that IMWW may be effective in the management of excessive worry. A relationship between dose and improvement justifies the use of log data to inform future developments. However, attention needs to be directed toward enhancing interaction with wider features of the app given that larger improvements were associated with greater engagement.

Introduction

Excessive worry represents a core characteristic associated with generalized anxiety disorder (GAD) [1], characterized as 6 or more months of chronic worry about several different events and little belief worry can be controlled, and is associated with general somatic symptoms of anxiety [2]. It is highly pervasive in high-income countries, with a lifetime prevalence rate of 7.8% in the United States [3] and a median age of onset between 24 and 50 years, and is more common in women and people who are unemployed [4]. Excessive worry is deleterious to the individual, and if it manifests into GAD, it places a significant burden on society and employers with an average of 6.3 days per month of work absenteeism [5]. Furthermore, treatment is associated with increased service use [6], thereby placing a significant burden on primary care settings within both the United Kingdom [7] and United States [8].

Despite excessive worry impacting on the individual quality of life with progression to GAD representing a major public health problem [9], treatment availability remains limited. The treatment gap for GAD has been reported to be as high as 67% in the United Kingdom and 70% in the United States [10]. In an attempt to address the treatment gap [11], innovations in the delivery of evidence-based psychological therapy have been witnessed, for example, by broadening the workforce delivering cognitive behavioral therapy (CBT) for late-life GAD with no differences in effectiveness demonstrated when delivered by bachelor-level lay providers compared with PhD-level experienced therapists [12]. Further attempts to address the treatment gap have been addressed within the Improving Access to Psychological Therapies (IAPT) program, implementing low-intensity cognitive behavioral therapy (LICBT) self-help for the management of mild to moderate common mental health problems alongside therapist-delivered high-intensity CBT for moderate to severe presentations [13].

While improved access has been facilitated through the IAPT program, predictions indicate that access will only be increased to 25% of the community prevalence of depression and anxiety disorders by 2023-2024 [14]. Furthermore, between 2021 and 2022, only 37% of patients completed a course of therapy [15]. Difficulties in reducing the treatment gap are further dependent on a number of individual-level barriers such as stigma, desire to handle the problem independently, and limited willingness to disclose problems [11].

Greater implementation of digital health technologies such as smartphone apps [16] has potential to address barriers at the level of the individual. Furthermore, with high use of smartphones, for example, 81% of adults within the United States [17], apps offer the promise of delivering mental well-being interventions at scale and derive cost savings with respect to delivery and increased productivity within the workplace [18]. The expansion of apps to manage challenges with well-being has predominantly been based on CBT [19]. CBT is particularly well suited to inform mental well-being apps with emphasis placed on active engagement with specific techniques rather than exclusive reliance on a supportive relationship with a behavioral health coach or therapist [13]. This is especially salient with regard to an approach based on "collaborative empiricism," whereby after engagement with specific CBT techniques, people are encouraged to explore outcomes for themselves [20]. In doing so, a better understanding of the way their mental health difficulty is affecting them can be derived through an appreciation of the cognitive behavioral model.

Despite CBT providing a compatible evidence-based approach for mental well-being apps with the potential to deliver at scale to close the treatment gap, implementation and uptake remain limited [21]. This is partly dependent on poor engagement with apps relying on factors such as poor usability, techniques inconsistent with user expectations, and poor health literacy [22]. Exploring ways to enhance engagement is of significance given that greater engagement has been reported to predict improvements in mental well-being [23]. In particular, focusing on obstacles and difficulties encountered in completing LICBT techniques is of significance given their effectiveness [24], while not dismissing common factors to establish a good "therapeutic relationship" generating a sense of genuineness, warmth, and collaborative working [25]. Focusing on both common and specific LICBT techniques used within the Iona Mind Well-being app for Worry management (IMWW) is therefore of importance given that the combination of both is crucial for bringing about therapeutic change [26].

This paper reports log data [27] to examine engagement with IMWW based on LICBT to help in the management of excessive worry. It has been proposed that rather than looking at overall engagement regarding areas such as number of sessions engaged with or session duration, it is better to focus attention on specific user interactions [28]. The focus of this paper is therefore directed toward appreciating engagement and interaction with specific LICBT techniques and wider features of IMWW to examine potential enhancements alongside wider usability. Furthermore, the relationship between engagement and outcomes

will be explored to inform ongoing development to maximize effectiveness.

Methods

Design

Areas representing the focus of log data analysis have been informed by recommendations identified as useful when seeking to address the effectiveness of eHealth technology alongside behavioral and theoretical models [27]. Analysis was only undertaken on data collected regarding "engaged users" and their log data associated with engagement with the LICBT techniques. To be considered an engaged user, the user was required to have completed at least 1 lesson related to the Worry Time and Problem Solving in-app modules within any time period. These criteria represented the "minimum dose" [29] necessary for the user to be considered to have engaged enough to be able to understand the in-app CBT techniques and apply them outside of the app to manage excessive worry. This approach to represent "engaged users" has previously been adopted. For example, with respect to a feasibility trial examining internet-administered LICBT for parents of children treated for cancer [30].

A χ^2 test of homogeneity was undertaken to compare demographic data provided by the engaged users and those who failed to engage with specific LICBT techniques to receive a minimum dose.

Sample

Over 6 months (July 19, 2022, to February 19, 2023), 956 adults 18 years and older with a GAD-7 score of 6 and above downloaded and opened IMWW and completed the sign-up process. Of these, 803 (84%) adults did not engage sufficiently with the app to be considered an "engaged user," resulting in 153 (16%) users engaging with the app sufficiently to be considered to have received a minimum dose (Table 1). Approximate data regarding the continent the user was accessing the app from were automatically collected by the app from the time zone set on the user's phone and therefore collected on all 956 adults.

χ^2 tests of homogeneity indicate that differences between engaged users and those who had downloaded the app but failed to receive a minimum dose were not significant at the 5% level across any of the demographic variables. In addition to the collection of demographic data, 41 of 153 (27%) engaged users responded to a question regarding receipt of other therapy, of whom 34 (83%) users indicated that they were not.

Table 1. Demographic questionnaire responses completed (N=956).

Variable	Engaged users (n=153)	Not received minimum dose (n=803)
Gender, n (%)[a]		
Women	43 (72)	50 (85)
Men	14 (23)	9 (15)
Other	3 (5)	0 (0)
Age range (years; n=53), n (%)		
18-24	18 (34)	16 (30)
25-34	20 (38)	19 (36)
35-44	9 (17)	12 (23)
45-54	2 (4)	6 (11)

Unknown	5 (3)	23 (3)

[a]A total of 60 engaged users and 59 users who did not receive the minimum dose responded.

Iona Mind Well-Being App for Worry Management

The IMWW is, in part, informed by the techniques described in the LICBT written self-help intervention for managing excessive worry [31], based on the CBT protocol for the management of GAD [32]. LICBT is recommended for the management of GAD [33] and is one of the most commonly adopted written self-interventions used within the IAPT program [34]. The focus of IMWW is explained during onboarding where the user is required to explicitly acknowledge its purpose as a

well-being tool. Users wishing to continue engagement acknowledge that they understand conditions related to use and consent to have their data processed.

Collection of Demographic Data

Demographic data were not used to inform the delivery or functionality of the app. Therefore, a screen requesting demographic data, or a question regarding receipt of other therapy, was only presented once the user had engaged with IMWW on 2 occasions at least 6 hours apart following enablement, and no other higher priority messages were pending. If higher priority messages were pending, the request to provide demographic data was repeatedly postponed to the following day until the user had supplied all data, completed specific questions, or declined the request to open the screen (Table 1). Due to the optionality and logic surrounding whether demographic data were requested from users who downloaded the app, such data were therefore not requested from all users and were not prioritized over other more useful app functionality. Collecting demographic data was not prioritized given that answering such questions on an app can increase the risk of disengagement [35].

Supporting Interaction

Interaction is supported by an algorithmically driven chatbot simulating a "conversation" between the conversational agent (CA) and the user. Users interact by entering raw text or selecting a predetermined response. The type of response depends on the type of content being delivered and varies between selecting a button from a list of options or entering free text when a personalized response is requested. User feedback is collected at the level of a user message supplied within the "conversation" through selecting a "thumbs up" or "thumbs down" icon.

Key principles associated with user-centered systems design were adopted to inform the development of IMWW [36]. The app was developed to manage excessive worry and support emotional wellness with an "SOS" button prominently displayed for users finding themselves in significant emotional distress. If selected, signposting information to a comprehensive list of local and international crisis helplines is presented alongside mindfulness practices to assist with mood stabilization. Before engaging, the user is further reminded that IMWW is not intended to deliver treatment but rather is a tool to support well-being and is not designed for anyone who has been diagnosed with a psychiatric disorder. Consequently, it is stressed that the app is not to be used outside of the context of a well-being self-help aid.

Progress Through IMWW

Engagement begins with users landing on the Today home screen and progressing through 6 educational modules through which they learn about and interact with the LICBT techniques (Multimedia Appendix 1).

Educational modules are chronologically ordered and unlocked as engagement is initiated. The order in which they are unlocked is dependent on user choice, reflecting whether they wish to initially address practical or hypothetical worries. However, the user is able to move forward and backward between these specific factors to address the different types of worries where preferred. After onboarding, the user is given the opportunity to complete the GAD-7 and Patient Health Questionnaire–8 (PHQ-8) weekly during their weekly review, with scores presented on a progress screen. However, following the completion of these measures during onboarding, subsequent completion is voluntary.

Home Screen

Informed by the CBT protocol for the management of GAD, which can also be used in the context of improving emotional well-being by supporting the management of worries [37], the Today (Home) screen supports the user to record their worries. This screen also presents a timer that counts down to the user's scheduled worry time and offers tips to complete Worry Time (Multimedia Appendix 1). Should the user not have completed the lesson, a placeholder is displayed inviting them to learn more about Worry Time. The screen has been designed to make it as easy as possible for users to record worries, plan Worry Time, and access the CBT content. A navigation bar at the bottom of the screen links to the screens related to the LICBT techniques through which users can engage depending on preference.

CBT Techniques

To promote engagement, the IMWW is informed by collaborative empiricism where the user actively engages with techniques associated with CBT [38]. Collaborative empiricism has been identified as core to the therapeutic relationship [39], supporting "learning by doing" fundamental to CBT [40]. Accordingly, LICBT techniques are presented as skills to be mastered through regular practice. The user is initially introduced to the CBT model followed by supporting them to record and categorize their worries. The user is then provided with the choice of Problem Solving or Worry Time to address practical or hypothetical worries, respectively.

CBT Model

An interactive CBT Five Areas model (introduced in October 2022) is presented [41], and the user is encouraged to interact and identify a current situation in the "here and now." In response to this current situation, the user is also encouraged to interact with boxes reflecting "Thoughts" that go through their head, "Behaviors" engaged in, "Physical Feelings," and to recognize "Emotions" (Multimedia Appendix 1). Additionally, the model helps them appreciate ways in which the specific LICBT techniques presented to address practical and hypothetical worries may be helpful. The model serves as psychoeducation, enabling the user to recognize the interaction between each of these areas, understand the nature of their worry, and appreciate factors that maintain their worry behavior and the impact of physical symptoms associated with anxiety.

Worry Diary

The primary function of the Worry Diary is to enable the user to actively add new worries as they arise throughout the day and as a record of worries for subsequent review (Multimedia Appendix 1). Prompts and predefined categories are used to

enable the user to differentiate between practical worries that have a solution and hypothetical worries that do not.

Problem Solving

Where practical worries are logged, the user is guided to list potential solutions, consider strengths and weaknesses for each solution, and select the most appropriate one. A time to try the solution out is then optionally scheduled by the user with a reminder given to complete it at the chosen time. After the chosen time has passed or 30 hours elapsed, on opening the app, the CA will ask the user to review how their solution went. Prompts ask the user if the problem was resolved and if not request further information regarding the challenges encountered. Advice is offered where problems have been encountered, putting the solution into action (eg, to break the problem down or work through and apply another solution).

Worry Time

Unless explicitly overridden by the user, all worries identified as hypothetical are displayed only during Worry Time at a time determined by the user and are blurred out at all other times. Users are reminded that their worry time is starting with a push notification to their phone. If the user opens the app during Worry Time, they are prompted to work through the time they have set aside to worry with the CA. If they choose to do so, the CA will list out all user worries and request that these be worried about for the specified period of time. Subsequently, the CA will review each worry with the user, asking them if it still remains an issue or if it now better represents a practical worry. Worry Time represents a form of cognitive exposure with users exposed to hypothetical worries written down during the day. This is proposed to overcome avoidance behavior and reduce intolerance of uncertainty when it is recognized that there are no solutions to the worry [37].

Maintaining Engagement

A chatbot informed by theoretically driven techniques is adopted to help establish a “therapeutic approach” to maintain and promote user engagement embedded within IMWW [38]. Such techniques help to establish an approach based on collaborative empiricism [39], whereby the user is encouraged to explore outcomes arising from engagement for themselves.

Conversational Agent

Support is omnipresent throughout the engagement and comes in the form of an algorithmically driven chatbot stimulating engagement between IMWW, the CA, and users. This helps them overcome difficulties encountered with the specific LICBT techniques and uses common factors to maintain engagement. Upon recognition that difficulties are experienced with any of the specific techniques, the CA is deployed to enable users to work through the specific techniques. If the user reports difficulties in trying out a solution they have planned, the CA will ask questions to determine the nature of the difficulty encountered and direct them to the appropriate parts of the app. For example, the user would be directed back to Problem Solving should they need to break the problem down, or Worry Diary if the worry appears to be hypothetical rather than practical (Table 1).

On other occasions, the CA provides the user with helpful tips and advice or the opportunity to ask FAQs to navigate difficulties experienced. For example, 2 days after learning about Worry Time, the CA will check back in with the user and ask how the exercise has been going. Depending on user response, advice will be given. For example, if the user forgets to engage with Worry Time, they are reminded to turn on their notifications and set an alarm on their phone to serve as a prompt. Consistent with the delivery of CBT, during engagement with the LICBT techniques, the CA brings the user back to the CBT model to reinforce their understanding of the intervention and maintain motivation for continued engagement.

Common Factors

The CA uses nontherapeutic common factor skills in the form of “therapeutic empathy” to instill a sense of hopefulness and encouragement to maximize engagement with the specific factors linked to symptom reduction [42]. Statements include those demonstrating an empathic stance highlighting a desire to help alongside empathic attunement where statements demonstrate an appreciation of the user’s emotional experience [42]. When recognizing that the user is experiencing difficulties in engaging or is not improving, the CA uses empathy to maintain engagement.

Behavior Change Techniques

Within the module on recording worries, Behavioral Contracting [43] encourages the user to sign an agreement to consistently engage with IMWW throughout the 6-week program with a separate Goal Setting lesson guiding the user to set approach, rather than avoidance, goals [44]. Behavior “Push” notifications serve to prompt or maintain behavior change while engaging with the app. Furthermore, constructs derived from self-determination theory [45] promote autonomy and intrinsic motivation that serve to facilitate collaborative empiricism [37].

Monitoring Progress

Throughout engagement, a progress screen presents a summary of the user’s app use and engagement with in-app lessons, previously entered goals, and scores regarding symptom severity associated with anxiety (GAD-7) [46] and low mood (PHQ-8) [47]; it also presents links to the settings page, which houses operational features such as typing speed (Multimedia Appendix 1). Given a potential association between providing feedback and improved outcomes, all data collected are repeatedly presented to the user throughout engagement [48].

Weekly Reflection

Consistent with face-to-face CBT [39], on a weekly basis, the CA prompts the user to reflect on their engagement with IMWW and the features found most helpful (Table 1). Using reflective learning within the app facilitates learning, with the CA encouraging engagement to promote self-discovery [49]. Furthermore, during the weekly reflection, the CA requests information on the LICBT techniques engaged with and highlights those found most helpful. In the event an identified technique was not engaged with, the CA also requested information as to the main reasons from a range of options provided.

Data Collection and Analysis

Log Data

Consistent with the aims of the study, analysis was undertaken on log data collected from engaged users to reflect their engagement with the specific LICBT techniques. Log data were collected by IMWW automatically logging the actions of each engaged user and requests to complete surveys throughout the use of the app. From these data, summary statistics for use in this paper were extracted. Progress of engaged users through IMWW was monitored and informed by data regarding the number of sessions completed, session duration, weekly reflections, and completion of LICBT techniques alongside summary statistics recorded. Engagement with IMWW was explored with respect to the number of users who reached the CBT model and interacted with it, text entered into each area, completion of the LICBT techniques, and general input and behavior during the engagement. Specific worry management techniques were examined with respect to the number of worries entered and the proportion classified as practical or hypothetical problems. With respect to Problem Solving, data analysis included the number of users who completed the lesson, the number of times the in-app tool was used to solve a practical problem, the number of practical problems entered, the number of users prompted to follow up on their problem-solving with the CA, and the number who engaged with it. Furthermore, analysis was undertaken on the number of engaged users who sought to manage hypothetical worries by learning about Worry Time, set a time for Worry Time, and started an in-app session alongside the number of hypothetical worries entered being recorded.

User responses from the Weekly Reflection conversation within IMWW were also collected and analyzed to gauge general engagement with the specific techniques. As a proxy for behavior change approaches adopted to maintain engagement within the app, the number of users who were delivered at least 1 push notification and the number of those who interacted were also examined. For engaged users completing more than 1 GAD-7 or PHQ-8 at assessment, the log of assessments and the number of times IMWW was used for more than 10 seconds, which is defined as a "session," were analyzed.

Potential Effectiveness

To examine the potential effectiveness of IMWW for engaged users, separate paired samples 2-tailed *t* tests were undertaken to examine the difference between outcome data collected regarding the severity of anxiety (GAD-7) and low mood (PHQ-8). This analysis was only undertaken for the 54 of 153 (35%) engaged users who completed the outcome measures during onboarding and at the end of the engagement.

Impact of Engagement on Potential Effectiveness

A multivariate linear regression model was used to investigate the impact that engagement with IMWW had on improvement in anxiety and low mood. In particular, the extent to which specific features were used to complete therapeutic exercises impacted on scores over time. Engagement with, and completion of, Worry Time and Problem Solving was expected to lead to improvements in the symptoms of anxiety, and hence a model to analyze this was specified. Because there are multiple discrete interventions being applied within IMWW and the dependent variable is not univariate, the multiple regression $y=\beta_0+\beta_1x_1+\beta_2x_2+$ was adopted. Within this model, y is the change in GAD-7 or PHQ-8 from the initial score at onboarding to the final input during progress review, x_1 is the binary variable indicating whether the user completed Problem Solving and resolved their problem, x_2 is the binary variable indicating whether the user completed at least 1 instance of Worry Time in-app, and is the stochastic error term. Additional controls were added to the model to examine the extent to which the number of in-app sessions completed, and the number of worries, problems, and solutions recorded predicted improvement in GAD-7 and PHQ-8. All models met OLS model assumptions associated with multicollinearity, heteroskedasticity, and normality of residuals.

Ethical Considerations

Users were only able to download IMWW after agreeing to Iona Mind's Terms of Service and Privacy policy, which required them to acknowledge that they understand conditions related to use and consent to have their anonymized data processed. Being based on anonymous, routinely collected log data from a nonclinical population, research ethics was not required for this study.

Results

General Engagement

Analysis of log data collected from the 153 engaged users indicated engagement with 1108 sessions (mean 7.2, SD 7.7) with an average session length of 6.2 (SD 6.2) minutes. The number of sessions and session length varied significantly across users with a median session length of 4.5 minutes and 6 being the median number of sessions (Multimedia Appendix 2).

Engagement With LICBT Techniques

Since inclusion (October 2022), 36 users started filling out the CBT model to reflect their current difficulties with anxiety, and of these, 31 (86%) users completed all areas in an average of 2.4 minutes (SD 1.7; median 1.7 minutes). The lesson on the Worry Time technique was successfully completed by almost all users (147/153, 96%). However, of these users, only 50 (33%) were observed to have performed Worry Time at their chosen time using the in-app tools.

Problem Solving was engaged with by 114 of 153 (74.5%) users; however, only 89 of 153 (58.2%) users actually completed the lesson. This indicates that 25 of 114 (21.9%) users engaged with the in-app tools to problem-solve one of their practical worries without completing the lesson. This behavior is permitted within the IMWW user experience because the user is able to choose the specific features of the app they wish to engage with. The majority of app features start in an unlocked state to encourage exploration and self-discovery. Only 42 of 153 (27%) users completed a follow-up conversation to review their solutions and progress using the Problem Solving protocol on their worries. During the interaction, engaged users recorded a total of 720 worries (mean 4.7, SD 6.1), and a median of 3

worries were recorded for each user. Of the worries recorded, 399 (55%) were categorized by the user as practical, 306 (43%) as hypothetical, and only 15 (2%) worries were not categorized. With respect to practical worries, 244 (61%) worries were problem-solved using the in-app tools with at least 1 possible solution added.

Weekly Reflection

In response to the CA asking the user to reflect on their experience of engaging with IMWW, in-app Weekly Reflections were completed by 58 of 153 (38%) users who recorded 206 responses (mean 3.6) identifying LICBT techniques engaged with, alongside 48 responses identifying the technique found most helpful (Table 2).

During the Weekly Reflection, 27 of 58 (47%) individual users reflected on engaging with Worry Time, of whom 19 (70%) were observed to have used the in-app tooling to complete it at their chosen time. A total of 8 of 58 (14%) users therefore engaged with Worry Time without using the in-app tools. In addition to asking which features of IMWW the user had engaged with, the CA also asked which feature they found most helpful. The users were asked this question during the weekly review, and for each weekly review, they could give at most 1 response.

Table 2. Weekly reflection techniques engaged with and found most helpful.

Technique	Engaged with[a] (n=206), n (%)	Most helpful (n=48), n (%)
Journaling worries	50 (24)	16 (33)
Worry time	46 (22)	11 (23)
Problem-solving	35 (17)	10 (21)
Avoiding worry behaviors	28 (14)	4 (8)
Watching out for different worry types (Worry categorization)	17 (8)	4 (8)
CBT[b] model[c]	8 (4)	1 (2)

[a]Users can respond multiple times.

[b]CBT: cognitive behavioral therapy.

[c]Introduced in October 2022.

Maintaining Engagement

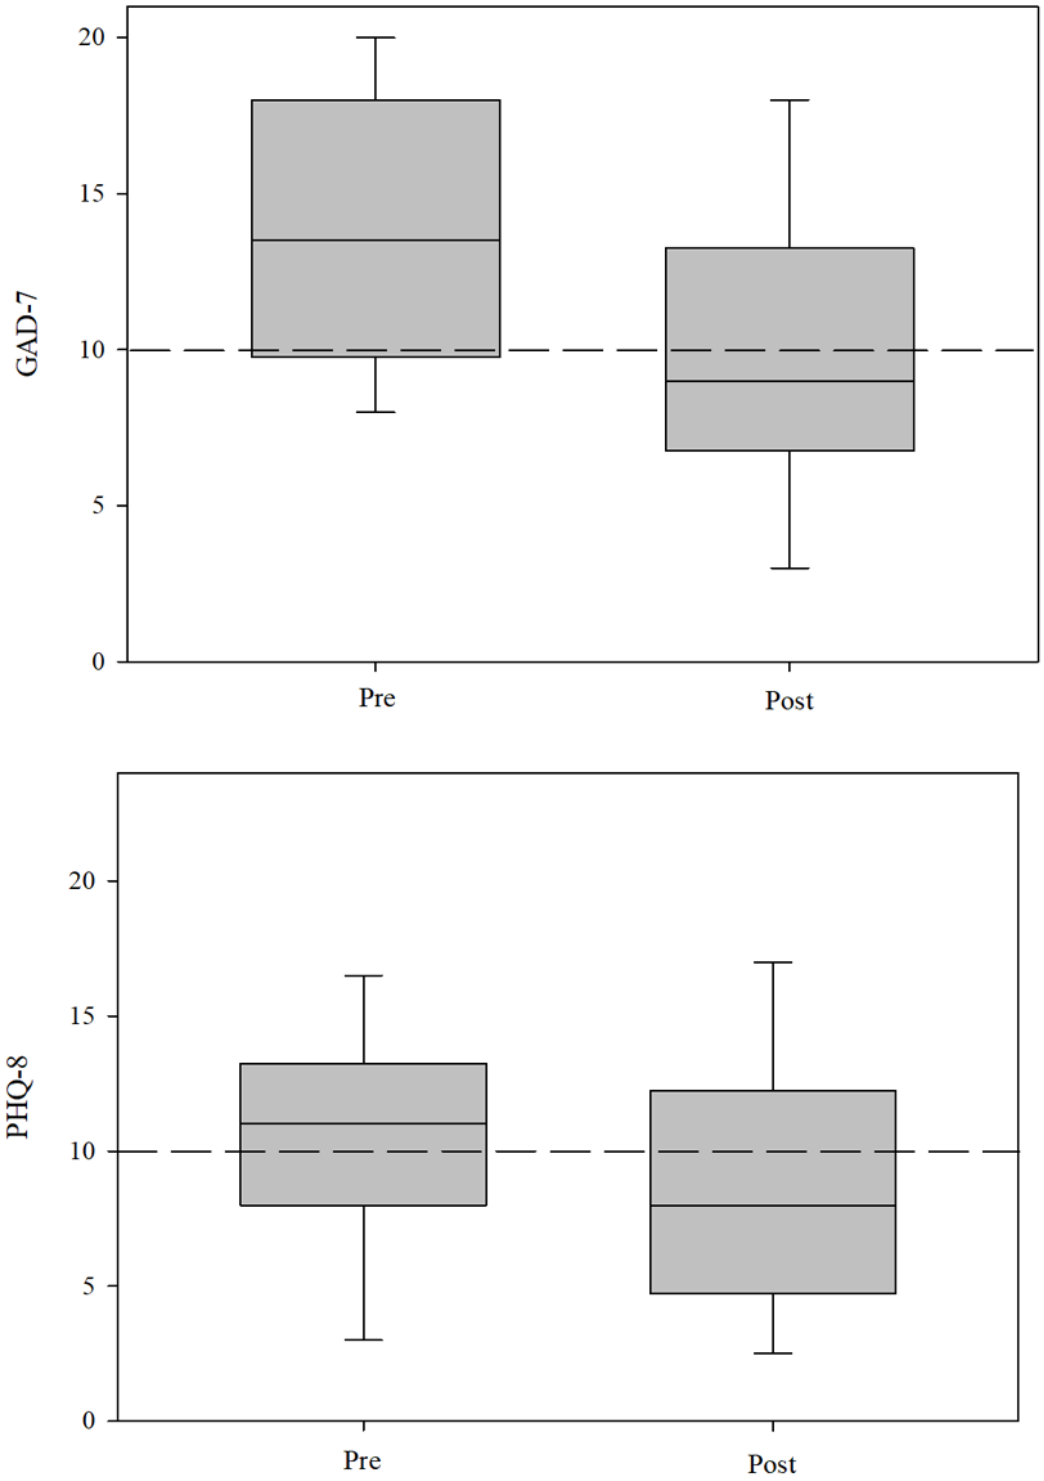
To maintain engagement with IMWW, 142 of 153 (93%) users were sent at least 1 push notification with 113 of 153 (74%) users responding. An average of 84 (SD 75) push notifications were sent to each engaged user throughout their engagement, although the quantity of push notifications per user varied substantially with use pattern and duration.

Potential Effectiveness

Separate paired sample 2-tailed *t* tests were conducted to examine the difference between the GAD-7 and PHQ-8 scores for 54 of 153 (35%) engaged users who completed the measures during onboarding and the final score provided. There was a significant reduction in both anxiety (t_{53}=5.5; *P*<.001; 95% CI 2.4-5.2) and low mood (t_{53}=2.3; *P*=.03; 95% CI 0.2-3.3), with severity dropping from moderate to mild in both instances (Figure 1).

Examination of individual-level data indicates that the vast majority of users (43/53, 81%) experienced a reduction in anxiety between baseline and final observation with the score of 2 (4%) users remaining unchanged. The majority of users (35/53, 66%) also saw a reduction in PHQ-8 with no difference arising for 4 (8%) users. Deterioration in GAD-7 was experienced by 9 (17%) users and rose to 15 (28%) users for low mood.

Figure 1. Pre-post mean differences (95% CI) for GAD-7 and PHQ-8. GAD-7: Generalized Anxiety Disorder–7; PHQ-8: Patient Health Questionnaire–8.



Impact of Engagement on Potential Effectiveness

The multivariate linear regression predicting changes in GAD-7 based on engagement reached statistical significance ($F_{2,51}$=6.73; P=.03), but the model predicting changes in the PHQ-8 did not ($F_{2,51}$=2.33; P=.11). Two-sided 2-tailed t tests were performed on the slope estimates in the models. The model predicting changes in GAD-7 estimates that the marginal effect of a user completing in-app Worry Time (β_2) is a –3.3 change in GAD-7 and is significant (P=.02). The constant β_0 and the marginal effect of the user successfully completing Problem Solving β_1 had respective values of –1.6 and –3.0. However, they failed to reach significance at α=.05 (P_0=.07, P_1=.08). The model had an R^2 of 0.21. Furthermore, an improvement in the GAD-7 and PHQ-8 was not predicted by the number of in-app sessions completed (P=.09) or the number of worries (P=.36), problems (P=.27), and solutions (P=.16) recorded.

Discussion

Principal Findings

While engaged users represented a minority of those who downloaded IMWW, a large number of these interacted with the LICBT techniques associated with the CBT protocol to manage excessive worry and support emotional well-being [31]. The vast majority of those who engaged completed all areas presented with the CBT model and were able to successfully record worries and categorize them as practical or hypothetical. The CA was commonly used to help engaged users overcome difficulties when engaging with practical worries. Worry Time was engaged with to a much lesser extent within the app; however, several users reported engaging with it outside of the app. Forgetting to engage with the LICBT techniques was identified as the most common reason for lack of engagement, while experiencing them as too difficult to comprehend was only reported by a small minority of engaged users. The change in the user GAD-7 score was predominantly explained by engagement with the LICBT techniques as opposed to the number of times they used IMWW.

Poor engagement with an app following download is not uncommon, with only 14% of people often using it the following day [50] and even lower rates typically associated with mental health apps [22]. Despite using common factors and behavior change techniques, however, only a minority of users who engaged with IMWW had enough engagement with the LICBT techniques to be considered engaged users. This is of some concern given that users failing to engage to a point where they have received an adequate dose to bring about recovery may serve as a barrier to seeking further support.

While engagement following download was poor, log data identified that engaged users had moderate to good levels of interaction and fidelity [51], with the CBT model alongside recording and categorizing worries. Fidelity and interaction with Problem Solving were also good, potentially arising from support provided through the CA. When engaging with Problem Solving, the CA was commonly used to support users to overcome difficulties in engaging with the LICBT techniques and to encourage continued engagement. There was less within-app engagement with Worry Time; however, some users reported engaging with it outside of the app. Engagement with the LICBT techniques included within IMWW may therefore have been greater than log data alone suggest. This supports the additional benefits of exploring out-of-app engagement with specific techniques to get a full appreciation of interaction [28]. Exploring ways to promote out-of-app engagement is of benefit given that engagement with techniques in face-to-face CBT between support sessions as “homework” is identified as important to improve clinical outcomes related to anxiety [52].

Although there were moderate levels of interaction with LICBT techniques used within IMWW, exploring additional ways to enhance interaction across all techniques and promote prolonged engagement would be highly beneficial. Enhancing engagement through approaches such as involving personalized support, guidance, and feedback regarding engagement has also been associated with improved effectiveness for mental well-being digital tools [48]. Furthermore, recommendations to enhance out-of-app homework compliance to deliver better outcomes have also been proposed [53]. These include ensuring that app content is congruent to the therapeutic approach adopted, learning is consolidated through engagement, and emphasis is placed on completion. Additionally, recommendations include ensuring that the app is tailored to specific populations and building connections with others has been identified as supporting engagement with homework [53]. Within IMWW the CA was used to enhance engagement through the use of common factor skills to encourage and motivate the user. However, greater focus needs to be directed toward maximizing the ability of the CA to enhance engagement within and outside of the app.

Maximizing engagement may be achieved by implementing mental well-being apps for use adjuvant to health professional support and integrated into clinical settings [54]. Benefits associated with providing support are recognized by the National Institute of Health and Care Excellence recommendations for supported LICBT for anxiety and depression [14]. This has resulted in Psychological Practitioner support for LICBT adopted by the IAPT program implemented across England [14]. Support enables the patient to engage with the interventions by using personalized common factor skills, monitor progress, and provide encouragement during weekly support sessions. However, it does not include a therapeutic role in the delivery of LICBT techniques within the clinical sessions [13].

However, nonprofessional forms of support have also been demonstrated to enhance engagement and improve outcomes with LICBT. For example, group support within community settings is provided by trained volunteers with varying backgrounds [55]. Furthermore, forms of support through technology such as web-based communities providing constructive peer support [55] and discussion forums [56] have been identified to enhance engagement with digital tools [54]. Potentially, therefore, using IMWW adjuvant to some form of minimal-contact support provided by a practitioner, volunteers within community organizations, or mediated through technology offers promise to result in enhanced effectiveness at reduced delivery costs.

With respect to outcomes, the average level of anxiety and low mood improved among users who engaged with IMWW to a degree they would be considered to have received a minimum dose of the LICBT techniques [29]. That anxiety and low mood are identified to share mechanisms has led to recommendations to combine techniques within a single app to reduce the commitment needed by users to maximize engagement [19]. However, when exploring recovery at the level of the individual user, the low mood of several more users deteriorated compared with anxiety. However, it would remain possible to develop a single app that included protocol-informed LICBT techniques to target low mood or anxiety once the main emotional difficulty being experienced was determined.

Strengths and Limitations

Providing a clear description of the LICBT techniques contained within IMWW informed by a theoretical basis represents a real strength of the paper. This has enabled the analysis of log data

to be interpreted with respect to interactions with the techniques. Clearer conclusions regarding the relationship between engagement and outcomes regarding the management of symptoms associated with anxiety were therefore able to be reached. This facilitates specific targeting of future development work on IMWW to ensure greater levels of engagement to derive improved outcomes.

There was a large difference between the number of people who downloaded IMWW and those who interacted with at least 1 lesson related to Worry Time and Problem Solving for them to be considered engaged users. While it is known that the background demographics of these 2 groups did not significantly differ, it is unclear as to why a large number of those who downloaded IMWW never went on to engage with one of these specific LICBT techniques. Unfortunately, reasons behind failing to engage with IMWW were not requested, and therefore the extent to which poor usability may have been a relevant factor is unknown. As the use of digital health technologies continues to increase [16], understanding the usability of apps is of increasing interest [57]. Future research exploring log data could therefore consider using a measure of usability, such as the mHealth Usability Questionnaire [58], alongside the collection of log data to gain a better understanding of the way in which an app is used alongside potential barriers to usability.

Finally, while data regarding outcomes can be considered promising with respect to IMWW as a tool to support worry management, this study does not enable definitive conclusions regarding effectiveness to be reached. As a consequence of the lack of clear end points when using log data, users can stop using the app at any time without completing outcome measures. This makes it difficult to reach conclusions regarding effectiveness. The use of multivariate regression with terms to represent proxy use of techniques was adopted to compensate for this. However, this cannot be considered to represent a substitute for the collection of clear and reliably collected end point data within a trial design comparing IMWW with an appropriate control [59]. Furthermore, reaching conclusions regarding effectiveness is further confounded given that only a minority of engaged users responded to a question regarding the current receipt of treatment.

Conclusions

While a large number of people downloaded IMWW, only a minority engaged with the app to be considered engaged users. Of these users, however, analysis of log data identified good interaction with the LICBT techniques associated with an evidence-based protocol to support worry management [31]. Although there were good levels of interaction, exploring additional ways to promote interaction with the LICBT techniques and other features of the app to result in prolonged engagement remains beneficial. This could involve adopting a “user-centric” design process whereby potential users are directly involved in ongoing development [22]. Considering log data as part of a user-centric design process may enhance engagement to a point where more users receive an appropriate “dose” to bring about improvement [29]. Log data can therefore be used to inform ongoing development to maximize engagement and protocol fidelity [51]. This is significant given the relationship between engagement and effectiveness. While effectiveness data associated with IMWW can only be seen as promising, capturing log data will serve to enhance ongoing intervention development. A high-quality randomized controlled trial would then enable definitive conclusions regarding effectiveness to be reached [54]. This would help address concerns that the current level of evidence derived from poor-quality trials does not enable recommendations regarding apps to enhance mental well-being to be reached [60].

Authors' Contributions

PF, PA, and PJR conceptualized and designed the project with EW and DR providing theoretical input informing the background of the paper. PF wrote the initial draft of the paper with all authors contributing to the development of the paper, interpretation of the analysis, and editing of the final manuscript. PF was not involved in any part of data analysis.

Conflicts of Interest

PF is currently on a paid sabbatical with Iona Mind from the University of Exeter. All other authors have confirmed they have no conflicts of interest to declare.

Abstract

Background: Interventions targeting the nutritional quality of grocery shopping have the potential to help improve diet and health outcomes.

Objective: This study aims to assess the feasibility and acceptability of receiving advice on healthier food purchases through SwapSHOP, a behaviorally informed smartphone app that allows users to scan barcodes of grocery products from the United Kingdom, providing nutritional information and personalized swap suggestions to encourage healthier purchases.

Methods: We randomized adult volunteers in a 6-arm parallel-group controlled feasibility trial. Participants used the SwapSHOP app to record their grocery shopping during a 2-week run-in period and were individually randomized in a 3:1 ratio to either intervention or control arms within 3 strata related to a nutrient of concern of their choice: saturated fat (SFA), sugar, or salt. Participants randomized to the intervention received the SwapSHOP app with a healthier swap function, goal setting, and personalized feedback. Participants in the control group were instructed to use a simpler version of the app to log all their food purchases without receiving any guidance or advice. The primary outcome was the feasibility of progression to a full trial, including app use and follow-up rates at 6 weeks. The secondary outcomes included other feasibility outcomes, process and qualitative measures, and exploratory effectiveness outcomes to assess changes in the nutrient content of the purchased foods.

Results: A total of 112 participants were randomized into 3 groups: SFA (n=38 intervention and n=13 control), sugar (n=40 intervention and n=15 control), and salt (n=5 intervention and n=1 control, not analyzed). The 2 progression criteria were met for SFA and sugar: 81% (30/37) and 87% (34/39) of intervention participants in the SFA and sugar groups, respectively, used the app to obtain healthier swaps, and 89% (68/76) of intervention participants and 96% (23/24) of control participants completed follow-up by scanning all purchases over the follow-up period. The process and qualitative outcomes suggested that the intervention was acceptable and has the potential to influence shopping behaviors. There were reductions of −0.56 g per 100 g (95% CI −1.02 to −0.19) in SFA and −1 g per 100 g (95% CI −1.97 to −0.03) in total sugars across all food purchases in the intervention groups.

Conclusions: People were willing to use the SwapSHOP app to help reduce sugar and SFA (but not salt) in their grocery shopping. Adherence and follow-up rates suggest that a full trial is feasible. Given the suggestive evidence indicating that the intervention resulted in reductions in sugars and SFA, a definitive trial is necessary to target improvements in health outcomes.

Introduction

Background

Consumption of saturated fat (SFA), sugars, and salt in the United Kingdom and most high-income countries currently exceeds dietary recommendations for good health [1]. These nutrients of concern contribute to the burden of diabetes and cardiovascular disease, either directly or through their effects on blood cholesterol, blood pressure, insulin sensitivity, and body weight [2-8]. Despite decades of nutrition education and efforts to promote healthier behaviors, significant and sustained dietary changes are yet to be observed. Evidence suggests that people need more than general knowledge of dietary recommendations to change behavior [9-11]; however, there is limited evidence for individual-level interventions that are feasible and effective in supporting dietary change at the population level.

Food purchasing is a key antecedent of food consumption, and improving the nutritional quality of food purchases presents a clear opportunity to intervene. Grocery stores account for 71% of the weekly expenditure on food and drinks, including a substantial proportion of foods high in SFA, sugar, and salt [12]. For many foods, there are usually alternatives with less SFA, sugar, or salt, which are functionally similar. This variation can be attributed partly to the natural differences in recipes, such as those found in ready meals or variances in ingredient costs. In addition, it can also be linked to product reformulation driven by consumer demand, such as the introduction of low-fat yogurts, or policy-driven actions, such as changes in soft drink formulations [13].

Systematic reviews have identified some intervention components to support individual dietary change, including providing information, tailored dietary advice, self-monitoring, and personalized feedback [9,14,15]. Specifically, recommending healthier swaps at the point of purchase or as part of individually tailored regular feedback has shown potential to help improve the nutritional quality of grocery shopping [16-20]. Technological advances such as smartphone apps can facilitate this by providing scalable, lower-cost support to help people make healthier choices while shopping.

A systematic review of smartphone apps identified only 2 studies that tested apps that can provide healthier alternatives at the point of choice [21]. Although there is evidence of similar apps in the scientific literature, these previous apps mostly provide healthier swaps to consumers without the option of self-monitoring the quality of their grocery shopping, and many apps have limitations regarding how information is presented to consumers or the limited comprehensiveness of the databases covering the UK food market [22,23]. Our recent proof-of-concept study tested the functionality of the SaltSwap app to help find lower-salt foods when grocery shopping, which included behavioral components such as nutritional information, prompts to lower-salt options, goal setting on swaps, feedback on swaps and salt reduction, and history of swaps [20].

Objectives

For this study, we have further developed the SaltSwap app into SwapSHOP, a new app that also provides swaps for SFA, sugars, and salt. This study aimed to assess the feasibility and acceptability of receiving dietary advice through the SwapSHOP app. It is a stand-alone intervention that allowed users to scan barcodes of grocery products from major UK stores to obtain nutritional information and suggestions for personalized swaps with lower SFA, sugar, or salt and also enabled users to set goals and monitor their shopping behavior.

Methods

Study Design

This was a prospectively registered (International Standard Randomised Controlled Trial Number: ISRCTN13022312) randomized 6-arm parallel-group controlled feasibility trial conducted in the United Kingdom. After giving written informed consent to participate in the study and completing screening and baseline assessment, participants entered a 2-week run-in period where they used a basic version of the SwapSHOP app (no swap or behavioral functionality shown) to record their grocery shopping. They were individually randomized to 1 of the intervention arms or control following a 3:1 ratio (intervention: control) within 3 strata related to a nutrient of concern of their choice (SFA, sugar, or salt). Individuals participated in the study for 6 weeks from screening to the final follow-up.

Ethical Considerations

This study was reviewed and approved by the University of Oxford Medical Sciences Interdivisional Research Ethics Committee (R67216/RE001). Informed consent was obtained from all the participants.

Participants and Procedures

Participants were recruited between April and October 2021 through the community (eg, word of mouth) and through social networks and media, online newsletters and newspapers, and electronic mailing lists. Participants were eligible if they were aged >18 years, were willing and able to give informed consent, were English speaking and able to understand the demands of the study, were looking for support to improve their diet, owned a smartphone with access to the internet and an email account, were willing to download and use a smartphone app to scan and track their grocery shopping for the 6 weeks during their participation in the study, were responsible for at least some of their household grocery shopping, and shopped regularly (eg, at least once a week in a physical store or online at any of the 6 major food retailers in the United Kingdom: Tesco, Sainsbury's, Waitrose, Asda, Morrisons, or Iceland). People were not eligible if they were already on a clinician-supervised diet or a restricted diet, were currently using apps to monitor the quality of their food shopping (excluding apps to track and monitor food intake), were currently participating in another study aimed at dietary change or asking them to change the way

they shop for food, or were planning on going away from home (holiday or other) for >2 consecutive weeks following enrollment in the study.

Eligible participants were invited to complete a baseline web-based questionnaire that collected demographic information, relevant self-reported medical history, and details about their shopping behaviors. Participants also reported the nutrient (SFA, sugar, or salt) they were most concerned about in their diet, which was used as a stratification factor during the randomization process. Participants then entered a 2-week run-in period during which they were asked to record all their food purchases, either by scanning the barcode of purchased grocery products or manually inputting what was purchased using a simpler version of the SwapSHOP app. Only participants who completed this task with good engagement with the app were randomized. Good engagement was defined as scanning products in at least 2 shops, each with products from at least 3 different predefined food categories (eg, fresh meat, chilled ready meals, and soft drinks), and scanning products from ≥5 of the food categories across the 2 weeks.

Randomization and Blinding

After the 2-week run-in period, participants were individually randomized to either an intervention arm or control following a 3:1 ratio (intervention:control) within each stratum depending on their chosen nutrient of concern (sugar, salt, or SFA). Participants who did not complete the baseline data collection were not randomized. Randomization was performed with a computer using a random allocation sequence (concealed to the investigators) and was stratified by the nutrient of concern using block randomization with block sizes of 4 and 8.

It was not possible to blind the participants to the intervention because of the nature of the intervention; however, randomization was performed remotely via computer-generated randomization, and the researchers were not aware of the treatment group until after randomization was complete.

Intervention

Participants randomized to the intervention arms were able to access an enhanced version of the SwapSHOP app, which included a healthier swap function, goal setting, and personalized feedback. Participants scanned the barcode of grocery products to receive nutritional information about the product using the UK traffic light system and were presented with healthier alternatives or swaps that were lower in SFA, sugar, or salt (depending on group allocation). The swaps that appeared after scanning the original product were chosen from a list of products within the same food category, which were ranked from a larger to a smaller reduction in the specific nutrient that was initially chosen. Participants could also set goals for the number of swaps they wanted to make in each shopping trip and record the products they swapped in the app. The app had specific functions to provide feedback on the achievement of their goals and feedback on the overall nutrient reduction achieved by making swaps. The app also had a section to display the ranking of all purchased foods contributing the most to each nutrient of concern (Figure S1 in Multimedia Appendix 1).

The SwapSHOP app included a comprehensive database of >70,000 grocery products available in January 2021 within major UK grocery stores (including Morrisons, Sainsbury's, Tesco, Waitrose, Iceland, and Asda) [24] and a bespoke system for categorizing products and selecting suitable alternative swap suggestions. SwapSHOP was based on a previous version developed exclusively for salt, and its theoretical basis is grounded in the Behavior Change Wheel [20,25], a framework that integrates the elements of capability, opportunity, and motivation, which are key for behavior change. A range of behavior change techniques from the taxonomy groups *goals and planning* and *feedback and monitoring* that were incorporated into this intervention have been associated with successful dietary change [9,26].

To enable assessment of changes in the nutritional composition of the shopping baskets, participants received weekly reminders to continue scanning and recording all their purchased products for the remaining 4 weeks of follow-up (with a minimum of 2 full weeks of grocery shopping data during the follow-up period).

Comparator

Participants randomized to the control arm were asked to continue using the simpler version of the app with no product nutrition information, swaps, or behavioral components, solely to record all their food purchases as part of the outcome assessment at the end of the 6-week follow-up.

Outcome Measures

Primary Outcomes

The primary objective of this study was to determine the feasibility of a larger study to evaluate the effectiveness of an app that offers healthier swaps while grocery shopping to improve the nutritional quality of food purchasing with respect to sugar, salt, or SFA. The primary outcomes were prespecified progression criteria as follows:

1. App use: at least 70% of participants in the active intervention group use the app to obtain swaps on at least 1 occasion by the end of the second week after randomization.
2. Follow-up rate: at least 60% of participants in total (intervention and control) complete follow-up by scanning all their purchases for a minimum of 2 weeks over the entire follow-up period (4 weeks).

Secondary Outcomes

Feasibility outcomes included (1) recruitment rates: total recruited (including number signed up, eligible, consented, and randomized), (2) time needed for recruitment of the final sample, (3) outcome reporting: number of participants who failed to scan their purchases for a minimum of 2 weeks during follow-up, and number of participants who failed to complete the end-of-study questionnaires.

Process Evaluation and Qualitative Outcome Measures

A summary of app-related use (within-app automatic recording) and acceptability measures was collected through the end-of-study questionnaires at follow-up: (1) average number

of shopping trips where the app was used to scan products to obtain a swap per week; (2) number of occasions the app was used to scan products for a swap per trip; (3) number of swaps made overall per week and per shopping trip; (4) nutrient (SFA, sugar, and salt) reduction per swap made; (5) use of specific functionality, for example, goal setting and feedback; (6) end-of-study questionnaires with free text to understand app use and acceptability of the swaps, app functionality (eg, if app scans most products), and if this prompted other behaviors such as reading nutrition labels.

Exploratory Effectiveness Outcomes

Measures included changes in the nutrient content (SFA and sugar in grams per 100 g) of household food purchases recorded in the app between baseline and follow-up in the intervention group compared with the control group.

Statistical Analysis and Sample Size

This study was planned as a feasibility study. A sample size of 120 (n=approximately 30 participants per intervention group and n=approximately 10 participants per control group) was prespecified as sufficient to enable testing of the trial methodology and outcome measures using parametric statistical models. The protocol was prospectively registered (International Standard Randomised Controlled Trial Number: ISRCTN13022312).

Baseline characteristics overall and by trial arm were summarized as means and SDs for continuous variables and counts and percentages for categorical variables. Baseline characteristics were coded as age (years), gender (man, woman, other, or not specified), ethnic group (Asian, Black, White, mixed, or other), education (no formal qualifications, secondary education, or higher education), income (>£15,000, £15,000-£24,999, £25,000-£39,999, £40,000-£75,000, and >£75,000; GBP £1=US $1.38), household size (1, 2-4, and ≥5), grocery shopping habits (eg, spending >£25) on groceries more than once a week, once a week, once a fortnight, once a month, and less than once a month), and relevant self-reported health history (eg, concerns related to weight, high blood pressure, diabetes, and heart disease).

Descriptive statistics were used to present the primary and secondary outcomes using all available data, regardless of whether the participants completed the trial or withdrew.

For the exploratory effectiveness measures, we used data from products purchased over the 2 weekly periods recorded at the beginning and end of the trial, with available information on weight or volume as well as the nutrient content (grams per 100 g) to estimate changes in SFA and sugar for food purchases recorded in the app. The excluded items in this analysis included those categorized as fresh fruits, vegetables, or with no or minimal nutrient content (eg, sugar-free gum) as well as products that were manually entered in the app or those missing nutrient or volume information. We used linear regression models to investigate changes in the nutrient content of food purchases between baseline and follow-up in the intervention and control groups. Tests for linear regression assumptions were conducted and met. The main models included adjustment for baseline values of the dependent variable. Potential confounding because of imbalance in baseline characteristics was investigated, and the following variables were adjusted in sensitivity analyses: age (years), gender (man, woman, other, or not specified), ethnic group (Asian, Black, White, mixed, and other), and income (>£15,000, £15,000-£24,999, £25,000-£39,999, £40,000-£75,000, and >£75,000). StataSE (version 16; StataCorp) was used for all the analyses. A *P* value of <.05 was set to denote statistical significance.

A descriptive analysis of the qualitative outcome measures was conducted using the method by Braun and Clarke [27] for thematic analysis in NVivo 1 software (Lumivero). Each response was line-by-line coded, and codes were inductively constructed based on the aim of the study. We then organized codes into subthemes using the One Sheet of Paper technique and produced top-level themes [28].

Patient and Public Involvement

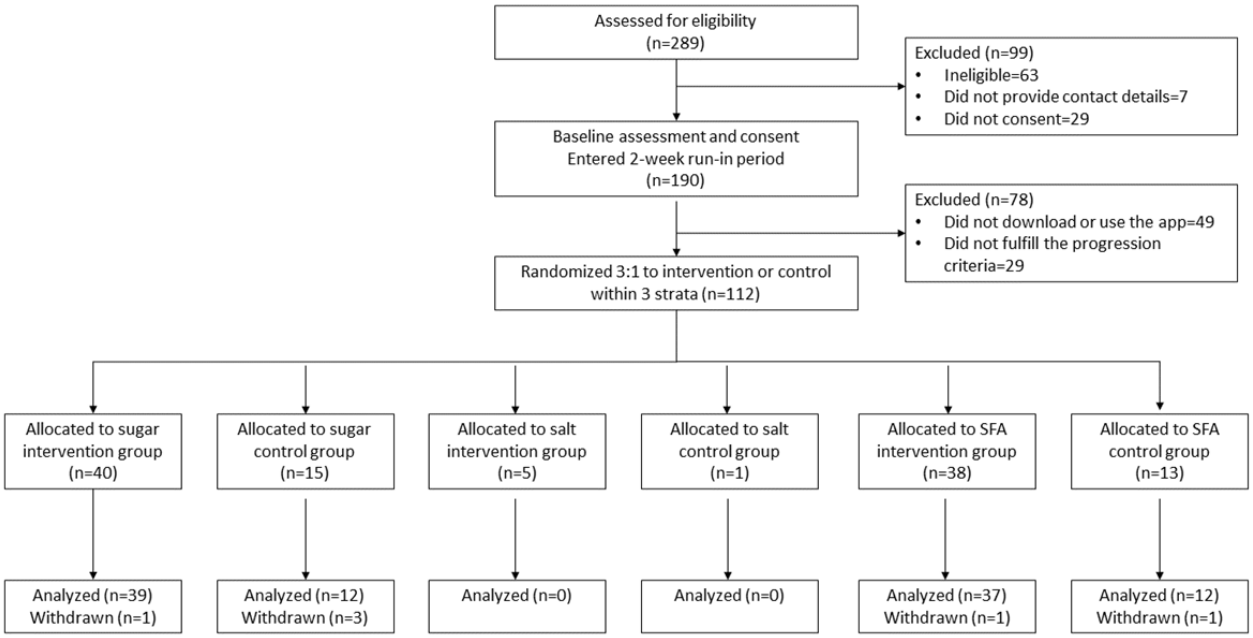
The SwapSHOP app was based on a previous version developed exclusively for salt reduction [20], which was conceived and tested using input from a patient and public involvement panel. People told us that they would also value an app to help change other aspects of their diet. The current app was also beta tested by members of the public recruited from the community.

Results

Participant Characteristics

Study participants were recruited between April and October 2021. Of the 289 interested participants, 190 (65.7%) were eligible, provided consent, and entered the 2-week run-in period. Of these 190 participants, 78 (41%) were excluded because they did not download or use the app (n=49, 63%) or did not fulfill the progression criteria based on their engagement with the app (n=29, 37%). The final sample of 38.8% (112/289) of participants successfully completed the task and were randomized (Figure 1). A total of 51 participants were randomized to the SFA group (n=38 to intervention and n=13 to control), 55 participants were randomized to the sugar group (n=40 to intervention and n=15 to control), and 6 participants were randomized to the salt group (n=5 to intervention and n=1 to control). Of the randomized participants, 100 (89%) completed the study and were analyzed as follows: 49 (96%) in the SFA group and 51 (93%) in the sugar group. A total of 2 participants in the SFA group and 4 participants in the sugar group were withdrawn from the study and excluded from the analysis because their data indicated fraudulent activity (eg, fake phone numbers and implausible shopping patterns). Data from 6 participants who were randomized to the salt group were not analyzed, as this group did not reach the target sample by the end of the recruitment period.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) diagram. SFA: saturated fat.



Participants in the analytic sample were, on average, aged 35 (SD 12) years, mostly women (80/100, 80%) of White ethnicity (79/100, 79%), and from higher education backgrounds (73/100, 73%; Table 1). Participants mostly lived in households with 2 to 4 other members, shopped once (61/100, 61%) or more than once a week (26/100, 26%), shopped mostly in larger grocery stores (89/100, 98%), or shopped on the internet (39/100, 39%). Most participants looked at SFA or sugar information on nutrition labels always, often, or sometimes and approximately half of the sample (54/100, 54%) reported concerns related to weight among the relevant medical conditions.

[a]The number of participants recruited for the salt group did not reach the target sample size. Data from the participants in this group were not analyzed further.

[b]GBP £1=US $1.38.

Primary Outcomes

The number of participants recruited for the salt group did not reach the target sample size despite additional recruitment attempts, suggesting that a full-scale trial for salt reduction would not be feasible. Data from the participants in this group were not analyzed further.

For participants randomized to the SFA and sugar groups, the 2 progression criteria were met above the set thresholds (Table 2). Overall, most intervention participants (30/37, 81% in the SFA group and 34/39, 87% in the sugar group) used the app to obtain swaps on at least 1 occasion by the end of the second week after randomization. In addition, 89% (68/76) of the intervention participants and 96% (23/24) of the control participants completed follow-up by scanning all purchases for a minimum of 2 weeks over the entire follow-up period.

Table 2. Primary and secondary outcomes—progression criteria and feasibility outcomes[a,b].

	Total population, n (%)			Sugar group, n (%)		Saturated fat group, n (%)	
	Total (N=100)	Control (n=24)	Intervention (n=76)	Control (n=12)	Intervention (n=39)	Control (n=12)	Intervention (n=37)
Primary outcomes—progression criteria							
Participants used the app to obtain healthier swaps on at least 1 occasion by the end of the second week after randomization	N/A[c]	N/A	64 (84)	N/A	34 (87)	N/A	30 (81)
Participants completed follow-up by scanning all purchases for a minimum of 2 weeks over the entire follow-up period	91 (91)	23 (96)	68 (89)	11 (92)	36 (92)	12 (100)	32 (86)
Secondary outcomes—feasibility outcomes							
Signed-up participants	289 (100)	N/A	N/A	N/A	N/A	N/A	N/A
Eligible participants	226 (78)	N/A	N/A	N/A	N/A	N/A	N/A
Consented participants	197 (68)	N/A	N/A	N/A	N/A	N/A	N/A
Completed baseline assessments	141 (49)	N/A	N/A	N/A	N/A	N/A	N/A
Randomized participants	106 (100)	28 (100)	78 (100)	15 (100)	40 (100)	13 (100)	38 (100)
Failed to complete follow-up or end-of-study questionnaire	16 (15)	0 (0)	16 (21)	0 (0)	9 (23)	0 (0)	7 (18)

[a]Percentage of eligible, consented, and completed participants was calculated based on the number of signed-up participants originally; the number of randomized participants (total population) excluded those randomized to the salt group, as these were not analyzed.

[b]The number of participants recruited for the salt group did not reach the target sample size. Data from the participants in this group were not analyzed further.

[c]N/A: not applicable.

Secondary Outcomes

The secondary outcomes provided evidence that a larger trial aiming at reducing sugars or SFA would recruit enough participants that adhere to the trial procedures (ie, completing baseline assessments) within the set time frames and that 84% (16/100 failed to complete follow-up) of those randomized would complete follow-up assessments.

Process Evaluation and Qualitative Outcomes

Participants randomized to the SwapSHOP intervention used the app regularly (Table 3). The average number of shopping trips where the app was used to obtain a swap was 5 in the SFA group (92% of shopping trips) and 5.4 in the sugar group (83% of shopping trips). The average number of occasions when the app was used to scan products for a swap in each shopping trip was 2.5 times in the SFA group and 3.3 in the sugar group. Overall, participants set goals averaging approximately 2 swaps per shopping trip. The results showed that individual product swaps were associated with an average reduction in total sugars (−12.5 g of sugar per 100 g, SD 6.97) or in SFA (−4 g of SFA per 100 g, SD 2.16) in the sugar and SFA groups, respectively.

Table 3. Secondary outcomes—process evaluation measures among participants using the swap function[a,b].

	Sugar group (n=34), mean (SD)	Saturated fat group (n=30), mean (SD)
Average number of shopping trips where the app was used to obtain a swap	5.41 (5.14)	5.07 (3.39)
Percentage of total shopping trips where the app was used to obtain a swap	83.15 (24.74)	91.62 (18.83)
Occasions the app was used to scan products for a swap per shopping trip	3.31 (2.30)	2.49 (1.94)
Average swap goals set in the app per shopping trip	2.14 (1.15)	2.01 (1.54)
Sugar reduction per swap (grams per 100 g)	−12.47 (6.97)	−0.48 (6.70)
Saturated fat reduction per swap (grams per 100 g)	−1.62 (2.57)	−4.02 (2.16)

[a]Sugar and SFA reduction per swap per 100 g were calculated as the average change in nutrient per 100 g of product across all swaps made during the intervention period.

[b]The number of participants recruited for the salt group did not reach the target sample size. Data from the participants in this group were not analyzed further.

The results of the qualitative research relating to the acceptability of the app, the feedback and swaps provided through the app, and the usefulness and comprehensiveness of the app were summarized into 4 themes (Table S1 in Multimedia Appendix 1). Overall, most participants shared positive experiences of the intervention, noting that the app was helpful and the swap suggestions were acceptable. They valued the novelty of the app and the traffic light food labeling system, which encouraged them to read food labels. The key barriers to usability were that some grocery stores were not supported by the app and that there was poor product coverage within the app database. Although participants could manually enter their food purchases to find alternatives, they reported that this was time consuming and a barrier to engagement. Some participants also found it difficult to locate the suggested swaps in the store or were frustrated that the suggested swaps were not available in the store or that the product database in the app did not include own-label products in some stores. One significant obstacle to accepting the intervention was the specificity of certain swap suggestions. These suggestions were not always direct replacements or tailored to personal or household dietary preferences, which made it challenging for shoppers to act upon the prompts. In other instances, some participants found it challenging to reduce one nutritional component if it involved an increase in another, and they expressed a desire for a swap suggestion that recognized the overall healthiness of the product. Participants suggested that more information on the fiber composition of swaps, recommended portion sizes, and price comparison would inform their purchasing behavior. Most participants noted that other visual self-monitoring techniques would improve engagement with the intervention.

Exploratory Effectiveness Outcomes

Baseline and follow-up data on food purchases with available information on volume and nutrient content were available for 86% (44/51) of the participants in the sugar group and 82% (40/49) of the participants in the SFA group. This analysis included all food purchases recorded in the app but excluded purchases that were entered manually (22%) or those with no, minimal, or missing nutritional information; 16%). The degree of missingness in the food purchasing data was comparable between the groups (manually entered products: 23% intervention vs 19% control group and missing nutrient information: 15% intervention vs 16% control group).

There was evidence of changes in the intended direction in both the intervention groups (Table 4). The sugar group reduced total sugars in their grocery purchases by −1 (95% CI −1.97 to −0.03) g/100 g, whereas the control group reduced total sugars in their grocery purchases by 0.32 (−1.47 to 2.11) g/100 g, though the differences between groups were not significant (−0.68, 95% CI −1.94 to 0.58 g/100 g; *P*=.28 adjusted for baseline values). The SFA group reduced total SFA in food purchases by −0.56 (95% CI −1.02 to −0.19) g/100 g, and the control group increased total SFA in food purchases by 0.52 (95% CI −0.19 to 1.22) g/100 g, with a significant between-group difference of −1.05 (95% CI −1.83 to −0.27) g/100 g and *P*=.009 adjusted for baseline values. These results were robust in sensitivity analyses adjusted for age, gender, ethnicity, and income (Table S2 in Multimedia Appendix 1).

Table 4. Secondary outcomes—exploratory effectiveness measures[a,b].

	Baseline, mean (SD)	Follow-up, mean (SD)	Change, mean (95% CI)	Change adjusted[b], mean (95% CI)	Between-group difference[b], intervention vs control	
					Mean (95% CI)	*P* value
Purchased sugar (g/100 g)						
Sugar group (n=34)	5.13 (2.63)	4.13 (2.34)	−1.00 (−1.97 to −0.03)	−0.86 (−1.67 to −0.05)	−0.68 (−1.94 to 0.58)	.28
Control (n=10)	4.26 (1.49)	4.58 (1.86)	0.32 (−1.47 to 2.11)	−0.18 (−1.14 to 0.79)	N/A[c]	N/A
Purchased SFA[d] (g/100 g)						
SFA group (n=28)	2.13 (1.18)	1.58 (0.98)	−0.56 (−1.02 to −0.10)	−0.55 (−0.89 to −0.22)	−1.05 (−1.83 to −0.27)	.009
Control (n=12)	2.10 (0.84)	2.61 (1.22)	0.52 (−0.19 to 1.22)	0.50 (−0.20 to 1.20)	N/A	N/A

[d]SFA: saturated fat.

Discussion

Principal Findings

Participants in this study were willing and able to use the SwapSHOP app as intended, and the research methods ran as planned, with high levels of adherence and follow-up recorded. This provided preliminary evidence of effectiveness to support dietary change to lower the intake of sugars and SFAs. There was little evidence that this general population sample was motivated to reduce salt intake using the SwapSHOP app. Further improvements to the app, especially enhancing the coverage of product data and the specificity of the swap algorithm, are needed to provide a higher quality user experience.

Comparison With Prior Work

Previous studies have shown the potential of instore swaps to support healthier choices, but there is very little evidence from interventions involving habitual shopping in physical stores. A quasi-experimental study evaluated the impact of the Change4Life Smart Swaps campaign to promote changes to lower fat or sugar foods when grocery shopping, showing that a higher percentage of participants in the intervention group reported choosing healthier options at the end of the study [29]. A total of 3 randomized controlled trials used a smartphone app to help reduce salt intake by promoting lower-salt swaps at the point of choice, showing changes in purchased salt in the intended direction but without evidence of changes in salt intakes [20,23,30]. Our previous study conducted in primary care settings provided individually tailored regular feedback on food shopping and offered lower-SFA swaps to patients with raised low-density lipoprotein cholesterol. The study showed modest but nonsignificant reductions in SFA consumption and SFA in purchased foods [18]. Other randomized controlled trials conducted in online retail environments, both real and experimental platforms, have shown that offering healthier swaps at the point of choice helps improve the nutritional quality of food shopping [16,17,19].

This SwapShop intervention showed promising signs of early effectiveness, with observed reductions of −1 g/100 g (95% CI −1.97 to −0.03) in total sugars and −0.56 (95% CI −1.02 to −0.19) in SFA in all food purchases in their respective intervention group, though this feasibility study was not powered to detect an effect in purchased nutrients. Data also show that smartphone app use is increasing across a wide range of demographic and age groups [31], and consumers are showing an increasing interest in healthier options [32]. However, although the app may be a useful tool for promoting healthier food choices through personalized advice and support, it is unlikely to be sufficient to achieve dietary recommendations. It is plausible that the impact could be enhanced by interventions to encourage product reformulation to offer greater availability of healthier alternatives. Moreover, price, promotions, positioning, and availability strategies within supermarkets have all been found to be major determinants of food choices [33-36], and these structural interventions are likely to be complementary.

Strengths and Limitations

This study's strength lies in its randomized design and the process evaluation used to investigate the intervention's pathway to impact. The qualitative components helped to provide context-specific information about the usability of the app and the acceptability of the swap suggestions. The SwapSHOP app had undergone extensive testing before this trial, given that it is an enhanced version of a previously tested app (SaltSwap) that was specifically designed to help people with hypertension choose lower-salt foods when grocery shopping in combination with face-to-face advice from a health care professional [20,37]. Furthermore, beta testing helped refine the app in line with the intended user feedback. SwapSHOP incorporated several behavioral elements with proven evidence to support dietary change [9,14,15], allowing people to set goals to swap to foods,

lower the nutrients of concern, identify major sources of SFA and sugar in their shopping, and provide feedback on achievement of their goal as well as on the overall nutrient reduction achieved through making swaps. A systematic review of interventions using apps to support dietary behavioral improvements suggested greater benefits of multicomponent interventions compared with single-component interventions [38]. Unlike SwapSHOP, the 2 other existing smartphone apps provided information on healthier swaps but did not offer the option of self-monitoring the nutritional quality of food shopping and had limitations regarding how information is presented to consumers or the limited comprehensiveness of the databases covering the UK food market [21,22].

Although the SwapSHOP app included the major UK grocery retailers, participants particularly reported issues related to the product database, the limited range of UK grocery stores, and the improvements needed in the swapping function to create a list of healthier options that are similar to the original product and to accommodate dietary preferences. These aspects must be addressed in future versions of the app to maximize usability and acceptability. Purchased products that were recorded manually by the participants or had missing nutrient information were excluded from the analysis of changes in total purchases, limiting the robustness of the exploratory effectiveness outcome results, although this should not differ by trial arm.

Another limitation is that the study recruited a small, self-selected sample of people who were motivated to take action to improve their diet quality. A large proportion of participants reported receiving higher education and living in less deprived geographical areas than the national average [39]. A lower socioeconomic status is related to poorer dietary quality and health outcomes; hence, the observed results may not represent a wider population with lower adherence to dietary recommendations [40]. Ethnicity is also related to food choice [41]. Although this study mostly included people of White backgrounds, the app database included a wide range of products available in the UK market, thus covering different dietary preferences that apply to other ethnic groups.

Conclusions

SwapSHOP is a behaviorally informed smartphone app that allows users to scan barcodes of grocery products from major UK supermarkets, providing tailored nutritional information and suggesting personalized swaps to support dietary change. This study provided evidence of feasibility as a stand-alone intervention to support motivated individuals wanting to reduce their SFA or sugar intake as well as preliminary evidence of effectiveness to support healthier food purchases. Given the low cost and scalability of this intervention, after further refinement of the app technology and expanded market coverage, a definitive trial is warranted to assess the potential of this tool to improve health outcomes.

Acknowledgments

This study was funded by the National Institute for Health Research (NIHR) Applied Research Collaborations Oxford. SAJ, MN, and AH were funded by the NIHR Oxford Biomedical Research Centre (BRC) Obesity, Diet and Lifestyle Theme. CP, GH, and SAJ were funded by the NIHR Applied Research Collaborations Oxford. CL was funded by the Engineering and Physical Sciences Research Council and the NIHR Oxford BRC. SPR was supported by a British Heart Foundation Clinical Research Training Fellowship (FS/16/34/32211). CP is currently funded by grant RYC2020-028818-I, MCIN/AEI/10.13039/501100011033 and “ESF Investing in your future” (Ministry of Science and Innovation, Spain). The funders had no role in designing the study, data collection, analysis, interpretation of data, writing the report, or the decision to submit the manuscript for publication. The authors would like to thank Peter Scarborough and Richard Harrington for their help and support in using the FoodDB database of food products included in the SwapSHOP app. The University of Oxford is the owner of the SwapSHOP app.

Data Availability

The data sets generated during and/or analyzed during this study are available on reasonable request. Access to the study data and the statistical code will be reviewed and granted upon request by the Nuffield Department of Primary Care PRimDISC committee (primdisc@phc.ox.ac.uk)

Authors' Contributions

All authors contributed to the concept and design of the study. CP, AH, CL, MN, GH, and SPR developed the study protocols and materials, performed the experiments, and collected the study data. CP and CL analyzed and interpreted the data. CP wrote the manuscript and generated the tables and figures. All authors discussed the results and implications and commented on the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: In response to the serious lack of physical activity among young adults, recent attempts have been made to encourage young people to exercise through exercise video distribution. However, merely distributing videos does not lead to improved physical activity levels. Metaverse space, which enables web-based interaction through avatars, allows users to watch exercise videos in the same space as other avatars.

Objective: This study explored whether exercise video distribution using metaverse space is effective in improving physical activity levels, along with mental health and locomotive function, among young people.

Methods: In this parallel-group randomized controlled trial participants were recruited using printed poster displays. A total of 48 young adults aged between 18 and 30 years were assigned to 3 groups of 16 each: the metaverse, YouTube, and control group. To encourage exercise, the metaverse group was given an exercise video each week with a load of around 4-8 metabolic equivalents of tasks (METs) for 8 videos delivered in the metaverse space. The YouTube group was sent a URL on YouTube every week to view exercise videos with the same content as the metaverse group. The control group was given no special instructions. The intervention period was 8 weeks. Pre- and postintervention physical activity, well-being, locomotive syndrome risk tests, and social capital were measured. Although this study was not blinded to the participants, the measurers did not know to which group the participants belonged. Mixed model repeated-measures analyses and a post hoc Wilcoxon signed rank sum test were performed to detect the effects of the intervention in all groups.

Results: The results of the mixed model repeated-measures analyses showed a significant interaction between groups and before and after the intervention for total physical activity (metaverse group: pre 737.1, SD 609.5 METs/week, post 1575.4, SD 1071.8 METs/week; YouTube group: pre 661.7, SD 710.7 METs/week, post 911.9, SD 1103.3 METs/week; and control group: pre 930.6, SD 665.1 METs/week, post 844.7, SD 701.8 METs/week; P=.04) but none for the indicators of well-being (P=.40), locomotive function scale (P=.17), and social capital (P=.23). A post hoc test showed a significant increase in physical activity in the metaverse group before and after the intervention (P=.006).

Conclusions: This study is the first to show that delivering exercise videos through metaverse space can increase physical activity in young adults by providing a gathering space for individuals similarly motivated for exercise practice. This way, the sense of isolation during exercise is reduced compared with merely distributing videos on YouTube. The use of metaverse space in health promotion is likely to spread, and this study provides a useful reference for its exploration.

KEYWORDS

exercise video distribution; exercise; metaverse; physical activity; web-based intervention

Introduction

Physical inactivity among young people is a serious problem, with 40.3% of men and 66.1% of women in their 20s reporting not exercising even once a week, according to the National Health and Nutrition Survey, 2019 [1]. Surprisingly, a study of 100 college students aged between 18 and 23 years found that 65% of them were in the high-risk group for locomotive syndrome, a condition that reduces physical function and mobility such as standing and walking. A study of young Japanese adults aged between 18 and 20 years revealed that 45.9% of them had a prevalence of frailty-prefrailty [2]. As Japan's aging society progresses, the number of people requiring nursing care also increases, and the reasons for this need are often locomotive disorders such as falls and joint diseases [3,4]. Therefore, establishing exercise habits at a young age and maintaining and improving locomotive function are important.

The spread of COVID-19 has led to a lack of exercise and a change to a more sedentary lifestyle, which has focused attention on exercise interventions over home-based web-based video delivery methods. This promotion of physical activity through exercise videos was intended to help address people's lack of motivation to engage in physical activity when gymnasiums and recreation centers had to close and physical distance was required [5]. An exercise intervention study using YouTube reported that when a new exercise video of approximately 5 minutes was delivered once a week for 12 weeks, physical activity and frequency of muscle training increased in the exercise intervention group [6]. Hence, the distribution of exercise videos through YouTube, the most accessible tool for young people, has shown some effectiveness and has become commonplace even as of 2023, when COVID-19–related restrictions have eased.

However, this conventional promotion of physical activity through the distribution of exercise videos has elements that fail to encourage behavioral changes. Self-determination theory, as it relates to exercise implementation, begins with the fulfillment of 3 basic human psychological needs: competency (the experience of achievement and efficacy), autonomy (the experience of motivation), and relatedness (the experience of connection with others) [7]. However, traditional exercise video distribution using YouTube and other media has focused on individual video-watching, which fails to provide opportunities for connecting with other people. In fact, another study of an exercise intervention using YouTube reported improvements in mental health with no increase in physical activities [8]. Studies showed connection with others as an important factor in exercise implementation and that being in an exercise group was more effective in increasing physical activity than exercising alone [9,10]. Further, social encouragement by those around an individual and exercising together had a positive impact on the acquisition of exercise habits [11,12]. In addition, people who shared their step count information using a special app tended to exercise the next day when other people "liked" or commented on their step counts [13]. Moreover, the group that was provided with peer interaction and social support showed positive effects on locomotive functions, such as improved results in stand-up tests, compared with the group that lacked these supportive activities [14]. Thus, adding an element of social community when promoting exercise is more effective.

The metaverse is an internet-based 3D virtual world. For the generation of digital natives born in the 1990s and 2000s, it is expected that the metaverse will increasingly become a space where they spend part of their daily lives [15]. In recent years, the metaverse space has gained attention in the health care field [16-18], and a bibliometric analysis of virtual and augmented reality showed that the metaverse has been adapted for diagnosis, surgical treatment, and rehabilitation of pain, stroke, anxiety, depression, fear, cancer, and neurodegenerative diseases, with satisfactory results [16]. In a metaverse space, people can interact with and encourage others on the web through their avatars, which are their own alter egos, and create a community of people who gather in the same space. Social distance is known to interfere with mental health [19], and the metaverse's ability to recreate a space for social interaction is expected to help improve the treatment of mental health symptoms such as anxiety, stress, and eating disorders [20-23]. Therefore, the use of the metaverse has the potential to improve mental health. Moreover, encouraging physical activity within the metaverse space has the potential to promote behavioral responses from users, such as motivating people to adopt a healthier lifestyle [24]. Therefore, exercise training using the metaverse is expected to develop as a method to promote physical activity among young people [16]; however, there is insufficient knowledge on whether physical activity can be promoted by distributing exercise videos in the metaverse space. This study verified whether exercise video distribution using an app that provides metaverse space is effective in improving physical activity levels, mental health, and locomotive function among young people. We hypothesized that the distribution of exercise videos in the metaverse space would increase physical activity and have positive effects related to mental health and locomotive function.

Methods

Study Design and Participants

This study was a parallel-group, randomized controlled trial. The participants were recruited among Hiroshima University students between August 10 and September 9, 2022. For recruitment, we displayed a poster explaining the study and indicated a contact person available for questions for those considering participation. Several people expressed their willingness to participate. Participants were offered an incentive of US $6.93. Written consent was obtained after we explained the study details face-to-face. All data were collected in person.

This study's specific participation criteria were as follows: individuals (1) aged 18 and 30 years at the time of obtaining consent, (2) who owned a smartphone or computer and had internet access, and (3) who did not belong to an exercise community such as a sports club. The exclusion criteria were as follows: individuals (1) who had a history of a disease that prohibited exercise, (2) whose physical activity was >3000 metabolic equivalents of tasks (METs)/week because a person with >3000 METs/week is defined as active [25-27], and (3) who were (or possibly) pregnant.

The sample size was calculated using G*power 3.1.9.2 (version 3.1.9.7; Heinrich-Heine-University Düsseldorf). When the effect size was calculated using raw data from a previous study with a similar design, which used a web-based exercise intervention with a physical activity measure as the main outcome [28], a large effect size of 0.34 was obtained with a partial η^2 of 0.108. When setting α error probability to .05, power (1–β error probability) to .8, number of groups to 3, and number of measurements to 2, the required sample size was 27 participants, with 9 participants per group. A total of 48 participants were required when the dropout rate was approximately 40% [8].

After completion of the baseline prequestionnaire and measurements, 3 participants who met the exclusion criteria and were physically active for >3000 METs/week were excluded. The participants were divided into 3 groups: "metaverse space-based exercise video distribution group (metaverse group)," "YouTube-based exercise video distribution group (YouTube group)," and "no video distribution group (control group)" in a 1:1:1 ratio. The allocation was performed by segregating blocks of size 3 to generate the sequence [29], and the allocation order was hidden until after each group was allocated. A total of 3 separate staff members performed each of the 3 tasks: generating the random allocation sequence, enrolling participants, and assigning participants to the interventions. We explained to all participants the nature of the 3 groups while obtaining their consent. After allocation, the metaverse and YouTube groups received an 8-week intervention in which the exercise videos were distributed, and a control group was established. The intervention period was from October 3 to November 27, 2022. Thereafter, a postquestionnaire survey and measurements were conducted for all 3 groups.

Intervention

Procedure

The recruitment ran for approximately a month, from August 10 to September 9, 2022, and the premeasurements were taken during a 2-week period from September 12 to 25, 2022. The 8-week intervention was conducted from October 3 to November 27, 2022. The postmeasurements were conducted over a period of 1 week (from December 5 to 11, 2022).

Metaverse Group

The participants in the metaverse group had access to Metaverse space (Spatial Systems Inc), where they could watch exercise videos whenever they wanted (Figure 1). The researcher created a metaverse space for watching exercise videos and set up new videos each week. The URL to access them was shared only with participants in the metaverse group. The unique feature of the metaverse was that users could enter a room to watch exercise videos with their avatars, which were their own alter egos and other avatars. The participants watched exercise videos, which were created by a physical therapist to increase their physical activity, for approximately 5 minutes [6,8]. Then, we instructed them to do the exercise while watching videos. The load setting was approximately 4-8 METs to train the trunk and the upper and lower extremities. A new video was released once a week [6], and the participants could watch 8 videos for 8 weeks. They were informed in advance that new videos would be updated every Monday and, as a reminder, were sent a SMS text message when a new video was available. A web-based survey regarding exercise video viewing frequency was administered, and adherence was tracked weekly.

Figure 1. The metaverse space in this study.

YouTube Group

The YouTube group was sent a message with the URL to access the exercise video every Monday. The YouTube group could watch videos at their preferred times by clicking on a link. The content and time of the video were identical to those of the metaverse group. As in the metaverse group, adherence to exercise implementation was confirmed through a web-based questionnaire, and video update reminders were sent every week.

Control Group

Participants were informed by email that they were assigned to the control group simultaneously with the start of the intervention in the Metaverse and YouTube groups. We asked the participants in the control group to spend 8 weeks as usual, without any special instructions or delivery of videos. This group was established as an indicator of the amount of physical activity that may be significantly affected by the infection status and government directives during the COVID-19 pandemic.

Outcome Measurements

Basic Information

The participants were asked and tested for age, height, weight, BMI, lifestyle, sex, living status, and frailty to characterize the basic information. The weight and frailty tests were measured by a physical therapist, and the other parameters were measured using a questionnaire.

Lifestyle

Breslow's 7 health practice scores were used to assess lifestyle [30,31]. The 7 parameters were: smoking (presence or absence), alcohol intake (high or low: consumption of ≥5 or <5 alcoholic beverages), sleep (≥7 hours or <7 hours), breakfast (eating or not eating), eating between meals (eating or not eating), exercise (≥2 times, 30 minutes/week or <2 times, 30 minutes/week), and proper weight (BMI <25 kg/m^2 or ≥25 kg/m^2).

Living Status

Regarding their living status, the participants were asked whether they lived alone or with others.

Frailty Test

The Japanese Cardiovascular Health Study criteria questionnaire was designed to indicate potential frailty, and its contents are as follows [32,33]: (1) have you lost 2 kg or more in the past 6 months? (2) Do you engage in moderate levels of physical exercise or sports aimed at improving health? (3) In the past 2 weeks, have you felt tired without reason? (4) Hand grip strength of <26 kg in men or <18 kg in women, and (5) gait speed of <1 m/second. Grip strength was measured using a hand dynamometer (TKK 5401; Takei). Each participant performed 2 trials, and the best value from both trials was used for the analysis. Walking speed was calculated by performing a 10-meter walk test and dividing the measured value by 10 to obtain the results per meter. All questions were rated 1 or 0, and higher scores indicated a higher possibility of frailty. Frailty, prefrailty, and robustness were defined by the number of applicable items: 3-5, 1-2, and 0.

Primary and Secondary Outcomes

The study assessed physical activity, well-being, locomotive syndrome risk tests, and social capital before and after the intervention for 8 weeks.

Primary Outcome: Physical Activity

The short form of the International Physical Activity Questionnaire was used to measure the effect of an intervention using exercise videos with different distribution methods (Metaverse and YouTube) on physical activity [34]. Total physical activity was measured as the average amount of vigorous physical activity, the amount of moderate activity, and the amount of walking (METs minutes/week). A MET is defined as the amount of energy required for a person to sit quietly. In the premeasurement, the participants answered for the most recent week, and in the postmeasurement, they responded for the week after the intervention was completed.

Secondary Outcomes: Well-being, Locomotive Syndrome Risk Tests, and Social Capital

Well-Being

To assess well-being and mental health, we used the Japanese version of the World Health Organization-Five Well-being Index [35]. Responses to each item were rated on a 6-point scale from 0 to 5 and consisted of 5 questions. The highest score is 25, with higher scores indicating better well-being.

Locomotive Syndrome Risk Test

We used the 25-question geriatric locomotive function scale, proposed by the Japanese Orthopedic Association [33,36], to measure levels of locomotive function based on normal daily activities and pain. All the items were answered on a scale of 0-4. The higher the score, the more impaired the motor function, which indicates a decline in mobility and interference with social life.

Social Capital

The social capital questions consisted of 11 items related to civic participation, social cohesion, and reciprocity, with a perfect score of 11 and higher scores indicating stronger social connections [37]. We included this question item because of the possibility that the sense of social participation could change in the metaverse group.

Supplemental Outcomes: Impression of Each Intervention (Metaverse and YouTube Groups)

We interviewed each of the metaverse and YouTube groups regarding their impressions of the intervention using exercise videos after the 8-week intervention. User experience is the experience of a user with the use of a product, system, or service. From the review of user experience, we selected the following list of questions: novelty, relatedness (connection with others), motivation, excitement, satisfaction, delight, comfort, attractiveness, expectation, and fulfillment [38]. The participants answered each question with a "good," "rather good," "rather poor," or "poor" response.

Statistical Analysis

Primary and secondary outcomes were analyzed by performing a mixed model repeated-measures ANOVA. This analysis was used to detect the effect of interventions between the metaverse, YouTube, and control groups. We assessed the main effect as well as group and time interactions on the outcome measure. A mixed model repeated-measures analysis is an intention-to-treat analysis with unbiased estimates that considers all available data from participants enrolled in the study [39]. The effect size *r* for the interaction effect of a mixed model repeated-measures analysis was calculated using F statistics. As a posttest, the Wilcoxon signed rank sum test was performed after confirming nonnormality to compare the pre- and postintervention outcomes of each group. The z-statistic was used to calculate the effect size *r*. Supplemental outcomes were analyzed by performing chi-square tests to compare the intervention impressions between the metaverse and YouTube groups. Note that to use the chi-square test, “rather good” was included in “good” and “rather poor” was included in “poor,” thus reorganizing responses into 2 groups. The effect size was calculated using Cramer *V*.

Statistical analyses were performed using SPSS (version 28.0; IBM Corp). The significance level was set at 5%.

Ethical Considerations

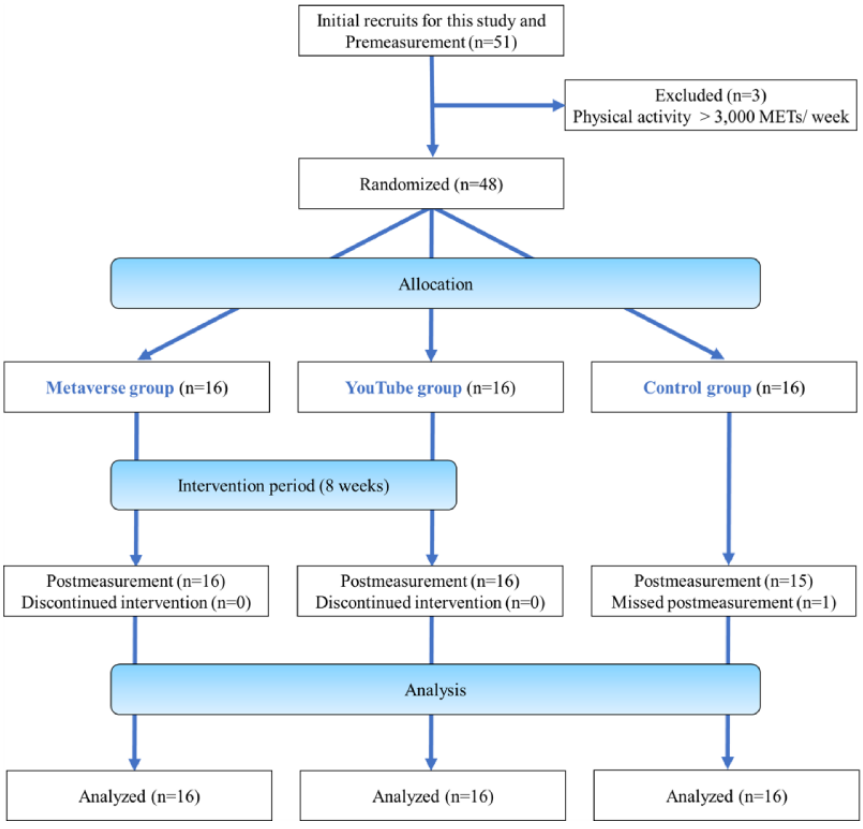
This study was approved by the Ethical Committee for Clinical Research at Hiroshima University (C2022-0004) and registered with UMIN (UMIN000048046). We followed the guidelines of the Consolidated Standards for Reporting Trials [40]. There were no significant changes in the method used after the study’s initiation.

Results

Participants

Figure 2 shows the participant flowchart. A total of 51 individuals expressed interest in the study; however, 3 were excluded because their physical activity was >3000 METs/week. All the participants in the metaverse and YouTube groups completed the intervention. Participants were also interviewed weekly during the 8-week intervention period to monitor their exercise implementation. The average frequency of exercise while watching the exercise video per week was 4.1 (SD 3.9) and 2.6 (SD 1.6) for the metaverse and YouTube groups, respectively (response rates: metaverse group 100% and YouTube group 99%). For the postmeasurement, a participant in the control group could not participate owing to illness.

Figure 2. Study flowchart. MET: metabolic equivalents of task.



Basic information, Lifestyle, Living Status, and Frailty Test

Table 1 presents the participants’ demographic characteristics (mean 22.4, SD 2.4 years; 32/48, 67% women). Prefrailty accounted for 41/48 (85%) participants because we recruited those who were not members of a sports club and whose physical activity was <3000 METs/week.

Table 1. Participant's demographics at baseline.

Variables	Total	Metaverse group (n=16)	YouTube group (n=16)	Control group (n=16)
Age (years), mean (SD)	22.4 (2.4)	22.9 (1.4)	22.5 (2.0)	22.0 (3.4)
Height (cm), mean (SD)	164.0 (7.9)	162.4 (6.6)	163.9 (6.2)	165.7 (10.3)
Weight (kg), mean (SD)	57.7 (11.6)	56.7 (9.8)	57.3 (10.2)	59.0 (14.8)
BMI (kg/m²), mean (SD)	21.3 (2.9)	21.4 (2.5)	21.2 (2.5)	21.3 (3.6)
Lifestyle, mean (SD)	4.6 (0.9)	4.6 (0.9)	4.4 (0.7)	4.7 (1.1)
Sex, n (%)

Physical Activity, Well-Being, Locomotive Syndrome Risk Test, and Social Capital

Table 2 shows the estimation results of the fixed effects from the mixed model repeated-measure analysis. Only total physical activity showed a significant interaction ($F_{2, 45.042}$=3.338, P=.04; effect size=0.263). The main effects for the time showed a significant difference in vigorous activity ($F_{1, 45.083}$=6.921, P=.01), locomotive function scale ($F_{1, 44.895}$=9.557, P=.003), and social capital ($F_{1, 44.650}$=5.085, P=.03).

Table 3 shows the results of the post hoc test comparison of the difference in total physical activity before and after the intervention in each group. In the metaverse group, a significant difference was detected between pre- and postintervention periods (P=.006; effect size=0.682).

Table 2. Estimate of the fixed effects from the mixed model repeated-measures analysis, (N=16).

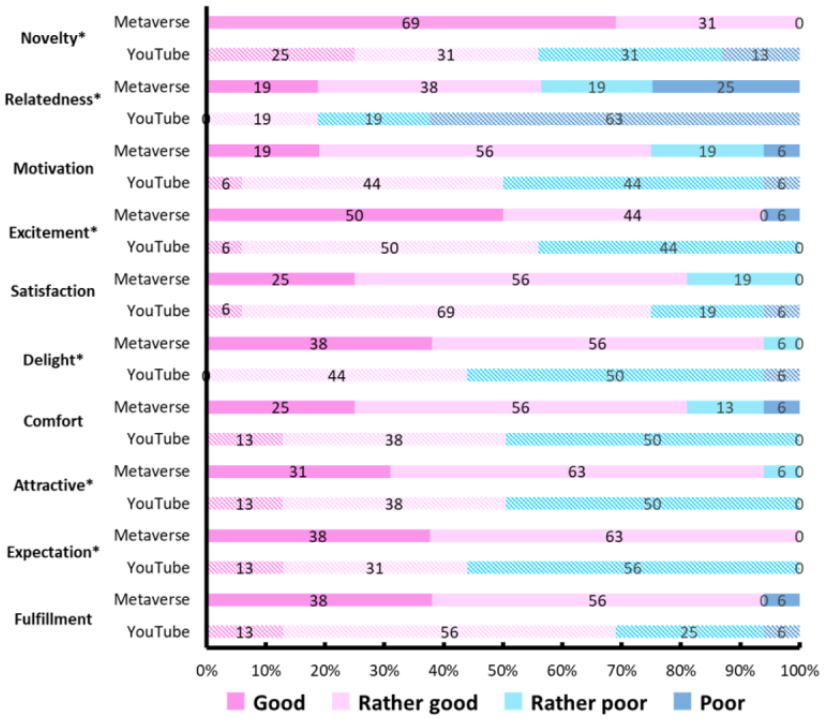
Comparison of Impressions of the Intervention Between the Metaverse and YouTube Groups

Multimedia Appendix 1 and Figure 3 show the results of a chi-square test on impressions of the intervention between the metaverse and YouTube groups. Significant differences were observed between the 2 groups in novelty (*P*=.003; effect size=0.529), relatedness (*P*=.03; effect size=0.387), excitement (*P*=.01; effect size=0.433), delight (*P*=.002; effect size=0.539), attractiveness (*P*=.006; effect size=0.487), and expectation (*P*<.001; effect size=0.626). The results did not reveal significant differences in motivation, satisfaction, comfort, or fulfillment.

Figure 3. Impressions of intervention in the Metaverse and YouTube groups. *P<.05.



Discussion

This study examined whether an exercise intervention using exercise videos in the metaverse space has a positive impact on physical activity. The main results show a significant interaction between groups and time (pre- and postintervention) in total physical activity, with post hoc analysis showing a significant increase in total physical activity in the metaverse group after compared with before the intervention and no significant change in the YouTube and control groups. This study is the first to show that using the metaverse space to deliver exercise videos can promote increased physical activity.

The current results support the hypothesis that the use of the metaverse increases physical activity. The exercise videos used in the metaverse, and the YouTube groups are identical, and the metaverse group differs from the YouTube group in that the exercise videos can be viewed in a shared space with other avatars in the metaverse space. Studies have noted that interacting with others is more effective than exercising alone at increasing physical activity and sustaining exercise [9-13]. Metaverse characteristics include the ability to form communities within virtual reality and the persistence of virtual reality regardless of individual user access [15]. In this study, no change in social capital was detected before and after the intervention; however, the percentage of those who had an impression of relatedness (connection with others) was also significantly higher in the metaverse group (9/16, 56%) than in the YouTube group (3/16, 19%)—indicating that more people felt connected to others when using the metaverse than when using YouTube. Additionally, strategies to increase physical activity include improving the physical environment, such as its construction, and the social environment, including social support [41]. The use of the metaverse resulted in the persistence of a purposeful social space for exercise that could be accessed at any time. Therefore, the existence of the metaverse space is an aspect of environmental improvement for exercise for participants who previously had no exercise habits, leading to increased exercise implementation and physical activity.

The reason indicators other than physical activity did not improve in the metaverse group is also an important area to consider. This study asked about well-being as an item that could be related to mental health. Exercise is known to promote the secretion of estradiol and serotonin and regulate cortisol levels, an internal change that reduces depression and other depressive symptoms [42-44]. Additionally, reducing loneliness and encouraging social interaction decreases the risk of depression and mental health problems [45]. Therefore, we expected to observe mental health improvements in the metaverse group; however, there were no significant differences among the 3 groups. The standard for suspicion of mental problems is a cutoff value of ≤11 points for well-being [35,46]. However, the mean values for participant well-being did not correspond to the cutoff values. Thus, mental health changes were unlikely to be observed even if the amount of physical activity increased because the group did not initially have low well-being.

The locomotive function scale, a measure of body pain and locomotor function, showed an improving trend in the metaverse group; however, the difference was not significant. A previous study found pain relief after an 8-week exercise program, including strength training of the trunk, in participants with low back pain that appeared to be caused by inactivity [47]. Several studies have reported muscle hypertrophy occurring within 6-8 weeks [48]. These facts indicate that if training is managed meticulously in the right way, the body can be changed in a period of 8 weeks. However, it is possible that the unmonitored, 8-week intervention period did not result in sufficient changes in motor function, even though the amount of physical activity increased. To improve motor function, training to improve muscle strength and endurance should be continued at least 3 times per week [49].

As for the differences in impressions of the intervention between the metaverse and YouTube groups, many factors such as novelty, relatedness, excitement, delight, attractiveness, and expectation were more positive in the metaverse group than in the YouTube group. Regarding novelty, a previous study stated that sufficient novelty for the target audience leads to successful health support using the app [50]. Even for young adults who were relatively familiar with and used apps and social networking services on a regular basis, the metaverse seemed to be a novelty, which may have supported the implementation of the exercise in this study. Delight is an important factor in many areas of life [51]. Studies have reported that delight is the most important predictor of commitment and participation in general youth and elite sports [52,53]. This amplification of delight using a metaverse space to distribute videos is meaningful in promoting exercise. Interestingly, the metaverse group found the intervention more attractive. A previous study that used apps to promote healthy lifestyles, including regular exercise, found that a combination of different services, such as health-related quizzes and the ability to record health status, led to successful interventions [54]. Exercise video-delivered studies have also shown that simply delivering videos does not increase physical activity [8]. The essence of using the metaverse may have increased the attractiveness of exercise video distribution in this study.

This study examined the effectiveness of exercise video distribution using metaverse space by comparing the previously used YouTube and a control population. This study's strength lies in making the first attempt to distribute exercise videos using metaverse space. Furthermore, it shows the potential of using metaverse space to improve the physical activity level of young adults.

However, this study has some limitations. First, selection bias may have occurred. We recruited participants who were not members of an athletic club and who did not exercise heavily. However, it is possible that the target population was composed of students who were interested in exercising, as suggested by their interest in participating in this study. Additionally, we recruited participants from a single university. The risk of selection bias may be reduced by conducting a study on a larger scale and involving more institutions. However, the 3 groups were randomly assigned in this study, and the required, precalculated sample size was secured. Second, it was difficult

to accurately determine the time and frequency of interactions between participants in the metaverse space. If a system can be implemented to monitor the time of entry into the metaverse space, the frequency of interactions, and so on, the mechanism for promoting physical activity through the use of the metaverse space could be made more visible. Third, participants could receive the intervention at the time of their choosing; however, the start time of the intervention was not monitored. The effectiveness of the intervention could be moderated or altered by the time of the intervention, and future researchers should accurately monitor the start time of the intervention. We note that the main outcome, the calculation of physical activity, did not depend on the starting time of the intervention. Final, there was room for improvement in the comfort of the interventions in the metaverse group. This study used metaverse space in the manner in which the videos were arranged. Metaverse space (Spatial, Spatial Systems, Inc) has the advantage of being a service that anyone can use free of charge; however, if industry and academia collaborate to devise a system more suited to the distribution of exercise videos and the promotion of exercise, it could have a more positive effect on physical activity and other aspects.

In the near future, services allowing access to the metaverse will likely continue to expand. Therefore, the number of opportunities for the general public to experience the metaverse will further increase. The fact that 100% of the metaverse group in this study had high expectations is a hopeful part of the development of using the metaverse to improve physical activity. This research provides a basis for establishing further methods of using the metaverse to promote exercise.

Abstract

Background: The Health eLiteracy for Prevention in General Practice trial is a primary health care–based behavior change intervention for weight loss in Australians who are overweight and those with obesity from lower socioeconomic areas. Individuals from these areas are known to have low levels of health literacy and are particularly at risk for chronic conditions, including diabetes and cardiovascular disease. The intervention comprised health check visits with a practice nurse, a purpose-built patient-facing mobile app (mysnapp), and a referral to telephone coaching.

Objective: This study aimed to assess *mysnapp* app use, its user profiles, the duration and frequency of use within the Health eLiteracy for Prevention in General Practice trial, its association with other intervention components, and its association with study outcomes (health literacy and diet) to determine whether they have significantly improved at 6 months.

Methods: In 2018, a total of 22 general practices from 2 Australian states were recruited and randomized by cluster to the intervention or usual care. Patients who met the main eligibility criteria (ie, BMI>28 in the previous 12 months and aged 40-74 years) were identified through the clinical software. The practice staff then provided the patients with details about this study. The intervention consisted of a health check with a practice nurse and a lifestyle app, a telephone coaching program, or both depending on the participants' choice. Data were collected directly through the app and combined with data from the 6-week health check with the practice nurses, the telephone coaching, and the participants' questionnaires at baseline and 6-month follow-up. The analyses comprised descriptive and inferential statistics.

Results: Of the 120 participants who received the intervention, 62 (52%) chose to use the app. The app and nonapp user groups did not differ significantly in demographics or prior recent hospital admissions. The median time between first and last app use was 52 (IQR 4-95) days, with a median of 5 (IQR 2-10) active days. App users were significantly more likely to attend the 6-week health check (2-sided Fisher exact test; $P<.001$) and participate in the telephone coaching (2-sided Fisher exact test; $P=.007$)

than nonapp users. There was no association between app use and study outcomes shown to have significantly improved (health literacy and diet) at 6 months.

Conclusions: Recruitment and engagement were difficult for this study in disadvantaged populations with low health literacy. However, app users were more likely to attend the 6-week health check and participate in telephone coaching, suggesting that participants who opted for several intervention components felt more committed to this study.

Introduction

Problem Statement

Obesity is a major contributor to disease burden, increasing the risk of chronic conditions, including ischemic heart disease, stroke, diabetes mellitus, chronic kidney disease, and hypertensive heart disease [1]. According to the Global Burden of Disease Study 2017 [2], high BMI was the cause of 4.72 million deaths and 148 million disability-adjusted life-years worldwide, making it the fourth leading risk for mortality in 2017. In 2017 to 2018, an estimated 36% of the Australian adult population were overweight (ie, BMI 25.0-29.9) and 31% of them had obesity (ie, BMI≥30.0) [3]. The proportion of people who are overweight or hose with obesity is higher in populations from lower socioeconomic backgrounds [3]. In 2017-2018, 72% of Australian adults residing in the lowest socioeconomic areas were overweight or had obesity compared to 62% from the highest, after adjusting for age [3]. People from the lowest socioeconomic areas were 1.9 times more likely to have diabetes in 2020 and 1.6 times more likely to have self-reported coronary heart disease in 2017-2018 than those from the highest socioeconomic areas [4].

Rationale for the Study

Other research has shown that mobile app-based interventions can facilitate weight loss in individuals who are overweight and those with obesity, but it requires regular app use. For example, Patel et al [5] reported that consistent weight self-monitoring via a mobile app could lead to clinically meaningful weight loss. However, the study classified only a quarter of participants as consistent trackers, which they defined as self-monitoring weight and diet on at least 6 days per week for at least 75% of the study weeks [5]. Their study highlighted that consistent tracking was crucial, but only a minority of participants did so. Similarly, Laing et al [6] found that providing access to a weight loss app to primary care patients who are overweight and those with obesity did not lead to significant weight loss compared to usual care. Only one-third of them logged into the app in the sixth month of the intervention, in which the median number of logins was 0 (IQR 0-2). The authors concluded that prescribing self-monitoring apps for caloric counting may be successful in primary care patients who are particularly motivated to lose weight [6]. Chin et al [7] analyzed user data from a popular commercial weight loss app and found that in a multivariate logistic regression model, the frequency of entering body weight and consumption of dinner particularly was associated with successful weight loss in app users. Considering other studies, the focus of this study was understanding how participants used a mobile app within the Health eLiteracy for Prevention in General Practice (HeLP-GP) trial and if its use led to improvements in health literacy and diet.

Description of the Intervention

The HeLP-GP trial was a behavior change intervention developed for implementation in Australian general practices aimed at Australians who are overweight and those with obesity from lower socioeconomic areas to help them reduce their weight. The intervention was based on the 5As framework (assess, advise, agree, assist, and arrange) [8]. It included health check visits with a practice nurse based on the 5As framework, the use of a purpose-built patient-facing mobile app called *mysnapp*, and referral to health coaching via the “Get Healthy” information and coaching service [9]. The *mysnapp* is based on a web-based platform developed by Lau et al [10].

The trial was a pragmatic, 2-arm, unblinded cluster randomized controlled trial, which continued for 12 months. Primary outcomes included changes in weight, blood pressure, health literacy, and eHealth literacy [11,12]. Secondary outcomes included lipids, diet (fruit and vegetable intake), level of physical activity, quality of life, advice received, and referral for diet, physical activity, and weight loss [12]. Participants who received the intervention could choose to use the mobile app and access the telephone coaching program. The HeLP-GP trial assessed the intervention’s effectiveness [12]. The intervention led to significant improvements at 6 months compared to the controls for health literacy (mean DiD 0.22, 95% CI 0.01-0.44) and diet (mean DiD 0.98, 95% CI 0.50-1.47). There were no associations with any of the other outcomes [12].

Objectives

The overall aim of this study, within the HeLP-GP trial, was to assess *mysnapp* app use, engagement, its association with other intervention components, and its association with study outcomes shown to have significantly improved (health literacy and diet) at 6 months.

Our objectives were to (1) explore differences in demographics and hospital admissions between participants who used the app and those who did not, (2) examine the duration and frequency of app use (app engagement) by participants overall and by module, (3) assess the association among app use, app engagement, and participation in other intervention components, and (4) examine the association between app use and app engagement on study outcomes that were shown to be significantly improved at 6 months (ie, health literacy and diet).

Methods

Ethical Considerations

The University of New South Wales Human Research Ethics Committee (HC17474) approved the trial. The University of Adelaide Human Research Ethics Committee ratified this approval. All participants provided consent to take part in this study.

Intervention

The methodology of the randomized controlled trial, of which this study is a subanalysis, was published previously [13] and prospectively registered with the Australian New Zealand Clinical Trials Registry (ACTRN12617001508369). In 2018, a total of 22 general practices were recruited from 2 Australian states, New South Wales (South West and Central Sydney) and South Australia (Adelaide), and randomized by cluster to the HeLP-GP intervention (11 practices) or usual care (11 practices). General practices were recruited through the local Primary Health Networks. Practices were located in local government areas with Socio-Economic Indexes for Areas scores [14] equal to or below the eighth decile. The Australian Bureau of Statistics reported that these are usually associated with lower health literacy levels in the population [15], with health literacy being defined by the Australian Institute of Health and Welfare in their latest Health Literacy Report as "how people access, understand and use health information in ways that benefit their health" [16]. In total, 4 strata based on the practice size (<5 general practice [GPs] and ≥5 GPs) and the state were created and then we randomly allocated practices to each stratum's intervention or usual care group. The intervention comprised a practice nurse–led health check; additionally, participants could choose whether to take up a lifestyle app, a telephone coaching program, or both. Potential participants were identified using the GPs' software. The general practitioners of the intervention sites also assessed their patients for eligibility. The eligible patients were provided with trial information and consent forms by the reception staff. Recruitment occurred between October 2018 and September 2019.

At the baseline health check, the practice nurses helped participants with the *mysnapp* setup and access the coaching program. They entered the participant's height, weight, waist circumference, and blood pressure into the app and set the health goals with the participant. For 6 weeks, the participants received a nutrition-related and a physical activity–related text message weekly. These were preprepared to be sent automatically each week and provided direct advice and a web link for further information. In addition, the telephone coaching program provided free, confidential health support to participants to reach personalized lifestyle goals concerning diet, physical activity, alcohol, and body weight [17]. The coaching was available in multiple languages through an interpreter service. The practice nurses conducted a 6-week health check in which they reviewed and revised the participants' health goals. Additionally, general practitioners conducted a 12-week health review. Text messages reminded participants to attend these follow-up visits.

Participants

Individuals were eligible for this study if they were aged 40-74 years, had a BMI of ≥28 and blood pressure levels recorded in the clinical software within the last 12 months, spoke English or Arabic, and had access to a smartphone or tablet. Potential participants were ineligible if they fulfilled any of the following exclusion criteria: recent weight loss (ie, >5% in the past 3 months), taking weight loss drugs (ie, orlistat or phentermine), diagnosed with insulin-dependent diabetes or cardiovascular disease (ie, angina, myocardial infarction, heart failure, heart valve disease, or stroke), cognitive impairment, or physical impairment disallowing them to perform moderate physical activity.

mysnapp Design

The *mysnapp* content was based on a web-based platform designed to help individuals control and maintain their health data and information to manage their health [10]. Research by Webb et al [18] and DiFilippo et al [19] into behavior change through mobile and electronic platforms informed the app design, including goal setting and self-monitoring, and additional methods to interact with individuals, mainly text messaging. The *mysnapp* app consisted of 4 core modules that allowed users to (1) set physical activity– and diet-based goals, (2) monitor their progress over the past 6 weeks, (3) take notes in a diary, and (4) learn about healthy eating and physical activity. Users could choose from the following goal options: set daily servings of fruits or vegetables or physical activity minutes; aim to drink fewer soft drinks, eat smaller portions, or eat fewer snacks or takeaway foods. In the self-monitoring module, they entered how many days of the week they achieved their goals. The educational material consisted of short text summaries and fact sheets about healthy foods, portion sizes, discretionary beverage consumption, physical activity benefits in English or Arabic, and links to simple exercise videos on YouTube.

Study Measures

App Use Measure

Data were collected on app use, specifically, when the study participants in the intervention group had an app account set up.

App Engagement Measures

Data were collected on the participants' app use directly through *mysnapp*. Each month, a cumulative data report was created about app logins and interactions with the different app modules from each participant for 12 months. App engagement included active days, duration of app use, and frequency of accessing app modules.

Other Intervention Component Measures

The data from the 6-week health check with the practice nurses (ie, occurrence) and the telephone coaching (ie, occurrence and completion status) were the other intervention component measures.

Outcome Measures

The participants' questionnaires at baseline and 6-month follow-up (ie, self-reported fruit and vegetable intake, and health literacy) were used.

Specifically, the diet questions were as follows: (1) How many servings of fruit do you usually eat each day? A serving is 1 medium-sized fruit such as an apple or 2 small-sized fruits or 1 cup of fruit pieces. (2) How many servings of vegetables do you usually eat each day? One serving is half a cup of cooked vegetables or 1 cup of salad vegetables. With the diet score being the portions of fruit intake (between 0 and a maximum of 2 per day) plus portions of vegetable intake (between 0 and a maximum of 5 per day) with a range of 0 to 7 based on the sum of fruit and vegetable scores. This diet measure has been validated against food frequency questionnaires [20].

Specifically, the Health Literacy Questionnaire domain 8 questions were used [11]: (1) find information about health problems; (2) find health information from several …. ; (3) get information about health so you…; (4) get health information in words you…; and (5) get health information by yourself. There is a 5-point response option scale for each question (cannot do or always difficult, usually difficult, sometimes difficult, usually easy or always easy). The scores are reported as averages for the domain (with a range between 1 and 5) with high scores representing higher health literacy.

Table 1 contains definitions for study measures. Duration of app use, active days, and consistent use had preset maximum values (365 days or 52 weeks); the values were capped when they exceeded the maximum.

Table 1. Measures and their definitions.

Measure	Type of variable	Explanation or definition
App use measures		
App user	Binary and input variable	Study participants in the intervention group who had an app account set up
App engagement measures		
Duration of app use	Continuous and input variable; maximum value: 365 days	Number of days between the first and last time a participant accessed the app
Active days	Continuous and input variable; maximum value: 365 days	Number of days a participant accessed the app
Consistent app use	Continuous and input variable; maximum value: 52 weeks	Number of consecutive weeks a participant accessed ≥1 time the app starting from the first app use
App module use	Binary and input variable	Participant accessed ≥1 the corresponding app module (goal setting, progress tracking, diary, or education)
Frequency of accessing app modules	Continuous and input variable	Number of times a participant accessed the corresponding app module (goal setting, progress tracking, diary, or education)
Other intervention component measures		
Practice nurse-led health check	Categorical and input variable	Attended and not attended
Telephone coaching	Categorical and input variable	Completed, not completed, and not participated
Outcome measures		
Health literacy	Continuous and output variable	Health literacy, specifically the self-reported ability to find good quality health information, according to domain 8 of the Health Literacy Questionnaire [11], at baseline and 6-month follow-up. The scores were reported as averages for the domain (with a range between 1 and 5) with high scores representing higher health literacy.
Diet score	Continuous and output variable	Self-reported daily fruit and vegetable intake at baseline and 6-month follow-up. Diet score was the portions of fruit intake (between 0 and a maximum of 2 per day) plus portions of vegetable intake (between 0 and a maximum of 5 per day) with a range between 0 and 7 based on the sum of fruit and vegetable scores.

Data Analysis

Descriptive and inferential analyses in RStudio (with the programming language *R*; *R* Foundation for Statistical Computing) using a significance level of .05 for all statistical tests were conducted. Normally distributed continuous variables were summarized using the mean and SD, and nonnormally distributed continuous variables with median and IQR. Box

plots compared continuous variables across the categories of nonnumerical variables [21]. Normality was tested using the Shapiro-Wilk normality test [22-24]. The 2-sided Welch *t* test was performed to compare the means of continuous variables between 2 subgroups (eg, participants using *mysnapp* versus those not using it) for normally distributed continuous variables [25]. Alternatively, the Wilcoxon signed rank test with continuity correction comparing the medians of nonnormally distributed continuous variables between 2 subgroups was used [26,27]. The Kruskal-Wallis rank-sum test was performed for more than 2 subgroups and nonnormally distributed continuous variables [28]. Pearson chi-square test with Yates continuity correction was used to test for associations between 2 categorical variables and the 2-sided Fisher exact test was used when there were less than 5 participants in any cell of the contingency table of expected frequencies [29-31].

For objective 4, we used 1-sided tests to assess whether app use versus nonapp use, or app engagement was associated with health literacy or diet between baseline and 6-month follow-up. Correlations between the app engagement and health literacy or diet score were measured with the Kendall rank correlation test (if variables did not follow a normal distribution) or Pearson product-moment correlation test (if they followed a normal distribution) [32,33].

Results

App Users

In total, 120 participants received the intervention, of which 62 (52%) people chose to use *mysnapp*. Among the 62 app users, 38 (61%) also opted for telephone coaching. Table 2 shows the results for the first objective, comparing the demographic characteristics of the participants who chose not to use *mysnapp* to those who decided to use it. There were no significant differences between app users and nonapp users.

Table 2. Demographic characteristics of participants in the intervention group (N=120).

Variables	Nonapp users (n=58)	App users (n=62)	Test statistics for differences between groups	*P* value
Age (years), mean (SD)	58 (8)	61 (9)	t_{115}=–1.56	.12
Women, n (%)	28 (48)	32 (52)	χ^2_1<0.1	.86
Born in Australia, n (%)	27 (47)	39 (63)	χ^2_1=2.6	.11
Preferred language is English, n (%)	54 (93)	58 (94)	OR[a] 0.93, 95% CI 0.16-5.26	>.99
Hospital admission in past 12 months, n (%)	15 (26)	12 (19)	χ^2_1=0.4	.53
Location New South Wales, n (%)	50 (86)	49 (79)	χ^2_1=0.6	.43

[a]OR: odds ratio.

App Engagement

The median duration of app use was 52 (IQR 4-95) days. Further, 2 participants used *mysnapp* weekly throughout the 12 months (Table 3). Active days ranged from 1 to 117 days, with a median of 5 (IQR 2-10) days. The median number of weeks participants consistently used *mysnapp* from baseline was 1 (IQR 1-2). Of the 62 app users, 60 (97%) opened the goal setting module, 55 (89%) the education module, 39 (63%) the progress tracking module, and 25 (39%) the diary. Table 3 shows the consistency of app use and how many modules the app users accessed over the entire period of the intervention. Of the 19 app users who had opened 3 of the 4 modules, 17 (89%) had accessed the goal setting, progress tracking, and education modules. Among the 16 who had opened 2 modules, 14 (88%) had accessed the goal setting and education modules.

Table 3. Consistency of app use and frequency of accessing app modules (n=62).

Variables and values	Participants, n (%)
Consistent app use (weeks)	
1	45 (73)
2-4	10 (16)
5-19	5 (8)
20-52	2 (3)
Number of modules accessed	
0	1 (2)
1	5 (8)
2	16 (26)
3	19 (31)
4	21 (34)
Frequency of accessing the goal setting module	
0-3	54 (87)
4-7	6 (10)

0-3	43 (69)
4-7	11 (18)
8-15	6 (10)
>15	2 (3)
Frequency of accessing the diary module	
0-3	48 (77)
4-7	5 (8)
8-15	4 (6)
>15	5 (8)
Frequency of accessing the education module	
0-3	41 (66)
4-7	12 (19)
8-15	6 (10)
>15	3 (5)

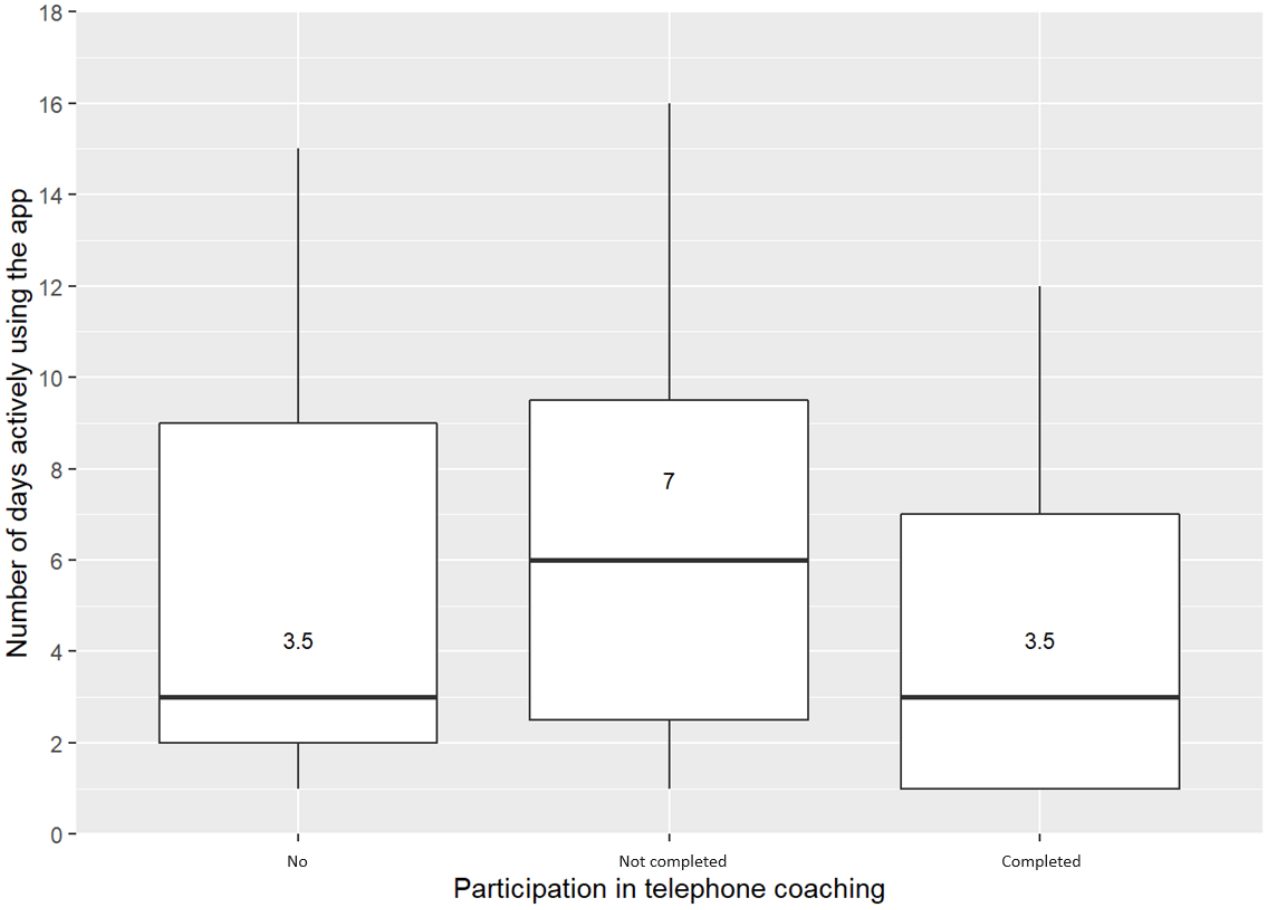
Association With Other Intervention Components

The difference in telephone coaching uptake between the app and nonapp users was statistically significant (Freeman-Halton extension of 2-sided Fisher exact test $P<.001$, Table 4). The median number of days using *mysnapp* for the app users who completed the telephone coaching was 3.5 (IQR 1-7) days, for the app users who did not complete the telephone coaching it was 7 (IQR 2.5-9.5) days, and for the app users who did not undertake the telephone coaching it was 3.5 (IQR 2-9) days (Figure 1). The difference in median active days by telephone coaching completion status was not statistically significant ($\chi^2_{19}=13.2$, $P=.83$).

Table 4. Association of app use with other intervention components (N=120).

Other intervention components and status	Nonapp users (n =58), n (%)	App users (n=62), n (%)	Test for differences between groups
Telephone coaching program			Freeman-Halton extension of Fisher exact test (2-tailed) *P*<.001
Not participated	47 (81)	24 (39)	
Not completed	8 (14)	16 (26)	
Completed	3 (5)	22 (35)	
A 6-week health check			Fisher exact test (2-tailed) *P*=.007
Not attended	54 (93)	46 (74)	
Attended	4 (7)	16 (26)	

Figure 1. Box plots of the number of days actively using mysnapp depending on the participation in telephone coaching; outliers excluded (two for no telephone coaching: 30 and 105 days, one for not completed: 117 days, and one for completed: 105 days).



The difference in the attendance rate of the 6-week health check between app users and nonusers was significant (2-sided Fisher exact test *P*=.007, Table 4). Those app users who attended the 6-week health check with the practice nurse did not have significantly more active days using *mysnapp* (median active days for 6-week health check attendees: 6, IQR 2-10 days, and for nonattendees: 4, IQR 2-10 days; *W*=374, *P*=.46).

Impact of App Use and App Engagement on Behavioral and Biomedical Outcome Measures

Differences in outcome measures between app users and nonusers, and app engagement were not significant (Tables 5 and 6) for study outcomes which were shown to be significantly improved at 6 months (ie, health literacy and diet).

Table 5. Health literacy and diet score at 2 time points for app and nonapp users, test for significant changes, and sensitivity analysis.

Consistent app use	*z*=0.43, *P*=.67, τ=0.06

[a]HLQ: Health Literacy Questionnaire.

Discussion

Principal Results

The overall aim of this study was to assess *mysnapp* app use within the HeLP-GP trial and its association with study outcomes shown to have significantly improved (health literacy and diet) at 6 months. With regard to the specific objectives, (1) there were no significant differences in demographics between participants who used *mysnapp* and those who did not; (2) among app users, the median duration of app use was 52 days, with a median of 5 active days; (3) more participants who chose to use *mysnapp* also attended the 6-week health check with the practice nurse and opted for telephone coaching; and (4) there was no association between app use and study outcomes shown to have significantly improved (health literacy and diet) at 6 months.

Length and Frequency of App Use and Module Access

Turner-McGrievy et al [34] aimed to identify the best criteria for defining adherence to dietary self-monitoring with mobile devices when predicting weight loss. They found that adherence, defined as the number of days participants tracked at least 2 meal times, explained the most variance in weight loss at 6 months [34]. We were not able to measure this because the diary, available for recording meals, could also be used for other reasons such as activities, appointments, plans for the future, and thoughts about progress. In the study by Jacobs et al [35], they analyzed data from 7680 users of a commercial weight loss app; high adherence to self-monitoring (ie, logging at least 1 food event within a reasonable time after a meal) was associated with increased weight loss. However, they also found that app users with higher adherence rates had significantly lower body weight at baseline than those with lower adherence rates [35]. The analysis only comprised people who entered data in the app at least once a week for 12 weeks. In our study, 4.9% (n=3) of the app users were still entering data at week 12. Analyzing data from the same commercial app, Carey et al [36] found significant differences in 7 different engagement measures (ie, number of articles read, meals logged, steps recorded, messages to coach, exercise logged, weigh-ins, and days with 1 meal logged per week) between app users with moderate or high weight loss (ie, 5%-10% or >10% body weight loss, respectively) and individuals with no change in body weight (ie, ±1% body weight). Their analysis indicated that people with moderate to high weight loss engaged with all app sections [36]. In our study, only 34% (n=21) of the app users had accessed all of the modules.

Impact of App Use and App Engagement on Behavioral and Biomedical Outcome Measures

Other studies showed promising results for weight loss apps, for example, Carter et al [37], Patel et al [5], and Antoun et al [38]. Specifically, Carter et al [37] conducted a pilot study of 128 volunteers who are overweight comparing a smartphone app (My Meal Mate) with a website and paper diary. They found the mean weight loss over 6 months for the app was higher (4.6 kg, 95% CI 3.0-6.2) than for the diary group (2.9 kg, 95% CI

1.1-4.7) or the website group (1.3 kg, 95% CI 0.1-2.7). Antoun et al [38] in their review of 34 studies that evaluated the use of smartphones for weight loss found an overall mean loss of 2.8 kg (95% CI 2.6-3.0) at 6 months. Patel et al [5] found that consistent tracking was associated with greater weight loss than inconsistent tracking at 6 months (2.1 kg, 95% CI 0.3-4.0). A difference between these studies and ours was that they did not specifically target disadvantaged populations with low health literacy. Therefore, their apps were more complex than ours. In contrast, Lanpher et al [39] developed a weight loss intervention suitable for individuals with low health literacy. A computer algorithm automatically allocated the self-monitoring goals (eg, no sugary drinks, no snacking after dinner, eating 5 fruits and vegetables a week). Participants reported whether they achieved the goals via interactive voice response calls [39]. The algorithm decided which goals to assign next based on previous adherence to goals so that individuals would rather receive goals to which they were receptive [40]. They also received tailored skills training through verbal calls and materials, one-on-one counseling calls, and a membership at the gym [39]. The results showed that the intervention group maintained or lost weight over 12 months, independent of their level of health literacy [38].

Bennett et al [40] extended the intervention to comprise a mobile app. They evaluated its effectiveness in a randomized controlled trial including socioeconomically disadvantaged patients with increased cardiovascular risk by comparing the intervention to usual care [40]. The app used interactive voice responses or text messaging to simplify self-monitoring, like in the previous study. Additionally, participants received in-person coaching and personalized feedback messages immediately after entering data [40]. The intervention group achieved meaningful weight loss, with more than 40% of participants reducing their body weight by at least 5% compared to 17% of participants in the usual care group [39]. Comparing this intervention to ours raises the question of whether the way people had to select and track their goals in our app contributed to the low engagement and the nonsignificant findings. Locke and Latham [41] explained that goal commitment, goal importance, self-efficacy, feedback, and task complexity act as moderators between goals and performance. Potentially, the app did not sufficiently address all 5 moderators.

Association With Other Intervention Components

This study showed that *mysnapp* users were more likely to attend the 6-week face-to-face health check with the practice nurse and to participate in the telephone coaching program than nonusers. Potentially, these individuals were more motivated to lose weight and, therefore, more willing to engage in the other intervention components. Another explanation could be that participants who opted for several intervention components felt more committed to study participation and, therefore, made more use of the individual intervention components. Griauzde et al [42] proposed a similar hypothesis in their mobile health–based prediabetes intervention study; they assumed that participants who received a more robust intervention were more committed to the study and subsequently more likely to complete the 12-week survey. Hutchesson et al [43] concluded that adding nondigital components, such as face-to-face visits and telephone coaching, to mobile health interventions can improve participants' accountability even though these additional features may not be necessary for the intervention's effectiveness.

Limitations

The plan for the randomized controlled trial was to recruit 800 study participants; however, only 215 individuals were able to be recruited (120 in the intervention and 95 in the control group) [13]. Further, despite targeting low socioeconomic areas, this study failed to recruit many participants with low health literacy. One needs to be cautious when interpreting the results of this study due to the small sample size and the high dropout. Despite considerable efforts and additional time to recruit participating practices and patients, the anticipated sample size was not achieved. Research by Perkins et al [44] has shown an ongoing issue with recruitment through Australian general practices. Another problem with the study was that the uptake of intervention components was determined by the clinician and patient. Thus, some chose to just have the app and others to just have the phone coaching. Additionally, the study may not be generalizable to other settings. Since recruitment was from 2 Australian urban areas, results could differ in rural areas or other urban areas. Diet score and health literacy level were self-reported, posing a risk of bias. Further, caution is required when interpreting the results in the context of low health literacy because the baseline health literacy levels were higher than anticipated [12]. According to data from the National Health Survey 2018, the health literacy level in this study's sample was comparable to that of Australians who are overweight or those with obesity in the general population [45]. A potential explanation is that this study's requirements (randomization, completing the questionnaire, and undertaking the health check) stopped people with low health literacy from participating. This rationale is in line with results from Kripalani et al [46], who found that people with low health literacy or numeracy were significantly less interested in participating in research.

Conclusions

There was no association between app use and study outcomes shown to have significantly improved (health literacy and diet) at 6 months. Recruitment and engagement were difficult for this study in disadvantaged populations with low health literacy. A potential explanation could be related to the self-selection of the goals and the weekly submission of the goal achievements. The practice nurses assisted participants at the beginning with the selection of goals. However, these may not have been relevant to participants, and nurses did not receive specific training in selecting meaningful goals for individuals.

However, app users were more likely to attend the 6-week health check and participate in telephone coaching, suggesting that participants who opted for several intervention components felt more committed to this study.

Acknowledgments

The authors would like to acknowledge the contribution to this research by An Tran, Carmel McNamara, Elizabeth Denney-Wilson, Katrina Paine, and Shoko Saito. We also acknowledge Louise Thomas for contributing to the trial protocol and early development. We are grateful for the partnership and support of the South Western Sydney, Adelaide and Nepean and Blue Mountains Primary Health Networks and the Australian Institute of Health Innovation. We would like to acknowledge the general practices and their staff and patients for participating in the research and consumers affiliated with Adelaide PHN for piloting *mysnapp*. This work was supported by the National Health and Medical Research Council of Australia (grant APP1125681, 2017).

Abstract

Background: Metabolic flexibility is the ability of the body to rapidly switch between fuel sources based on their accessibility and metabolic requirements. High metabolic flexibility is associated with improved health outcomes and a reduced risk of several metabolic disorders. Metabolic flexibility can be improved through lifestyle changes, such as increasing physical activity and eating a balanced macronutrient diet. Lumen is a small handheld device that measures metabolic fuel usage through exhaled carbon dioxide (CO_2), which allows individuals to monitor their metabolic flexibility and make lifestyle changes to enhance it.

Objective: This retrospective study aims to examine the postprandial CO_2 response to meals logged by Lumen users and its relationship with macronutrient intake and BMI.

Methods: We analyzed deidentified data from 2607 Lumen users who logged their meals and measured their exhaled CO_2 before and after those meals between May 1, 2023, and October 18, 2023. A linear mixed model was fitted to test the association between macronutrient consumption, BMI, age, and gender to the postprandial CO_2 response, followed by a 2-way ANOVA.

Results: The model demonstrated significant associations (P<.001) between CO_2 response after meals and both BMI and carbohydrate intake (BMI: β=–0.112, 95% CI –0.156 to –0.069; carbohydrates: β=0.046, 95% CI 0.034-0.058). In addition, a 2-way ANOVA revealed that higher carbohydrate intake resulted in a higher CO_2 response compared to low carbohydrate intake ($F_{2,2569}$=24.23; P<.001), and users with high BMI showed modest responses to meals compared with low BMI ($F_{2,2569}$=5.88; P=.003).

Conclusions: In this study, we show that Lumen's CO_2 response is influenced both by macronutrient consumption and BMI. The results of this study highlight a distinct pattern of reduced metabolic flexibility in users with obesity, indicating the value of Lumen for assessing postprandial metabolic flexibility.

Introduction

Background

The presence of obesity is the leading risk factor for metabolic disorders such as type 2 diabetes (T2D) and cardiovascular diseases (CVDs), and it has been linked to a reduced life expectancy [1,2]. Metabolic syndrome represents a collection of metabolic abnormalities that includes obesity as well as insulin resistance, hypertension, and dyslipidemia [3]. Changing the macronutrient distribution, such as low-fat or low-carbohydrate diets, has been proposed for the treatment and management of metabolic syndrome [4], and they have been shown to improve several clinical features of metabolic syndrome, including weight loss and cardiovascular risk [5,6].

Metabolic flexibility is the ability to switch between fuel sources (such as carbohydrates and fats) in response to their availability and metabolic demands, which is crucial for maintaining overall health and well-being [7,8]. Lifestyle modifications, such as exercise and a balanced diet, can therefore enhance metabolic flexibility, and high metabolic flexibility is associated with improved health outcomes, including a reduced risk of metabolic syndrome [7]. In addition, it was found to be impaired in individuals with obesity and T2D compared to lean and healthy individuals [9,10]. Assessment of metabolic flexibility can be conducted through postprandial changes (following a meal or any other insulin stimulation) in the respiratory exchange ratio (RER) from the metabolic cart [11,12], which estimates the body's preference for macronutrient oxidation. Accordingly, several studies showed different RER responses between participants with high metabolic flexibility compared with participants with low flexibility for fasting, a high-carbohydrate diet, and a high-fat diet [13]. A recent study has shown that RER is greater after high-carbohydrate overfeeding than high-fat overfeeding, and impaired metabolic flexibility, as measured by ΔRER, is associated with greater weight gain over the following 6- and 12-month periods [14]. Furthermore, ΔRER is significantly elevated after high-carbohydrate intake compared with high-fat intake, indicating that metabolic flexibility is influenced by macronutrient composition [15]. These studies show that metabolic flexibility can be assessed based on RER from the metabolic cart.

However, metabolic carts are expensive, time-consuming, and only available in health care laboratories [16]. Thus, a small handheld device was developed to measure metabolic fuel usage by analyzing exhaled carbon dioxide (CO_2). The Lumen device is a portable breath-analyzer that measures metabolic fuel use through exhaled CO_2 and was found to be in agreement with the RER measured by the metabolic cart [17]. Furthermore, Lumen was found to be able to detect different metabolic responses to low- or high-carb lifestyles through CO_2 changes [18].

A variety of mobile health apps, including Lumen, which are designed for mobility and ubiquity, have demonstrated promising results in enhancing metabolism and facilitating weight management [19]. Using real-time data tracking, these tools empower individuals to make more informed health decisions [20]. As such, mobile apps such as Lumen have the potential to make a positive difference in people's health and well-being [21].

Objective

This study examined data collected from Lumen users' exhaled CO_2 measurements taken before and after logging a meal. The objective of this analysis was to investigate the postprandial response of Lumen's CO_2 measurements to meals logged by Lumen users and to understand the association of this response with macronutrient consumption as well as users' age, gender, and BMI.

Methods

Ethical Considerations

This study was determined to be exempt from institutional board review (IRB) under category 2, as detailed in 45 CFR 46.104(d) and the standard operating procedure of the Biomedical Research Alliance of New York (BRANY), by the BRANY Social, Behavioral, and Educational Research (SBER) IRB on May 9, 2023 (BRANY IRB File 23-119-1476).

Study Design

This is a retrospective observational study based on deidentified data collected from users of the Lumen device and app.

Participants

Participants' data were collected retrospectively between May 1, 2023, and October 18, 2023. All users in the analysis were aged 18 years or older. Since only 12 users who were underweight (BMI≤18.5) were found in the database, they were removed from the analysis.

Data Sources

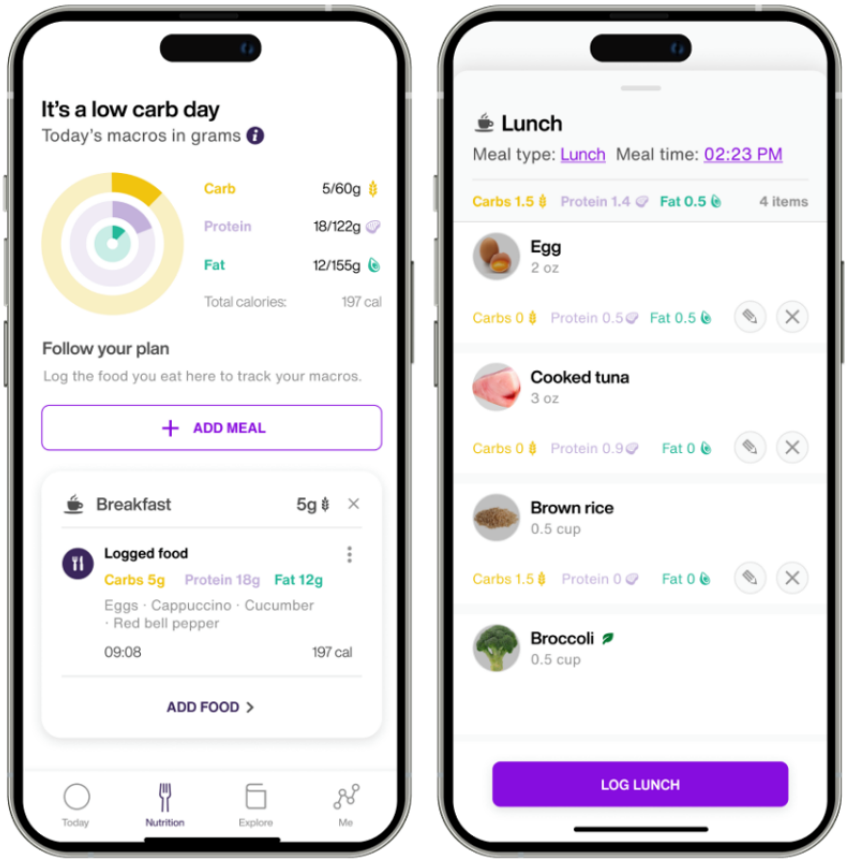
As part of the onboarding process, users were required to specify their gender, date of birth, height, and weight. The use of the Lumen app includes an optional morning fasted measurement with the Lumen device, as well as recommended pre- and postmeal measurements throughout the day and a bedtime measurement before sleeping. The app provides nutritional recommendations based on the user's personal preferences as well as their morning CO_2 measurement regarding the amount of macronutrients one should consume during the day. The app also allows users to log their meals—whether they are breakfast, lunch, dinner, or snacks. The macronutrient composition of these meals is determined by the nutritional database of Nutritionix [22], which includes all nutritional data available from the United States Department of Agriculture's (USDA) Food Composition Database, restaurant chain data, and foods added by Nutritionix's dietitians. An example of the food log feature in the app is shown in Figure 1.

Exhaled CO_2 measurements were obtained using the Lumen device (Metaflow Ltd). The Lumen mobile app guides the user through each phase of the Lumen maneuver (inhale, breath hold, and exhale), as previously described [17].

In this study, premeal and fasting measurements were defined as "premeal %CO_2," while postmeal and bedtime measurements

were considered to be the "postmeal $\%CO_2$" measure, with a maximum of 210 minutes between pre- and postmeal measurements selected for the analysis. The relative change in $\%CO_2$ from premeal to postmeal was calculated for the final analysis. In addition, meals that were tagged as either breakfast, lunch, or dinner were selected for the analysis, while snacks were removed. Further data were excluded from the analysis using the Tukey method for outlier removal with an IQR of 1.5 for all macronutrients.

Figure 1. Lumen mobile app screenshots detailing the logged meals and their macronutrient distribution.



Statistical Analysis

Data were analyzed using Python JupyterLab (version 3.6.3; Project Jupyter), and all statistical analyses were conducted with the Python programming language, using custom scripts and the *statsmodels* package [23]. Figures were made with GraphPad Prism (version 10.1.0 for Windows, GraphPad Software) [24].

A linear mixed model (LMM) was fitted in order to test the relationship between the quantity of macronutrients (carbohydrates, fats, and proteins) and personal information (gender, age, and BMI) to the outcome variable of percentage of change in $\%CO_2$ from premeal to postmeal, where users' unique ID was adjusted for as a random effect [25]. A 2-way ANOVA was used to test the differences between different groups of statistically significant variables in the LMM. Among all the analyses performed, a 2-sided $P \leq .05$ was considered statistically significant.

Results

Participants

Overall, a total of 2607 users who completed 6671 coupled pre- and postmeal sessions from 6207 logged meals were used in the final analysis, with most users contributing only 1 session into the analysis (median 1, IQR 1-2 sessions per user).

Descriptive

A total of 81.97% (2137/2607) of the participants were women, and men and women did not differ in their ages or BMIs. A summary of the characteristics of the participants in the study is presented in Table 1.

Additionally, the macronutrient composition of the meals consumed by the participants was primarily carbohydrates, followed by proteins and fats, as detailed in Table 2.

Table 1. Sample characteristics of users (N=2607).

Characteristics	Values
Gender (female), n (%)	2137 (81.97)
Age (years), mean (SD)	47.6 (9.4)
BMI (kg/m^2), mean (SD)	28.8 (6.0)

Table 2. Macronutrient composition of meals (N=6207).

Parameters	Values, mean (SD)
Carbohydrates (grams)	32.5 (20.5)
Proteins (grams)	29.7 (14.7)
Fats (grams)	22.5 (13.7)

Evaluation Outcomes

The overall CO_2 response after meal consumption at various time points is shown in Figure 2. As expected, %CO_2 measured by Lumen 30 to 210 minutes following meal intake increased significantly compared to premeal measurement.

The relationship between postprandial CO_2 response and macronutrient intake, as recorded in the Lumen app and users' personal information, was examined using Linear Mixed Modeling (LMM). The users' unique ID was incorporated as a random effect in the analysis. The model revealed a statistically significant relationship between the CO_2 response and the BMI of the users (P<.001), as well as their carbohydrate intake (P<.001). Lower BMI predicted a more significant increase in postprandial CO_2 response, and increased carbohydrate intake predicted a greater postprandial CO_2 response (Table 3). In contrast, their postprandial CO_2 response was not significantly influenced by their age, gender, fat intake, or protein intake (all P>.05; Table 3).

As the LMM analysis demonstrated significant associations between BMI, carbohydrate intake, and postprandial CO_2 response, these parameters were then divided into 3 categories each. BMI was classified as healthy (18.5-25 kg/m^2), overweight (25-30 kg/m^2), and obese (≥30 kg/m^2), while carbohydrate intake was classified as low (0-30 grams), medium (30-60 grams), and high (≥60 grams).

To examine how the CO_2 response differed between each BMI category for each carbohydrate intake class, we conducted a 2-way ANOVA. In this analysis, only the last session of each user was used to eliminate the effect within the same user's sessions. In agreement with the results from the LMM, this analysis revealed a significant effect of users' BMI category ($F_{2,2569}$=5.88; P=.003) and level of carbohydrate intake ($F_{2,2569}$=24.23; P<.001), where users with obesity tended to have a lower postprandial CO_2 response than those with healthy BMI, and high consumption of carbohydrates resulted in a higher CO_2 response (Figure 3). Nevertheless, users with high BMI had similar elevated CO_2 response as overweight and healthy users when consuming meals high in carbohydrates.

Figure 2. Exhaled carbon dioxide (CO_2) response to meal at different time intervals (N=6671). Results represent mean (95% CI).

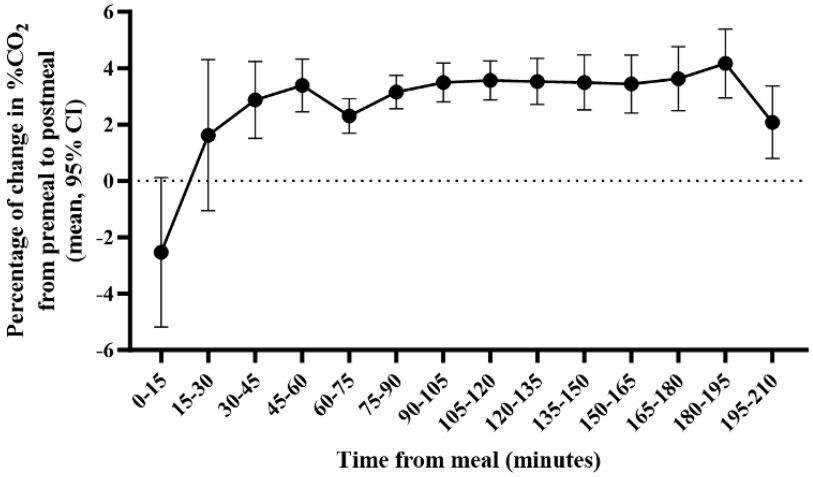


Table 3. Determinants of CO_2 response to food intake (N=6671).

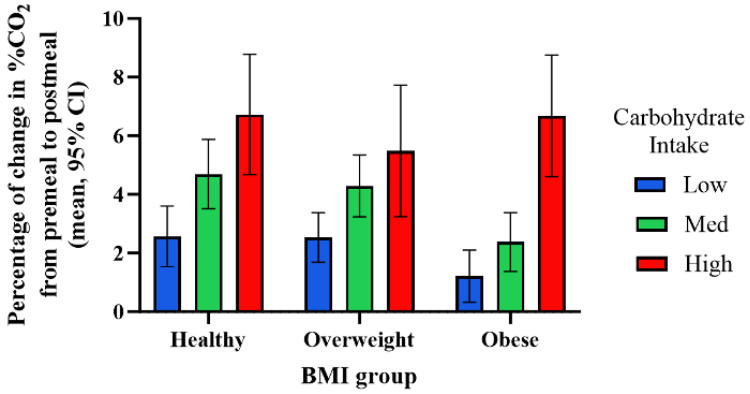
Variables	β (95% CI)	*z* statistics	*P* value
Intercept	5.221 (3.242 to 7.199)	5.172	<.001
BMI	–0.112 (–0.156 to –0.069)	–5.026	<.001
Age	–0.021 (–0.049 to 0.007)	–1.483	.14
Gender	–0.612 (–1.324 to 0.100)	–1.683	.09
Carbohydrates	0.046 (0.034 to 0.058)	7.496	<.001
Fat	0.018 (–0.001 to 0.038)	1.816	.07
Protein	0.016 (–0.002 to 0.035)	1.755	.08

Figure 3. Carbon dioxide (CO_2) response to different carbohydrates intake in different BMI categories (N=2607). Results represent mean (95% CI).



Discussion

Principal Findings

This study showed how the Lumen device can detect the $\%CO_2$ response to meals with a different macronutrient composition (mixed meals). Notably, this response is influenced by the carbohydrate consumption in each meal as well as the BMI of the user. Lumen's measured exhaled $\%CO_2$ was higher when carbohydrate intake was higher, in accordance with previous studies describing the association between RER and carbohydrates [11,14,15,18]. In addition, it reveals metabolic inflexibility in individuals with obesity as they show a reduced $\%CO_2$ response compared with healthy individuals, which again is in accordance with the literature on metabolic flexibility [8,9,26].

Comparison With Previous Work

A recent prospective study has shown that a high-carbohydrate diet results in an elevation of Lumen's $\%CO_2$ compared with a low-carbohydrate diet [18]. In this retrospective analysis of Lumen users, we show similar results, as $\%CO_2$ is elevated when carbohydrate consumption is increased, which highlights Lumen's ability to detect changes in carbohydrate intake. Although previous studies that included high-fat and high-protein consumption resulted in elevated RER [14,27,28], we did not observe this in this study. Further study with a larger sample size is warranted to check for the effect of dietary fats and proteins on exhaled $\%CO_2$.

The duration of $\%CO_2$ elevation has shown a consistent plateau, spanning from 45 minutes postmeal to the last checkup at 210 minutes, where a subsequent decline was observed. Lumen users often analyze their postmeal breath between 60 and 120 minutes, so understanding how $\%CO_2$ responds over longer periods is challenging. Woerle et al [29] showed carbohydrate oxidation up to 360 minutes after meal consumption, long after glucose and insulin levels in the plasma peaked. Future prospective studies should address when $\%CO_2$ decreases after a mixed macronutrient meal and how it changes compared to other metabolites.

The impact of postprandial measurement of glucose levels on metabolic disease prevention has been discussed in previous studies [30]. Novel technological advancements have made it available to consumers, mostly with recent developments in continuous glucose monitoring (CGM) [31]. Other metabolic indicators, such as insulin, lipids, metabolomics, and indirect calorimetry, have also been used to assess metabolic flexibility and were found to be predictive of body weight, metabolic syndrome, T2D, and CVDs [11,25,32,33]. As of today, CGM devices need replacing every 2 weeks and are somewhat invasive, whereas most of the other aforementioned measurements can only be performed in a laboratory setting. In contrast, the Lumen device can be used at home and measures an individual's metabolic state with a simple breath maneuver, which was found to be in agreement with the RER measured in the metabolic cart [17]. Moreover, compared to the metabolic cart, the portability of the Lumen device enables the collection of CO_2 measurements from a large number of participants after

consuming mixed macronutrient meals, which provides a higher level of external validity.

In addition to the effect of carbohydrate consumption, BMI was also found to be a key parameter in the postprandial $\%CO_2$ response, as a higher BMI resulted in a reduced response. These results are in accordance with the literature from the metabolic cart, where participants with obesity and T2D showed low ΔRER after insulin stimulation [9,10].

In this analysis, the majority of participants were women (2137/2607, 81.97%), in line with similar nutrition and weight management studies finding that women participate 3 times more often than men [34,35]. Age and gender were both statistically insignificant in their effect on the postprandial $\%CO_2$ response in the LMM, while some studies mention that metabolic flexibility is reduced with age [36]. Although progesterone is directly associated with CO_2 [37,38], our analysis did not reveal any influence of gender on metabolic flexibility, possibly since women may have been in different phases of their menstrual cycle or at menopause. Future studies should investigate the effects of gender and the menstrual cycle on Lumen's $\%CO_2$.

This study shows the potential of the Lumen device and mobile app to improve outcomes for people with metabolic disorders. There is increasing evidence showing that mobile health technologies can improve metabolic outcomes, in particular for lifestyle modifications in T2D and weight loss [39-41]. While most of these technologies incorporate a mobile app only, many studies have shown the benefits of an app accompanied by a device capable of providing real-time feedback on how those lifestyle modifications affect their measurements, which can improve engagement with them [42-45]. In a recent pilot clinical study, Lumen device and app usage improved several metabolic parameters in prediabetic patients after 3 months [46]. In light of these findings, the potential public health implications of mobile and ubiquitous health tools such as Lumen are noteworthy, showing great promise for addressing the epidemic of metabolic dysfunction across the globe in the near future.

Limitations

Despite the large data set of real-world evidence that was used in this analysis, several limitations need to be mentioned. First, due to its retrospective and observational nature, we cannot identify causal relationships between any of the variables in this study. Second, since this analysis is based on real-world data, the macronutrient consumption of each meal may be miscalculated or incomplete (recall bias), and a misuse of the device might occur as well. Moreover, the heterogeneous composition of the meals makes it difficult to determine if other factors in the meal might influence the $\%CO_2$ as well, in particular the type of carbohydrate and the fiber composition. In addition, Lumen users' macronutrient intake might not be representative of most typical diets, as the Lumen app guides them toward a specific diet, primarily low in carbohydrate, and with most of them on a weight loss journey. As this study has specific user characteristics, caution should be exercised in interpreting these conclusions for a broader audience. Furthermore, this analysis did not consider the fasted $\%CO_2$ levels, which, together with the postprandial levels, could also be useful in the metabolic flexibility assessment [47]. Nonetheless, we believe that due to the nature of the outcome variable, which is the percentage of change from premeal to postmeal, it might have limited to no effect on the current results.

Lastly, postprandial $\%CO_2$ might be affected by other confounding variables, including preexisting conditions; medication use; dietary restrictions; the menstrual cycle; and lifestyle factors such as stress, sleep, and physical activity, which were not controlled for in this study. Future studies, both prospective and retrospective, should aim to address these limitations, particularly through controlled prospective investigations involving diverse populations and retrospective analyses that comprehensively consider potential covariates.

Conclusions

In conclusion, Lumen's ability to evaluate metabolic flexibility following mixed meals was demonstrated through this retrospective analysis of postprandial exhaled $\%CO_2$, in which increased $\%CO_2$ was specific to carbohydrate consumption but not to fat consumption. Furthermore, a moderate $\%CO_2$ response was also observed among users with a high BMI, which suggests metabolic inflexibility among this group. As such, we propose Lumen as an accessible tool allowing individuals to make informed dietary choices conducive to metabolic health.

Acknowledgments

This study was funded by Metaflow Ltd. The authors would like to express their thanks to all app users who contributed their data to this study and to the Lumen team for their support. We would also like to thank all the reviewers for their timely and constructive inputs to this manuscript.

Authors' Contributions

SY, TC, and MM led the design and conceptualization of the study. MM was the principal supervisor of the study. SY led the curation of the data and conducted data interpretation and formal analysis. SY wrote the first draft of the manuscript. TC and DS contributed to the data analysis. All authors critically revised the manuscript and gave their final approval.

Conflicts of Interest

MM is the chief scientific officer and the cofounder of MetaFlow Ltd. DS is a consultant at MetaFlow. SY and TC are paid employees at MetaFlow.

Abstract

Background: Numerous smartphone apps are targeting physical activity (PA) and healthy eating (HE), but empirical evidence on their effectiveness for the initialization and maintenance of behavior change, especially in children and adolescents, is still limited. Social settings influence individual behavior; therefore, core settings such as the family need to be considered when designing mobile health (mHealth) apps.

Objective: The purpose of this study was to evaluate the effectiveness of a theory- and evidence-based mHealth intervention (called SMARTFAMILY [SF]) targeting PA and HE in a collective family–based setting.

Methods: A smartphone app based on behavior change theories and techniques was developed, implemented, and evaluated with a cluster randomized controlled trial in a collective family setting. Baseline (t_0) and postintervention (t_1) measurements included PA (self-reported and accelerometry) and HE measurements (self-reported fruit and vegetable intake) as primary outcomes. Secondary outcomes (self-reported) were intrinsic motivation, behavior-specific self-efficacy, and the family health climate. Between t_0 and t_1, families of the intervention group (IG) used the SF app individually and collaboratively for 3 consecutive weeks, whereas families in the control group (CG) received no treatment. Four weeks following t_1, a follow-up assessment (t_2) was completed by participants, consisting of all questionnaire items to assess the stability of the intervention effects. Multilevel analyses were implemented in R (R Foundation for Statistical Computing) to acknowledge the hierarchical structure of persons (level 1) clustered in families (level 2).

Results: Overall, 48 families (CG: n=22, 46%, with 68 participants and IG: n=26, 54%, with 88 participants) were recruited for the study. Two families (CG: n=1, 2%, with 4 participants and IG: n=1, 2%, with 4 participants) chose to drop out of the study owing to personal reasons before t_0. Overall, no evidence for meaningful and statistically significant increases in PA and HE levels of the intervention were observed in our physically active study participants (all P>.30).

Conclusions: Despite incorporating behavior change techniques rooted in family life and psychological theories, the SF intervention did not yield significant increases in PA and HE levels among the participants. The results of the study were mainly limited by the physically active participants and the large age range of children and adolescents. Enhancing intervention effectiveness may involve incorporating health literacy, just-in-time adaptive interventions, and more advanced features in future app development. Further research is needed to better understand intervention engagement and tailor mHealth interventions to individuals for enhanced effectiveness in primary prevention efforts.

Introduction

Background

Physical activity (PA) and healthy eating (HE) are protective factors for general health and can also enhance health [1]. In contrast, a lack of PA, too much sedentary behavior (eg, excessive screen time and nonactive media use), and an unhealthy diet are serious concerns and increase the risk of health conditions across all ages [2-5]. Although preschool children seem to show high adherence to PA guidelines [6], they have low adherence to screen time guidelines [7]. Research revealed that children, as they become older, and adolescents do not engage sufficiently in PA [8] and frequently make unhealthy food choices [9,10]. Worldwide, 81% of children and adolescents (and 23% of adults) do not meet recommendations on PA levels and HE, that is, fruit and vegetable intake (FVI) [11]. In this regard, a dose-response relationship (ie, the relationship between the dose of PA and the effect observed) was detected, with even slight increases in PA leading to physiological and psychological health benefits in children and adolescents [12,13] and in adults. Hence, health behavior interventions should aim at sustaining PA and HE levels for those adhering to guidelines or at increasing these behaviors in those who do not adhere to guidelines [7,11]. As longitudinal studies showed that behavioral patterns in childhood and adolescence have a low-to-moderate influence on PA patterns in adulthood [14-19], there is a need for interventions already targeting children and adolescents to promote a sustainable and healthier lifestyle.

To achieve this goal, it is important to recognize that health-related behaviors, such as PA and HE, are influenced by social contexts, such as the family environment, and are shaped by social relationships and connections [20,21]. Leisure time PA of children is, for example, directly linked to parental PA levels [22,23], and the eating behavior of children is dependent on their parents' food choices [24-26]. Therefore, addressing behavioral changes embedded in social contexts might be a promising approach for facilitating an individual's behavior change. When focusing on children and adolescents, the most imprinting social context is daily family life. Family meals, for example, are often an important part of everyday life in families, and there is accumulating evidence that this collective behavior is associated with a better overall diet quality and BMI [27-29]. In a similar vein, there is some evidence that family-based PA is positively associated with individual PA levels [30]. It has been shown that supportive interactions within a family and shared values about health behavior affect PA engagement [31] and the eating behavior of children [32]. In addition, results of intervention studies indicate that social support is significantly associated with the continuation of exercise programs [33-37] as well as participation in weight loss interventions [38-40].

Families are difficult to reach with typical in-person interventions, as the daily lives of family members are highly different regarding their content and time schedule. Hence, mobile health (mHealth) technologies might be the means of choice, as they are increasingly used as a delivery mode for health behavior change interventions across different age groups. Specifically, smartphone-based apps offer great promise for enhancing PA and HE as well as making health care more accessible and scalable, more cost-effective, and more equitable [41,42]. Reviews and meta-analyses support the view that app‐based mobile interventions are effective and highly promising for changing PA [36,43] and nutrition behaviors [44], especially when implemented in a family setting, including parental involvement [45]. Moreover, a systematic review of economic evaluations of mHealth solutions found a consistent overall reporting of positive economic outcomes (eg, increase in life-years gained, cost savings, and cost-effectiveness) [46].

Regarding functional principles of such mHealth apps, reviews indicate that the strategies or central *building blocks* of app-based interventions mainly encompassed 4 behavior change technique (BCT) clusters [47], including goal setting, feedback and self-monitoring, information, and social support provision, which coincides with successful conventional individual and group-based interventions [44,48,49]. On the basis of causal analyses, an umbrella review found that the effectiveness of interventions was increased by engaging social support, targeting both PA and HE, and using well-defined or established BCTs. However, because mobile interventions distinguish themselves by being interactive, adaptive, time sensitive, and intraindividually dynamic, more dynamic concepts, including the timing of feedback and tailoring tasks and goals to individual progress and capacities as specified in persuasive technology and gamification approaches, might be essential ingredients of effective and focused mobile interventions [44,50,51].

Moreover, mobile interventions are capable of fulfilling the abovementioned demands to be embedded into a social system so that all members of this system, that is, a family, can simultaneously and collectively take part in an intervention and share their goals and progress. However, currently available apps for health promotion are almost exclusively tailored to an individual level [52]. Motivation for behavior performance is higher when the individual is embedded in a social system of mutual appreciation and importance, according to self-determination theory (SDT) [53,54], which was successfully used in PA interventions by enhancing autonomous motivation and fulfilling the 3 basic psychological needs: "autonomy," "competence," and "relatedness" [53]. As healthy or unhealthy

behavioral patterns are developed and maintained in social contexts, embedding a mHealth intervention in a family setting and targeting all family members might be promising and corresponds to assumptions of family-as-systems approaches [55]. An umbrella review about digital interventions for health behavior change in PA and HE found a lack of studies focusing on the social contexts, while BCTs and a theoretical foundation were associated with higher intervention effectiveness [56]. Another review of the effect of family-based mHealth interventions found heterogeneous results in a limited research body and called for more experimental studies in this area [57]. Overall, there is a lack of randomized controlled mHealth studies that use important key facets of effective interventions such as BCTs and a theoretical foundation while considering the social system of participants.

Objectives

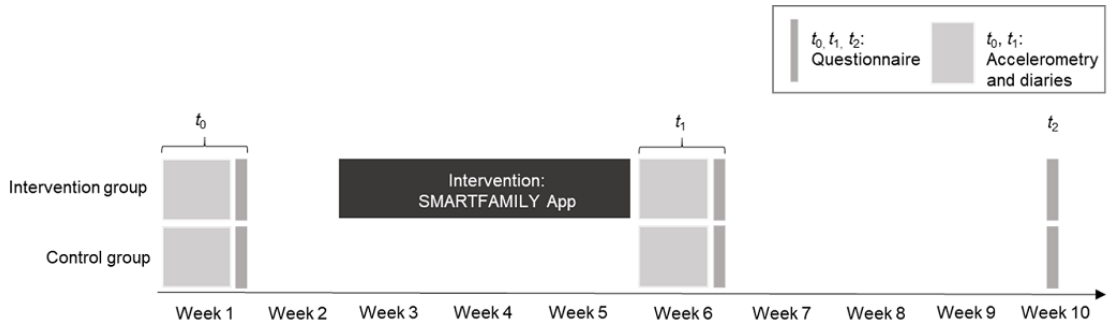
This study aimed to evaluate the effectiveness of a mobile stand-alone smartphone intervention app that incorporates the family as a social system of high relevance for its single members. We designed and evaluated a multicomponent mHealth intervention that aimed to improve PA and HE in families. The development of the app was based on behavior change theories, including SDT, and the use of BCTs. The behavior of children and parents was targeted to induce family- and individual-based behavior changes. Specifically, family members were using the SMARTFAMILY (SF) app individually and cooperatively. The complete study protocol and more details are available in the study by Wunsch et al [58]. It was hypothesized that the mHealth intervention would positively influence PA variables (steps and moderate to vigorous PA [MVPA]) and the HE variable (FVI) in the whole family.

Methods

Study Design

The study was conducted and described according to the corresponding study protocol and the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist that provides guidance for standardized reporting of eHealth and mHealth interventions (Multimedia Appendix 1) [36,41-44,46,53,54,59-66]. This is a cluster randomized controlled trial with two groups: (1) an intervention group (IG) receiving the app intervention and (2) a nonintervention control group (CG) that neither received material nor was contacted during the intervention period. The outline of the SF trial is presented in Figure 1. Assessment of outcomes was completed at baseline (t_0), after the 3-week intervention (or no-intervention) period (postintervention; t_1), and 4 weeks after the measurement (follow-up; t_2). As the study protocol is freely accessible [58], the study design and measurements will only be described very briefly. For a complete overview, please refer to the study protocol.

Figure 1. Detailed study design.



All eligible members of each family participated in an initial visit to the research facility, where they received instructions on how to use various tools that would be used throughout the study. These included wearable devices called accelerometers, which recorded PA levels, as well as paper diaries for tracking their behavior over time. At the end of this initial phase, participants also answered questions related to their habits and behaviors in the past week, which served as a baseline. This information was shared with those participating in the intervention so they could set family goals for themselves based on this starting point.

Participants assigned to the IG were given specially designed smartphones equipped with our SF app. The app was created in an iterative process, incorporating feedback from both the target audience and experts. The development process also drew upon insights from previous research conducted as part of the SMARTACT project, as well as behavioral theories. The programing of the apps was carried out by the Human-Computer Interaction Workgroup at the University of Konstanz, as a component of the SMARTACT project. Study staff ensured that all participants had access to similar technology by providing them with these phones. Providing additional study smartphones was also recommended by the ethics committee for data security reasons. The study staff also carefully explained the app's functionality to families, handed out a study manual, and were available to assist with any issues that arose. In addition, the accelerometers worn by participants were synced wirelessly with the smartphones through Bluetooth low-energy connections.

When the 3-week intervention began, families in the IG were instructed to establish collective weekly objectives for both PA and HE. The 3-week period was chosen due to practical concerns, as we examined families in their natural setting. In Germany, a continual school period lasts a maximum of 6 to 8

weeks, followed by a vacation period. To conduct the core assessments, including pre- and posttesting accelerometry during 1 continual school period, an intervention period >3 weeks was not feasible for the study design. Longer intervention periods would inevitably mean that there is a cofounding between the assessment period (school time vs vacation). Specifically, they aimed to accumulate a certain number of steps, engage in appropriate amounts of moderate or vigorous PA, plan enjoyable family activities together, and consume adequate portions of fruits and vegetables as well as joint family meals. Families were instructed to formulate the goals together based on their previous performance from the baseline assessments. The goals were set on 1 smartphone for the whole family, and the app notified the family every Sunday to set new goals. Participants were encouraged in the initial explanation phase by the study staff to strive for progressively more ambitious but realistic goals based on their previous behavior. As part of the program, participants revisited and adjusted their goals regularly to keep challenges manageable while promoting continuous improvement. All smartphones were retrieved after the intervention period ended. Therefore, the IG had neither access to the app during t_1 nor afterward.

The app included 10 BCTs [47] for the IG and no BCT for the CG. Intervention BCTs were behavioral goal setting, prompt review of behavioral goals, prompt self-monitoring of behavior, providing feedback on performance, planning social support or social change, prompt identification as a role model or position advocate, setting graded tasks, shaping, prompt rewards contingent on effort or progress toward behavior, and providing rewards contingent on successful behavior.

Once the intervention or control period ended, participants underwent 2 more testing sessions (t_1 and t_2). Our investigation used a single-blind design, and the survey instruments were evaluated for user-friendliness and technical reliability beforehand.

Eligibility Criteria

Households comprising at least 1 adult caregiver and 1 child aged >10 years residing together could participate in the research. If applicable, other siblings were welcome to join the project as well. Everyone taking part had to possess basic proficiency in handling mobile devices, be physically able to participate in PA independently, and communicate effectively in German. However, exceptions might have been made for younger siblings who met this requirement.

Ethical Considerations

Before commencement, participants (including minors), parents, or legal guardians signed informed consent forms. Full ethics approval was granted by the University of Konstanz and the Karlsruhe Institute of Technology. This research adhered to the guidelines outlined in the Helsinki Declaration. Furthermore, during the testing sessions, ethical standards were upheld, and personal data were protected.

Families who completed the study were eligible to participate in a prize draw at the end of the study, having the chance to win one of three family-tickets for a big theme park in Germany.

Randomization and Blinding

This study used a cluster randomized controlled design comparing 2 distinct groups: an IG that received the intervention and a CG that did not receive any treatment. Consenting families were randomly assigned to either arm through a straightforward allocation scheme suitable for cluster trials [60]. While members of the IG were aware of the mHealth aspects of the study, participants in the CG were merely informed about contributing to an epidemiological examination of PA and overall health. Accordingly, all participants wore accelerometers for 1 week twice across a 10-week duration to ensure accurate and dependable measurements. In addition, participants completed various questionnaires during this period.

Participants

Participants were recruited in schools, school holiday programs, music schools, and sports clubs via personal communication, newspapers, social media, and email distribution lists of the Karlsruhe Institute of Technology.

Overall, 48 families (CG: n=22, 46%, with 68 participants and IG: n=26, 54%, with 88 participants) were recruited for the study. Two families (CG: n=1, 2%, with 4 participants and IG: n=1, 2%, with 4 participants) chose to drop out of the study owing to personal reasons before t_0.

Measurements

PA Measures

Device-Measured PA (Accelerometry)

Hip-worn (right side) 3-axial accelerometers (Move 3 or Move 4, Movisens GmbH) were used to continuously record PA levels. These accelerometers are scientific research instruments with a measurement range of +16 g to −16 g, an output rate of 64 Hz, physical dimensions of 62.3×38.6×11.5 mm, a weight of 25 g, and custom epoch lengths (ie, 10 s). Data were recorded in a raw format (64 Hz) and were summarized afterward in the epoch lengths of choice. Epoch length was chosen as 10 seconds as shorter epoch lengths are believed to be more appropriate to estimate vigorous PA and assess PA in children owing to intermittent movement behavior [67,68]. Validity has been evaluated for a previous version of the accelerometer (Move 2), which uses comparable digital signal processing as the Move 3 or Move 4 has been considered accurate for assessing steps [69] and energy estimation [70,71] in adults. Handling the accelerometer was explained and demonstrated by a study instructor. Participants were instructed to wear the accelerometer during wake time and remove it only during a shower, swimming, or certain sports involving bodily contact to minimize the probability of injuries. The outcomes for the accelerometer that were used for this study were MVPA (>3.0 metabolic equivalents [MET]) and steps for all participants. MET values were calculated based on activity class (based on acceleration and barometric signals), which determines the estimation model. Afterward, movement acceleration, altitude change, and demographics were combined in the model for the MET estimation [71]. Accelerometer data were included if a minimum wear time of at least 8 hours a day for at least 4 of the 7 days during the measured week was obtained. Nonwear

time was calculated in 30-second intervals. The nonwear time detection was based on an algorithm that used accelerometry and temperature signals over a 10-minute window to distinguish between wear time, nonwear time, and sleep, as described elsewhere [72]. For valid measurements, the average of MVPA and steps per valid day was multiplied by 7 to estimate the total minutes per week.

Self-Reported PA

At the end of each measurement week, adults were asked to fill short version of the International Physical Activity Questionnaire in German [73], asking retrospectively for activities during the previous week. The results of the question relating to minutes spent in moderate (comprising moderate activity and walking) and vigorous PA were calculated for this study by multiplying the reported number of days with the reported duration of the indicated activity per day and then adding the values of moderate and vigorous PA to MVPA per week. Children completed the 60-Minute Screening Measure [74] for MVPA, which yields the number of days with at least 60 minutes of MVPA according to the (now outdated) World Health Organization guidelines [75]. In addition, a PA diary was used for all participants at t_0 and t_1, which is not included in the current examination owing to noncomparable results [68]. Parents and children were instructed to fill out their self-reported questionnaires and diaries independently.

FVI Measures

FVI was assessed using a single item asking for the total amount of fruits and vegetables consumed within a typical week [76] in the questionnaire as well as using a description of detailed food consumption during t_0 and t_1 by indicating the time of the meal, ingredients, portions of FVI, and whether the meal was consumed within the family or alone in a diary.

Secondary Outcomes

Demographics

In the t_0 questionnaire, demographic information of the participants was collected, including sex, age, height, and weight.

Health Status

Perceived general health was assessed using a single item [76].

Intrinsic Motivation Toward PA

According to the SDT, activity-related self-determination was assessed using the Behavioral Regulation in Exercise Questionnaire (BREQ-2) [77]. BREQ-2 assesses the manifestation of the 5 different regulation modes by the SDT, reflected by the subscales of amotivation (4 items), external (4 items), introjected (3 items), identified (3 items), and intrinsic (4 items) regulations. Responses were made on a 4-point Likert scale, ranging from 0=*not true*, 1=*rather not true*, 2=*rather true* to 3=*true*. For the analysis, a relative autonomy index was formed. It is derived from the subscales and gives an index of the degree to which respondents feel self-determined. The index is obtained by applying a weighting to each subscale and then summing these weighted scores. In other words, each subscale score is multiplied by its weighting, and then these weighted scores are summed. Higher, positive scores indicate greater relative autonomy; lower, negative scores indicate more controlled regulation.

Intrinsic Motivation Toward HE

For assessing dietary-related intrinsic motivation, the Regulation of Eating Behavior Scale [78] was used. The dimension "integrated regulation" was omitted, resulting in a total of 5 subscales, coded from 0 to 3. A sum score was built analogous to the BREQ-2.

Self-Efficacy for PA and HE

Activity-related self-efficacy and dietary-related self-efficacy were assessed using the health-specific self-efficacy scales, comprising 5 items for each behavior-related dimension [79]. Participants were asked how certain they were to handle different health-specific barriers. Responses were given on a 4-point Likert scale, ranging from 1=very uncertain, 2=uncertain, 3=certain to 4=very certain. A sum score was built for both scales.

Family Health Climate

Shared perceptions and cognitions regarding health behaviors were assessed by use of the Family Health Climate (FHC) Scale [80], comprising the 2 separate scales for PA (FHC-PA) and nutrition (FHC Nutrition [FHC-NU]). FHC-PA contains 14 items, which are assigned to the 3 subscales of value (5 items), cohesion (5 items), and information (4 items). FHC-NU includes 17 items, comprising the 4 subscales of value (4 items), cohesion (5 items), consensus (3 items), and communication (5 items). Responses for each dimension were scored on a 4-point Likert scale ranging from 0=*not true*, 1=*rather not true*, 2=*rather true* to 3=*true*. Sum scores were built for both scales.

Joint PA and Meals Within the Family

Joint PA and nutrition were assessed using a single item that referred to the number of activities and meals in which the whole family was involved during the past week. The mean value per family was used for the analysis.

Statistical Analysis

The analyses were run with different packages of R (R Foundation for Statistical Computing) [81] and RStudio (Posit) [82]. The package *ggplot2* was used for visualizations [83] following the instructions by Allan et al [84]. Mixed models were calculated using the package *lmerTest* [85] with participants (level 1) nested in families (level 2) to acknowledge the hierarchical structure of the data. The result tables of the regression analyses were generated using the package *sjPlot* [86]. In total, 6 final models were calculated, 1 with each measurement method and outcome parameter (1 steps, 3 MVPA, and 2 FVI intake per wk) as dependent variables. Assumptions were checked using the visualization of the *performance* package [87]. A hierarchical approach was used for the inclusion of the control variables, and the model fit was assessed with the Akaike information criterion for sensitivity analysis. In addition, 2 models were calculated for joint PA and nutrition based on the family mean values without the random factor family because it was defined as "all family members were present."

The predictor group (ie, control=0 and intervention=1)×time (dummy coded with t_0 as reference for t_1 and t_2) was included in the models to evaluate the interaction effect (main effect) of the intervention on the 8 outcome parameters. To assess sensitivity regarding the additional variables, the secondary outcome parameters self-efficacy, intrinsic motivation, and the FHC were added either referring to PA or FVI depending on the outcome, and the control variables health status, population (adult=0 and children=1), sex (0=male and 1=female), and nonwear time per week—only for the device-measured PA models—were tested for the inclusion in the random effect models. In addition, the inclusion of random slopes and random intercepts were evaluated based on the model fit. The level of statistical significance was set a priori to $\alpha<.05$ with no correction for multiple comparisons.

Results

Data Availability and Participant Characteristics

In total, 46 families with 148 participants (74/148, 50% adults: 45/74, 61% female and 29/74, 59% male; and 74/148, 50% children: 38/74, 51% female and 36/74, 49% male) participated in the study. The mean ages of adults and children were 47.8 (SD 5.0) and 13.3 (SD 2.7) years, while the average BMI values were 24.8 (SD 4.1) and 19.0 (SD 3.3), respectively. Testing took place between December 1, 2017, and January 31, 2020. Technical issues with the app during the intervention, insufficient wear time of the accelerometer (ie, <4 days with >8 hours wear time), and missing data for the self-reported items led to the inclusion of a differing number of participants for each calculated model (depending on the outcome variables; Multimedia Appendices 2 and 3). Participant characteristics of the 46 families separated by group (CG vs IG), population (children vs adults), and sex (male vs female) are displayed in Table 1. Descriptive results for all included outcomes and predictors can be found in Table 2.

Table 1. Participant characteristics of the 46 families included in the SMARTFAMILY trial.

Characteristics	Control group		Intervention group	
	Children (n=32)	Adults (n=32)	Children (n=42)	Adults (n=42)
Sex, n (%)				
Male	15 (47)	11 (34)	21 (50)	18 (43)
Female	17 (53)	21 (66)	21 (50)	24 (57)
Age (y), mean (SD)				
Male	13.1 (3.23)	49.1 (5.02)	13.4 (2.48)	50.2 (5.58)
Female	13.4 (2.61)	47.0 (3.90)	13.5 (2.58)	46.1 (4.70)
BMI (kg/m^2), mean (SD)				
Male	18.7 (2.59)	25.7 (3.30)	19.0 (4.06)	26.6 (5.35)
Female	19.2 (3.14)	24.7 (3.63)	18.9 (3.00)	23.3 (3.01)

Table 2. Descriptive results of the 46 families included in the SMARTFAMILY trial. Data were assessed for the three measurement weeks: baseline (t_0), after intervention (t_1), and 4 weeks after intervention at follow-up (t_2).

[a]Not measured at t_3.

[b]MVPA: moderate to vigorous physical activity.

[c]IPAQ: International Physical Activity questionnaire.

[d]The International Physical Activity questionnaire was used for adults, and the 60-Minute Screening Measure was used for children.

[e]KIKA: 60-Minute Screening Measure.

[f]FVI: fruit and vegetable intake.

[g]M intrinsic NU: intrinsic motivation toward nutrition.

[h]RAI: relative autonomy index.

[i]M intrinsic PA: intrinsic motivation toward physical activity.

[j]FHC: Family Health Climate.

[k]NU: nutrition.

[l]PA: physical activity.

All control variables (except sex for the PA questionnaire of children) improved the model fit based on the Akaike information criterion and were therefore included in the final sensitivity models. Random slopes were not supported by the data, but random intercepts were used for all models. Sensitivity analysis showed no difference in patterns for the effectiveness of the intervention (Tables S1-S6 in Multimedia Appendix 3). Therefore, only the main models are reported. Data and code are available at the Open Science Framework [88].

Effect of the Intervention on PA

Results of the multilevel models indicate no significant main effect for the interaction of the group with time in the PA outcomes (Tables S1-S4 in Multimedia Appendix 2). The only significant main effect was found between t_0 and t_1 for the self-reported 60-Minute Screening Measure in children (P=.03; β=−.35). Figures 2 and 3 display the descriptive results of the main effects for device-measured PA outcomes, MVPA, and step count. As displayed by the gray dotted lines in Figure 2, both mean and median values are clearly above the recommendation for MVPA [89] for both children (ie, 60 min/d on average, 420 min/wk) and adults (ie, 150 min/wk) in both groups and at both measurement periods. For steps, mean and medium values are shortly below the commonly used 10,000 steps per day goal [90,91] for all participants (Figure 3).

Figure 2. Interaction effect of group×time for device-measured physical activity (PA) for the parameter minutes of moderate to vigorous PA (MVPA) per week. Displayed are the mean MVPA (y-axis) of 109 participants during 1 week of baseline measurement (t_0) and 1 week of postintervention measurement after a 3-week intervention and waiting period (t_1) for the control group (green) and the intervention group (red), stratified by children and adults. The gray dashed lines represent the PA recommendations for children (420 min/wk) and adults (150 min/wk).

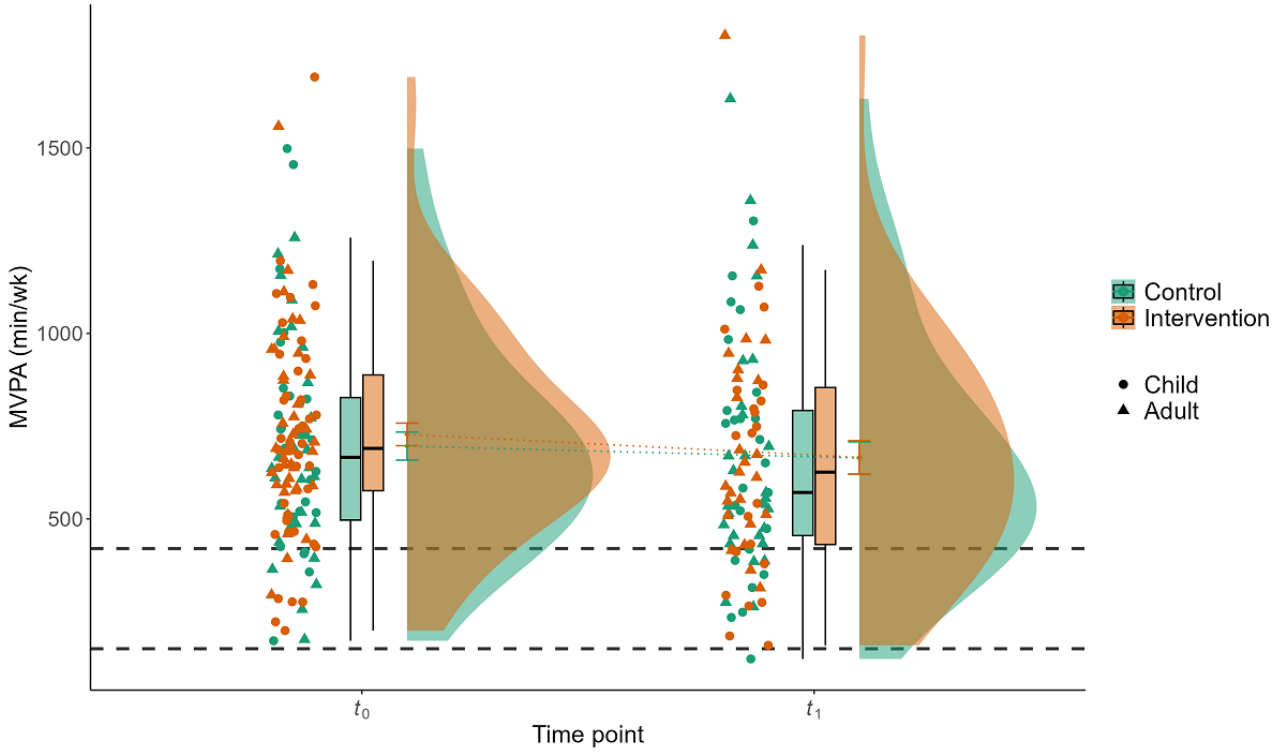

Figure 3. Interaction effect of group×time for device-measured physical activity for the parameter steps per week (steps). Displayed are the mean step count (y-axis) of 109 participants during 1 week of baseline measurement (t_0) and 1 week of postintervention measurement after a 3-week intervention and waiting period (t_1) for the control group (green) and the intervention group (red), stratified by children and adults. The gray dashed line represents the commonly used step recommendation of 10,000 steps per day (70,000 steps/wk).

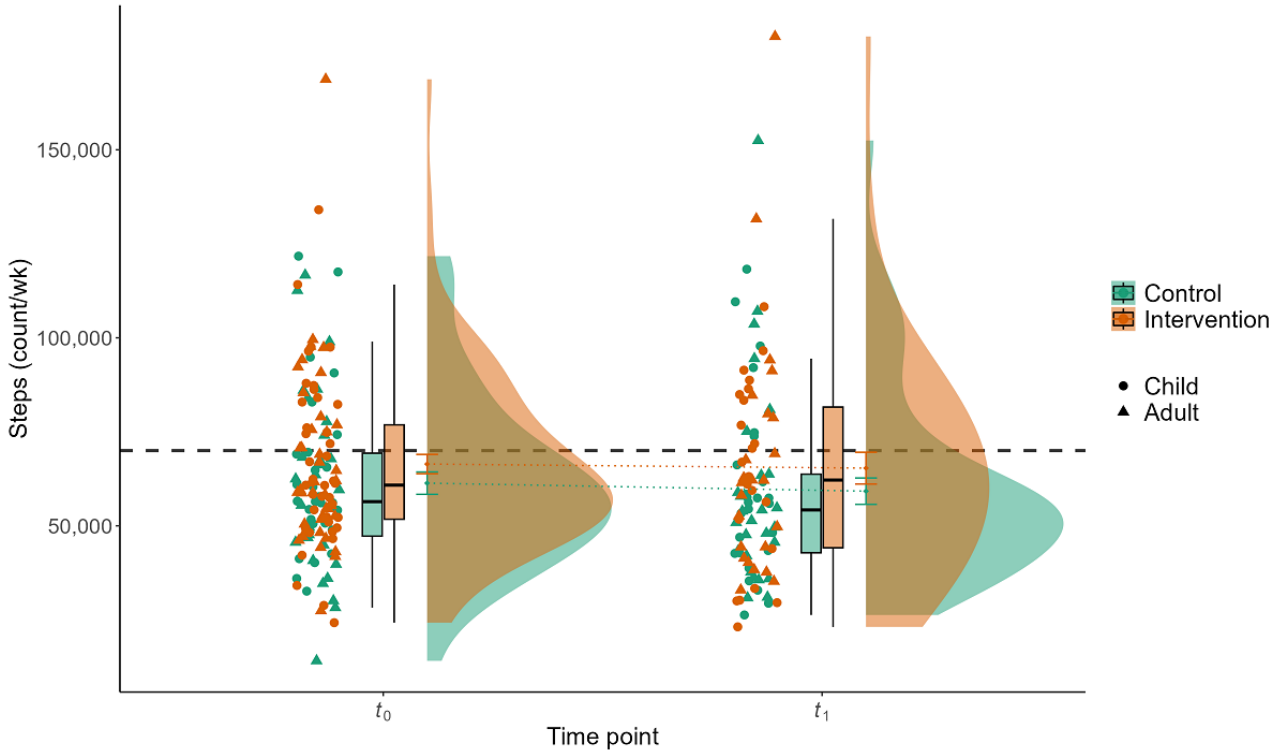
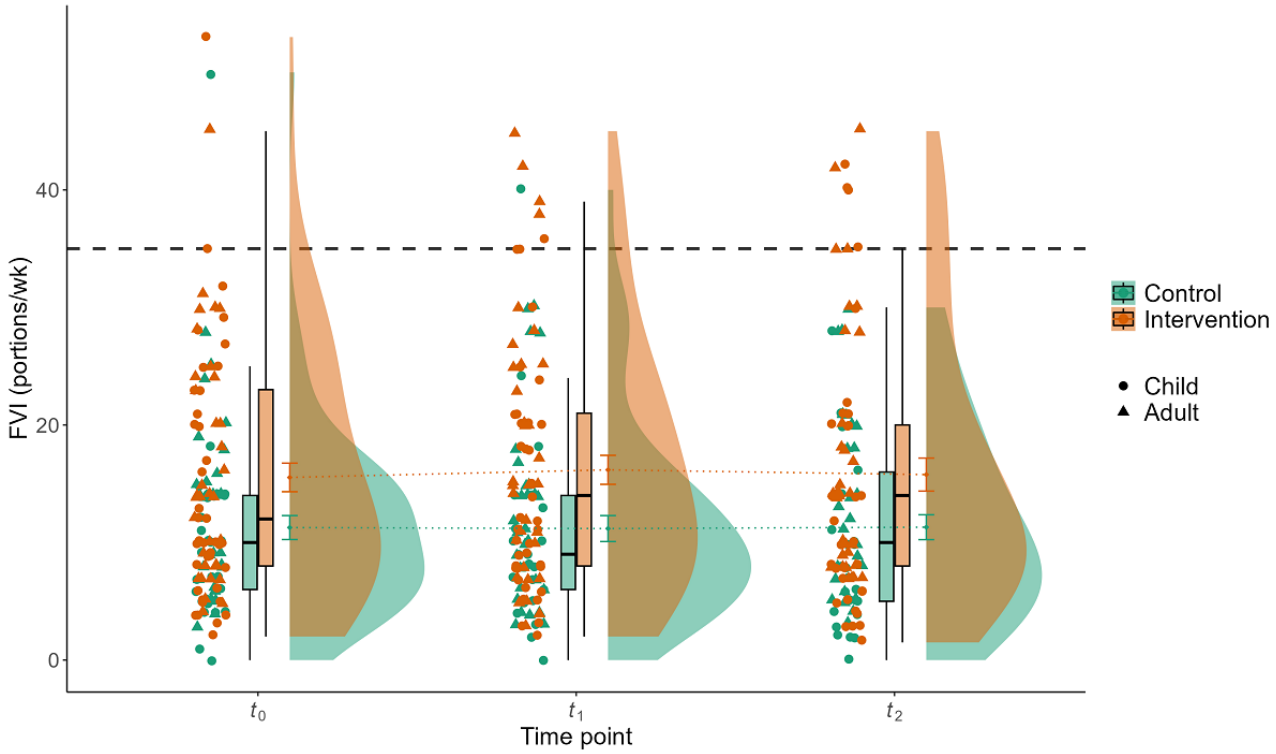


Effect of the Intervention on FVI

Results of the multilevel models indicate no significant interaction of group×time concerning FVI (Tables S5 and S6 in Multimedia Appendix 2). The only observed significant main effect was a group effect for FVI from the questionnaire (P=.049; β=.23). Figure 4 displays the descriptive results for self-reported FVI per week assessed by the questionnaire. Here, both mean and median values are clearly below the recommended FVI of 35 portions per week [92].

Figure 4. Interaction effect of group×time for the parameter fruit and vegetable intake (FVI) per week assessed by questionnaire. Displayed are the mean FVI (y-axis) of 118 participants related to the week of baseline measurement (t_0), the week of postintervention measurement after a 3-week intervention and waiting period (t_1), and the week of follow-up measurement (t_2) for the control group (green) and the intervention group (red), stratified by children and adults. The gray dashed line represents the recommendation for daily FVI of 5 portions (35 portions/wk).



Effect of the Intervention on Joint PA and Meals

Results of the linear model indicate no significant effect for group×time but a significant main effect for group (P<.001; β=.25) in joint PA. For joint meals, a significant effect for group× time (t_2) was observed (P=.04; β=.16). In addition, a significant reduction of joint meals between t_0 and t_1 was observed (P=.001; β=−.31). All results are displayed in Tables S7 and S8 in Multimedia Appendix 2.

Discussion

Principal Findings

The SF trial evaluated the effectiveness of a mHealth intervention to increase PA and HE in families. Extending previous research, the behavior of children and parents was targeted to induce individual behavior changes that are anchored in daily family life. Moreover, besides a theoretical foundation, several BCTs were included, which contribute to the fulfillment of basic psychological needs according to the SDT [53,54]. Overall, no evidence for meaningful and statistically significant increases in PA and HE levels of the intervention was observed in our physically active sample. Guidelines for weekly MVPA were highly over exceeded in this study sample. However, PA levels were sustained and did not decrease, independent of group affiliation. Intervention effectiveness will be re-evaluated in the SMART*FAMILY2.0* trial, which includes gamification features, health literacy, a just-in-time adaptive intervention, and more sophisticated app features.

PA and HE

Neither hypotheses, that PA or HE would increase as a result of the intervention, were supported by any self-reported or device-based measure. This is in line with previous digital health studies that also found heterogeneous results, with a majority of studies, however, revealing at least some significant benefit of interventions [44,56]. However, it needs to be noted that the current sample was exceedingly high in their amount of PA, which might have impacted the current null findings. Regarding PA, participants exceeded the recommended amount of 420 minutes of MVPA per week for children and adolescents by 230 minutes on average but fell short of the recommended amount of 35 portions of fruits and vegetables by 21 portions. Although the current sample can be classified as being highly active in a national and international comparison [93], they cannot be classified as equally healthy regarding their eating behavior. In a German-wide representative sample, 17% of 6- to 11-year-olds and 20% of 12- to 17-year-olds reached the recommendation on fruit consumption, 7% and 23%, respectively, for vegetable consumption [94]. Comparable studies are rare. A systematic review and meta-analysis of the efficacy of mHealth interventions to improve PA only focused on inactive participants, as the largest effects are to be expected in this group [95]. In the review [95], only 2 studies were found that implemented a stand-alone mHealth intervention. However, the results were in favor of the interventions for inactive participants. Another review found only 50% of mHealth interventions to be effective [96].

Another impacting factor in our investigation might have been that the intervention duration was rather short; however, it was

determined by the short intervals between school holidays, which were omitted within the measurement periods. Hence, the intervention was only carried out within school periods to depict "normal" days. The structured-day hypothesis postulates that health behaviors differ between structured days and school vacation times or weekends. A meta-analysis has shown that the largest effects can be expected for interventions that last over several weeks [97], which might have had a positive influence on intervention effectiveness. However, mHealth intervention studies even revealed significant behavior change effects with intervention durations of only 1 [98], 2 [99], and 3 weeks [100]. These results collectively suggest that both health behaviors should be considered separately but can be addressed together in interventions to harness their synergistic impact on health, a notion supported by other studies as well [101,102]. Although not everyone might need an intervention in both factors, few fulfill both PA and FVI guidelines.

Family-Based Interventions

Studies focusing on mHealth family-based interventions are rare, especially those including randomized controlled trials. Results for parent- and child-based digital interventions are heterogeneous regarding their reported effectivity, often combined with nondigital interventions, and focused on the behavior of the children instead of the behavior of the whole family [103,104]. A recent review pointed to the effectiveness of digital interventions for obesity prevention, including the enhancement of HE and PA in children, but only 2 of the included studies focused on mHealth interventions [105]. The first study that focused on children with obesity used an app for self-monitoring of weight and goal setting, which led to a greater reduction of weight than the standard care group after 6 months [106]. The other study aimed to improve fundamental movement skills in 3- to 6-year-old children and found an improvement in these skills after a 2-month intervention period compared to a CG [107]. Of the 7 studies included in another review [57], 2 pilot studies reported significant improvements in PA; 3 studies found evidence for some improvements in PA measures, for example, collaborative PA of children and parents; and the remaining 2 studies found no evidence for an effect. Interestingly, 1 study pointed out that the adolescent dropout rate was 12.2 times higher if their parents stopped using the app.

In this regard, analyzing family behavior and dyadic relationships will be a promising approach for future investigations. Studies suggest that family meal practices and values can support HE [108] and that the frequency of shared family meals is significantly related to nutritional health in children and adolescents [27-29]. The results of this study do not support the assumption that joint PA or joint meals (ie, some type of "quality time" within the family) impacts PA or HE behavior. However, it needs to be acknowledged that joint PA was rather low in our sample (only about 1 joint activity per wk).

In summary, the results of this study point to an urgent need to better understand intervention engagement, both quantitatively and qualitatively, to design effective interventions [109,110]. If researchers have a better idea about what works when and for whom, then mHealth interventions can be tailored more specifically and facilitate the benefit of individualization, which was found to be related to enhanced effectiveness [51]. This knowledge can be used for just-in-time adaptive interventions, which aim to support in the exact moment when support is needed and behavior change is realistic [50,111]. Overall, research on mHealth interventions for families remains limited, particularly in the realm of primary prevention. However, theoretical frameworks emphasize the significance and potential of such interventions for promoting PA and HE [56,105]. An important consideration for designing future evaluations of interventions is to additionally account for methods that go beyond pre-post follow-up designs to account for the timelines and complexity of mHealth interventions on a minute-to-minute basis. This would allow important insights for the analysis of continuous longitudinal data in ambulatory assessment studies [112]. In addition, future studies would benefit from recruiting participants with more diversity in their activity and BMI levels and from either restricting the age of children and parents more clearly or tailoring the mHealth intervention specifically to the age of participants [51] to factor the different needs, for example, while growing up [113]. It needs to be noted that already active participants are still a valid target for interventions to maintain a sufficient PA level throughout life. Future primary prevention–focused interventions should, however, clearly define a PA level–specific aim. An example would be to aim for PA maintenance in sufficiently active participants and PA increase in insufficiently active ones and to frequently evaluate PA levels to allow for early interventions. However, both strategies need different accompanying BCTs (adjusted for maintenance purposes), which should also be accounted for.

Strengths and Limitations

The main strengths of the SF intervention are as follows: it collaboratively targets the family, it is designed as a cluster randomized controlled trial, it is theory based, and it incorporates 10 different BCTs. Furthermore, the goal-setting feature in the app is ad libitum selected by the family to fit their schedule and preferences with guidance from the results of the first measurement week. This enables the families to set self-selected goals, which have been found to increase motivation and adherence [114,115]. Another strength regarding the evaluation is that multiple outcome measures of self-reported and device-measured PA were considered. This is important as these measures are known to yield different results, and including multiple measurement tools improves the plausibility of the results [68]. Finally, using advanced statistical methods to consider the nested structure of the data by applying multilevel analyses enhanced the accuracy of the results, as it considered the variance based on the clustering of participants in families.

However, some limitations must be acknowledged. The actual sample size differed from the planned size by 6 families and 8 participants, falling short of the intended 52 families and 156 participants as determined by the power analysis in the study protocol [58]. This varied from analysis to analysis owing to missing values in distinct variables. In addition, the total population of the IG and CG were not perfectly balanced, and the level of significance was not adjusted for multiple primary outcomes. However, the observed *P* values for the interactions

in this paper are not close to .05, except for the group×time point interaction for joint meals per week and joint physical activities. Therefore, the abovementioned issues have likely no large impact on the study results. Regarding our sample, family sizes and ages within families have been very diverse. However, there is a lack of knowledge about how these composite family structures influence results regarding behavior change or the accomplishment of healthy lifestyles. For example, it might be assumed that older parents might be more aware of healthy food choices, as they consider healthy nutrition as being more important for themselves than their younger counterparts [116]. Advanced paternal age is associated with an increased risk of eating disorders in children, whereas younger paternal age is associated with a decreased risk of eating disorders in children [117]. A further restriction might be the age range, especially for children and adolescents. As this study includes the whole family, children of different ages and with different needs and perceptions were addressed similarly by the app, which might have affected intervention effects. Future interventions should aim to address the individual needs of the family members and tailor the intervention more specifically to the participants. Regarding the assessment of theoretical assumptions, it would have been interesting if the included influenced the effectiveness of our intervention. This cannot be answered by this study, as we only assessed the influence of covariables on PA and not on the effectiveness. Hence, the key constructs of the SDT [53,54] might separately be assessed in future studies. Another important factor concerning the sample of this study, which could explain the lack of significant effects for PA, was probably the highly active sample with approximately 650 minutes of MVPA per week per person, which already fulfilled the guidelines of the World Health Organization for PA [118]. This is in contrast to recent research about PA guideline fulfillment, which reliably reveals only small proportions of participants fulfilling the PA recommendations, with lower amounts corresponding to increasing ages [8,119]. Hence, future interventions should either aim at recruiting inactive participants to be able to detect changes in PA or should adjust statistical analyses and intervention design for monitoring PA maintenance over time. Our sample also deviated from the general German population regarding body composition and HE behavior [94]. With BMIs between 18 and 19 in children, and between 23 and 26 in adults, our study participants were of normal weight. Studies have shown that intervention effects can be expected to be higher on participants with overweight or obesity, both for HE and PA interventions [120]. This might be a probable explanation for the absence of intervention effects (ie, there was no or only little room for improvement in our sample). An additional aspect was that the participants had to use the provided smartphones instead of their own for equality and data security reasons, which can be burdensome. However, previous research showed no differences in engagement between participants with their own smartphones versus additional smartphones [121]. If a program aims for long-term sustainability beyond a scientific scope, the use of an additional phone must be considered very carefully. Another potentially limiting factor is the comparably short duration of the intervention. On the basis of literature regarding behavior change theories (ie, the transtheoretical model) [122,123], an intervention duration of 3 weeks might not have been sufficient [44], as the largest effects are expected for interventions that last over several weeks [97] in behavioral studies. However, mHealth intervention studies even revealed significant behavior change effects with intervention durations of only 1 [98], 2 [99], and 3 weeks [100]. In a similar vein, a recent meta-analysis of mobile apps for diet showed that interventions with longer duration were not generally more effective [44].

Conclusions

Taken together, the evaluation of the SF trial expands the existing body of evidence as it investigated the influence of a theory-based mHealth intervention targeting PA and HE in a collective family–based setting. However, no significant evidence for the effectiveness of the trial has been found. This finding, however, is not unique to mHealth interventions [56] and might be attributable to an initially active sample with a normal BMI. Therefore, future evaluations of interventions should also (1) consider methods that go beyond pre-post follow-up designs to account for the timeliness and complexity of mHealth interventions, (2) consider recruiting participants of all activity and weight levels, and (3) control for or restrict ages of children and parents.

Abstract

Background: Reproductive health literacy and menstrual health awareness play a crucial role in ensuring the health and well-being of women and people who menstruate. Further, awareness of one's own menstrual cycle patterns and associated symptoms can help individuals identify and manage conditions of the menstrual cycle such as premenstrual syndrome (PMS) and premenstrual dysphoric disorder (PMDD). Digital health products, and specifically menstrual health apps, have the potential to effect positive change due to their scalability and ease of access.

Objective: The primary aim of this study was to measure the efficacy of a menstrual and reproductive health app, Flo, in improving health literacy and health and well-being outcomes in menstruating individuals with and without PMS and PMDD. Further, we explored the possibility that the use of the Flo app could positively influence feelings around reproductive health management and communication about health, menstrual cycle stigma, unplanned pregnancies, quality of life, work productivity, absenteeism, and body image.

Methods: We conducted 2 pilot, 3-month, unblinded, 2-armed, remote randomized controlled trials on the effects of using the Flo app in a sample of US-based (1) individuals who track their cycles (n=321) or (2) individuals who track their cycles and are affected by PMS or PMDD (n=117).

Results: The findings revealed significant improvements at the end of the study period compared to baseline for our primary outcomes of health literacy (cycle tracking: D^{-}=1.11; t_{311}=5.73, P<.001; PMS or PMDD: D^{-}=1.20; t_{115}=3.76, P<.001) and menstrual health awareness (D^{-}=3.97; t_{311}=7.71, P<.001), health and well-being (D^{-}=3.44; t_{311}=5.94, P<.001), and PMS or PMDD symptoms burden (D^{-}=–7.08; t_{115}=–5.44, P<.001). Improvements were also observed for our secondary outcomes of feelings of control and management over health (D^{-}=1.01; t_{311}=5.08, P<.001), communication about health (D^{-}=0.93; t_{311}=2.41, P=.002), menstrual cycle stigma (D^{-}=–0.61; t_{311}=–2.73, P=.007), and fear of unplanned pregnancies (D^{-}=–0.22; t_{311}=–2.11, P=.04) for

those who track their cycles, as well as absenteeism from work and education due to PMS or PMDD (D^{-}=–1.67; t_{144}=–2.49, P=.01).

Conclusions: These pilot randomized controlled trials demonstrate that the use of the Flo app improves menstrual health literacy and awareness, general health and well-being, and PMS or PMDD symptom burden. Considering the widespread use and affordability of the Flo app, these findings show promise for filling important gaps in current health care provisioning such as improving menstrual knowledge and health.

Introduction

Many women of childbearing age lack foundational knowledge about their menstrual cycle despite it being a vital indicator of women's health [1]. Nearly half of all women are unaware of the average length of a regular menstrual cycle and around 40% are unfamiliar with the ovulatory cycle [1,2]. Poor knowledge about menstrual health can hinder women's ability to make informed decisions about their health [3], negatively impact their daily sociocultural activities [4-6], and contribute to misconceptions and taboos that compromise their overall physical and mental well-being [7,8]. For example, a recent systematic review found that poor knowledge regarding menstrual health may lead to negative experiences such as shame and the lack of confidence to engage in social activities, ultimately increasing mental burden [9]. Further, low menstrual literacy has been associated with inadequate self-care behaviors [10] and reduced satisfaction with medical visits, attributed to ineffective communication between patients and health care providers [11]. This is further evidenced by the results of the UK Women's Health Strategy Survey, where as many as 1 in 4 women reported not feeling comfortable talking to health care professionals about their menstrual cycle [12]. Interventions aimed at improving menstrual cycle knowledge are therefore likely to be associated with improvements in a wide range of domains relevant to women's physical and mental health.

A good example of where improved menstrual and reproductive health literacy may have beneficial outcomes is in the case of premenstrual syndrome (PMS) and premenstrual dysphoric disorder (PMDD). PMS and PMDD, a more severe form of PMS, are common, with a worldwide prevalence of 48% for PMS [13,14] and 3% to 8% for PMDD [14]. Affected individuals report a broad range of psychological and physical symptoms occurring in the luteal phase of the menstrual cycle, which can cause social or economic dysfunction and affective and functional impairment [15,16]. Severe PMS symptoms are associated with poorer ratings of quality of life and higher levels of stress [14,17,18]. Similarly, the health burden of PMDD has been deemed greater than type 2 diabetes and hypertension in terms of reported pain [14,18]. Both PMS and PMDD have a proven negative impact on workplace productivity and in some cases even lead to absenteeism [19,20]. Despite this heavy burden on individuals and society, these conditions are often poorly treated and overlooked in research. Evidence suggests that the symptoms of PMS and PMDD may be dismissed by health care professionals, and even by the affected women themselves, who might consider them as a normal part of the menstrual cycle [21,22], highlighting how poor health literacy can result in delays in seeking care for reproductive health conditions [1,23,24].

While there is a notable lack of research into topics related to women's health [25], there is an acute shortage of research that validates the effectiveness of educational interventions for menstrual health literacy. Most studies have relatively small sample sizes or focus on limited populations or age ranges [26,27]. Digital, internet, and mobile-based health technologies can provide novel ways to deliver interventions for menstrual health and have gained popularity due to their scalability, availability, and anonymity [28,29], with the latter being crucial for menstrual and mental health [30-35]. Health apps focusing on menstrual and reproductive health can help individuals feel more prepared for their menstrual cycle symptoms, be more aware of their body signals throughout the cycle, and be better able to manage associated symptoms [36]. Additionally, evidence suggests that self-guided interventions using mobile phones can successfully equip individuals experiencing PMS and PMDD with strategies to promote and maintain healthy behavior, improve PMS symptoms, and reduce their interference with everyday life activities [37,38]. Although preliminary studies show promising results, research on the efficacy of such health solutions remains limited.

The Flo smartphone app [39] (Flo Health) is a period tracking and reproductive health app. It provides personalized menstruation and ovulation predictions, symptom forecasts based on user input, and expert-reviewed content accessible via the library or the health assistant (chatbot). The users of the Flo app also interact anonymously on a community platform called "Secret Chats," which facilitates conversations on stigmatized topics such as sexual and menstrual health [29,30,33].

The primary objective of these 2 pilot randomized controlled trials (RCTs) was to measure the efficacy of the Flo app in improving menstrual-related health literacy and awareness and well-being outcomes in (1) individuals who reported an interest

in using the app to track their cycles and symptoms (trial 1) or (2) individuals who reported an interest in using the app to track their cycles and symptoms and reported being affected by symptoms of conditions of the menstrual cycle such as PMS and PMDD (trial 2). The secondary objective was to investigate the effect of app use in these populations on overall feelings of health management, communication about health (eg, with health care providers or with their partner), menstrual cycle stigma, fear of unplanned pregnancies, quality of life, productivity at work, absenteeism, and body image. For trial 1, we hypothesized that the use of the Flo app would significantly improve menstrual-related health literacy and awareness and general health and well-being outcomes in the interventional group compared to the waitlist control group; for trial 2, we hypothesized that PMS- or PMDD-related health literacy and PMS or PMDD symptom burden would significantly decrease in the interventional group compared to the waitlist control group. We also hypothesized that all secondary outcomes would either significantly improve (feelings of health management, communication about health with health care providers or with a partner, quality of life, productivity at work, and body image) or decrease (menstrual cycle stigma, fear of unplanned pregnancies, and absenteeism from work or school due to PMS or PMDD symptoms) compared to the waitlist control group.

Methods

Study Design

We intended to conduct 2 fully powered, 3-month, unblinded, 2-armed RCTs, with a between-subjects component (group: intervention or control) and a within-subjects component (time point; see Multimedia Appendix 1 for the CONSORT [Consolidated Standards of Reporting Trials] checklist).

Trial 1 aimed to investigate the efficacy of the Flo app in improving health literacy and health and well-being outcomes in participants who report their current reproductive health aim as (1) cycle tracking, (2) trying to conceive (TTC), or (3) pregnancy tracking. Trial 2 aimed to investigate the efficacy of the Flo app in improving health literacy and PMS and PMDD symptom burden outcomes in participants who report moderate-to-severe PMS or PMDD symptoms. Trials 1 and 2 have been registered on the Open Science Framework [40,41].

Due to recruitment issues in trial 1, very low numbers of eligible participants were recruited in the pregnancy tracking group, and an extremely low number of participants completed the study in the TTC group. We therefore deviated from the preregistered study design by excluding these groups from the further analyses and focused only on the cycle tracking group. Additionally, as both trials had relatively low numbers of study participants who followed the study protocol, we converted our trials into feasibility pilots to inform further full RCTs with improved recruitment strategies. All questionnaire measures were self-reported through a web-based questionnaire platform (Survey Monkey).

Ethical Considerations

Trials 1 and 2 were approved by an independent ethical review board (WCG IRB, ethics applications 20222535 and 20222597, respectively), using protocols specific to each population. All participants provided informed, electronic consent via a checkbox prior to their enrollment in the study, and data were deidentified. Participants who fully completed all data collection activities received a free yearly subscription to Flo Premium (US $39.99) and were entered into a lottery to win up to US $600 in Amazon Vouchers. This study was funded by Flo Health UK LTD. The authors assert that all procedures contributing to this work comply with the ethical standards of the relevant national and institutional committees on human experimentation and with the Helsinki Declaration of 1975, as revised in 2008.

Recruitment

For both trials, computer and internet-literate participants were recruited using participant pools (SurveySwap, PureSpectrum, and Prolific) as well as via social media and mailing lists. Recruitment took place between July and December 2022, and potential participants were screened for eligibility via screening SurveyMonkey surveys (screening stage). It may have been possible for the same participant to respond under different email addresses, but these addresses would also need to be registered to the Flo app.

Inclusion criteria for trial-1 participants included being aged 18-40 years, being a US resident, being fluent in English, not being a current or former user of Flo app, having a cycle tracking health goal, scoring less than 80% on the cycle tracking health literacy quiz (see the *Measures* section), and scoring less than 80% on the general health and well-being survey (see the *Measures* section). Participants were excluded from trial 1 if they were currently using any form of hormonal contraception (eg, pill, injection, implant, and hormonal coil) as these would influence or stop their natural menstrual cycle. Participants in trial 1 were additionally excluded if they became pregnant during the study period.

Participants were included in trial 2 if they were older than 18 years, scored at least moderate on the Premenstrual Screening Tool (PSST) [42] (see the *Measures* section), scored less than 80% on the PMS or PMDD health literacy quiz (see the *Measures* section), and had never used Flo before. Further, participants were excluded from trial 2 if they were currently taking antidepressants or were currently or had previously received psychiatric treatment or had been diagnosed with a psychiatric disorder other than PMDD at the time of recruitment.

Participants were excluded from any trial if they had their last period more than 90 days prior or were pregnant at the time of recruitment.

Randomization and Blinding

If participants met inclusion criteria at the screening stage, they were then randomized by minimization using a Python script based on the following factors: cycle tracking or PMS or PMDD health literacy quiz scores, age, yearly household income in US $, highest level of education completed, race or ethnicity, and reproductive health disorders (Multimedia Appendix 2). Trial-1 participants were additionally minimized on general health and well-being scores, along with the number of children and number of pregnancies that did not result in a live birth, to control for differences in health literacy and awareness that

might result from previous experience of conception and pregnancy. Trial-2 participants were additionally minimized on PSST score and current day of cycle, to attempt to control for differences in PMS or PMDD symptom burden due to the menstrual cycle phase.

Participants were either allocated to the trial-specific intervention condition and instructed to use the Flo Premium app for 12 weeks (trial 1) and 3 months (trial 2) or to the waitlist control condition, which received the intervention at the end of the study. An example of the Flo app user interface is shown in Figure 1.

Figure 1. Example of the Flo user interface including the main screen, tiles linking to educational content, cycle day information, and the symptom logging interface.

Intervention Groups

Both trial participants were provided with detailed tutorials via email on how to use the Flo app and instructed to interact freely with the app for the whole duration of the study. All participants were provided with the premium version of the app for 1 year. In comparison to the free offering, premium app users have access to the full range of in-app educational content, all symptom- and cycle-related chatbots, as well as all community features.

Waitlist Control Groups

Participants who were randomized into the control group were not provided with access to the Flo app during the study period and were instructed not to use the Flo app in any form for the duration of the study. At the end of the study, control participants were provided with the premium version of the app for 1 year.

Measures

Demographics

Demographic information for both trials was collected using a demographic questionnaire, which asked about previous Flo use, US residency, age, race or ethnicity, household income and composition, education, gender identity, reproductive health, contraception use, and timing of last period (Multimedia Appendix 3). Trial-1 participants were additionally asked about English proficiency, parity, prior pregnancy outcomes, and reproductive health goals (cycle tracking, TTC, or pregnancy). Trial-2 participants were additionally asked about employment, present pregnancy status, use of antidepressants, diagnosis of a psychiatric disorder, past or present receival of any treatment for a psychiatric disorder, and perimenopause or menopause symptoms.

Primary Outcomes

Menstrual and PMS- or PMDD-Related Health Literacy

Menstrual-related health literacy was examined in trial-1 participants using a set of 12 questions regarding general knowledge about the menstrual cycle, such as typical bleeding length, how the length of the menstrual cycle is calculated, and how menstrual symptoms such as pain can be relieved (Multimedia Appendix 4). Knowledge about PMS or PMDD in trial-2 participants was measured through a set of questions investigating PMS and PMDD incidence, symptoms, and methods that can be used to help manage symptoms (Multimedia Appendix 5). The questions used were developed internally by Flo, using input from Flo Health's medical advisors.

Self-Reported Menstrual Health Awareness

Menstrual health awareness was only examined in the trial-1 participants using 7 questions selected from the 33-item Health Literacy Instrument for Adults [43] and modified to be specifically relevant to cycle tracking (Multimedia Appendix 6).

Self-Reported General Health and Well-Being

The trial-1 participants answered a set of 14 questions, selected both from domain 2 of the World Health Organization Quality of Life Brief Survey [44] and designed internally by Flo, using input from Flo Health's medical advisors. These questions assessed self-reported physical, mood, and menstrual symptoms experienced over the previous 3 months, as well as satisfaction with overall health, sex life, personal relationships, and support from friends (Multimedia Appendix 7).

PMS and PMDD Symptom Burden

PMS and PMDD symptom burden and the extent to which PMS or PMDD symptoms interfere with daily life were only assessed in trial-2 participants using the PSST [42] (Multimedia Appendix 8).

Secondary Outcomes

Overview

Feelings of control and management over health, communication and emotional well-being, menstrual cycle stigma (Menstrual Attitude Questionnaire [45]), fear of unplanned pregnancy, and body image and appreciation (Body Appreciation Scale-2) [46] were assessed (Multimedia Appendix 9) in trial-1 participants. Absenteeism due to PMS or PMDD symptoms, work productivity using the Stanford Presenteeism Scale-6 [47], and quality of life and satisfaction using the Quality of Life Enjoyment Satisfaction Questionnaire [48] were additionally assessed in trial-2 participants (Multimedia Appendix 10).

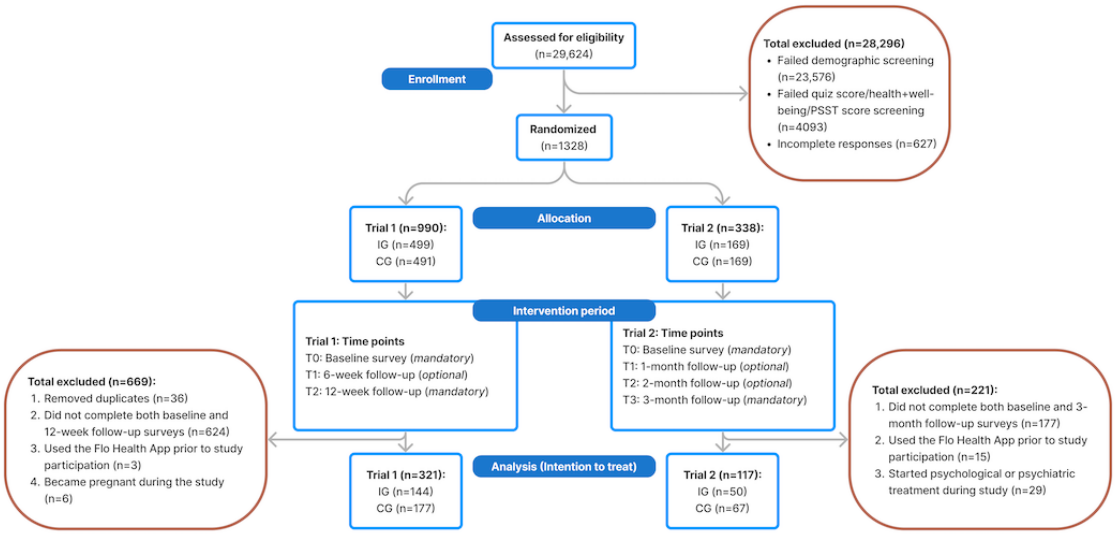
App Engagement

Data on app use by the intervention groups were also calculated, including the mean total number of sessions (log-ins), the mean length of sessions in seconds, and the mean number of days of app use (active days).

Data Collection Time Points

Trial-1 (cycle tracking) participants responded to questionnaires at 3 time points: screening or baseline, 6 weeks after baseline, and 12 weeks after baseline (Figure 2). The screening survey included demographic information, menstrual health literacy, and general health and well-being questions. The baseline and 6-week surveys included menstrual health awareness and all cycle tracking secondary outcome measures. The 12-week survey included the menstrual health literacy, general health and well-being questions, and all cycle tracking secondary outcome measures.

Figure 2. Participant flow diagram through trial 1 (cycle tracking) and trial 2 (premenstrual syndrome or premenstrual dysphoric disorder) intention-to-treat analysis. IG: intervention group; CG: control group; PSST: Premenstrual Screening Tool.



Trial-2 (PMS or PMDD) participants responded to survey questions at screening or baseline, 1 month after baseline, 2 months after baseline, and 3 months after baseline (Figure 2). The screening questionnaire included demographic information and primary outcomes. The baseline survey included all secondary outcome measures, while the month-1 and month-2 questionnaires included PMS or PMDD symptom burden, as well as all secondary outcome measures. The month-3

questionnaire included all primary and secondary outcome measures.

The difference in data collection time points between trials 1 and 2 was due to the need to measure PMS or PMDD symptoms monthly in trial 2.

Statistical Analyses

Data Exclusion

Any participant who did not meet the inclusion criteria based on responses from the screening survey was excluded from the study. To reduce the effect of bias due to noncompliance, we aimed to conduct an intention-to-treat (ITT) analysis and a per-protocol (PP) analysis. In the ITT analysis, participants were analyzed according to the group (intervention or control) they were randomized to, as long as the inclusion criteria were met and the screening, baseline, and final surveys were completed. In the PP analysis, all participants who completed all data collection waves and used the app at least once a month throughout the study duration were included.

Data Analysis

Main analysis of all outcomes was conducted using a Mixed Models for Repeated Measures (MMRM) approach. Models were constructed using an unstructured correlation where the outcome of interest was predicted by time point and condition status, including the interaction between time point and condition. Age, highest education level completed, and household income were included as fixed effects. Individual ID and time point were included as random effects. Preplanned pairwise contrasts between baseline outcome scores and final time point scores were used to assess change in outcome scores.

All data analyses were conducted using statistical and data science packages in R (version 4.3.0l R Foundation for Statistical Computing) [49] running on Mac OS X 13.3.1. Packages used included *arsenal* version 3.6.3 [50], *emmeans* version 1.8.6 [51], *ggpubr* version 0.6.0 [52], *gtools* version 3.9.4 [53], *gtsummary* version 1.7.1 [54], *longpower* version 1.0.24 [55-60], *mmrm* version 0.2.2 [61], *patchwork* version 1.1.2 [62], and *tidyverse* version 2.0.0 [63].

Power

Using MMRM analysis with 4 data collection waves as is the case in the PMS or PMDD group, an attrition rate of 10% per wave, and a SD of the outcome of interest of 2.5 points, the minimum sample size required to detect a change in score of 1 point with 80% power would be 126 participants in each group. Using 3 data collection waves as in the cycle tracking group, 115 participants assigned to each condition would be required. Due to difficulties in recruiting samples to meet these target group sizes, we converted both trials from full RCTs to feasibility pilot trials.

Results

Baseline Sample Characteristics

A total of 438 participants (194 intervention and 244 control) were included in the ITT sample, of which 321 were included in trial 1 (cycle tracking; 144 intervention and 177 control) and 117 were included in trial 2 (PMS or PMDD; 50 intervention and 67 control; Figure 2). The PP sample was comprised of 233 participants (43 intervention and 190 control), of which 174 were included from trial 1 (17 intervention and 157 control) and 59 were included from trial 2 (26 intervention and 33 control; Multimedia Appendix 11). Due to a low number of participants completing all protocol steps, and therefore being eligible for the PP analysis, we present the results and interpretation of the ITT analysis in the main text and avoid interpretation of our underpowered PP results. However, the results of the PP analyses can be found in Multimedia Appendices 8-17.

In the ITT trial-1 and trial-2 samples, we found no differences in demographic characteristics (including age, income, education, or race or ethnicity). At baseline, PMS- or PMDD-related health literacy scores were higher in the intervention group in trial 2. No other primary outcome measures differed between groups in either trial at baseline (Table 1). Demographic and baseline measures for the PP analyses are presented in Multimedia Appendix 12.

Participants in the ITT trial-1 intervention group had a mean session length of 234.45 (SD 181.98) seconds, a mean total number of sessions of 29.94 (SD 20.94), and a mean number of active days of 15.44 (SD 10.95). Participants in the ITT trial-2 intervention group had a mean session length of 146.98 (SD 122.85) seconds, a mean total number of sessions of 70.35 (SD 55.63), and a mean number of active days of 36.08 (SD 24.50). App engagement statistics for the PP sample are shown in Multimedia Appendix 13.

The mean time between completing the screening and baseline surveys was 8.56 (SD 9.86) days in the ITT trial 1 analysis and 9.45 (SD 9.18) days in the ITT trial 2 analysis.

Primary Outcomes

Menstrual Health Literacy (Trial 1)

Our MMRM analysis in the ITT trial-1 sample revealed significant main effects of time point (β=.523; *P*=.003) and highest education level (β=.488; *P*=.001) on menstrual health literacy, such that menstrual health literacy scores were higher postintervention and in individuals with higher levels of education (Table S1 in Multimedia Appendix 14). We found a significant group by time point interaction (β=.585; *P*=.02), such that greater improvement in menstrual health literacy was observed in the intervention group compared to the control group, with an estimated mean improvement between prescreen and the end of the intervention of 1.1 (SE 0.193) points in the intervention group and to 0.52 (SE 0.173) in the control group (Figure 3A; Table 2). There were no significant associations between menstrual health literacy scores and age group or household income. Similar improvements in estimated mean health literacy scores were seen in the PP analysis (Multimedia Appendix 15).

Figure 3. Estimated mean health literacy scores and 95% CIs from Mixed Models for Repeated Measures analysis at screening and end of intervention for the (A) intention-to-treat trial 1 (cycle tracking) and (B) intention-to-treat trial 2 (PMS or PMDD). PMDD: premenstrual dysphoric disorder; PMS: premenstrual syndrome.

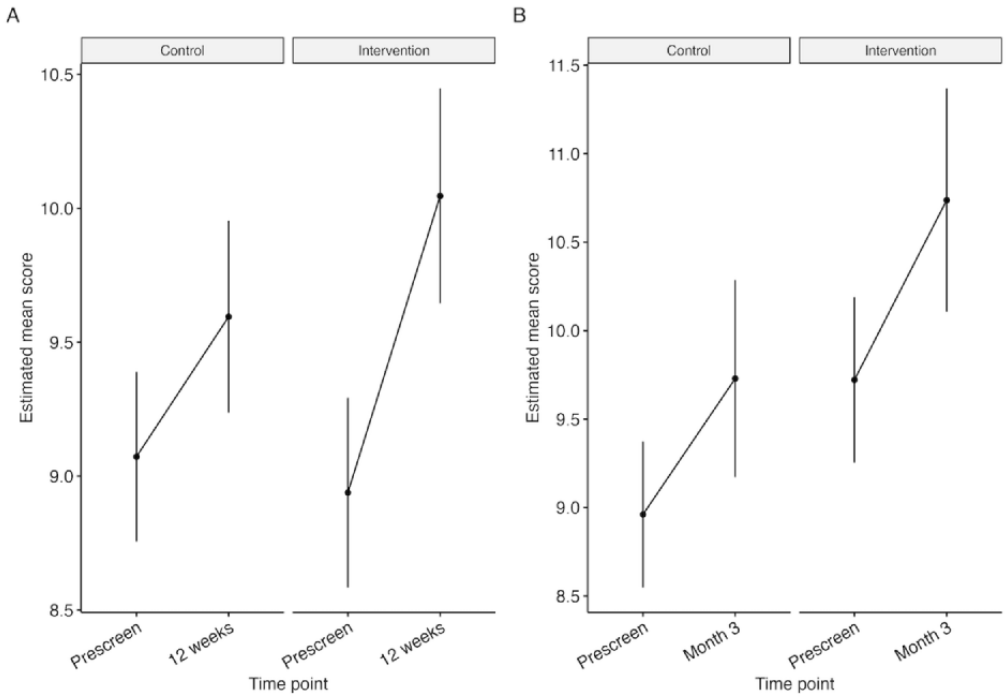

Table 2. Estimated mean differences in Menstrual Health literacy in the ITT[a] trial-1 analysis (cycle tracking) and PMS[b] or PMDD[c] health literacy scores in the ITT trial-2 analysis (PMS or PMDD) between baseline and the end of the intervention.

Trial	Control or intervention	Estimated mean difference (SE)	*T* ratio (*df*)	*P* value
Trial 1 (cycle tracking)	Control	0.523 (0.173)	3.026 (311)	.003
Trial 1 (cycle tracking)	Intervention	1.108 (0.193)	5.729 (311)	<.001
Trial 2 (PMS or PMDD)	Control	0.642 (0.276)	2.327 (115)	.02
Trial 2 (PMS or PMDD)	Intervention	1.200 (0.319)	3.758 (115)	<.001

[a]ITT: intention-to-treat.

[b]PMS: premenstrual syndrome.

[c]PMDD: premenstrual dysphoric disorder.

PMS- or PMDD-Related Health Literacy (Trial 2)

Estimated mean PMS or PMDD health literacy score also improved in both the ITT trial-2 intervention and control groups between baseline and end of intervention (Figure 3B; Table 2). We observed significant main effects of the highest education level (β=.430; *P*=.04), condition (β=.819; *P*=.03), and time point (β=.642; *P*=.02; Table S2 in Multimedia Appendix 14). Individuals with higher education had higher average health literacy scores, participants in the intervention group had higher average health literacy scores than controls at both time points, and health literacy scores increased after the intervention in both groups. No association between household income or age group and PMS or PMDD health literacy score was found. Estimated mean health literacy scores increased by 1.2 (SE 0.319) points in the intervention group compared to 0.64 (SE 0.276) in the control group (Table 2). Similar improvements were found in the PP analysis (Multimedia Appendix 15).

Self-Reported Menstrual Health Awareness (Trial 1)

In the ITT trial-1 analysis, we observed significant associations between menstrual health awareness and age group (β=1.053; *P*=.03) and time point (β=1.845; *P*<.001; Table S3 in Multimedia Appendix 14), where individuals in the older age groups had higher menstrual health awareness scores, and menstrual health awareness scores were higher after the intervention. We also found a significant interaction between treatment group and time point (β=2.126; *P*=.002), indicating that individuals in the intervention group had a greater improvement in menstrual health awareness scores (Figure 4). No association was found between highest education level, household income or treatment group, and menstrual health awareness scores. Estimated mean scores increased by around 4 (SE 0.515) points in the intervention group, as compared to 1.8 (SE 0.461) points in the control group (Table 3). Similar improvements in menstrual health awareness were observed in the PP analysis (Multimedia Appendix 15).

Figure 4. Estimated mean self-reported menstrual health awareness scores and 95% CIs from ITT MMRM analysis at baseline and 12 weeks after baseline for trial 1 (cycle tracking).

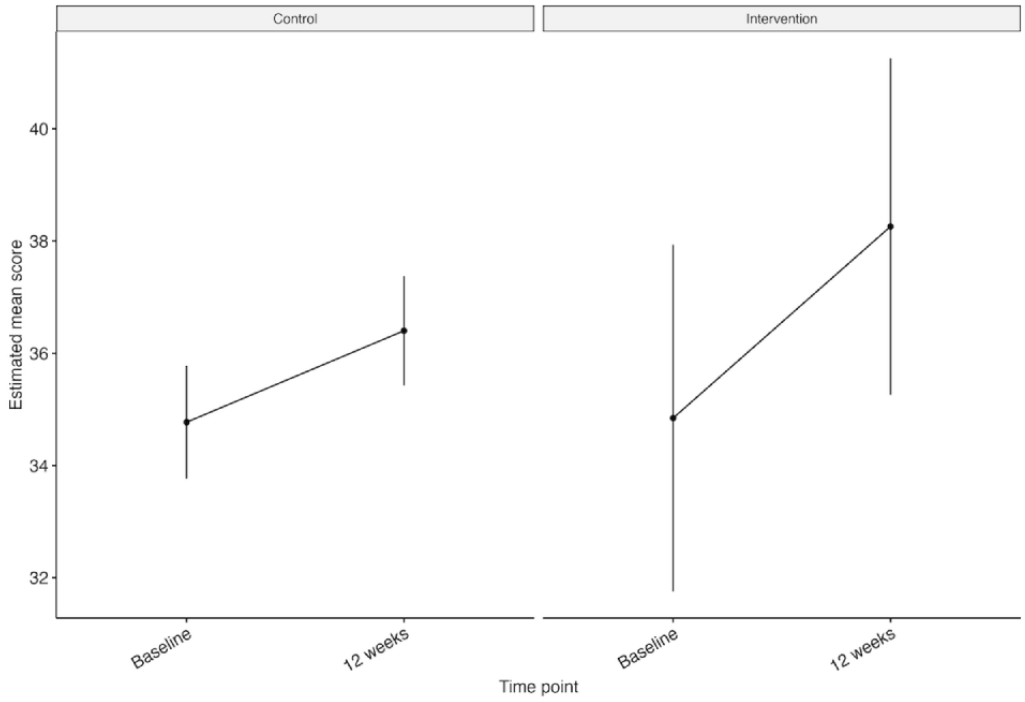

Table 3. Estimated mean differences in menstrual health awareness from trial 1 (cycle tracking).

Control or intervention	Estimated mean difference (SE)	*T* ratio (*df*=311)	*P* value
Control	1.845 (0.461)	4.005	<.001
Intervention	3.971 (0.515)	7.706	<.001

Self-Reported General Health and Well-Being (Trial 1)

Our ITT MMRM analysis revealed significant associations between household income and general health and well-being scores (β=1.444; *P*<.001; Table S4 in Multimedia Appendix 14), with individuals with higher income having better health and well-being scores. We found significant interactions between the treatment group and the 6-week time point (β=1.618; *P*=.03) and treatment group and 12-week time point (β=2.674; *P*=.001), indicating at both time points that individuals in the intervention group had greater improvement in health and well-being scores than in the control group. No association was found between age group, treatment group, or 6- and 12-week time points, and health and well-being scores. Estimated mean health and well-being scores improved by 3.44 (SE 0.579) points in the intervention group as compared to 0.76 (SE 0.517) points in the control group, with a significant improvement in estimated mean health and well-being scores between screening and the end of intervention observed in the intervention group alone (Figure 5; Table 4). Improvements in health and well-being scores were found in the intervention condition only in the PP analysis (Multimedia Appendix 15).

Figure 5. Estimated mean general health and well-being scores and 95% CIs from intention-to-treat Mixed Models for Repeated Measures approach analysis at screening, 6 weeks, and 12 weeks after baseline for trial 1 (cycle tracking).

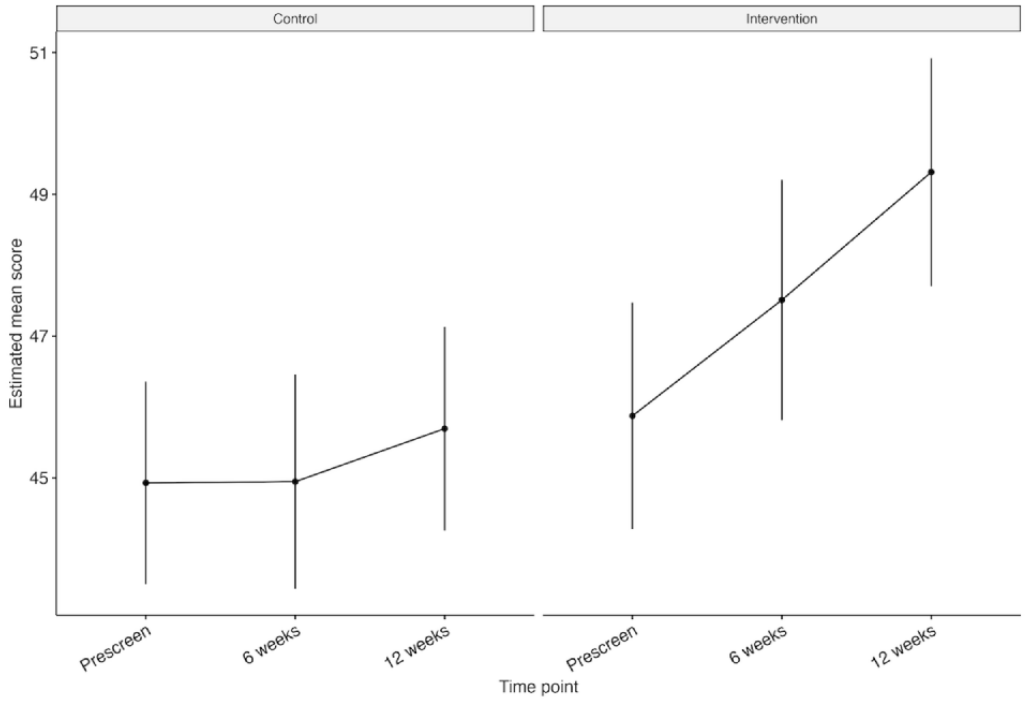

Table 4. Estimated mean differences in general health and well-being scores between screening and 12 weeks after baseline for the ITT[a] trial-1 (cycle tracking) analysis.

Control or intervention	Estimated mean difference (SE)	*T* ratio (*df*=311)	*P* value
Control	0.764 (0.517)	1.478	.14
Intervention	3.439 (0.579)	5.944	<.001

[a]ITT: intention-to-treat.

PMS or PMDD Symptom Burden (Trial 2)

We found significant main effects of group (β=4.094; *P*=.014), month-1 time point (β=–4.246; *P*<.001), month-2 time point (β=–5.133; *P*<.001), and month-3 time point (β=–5.239; *P*<.001; Table S5 in Multimedia Appendix 14). There were no significant interactions, and no associations were found between age group, highest education, household income, or treatment group with PMS or PMDD symptom burden. Estimated mean PSST scores improved by 7.1 (SE 1.300) points in the intervention group as compared to 5.2 (SE 1.123) points in the control group (Figure 6; Table 5). PMS or PMDD symptom burden also improved in both groups in the PP analysis (Multimedia Appendix 15).

Figure 6. Intention-to-treat Mixed Models for Repeated Measures estimated mean Premenstrual Screening Tool scores at each timepoint for intention-to-treat trial 2 (premenstrual syndrome or premenstrual syndrome).

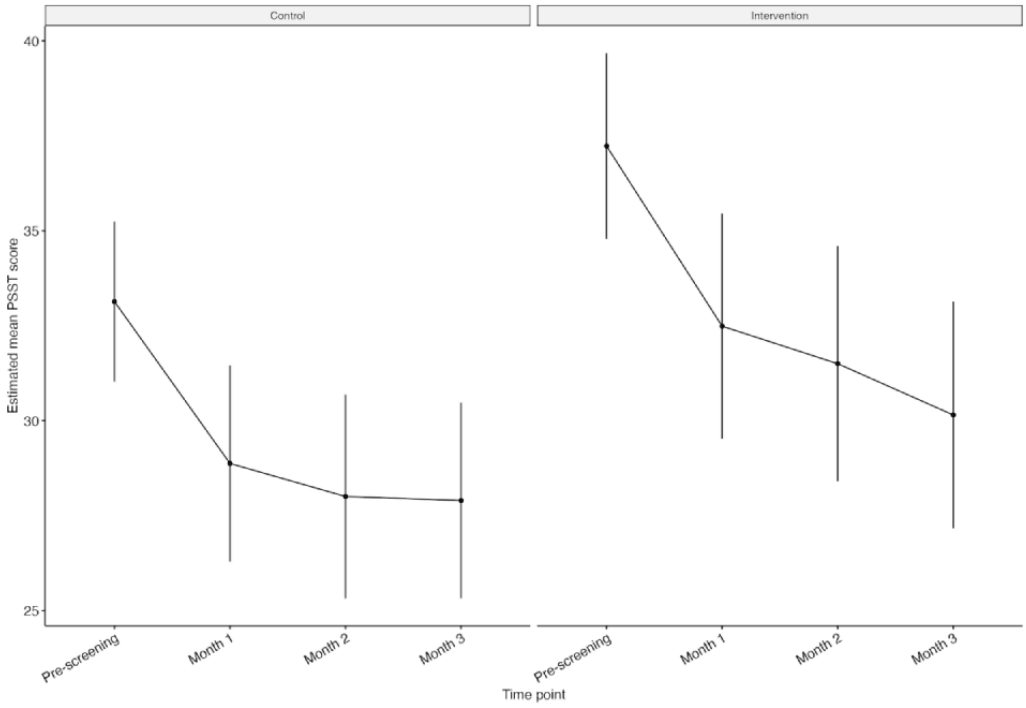

Table 5. Estimated mean differences in PSST[a] score between screening and month 3 for the ITT[b] trial-2 (PMS or PMDD) analysis.

Condition	Estimated mean difference (SE)	*T* ratio (*df*=115)	*P* value
Control	–5.239 (1.123)	–4.663	<.001
Intervention	–7.080 (1.300)	–5.444	<.001

[a]PSST: Premenstrual Screening Tool.

[b]ITT: intention-to-treat.

Secondary Outcomes

In trial 1, we observed improvements in many of our secondary outcomes after 12 weeks of using Flo in our ITT analyses. Communication and emotional score improved only in the intervention group by 0.93 points (*P*=.02). Similarly, the ratings of menstrual cycle stigma and fear of unplanned pregnancy improved by 0.61 points (*P*=.01) and 0.22 points (*P*=.04), respectively, in the intervention group only. Finally, the score of feeling of control and management of health improved in both the intervention and control groups after using Flo for 12 weeks by 1.00 (*P*<.001) and 0.45 points (*P*=.01), respectively. However, we saw no improvement in body image scores in either the intervention or control groups.

In the trial-2 ITT analysis, we observed improvements in absenteeism due to PMS or PMDD symptoms, with participants in the intervention group taking fewer absent days from work or education (estimated mean difference=–1.67, SE 0.319; *P*=.04), while no improvement was seen in the control group. We also saw no improvement in quality of life or work productivity scores in either of the trial-2 intervention or control groups.

Full ITT analysis results for trial-1 and trial-2 secondary outcomes are presented in Multimedia Appendix 16, while full PP results are presented in Multimedia Appendix 17.

Discussion

Principal Findings

In this study, we present the findings of 2 pilot, 2-armed RCTs on the effect of using the Flo app in (1) individuals who track their cycles and (2) individuals who track their cycles and are affected by PMS or PMDD. Our ITT analysis demonstrated improvements postintervention in all primary outcomes, namely health literacy and awareness, health and well-being, and PMS or PMDD symptom burden. As for secondary outcomes, positive effects were observed for control and management over health, communication about health, menstrual cycle stigma, and fear of unplanned pregnancies for those who track their cycles as well as absenteeism for PMS or PMDD. Quality of life, body image, and workplace productivity did not show improvement.

Comparison With Prior Work

The primary hypothesis of this study was that using the Flo app would increase health literacy and awareness around menstrual and reproductive health. We found that menstrual (trial 1) and PMS or PMDD (trial 2) health literacy scores as well as

menstrual health awareness (trial 1) significantly improved in both intervention and control groups, albeit with larger improvements in the intervention groups.

These results are consistent with preliminary observational data, which find that the Flo app can help women and people who menstruate feel more prepared throughout their menstrual cycles, helping them understand their bodies and symptoms [36,64]. These results are also consistent with previous research finding that psychoeducational and information-based interventions can improve health literacy around PMS and PMDD [37,38] and symptom scores in PMS [65]. Low health literacy has a negative impact on both individuals and health care systems alike. Poor health literacy has been associated with poorer well-being [66] and self-care [67] while contributing to higher health care costs [68], resulting from underuse of preventive services [69]. Further, the lack of knowledge and low symptom awareness often lead to delays in seeking care [70], leading to worse health outcomes. Thus, easily accessible tools addressing reproductive and menstrual health literacy have the potential to fill in the gaps in current provisioning.

Health and well-being scores (measured via a shorter version of the World Health Organization Quality of Life Brief Survey) improved in the trial-1 cycle tracking intervention group but not in the control group. PMS or PMDD symptom severity ratings (indicated by a drop in PSST scores at the final time point compared to baseline) improved in both the control and intervention groups, with a larger improvement in the intervention group. These findings are in line with previous research demonstrating that educational programs can help reduce the negative impact of menstrual and PMS or PMDD symptoms on women's lives [71,72]. Tracking symptoms over time and identifying patterns may help individuals feel better prepared and equipped to deal with their symptoms and manage their conditions. It is also possible that the observed improvements in health and well-being may have been driven by interaction with community-based tools such as Flo's Secret Chats, which could help individuals normalize their menstrual cycle experiences and decrease feelings of loneliness or social exclusion [29,30,33,73,74]. Improvements in PMS or PMDD symptom burden observed in the control condition could be due to participants using the app without our knowledge, motivation through exposure to study materials to think about how they may better manage any symptoms they experience, or use of other out-of-app menstrual health and PMS or PMDD resources to improve symptom management.

While the lack of existing literature on the efficacy of digital health interventions for menstrual health makes comparative analysis difficult, the magnitude of changes observed in our primary outcomes is comparable both to a previous RCT for a PMS educational app [65] and to app-based interventions for other health conditions such as sleep difficulties [75] or depression and anxiety [76,77].

In terms of secondary outcomes, questions addressing feelings of control over one's own reproductive health showed improvements in both cycle tracking intervention and control groups, with a stronger effect observed in the intervention groups. Again, improvements in the control group are likely due to unidentified or anonymous use of the app (using the anonymous mode) by control group participants or motivation to seek out external resources and think about health management. Positive effects were observed in the cycle tracking intervention group only for outcomes including communication about health, stigma around menstrual health, and fears of unplanned pregnancies. Being able to effectively communicate with health care providers and share feelings and concerns about one's own health are particularly important for menstrual and reproductive health. The findings from a large governmental investigation (UK Women's Health Strategy Survey) highlighted how women and people who menstruate do not feel heard when talking to their health care provider, with 1 in 4 declaring not feeling comfortable sharing information about their menstrual cycle [12]. This could contribute to delays in diagnosis as women may not be bringing up concerning symptoms in a timely manner. Further, the finding that feelings of stigma were reduced highlights the potential of solutions like Flo app to help normalize discussions around symptoms and overall reproductive and menstrual health. Finally, fears of unplanned pregnancies may have been reduced due to the exposure to content aimed at educating users about effective contraception methods. Absenteeism was measured in the PMS or PMDD group and showed a reduced number of days taken in the intervention group only. This finding is in line with previous research highlighting the impact of conditions of the menstrual cycle on workplace productivity [36,78-81] and further suggests that psychoeducational tools may help individuals better manage their symptoms [64].

We did not observe improvements in other secondary outcomes. This could be due to a number of factors. First, while we hypothesized that better knowledge and improved management of the menstrual cycle would translate into improvements in quality of life, workplace productivity, and body image, these are complex and multifaceted outcomes. Each of these outcomes is heavily influenced by health or social and economic factors beyond those relevant to menstrual health that Flo app is not targeted to address fully. Second, while 3-month interventions tend to be the norm in the digital health field [82], quality of life, workplace productivity, and body appreciation may require longer interventions for smaller effects to be detectable and sustained over time. Finally, it has been shown that studies targeting multifactorial health behaviors tend to be less efficacious [29]. Due to this, further research, with a better-powered sample and longer timeframes, is needed to explore whether solutions like Flo app can help tackle these issues.

Limitations and Future Research

This study does have limitations. First, as stated above, we cannot be sure that participants in the control group did not use Flo app. While our ITT analyses excluded individuals in the control condition who we identified as using the app before or during the study period, this identification was carried out using email addresses provided by study participants. If control participants signed up for the app using a different email address than the one provided to study staff, or used the Anonymous Mode feature, we would not be able to identify these individuals and exclude them on the basis of app use. Hence, any

improvements in the control condition of both trials could be due to the fact that some control participants did use the Flo app, despite instructions not to. Further, participants in the control group may also have been motivated to look for other sources of knowledge on reproductive health by virtue of taking part in this study, hence improving their final scores.

Our primary findings are based on an ITT analysis, which should be considered conservative, as we included all intervention participants with some exposure to the intervention. This means that any null findings could be due to noncompliance, or low usage of the app in intervention participants. Encouragingly, however, our PP analyses do broadly show similar improvements in outcomes as in the ITT analyses.

Additionally, the intervention period was only 3 months. While this was appropriate for this kind of pilot RCT, a longer interventional period may have allowed for the detection of additional effects, particularly in the secondary and exploratory outcomes.

Furthermore, due to participant dropout, we did not achieve an adequately powered sample for the PMS or PMDD ITT analysis and all PP analyses, and therefore these results should be considered as needing further validation. Follow-up studies should investigate methods of reducing participant dropout and improving rates of completion of measures. As a remote study, some attrition is expected, but closer monitoring of participants, additional reminders or prompts to complete data collection, along with personalized and improved incentives could allow for a greater proportion of participants to fully complete the study. In-person recruitment and data collection should also be considered to aid data quality and completeness and prevent app use by participants in the control group.

Finally, the study population was limited to individuals from the United States who were English speakers and may not be fully representative of other populations worldwide. Future research should prioritize inclusion of a diverse study population by including participants from different cultural, linguistic and socioeconomic backgrounds in order to allow for robust and generalizable results.

Conclusions

Low menstrual and reproductive health literacy and awareness can have a significant negative impact on the overall health and well-being of individuals. Further, health literacy and awareness of one's own symptoms can greatly influence the course of conditions of the menstrual cycle and help improve knowledge of how individuals can manage them. Digital tools such as the Flo app are widely accessible and provide users with a wealth of content and tools that can be successfully turned into actionable insights. The findings from this study show how increased health literacy, symptom tracking, and exposure to a community of like-minded individuals can improve menstrual and reproductive health knowledge, symptom management, and overall health outcomes.

Abstract

Background: Depression acts as a significant obstacle to the overall well-being of individuals. Given the significant consequences, timely recognition and proactive steps to manage symptoms of depression become essential. Such actions not only reduce personal distress but also play a crucial role in reducing its far-reaching impact on society as a whole.

Objective: In response to this concern, the objective of this study was to explore the use of mobile-based interventions as a possible remedy. More specifically, this study aimed to investigate the effectiveness of 2 types of physical activity (PA), progressive and fixed, within a mobile-based app on depression, perceived stress, anxiety, physical health, and psychological health, aiming to contribute to the optimization of mental health benefits.

Methods: Participants (N=60; mean age 25.29, SD 6.10 years) were recruited using a combination of web-based and offline methods, and the study lasted for 8 weeks. The baseline and posttest questionnaires were administered to all participants. The participants were randomly assigned to 1 of the 3 groups: progressive group (n=20; performing mobile-based progressive PA), fixed group (n=20; performing mobile-based fixed intensity PA), and control group C (n=20). Data analysis involved comparing scores between the experimental and control groups using a one-way ANOVA, paired sample *t* tests (2-tailed), and repeated measures ANOVA with a 3 (group)×2 (time) design.

Results: The findings revealed significant improvements in mental health indicators among participants engaged in both fixed and progressive PA groups compared with the control group. However, the fixed PA group demonstrated more significant reductions in symptoms. Specifically, the progressive PA group showed significant reductions in depression ($F_{1,36}$=6.941; P=.01; η_p^2=0.16) and perceived stress ($F_{1,36}$=5.47; P=.03; η_p^2=0.13), while the fixed PA group exhibited significant reductions in depression ($F_{1,37}$=5.36; P=.03; η_p^2=0.12), perceived stress ($F_{1,37}$=7.81; P=.008; η_p^2=0.17), and general anxiety disorder ($F_{1,37}$=5.45; P=.03; η_p^2=0.13) compared with the control group.

Conclusions: This study underscores the potential of mobile-based PA in improving mental health outcomes. The findings offer significant insights for mental health professionals and researchers aiming to optimize mental well-being through innovative mobile therapies.

Introduction

Background

Depressive disorder, commonly known as depression, is a widespread mental condition characterized by persistent feelings of sadness, loss of interest or pleasure in activities, and prolonged symptom duration [1]. Unlike normal mood fluctuations, depression significantly impairs an individual's ability to function effectively in daily life, affecting relationships, work, and engagement in once-enjoyed activities. It can also affect concentration, memory, decision-making, and motivation, making simple tasks challenging [2]. Notably, approximately 280 million people worldwide experience depression, with a prevalence of 3.8% in the population, including 5% of adults (4% in men and 6% in women) and 5.7% among adults aged ≥60 years [3,4]. Consequently, this creates an economic burden, resulting in annual losses of approximately US $36.6 billion [5]. South Korea, which has the greatest suicide rate among Organisation for Economic Co-operation and Development countries, is a nation that encounters unique challenges in this regard. Depression rates in Korea are increasing annually, and the annual social and economic costs associated with suicide, which include the potential reduction in income, amount to approximately ₩ 4.83 trillion or KRW 4.83 trillion (equivalent to US $3.67 billion) [6]. These figures emphasize the critical nature of directing national focus toward the assessment and treatment of depression. Despite the availability of effective treatments for mental disorders, inadequate investment in mental health care, limited availability of trained health care professionals, and social stigma surrounding mental disorders contribute to barriers that impede access to effective care [7,8].

Physical activity (PA) is widely recognized as a significant contributor to mental well-being and a protective factor against depressive symptoms [9-15]. Regular participation in PA not only decreases the frequency and intensity of health problems and chronic illnesses but also improves the general standard of living, playing a vital role in maintaining good health [16]. The underlying mechanisms of the beneficial impacts of PA on depression can be outlined as follows: first, PA stimulates the secretion of endorphins, which are natural substances that elevate mood, relieve pain and tension, and induce a state of relaxation and overall contentment, and it also plays a vital function in the regulation of neurotransmitters, including serotonin, dopamine, and norepinephrine. These neurotransmitters are essential for regulating mood and emotions, ultimately contributing to enhanced mental well-being. Second, PA also serves as a means of alleviating stress, leading to a decrease in overall stress levels and enhancing persons' ability to effectively manage daily obstacles. Third, regular PA not only improves physical fitness and body image but also boosts self-esteem and self-confidence, which in turn has the potential to decrease depressive symptoms. Fourth, PA has been linked to better sleep quality and can help regulate sleep patterns, addressing one of the common issues faced by those with depression [17-24]. Thus, regular PA can alleviate the symptoms of depression and improve overall quality of life by addressing various aspects of human functioning. Indeed, the body of scientific research supporting the benefits of PA continues to expand, highlighting its positive effects on mental health recovery and enhancement [9-16]. For instance, Marques et al [9] conducted a 4-year follow-up analysis on 32,392 European adults from 14 countries and revealed that participating in moderate or vigorous PA was linked to reduced depression scores in both genders. This association remains significant even when accounting for self-rated health, sociodemographic factors, and chronic diseases, indicating a negative correlation between PA and depression symptoms. Even a modest frequency of PA, such as twice a week, was found to lead to cumulative benefits [25].

Despite the recognized importance of PA in mental health recovery, significant limitations to participating in PA exist in traditional face-to-face PA. These limitations, which revolve around accessibility issues, create barriers that hinder people's engagement in PA [26-28]. One aspect of accessibility is psychological distance, which encompasses factors such as a lack of interest, lack of perseverance, and limited PA knowledge. These psychological barriers contribute to individuals feeling distant from engaging in PA, reducing their motivation to participate [28-30]. Aside from psychological barriers, geographical distance poses a hindrance to involvement. Proximity to PA facilities and the timing of PA programs can significantly impact convenience for participants, adding to the psychological distance they experience [27]. Face-to-face programs typically operate on fixed schedules, which may not align with everyone's availability. This lack of flexibility also poses challenges for individuals with busy lifestyles or conflicting commitments, making it difficult for them to commit to specific classes or training sessions. The financial aspects further emphasize the constraints of face-to-face PA programs. Face-to-face PA programs typically involve additional expenses, such as fees for gym memberships, classes, or personal training. These financial responsibilities can serve as obstacles, especially for individuals with constrained budgets or restricted financial means [31]. Collectively, these factors serve as obstacles to face-to-face PA engagement, hindering persons from experiencing the advantages of PA for mental health improvement and enhancement. Considering these limitations, it is crucial to identify alternative choices that provide enhanced accessibility, flexibility, and affordability to ensure that individuals participate in PA and benefit from its favorable effects on their mental well-being.

Mobile-based PA programs are structured interventions that use mobile technology, such as smartphones, tablets, wearable activity trackers, and PDAs. These programs deliver personalized plans for PA, including aerobic exercises, strength training, and flexibility routines. They also incorporate real-time monitoring and tracking features to assess participants' progress

[32]. Compared with traditional face-to-face PA approaches, mobile-based PA programs offer several advantages. First, it tackles the accessibility concerns by enabling individuals to participate in PA at any time and in any location, thus eliminating the limitations of time and place that are associated with face-to-face PA. Studies indicate that mobile-based programs can successfully encourage participation in PA without the requirement of physical gym facilities [33]. In addition, the use of mobile technology allows mobile-based PA programs to provide systematic supervision through customized workout plans and tailored PA activities that cater to the specific demands and fitness levels of individuals [34]. This process offers them prompt feedback and encouragement to adhere to their fitness objectives. Finally, the use of mobile PA apps provides a cost-efficient method for reducing expenses connected to facility use and health concerns [35] while it significantly improves physical health variables, such as managing weight; self-confidence; and mental health aspects, such as decreasing depression, stress, and increasing enjoyment of life [36-41]. For example, Murray et al [39] found that college students who engaged in approximately 150 minutes of moderate to vigorous PA per week over an 8-week period showed significant decreases in depression and anxiety. In general, the mobile-based PA program offers the ability to overcome the restrictions of accessibility, cost, and interest that are commonly associated with in-person PA.

Recognizing the beneficial effects of mobile-based PA programs on mental well-being, it is imperative to further investigate and analyze the impact of different types of PA on mental health. One of the fundamental principles of fitness training is progressive exercise, which involves a gradual increase in the intensity, duration, or complexity of the exercise program over time. The objective of progressive exercises is to continually challenge the body and induce adaptation, leading to improvements in strength, endurance, flexibility, and other desired fitness outcomes [16]. While this type of PA has proven to effectively enhance physical health among individuals, research has also demonstrated the effectiveness of progressive PA in affecting various indicators of mental health [42,43]. For example, Singh et al [42] conducted a 10-week randomized controlled trial involving older adults aged ≥60 years and found that progressive resistance training significantly reduced depression measures. In addition to its impact on the symptoms of depression, previous literature has revealed that individuals engaging in regular PA, including progressive PA, experienced improved mood, well-being, and quality of life compared with those with sedentary lifestyles [43]. These studies offer compelling evidence supporting the positive effects of progressive PA on mental well-being, encompassing reductions in depressive and anxiety symptoms, improvements in mood, and an overall enhancement of quality of life. While research has already demonstrated the benefits of progressive PA in traditional settings, there remains a need for further investigation to explore its effectiveness and implementation in the context of mobile-based PA. Remarkably, no studies have specifically examined the application of progressive exercise principles within a mobile-based PA framework. Understanding the potential impact of progressive PA within mobile-based interventions could have substantial implications for promoting mental health and well-being in an increasingly digitally connected world.

Objective

In summary, previous studies have successfully demonstrated that regular PA has a positive impact on alleviating mental issues such as depression, anxiety, and stress and improving the quality of life. However, it is important to note that most previous research has predominantly focused on face-to-face PA interventions or mobile-based PA characterized by a fixed intensity. Unfortunately, limited studies have ventured into exploring the potential benefits of mobile-based PA through apps or the implementations of progressive PA approaches. To address this research gap, this study aimed to investigate the effects of both progressive and fixed PA interventions, using a mobile app, on depression, stress, anxiety, and quality of life of adults in South Korea. We hypothesized that both progressive and fixed PA interventions could lead to improvements in mental health indicators such as depression, perceived stress, and anxiety, as well as enhance quality of life indicators related to physical and psychological health. Through this exploration of the benefits of mobile-based PA programs and their potential to positively influence mental health outcomes, we aimed to have a deeper understanding of how technology-enabled interventions can play a significant role in promoting well-being in modern society.

Methods

Participants

The recruitment of participants was meticulously designed to ensure a representative and diverse sample. In order to do this, a blend of web-based and offline recruitment techniques was used, with each method playing a role in the random sampling procedure. Web-based recruitment efforts targeted a diverse pool of potential participants by leveraging various digital platforms such as social media groups, forums, and university websites. Our objective was to attract individuals with diverse backgrounds who were interested in contributing to mental health research. Offline recruitment strategies complemented the web-based efforts by reaching individuals who may not have regular access to internet resources. Promotional materials were disseminated in public venues such as university counseling centers, local community centers, and coffee shops. These venues were selected to ensure visibility and accessibility to individuals lacking access to internet platforms. By using a combination of web-based and offline recruitment techniques, we aimed to create a sample that reflects the diversity of the target population. The recruitment period lasted from the first to the fourth week of March 2023, and both web-based and offline advertisements were used. The participants completed the baseline and posttest questionnaires in the first weeks of April and June 2023, respectively.

Eligibility criteria were predetermined; participants should be (1) healthy adults, aged between 18 and 65 years to ensure a sample representative of the adult population; (2) fluent in reading, writing, and conversing in Korean to ensure participants could fully understand and engage with study materials and instructions; (3) having no contraindications for PA as assessed

by the Physical Activity Readiness Questionnaire (PAR-Q) [44] to ensure participant safety during the intervention period; (4) willing to be randomized into an intervention that may require up to 2 hours per week of their time to ensure participant commitment and adherence to the study protocol; (5) familiar with using a smart mobile phone to ensure participants could adequately perceive and respond to visual and auditory stimuli presented during the study; (6) having normal (or corrected-to-normal) vision and hearing; and (7) having no history of psychosis to minimize potential risks associated with mental health conditions during the intervention period.

Sample Size Calculation

In this study, the appropriate sample size was determined using the G* power calculator (version 3.1.9.4; Heinrich-Heine-Universität) [45]. The aim was to achieve a significance level of .05 and a statistical power of 95%, with an effect size of 0.36, based on the data from a prior study that investigated the impact of mobile-based PA interventions on depression [41]. The calculations indicated that 30 participants were required to reach the desired power of 0.95. Accounting for a 57% dropout rate observed in computer-based psychological treatment [46], the total sample size needed was calculated to be 47 participants to maintain a power of 0.95. Therefore, including 60 participants was anticipated to provide sufficient statistical power for the study.

Procedure

Initially, a total of 60 participants were recruited. Following the fulfillment of inclusion criteria, the process of participant allocation used a simple block randomization methodology. This approach involved using the resources available on the open-source website to assign a total of 60 participants into 3 distinct groups: the progressive group, the fixed group, and the control group. Each group comprised 20 participants. The procedure involved the creation of 10 blocks, each containing 6 participants, as the designated units for randomization. Participants were allocated to the 3 groups within each block using randomization, guaranteeing an equal distribution of participants among the groups throughout each block. At first, the groups had the following gender distribution: the progressive group consisted of 10 men and 10 women, the fixed group consisted of 14 men and 6 women, and the control group consisted of 12 men and 8 women. After the random selection, 2 women from the fixed group expressed a preference for the control group due to their disinclination for PA, while 2 men from control group wished to switch to the fixed group in order to participate in PA. Consequently, the research protocol allowed these participants to transfer between groups, leading to the following revised composition: the progressive group consisted of 10 men and 10 women, the fixed group consisted of 16 men and 4 women, and the control group comprised 10 men and 10 women.

After the randomization, the researchers contacted the participants via the Webex platform (Cisco) for both baseline and posttest evaluations at baseline and 8 weeks. Initially, the participants were instructed to fill out the web-based questionnaire, which encompassed an explanation of the study's objectives, privacy safeguards, and procedures to ensure confidentiality during the baseline evaluation, informed consent, and Physical Activity Readiness Questionnaire (PAR-Q) [44]. During the intervention phase, the researchers consistently spoke with the participants on a weekly basis to ensure that they followed the instructions and to track their advancement. They supervised the completion of the assigned PA and provided assistance for any personal queries. To validate the participants' activities, the researchers received verification photos via messenger, showing the number, duration, and type of PA sessions for each week. To uphold consistency and anonymity, all surveys were collected without personal identifiers, and each participant used a unique ID for completing the surveys during both the baseline and postevaluation phases.

Ethical Considerations

This study received ethical approval from the institutional review board of Hankuk University of Foreign Studies (approval number HIRB-202306-HR-001). Before commencing the study, all necessary approvals were obtained to ensure compliance with ethical standards and the protection of participants' rights. The objectives and methods of the study were clearly explained to potential participants, and only those who provided written informed consent and willingly chose to participate were included.

Instrument

Depression

Depression was measured using the Korean version of the Patient Health Questionnaire-9 (PHQ-9). The PHQ-9 has been reported to be a reliable and valid tool for screening and assessing depressive symptoms [47]. The inventory has 9 items pertaining to symptoms of depression, including diminished interest or pleasure, mood fluctuations, disruptions in sleep patterns, exhaustion, and alterations in food behavior. The scoring system ranges from 0 (not at all) to 3 (nearly every day) for each item. A greater cumulative score on the PHQ-9 signifies a higher level of depression symptoms, whereas a lower score signifies a lower level of symptoms. The Cronbach α coefficients were 0.86 for the study sample and 0.81 in the initial validation [47].

Perceived Stress

The assessment of perceived stress was conducted by using the Brief Encounter Psychosocial Instrument-Korean version (BEPSI-K). BEPSI-K is a tool that has been created using the dynamic interaction model of stress and its detrimental effects on health [48]. This is a Korean version of the original BEPSI that has been tested and confirmed to be reliable and legitimate [49]. The scoring system for each item is based on a scale that spans from 1 (not at all) to 5 (always). Consequently, elevated scores on the BEPSI-K signify an increased perception of stress, whereas lower scores indicate a decreased experience of stress. In our investigation, the Cronbach α coefficient obtained from our sample was 0.81, which is somewhat higher than the value of 0.80 reported in the original validation [48].

Anxiety

We used the Generalized Anxiety Disorder-7 (GAD-7) to evaluate the symptoms associated with generalized anxiety

disorder. The GAD-7 is beneficial because of its simplicity and limited number of components, which allows for easy access [50]. The scale has 7 items that evaluate anxiety symptoms. Each item is rated on a scale ranging from 0 (not at all) to 3 (nearly every day). The GAD-7 scores are directly proportional to the frequency and severity of symptoms associated with generalized anxiety disorder. Higher scores indicate a greater number and intensity of symptoms, whereas lower scores indicate a lesser number of symptoms. The Cronbach α coefficient in our study sample was 0.90, although the original validation study reported a value of 0.92 [50].

Quality of Life

The study used the Korean version of the World Health Organization Quality of Life-Brief assessment questionnaire to measure the quality of life. The World Health Organization Quality of Life-Brief is a reliable and valid tool developed by the WHO in 1996 as a shortened version of the WHOQOL-100, which scientifically measures and evaluates the quality of life [51]. It comprises 5 domains: physical health, psychological health, social relationships, environmental factors, and overall quality of life. This study used 13 items, including 7 items related to physical health and 6 items related to psychological health. These items assess various aspects, such as physical satisfaction, need for treatment, sleep quality, and negative emotions. Scores range from 1 (not at all) to 5 (very much)**.** The Cronbach α values were 0.79 (physical health) and 0.81 (psychological health) for the study sample, and 0.71 (physical health) and 0.83 (psychological health) in the original validation [51]. In our study sample, the Cronbach α values were 0.79 for physical health and 0.81 for psychological health, while the original validation reported values of 0.71 for physical health and 0.83 for psychological health.

Mobile-Based PA Program

The program used in this study is a personalized health care app that provides artificial intelligence–based wellness services in the areas of PA, diet, nutrient, and mental health. The app offers various PA videos tailored to different goals including 32 stretching movements, 44 full-body aerobic PA, 20 upper-body strengthening PA, and 18 lower-body strengthening PA, categorized according to difficulty (easy, moderate, and difficult). Thus, participants could select desired movements and adjust the number of sets to create personalized PA lists. All participants, irrespective of their group assignment, were granted equal access to the complete app. They were provided the freedom to choose and combine PA according to their individual preferences and needs and had the flexibility to adjust the number of sets as desired.

In the context of this app-driven intervention, participants in both the progressive and fixed groups were instructed to engage in PA for 8 weeks, with a minimum of 3 sessions per week and a minimum PA duration of 15 minutes per day. For the progressive group, participants were guided to participate in progressive PA, which involved a daily and weekly gradual increase in difficulty level, duration, and intensity. For example, the daily program of the progressive group mostly involved performing 2 to 3 movements at each difficulty level, with the number of repetitions increasing as the difficulty level increased. That is, the routine started with easier movements and became more difficult over time, with more repeats and higher levels of difficulty during each session. Furthermore, the progressive group performed 12 sets in weeks 1 to 2, a total of 18 sets in weeks 3 to 4, a total of 27 sets in weeks 5 to 6, and 36 sets in weeks 7 to 8. Finally, the progressive group was encouraged to gradually increase the duration of PA, starting with a minimum of 15 minutes in the first week and progressing up to approximately 30 minutes by the eighth week. This methodology facilitated a seamless transition toward progressive PA engagement.

The fixed group in our study followed a different approach compared with the progressive group. Instead of experiencing a gradual increase in intensity, frequency, duration, and difficulty levels, participants in the fixed group engaged in a consistent and predetermined intensity level and set of PA throughout the 8-week period. As for the intensity levels, they were guided to choose and proceed with a moderate intensity PA in the app. The participants freely chose and performed 6 types of PAs that they desired at the specified intensity level. They also performed the PA with a fixed number of sets and repetitions for each session, maintaining a PA frequency of approximately 16 to 17 minutes per session, 3 times a week, from the first to the eighth week. This steady and consistent PA routine was maintained without the progressive changes in difficulty levels and repetition experienced by the progressive group. In contrast, the control group did not participate in any structured PA during the study period.

Covariate

In this study, gender was incorporated as a covariate variable in the statistical analysis to consider its potential impact on mental health outcomes, such as depression, anxiety, and perceived stress. Research has consistently demonstrated gender differences in the occurrence, presentation, and management of mental health disorders [52,53]. By controlling for gender, we aimed to mitigate the potential confounding effects of gender-related factors on the study outcomes, thereby enhancing the internal validity of the expected findings. Furthermore, by implementing gender control, we aimed to distinguish the specific impacts of the independent variable, specifically, the PA intervention type, on the dependent variables, facilitating more accurate conclusions from the findings.

Data Analysis

Initially, we conducted descriptive analysis to obtain frequencies and percentages for categorical variables and means and SDs for continuous variables. Subsequently, we assessed differences between groups at baseline and posttest evaluations by using a one-way ANOVA for continuous variables and a chi-square test for categorical variables. When we found statistically significant differences between the groups through the initial one-way ANOVA, we proceeded with post hoc tests for further analysis. We used the appropriate Tukey honestly significant difference test. By performing post hoc tests, we aimed to explore and interpret the significant differences observed during the initial analysis, contributing to a more nuanced interpretation of the study results. To evaluate the effects of the mobile-based PA, we compared and analyzed self-report questionnaire scores

between the experimental and control groups using SPSS Statistics for Windows (version 22.0; IBM Corp). Initially, we conducted paired sample *t* tests within each group to compare the baseline and postevaluation measurements separately for both groups. Subsequently, we performed a 3 (group)×2 (time) repeated measures ANOVA (RMANOVA) using baseline and postevaluation measurements, with the group as the independent variable. To control for their influence on the study outcomes [52], we included gender as a covariate in our analysis. Upon finding significant differences in the 3×2 RMANOVA, we further examined the individual group comparisons using a 2 (group)×2 (time) RMANOVA. Specifically, we compared the progressive PA group with the control group, as well as the fixed PA group with the control group, to identify which specific group differences contributed to the observed effects.

Results

Demographic Characteristics at Baseline

Figure 1 illustrates the CONSORT (Consolidated Standards of Reporting Trials) diagram, presenting the participant flow throughout the study. The initial 60 participants were divided into 3 groups: progressive group, fixed group, and control group. The progressive group followed a mobile-based progressive PA program, with a daily and weekly gradual increase in the intensity and difficulty levels. More specifically, 20 (33%) participants were assigned to each of the experimental groups A and B, while 20 (33%) participants were allocated to the control group C. Notably, 98% (39/40) of the participants in progressive and fixed groups and 100% (20/20) of the participants in the control group completed the posttest assessment.

In this study, a comprehensive statistical analysis was performed to investigate potential demographic differences between the study groups. The results indicated no statistically significant variations in gender (P=.10), age (P=.78), height (P=.06), weight (P=.15), BMI (P=.31), and internet self-efficacy (P=.58) among the groups. In addition, the level of internet self-efficacy remained consistent throughout the various study groups. Table 1 displays the demographic attributes of the participants.

Differences Observed in the 3 Groups

This study used a one-way ANOVA to examine the variables of depression, stress, anxiety, and physical and psychological health among 3 unique groups at both the baseline and postevaluation stages. The Levene test was conducted to assess whether the variances were equal across the 3 groups (PHQ-9, *P*=.92; BEPSI-K, *P*=.57; GAD-7, *P*=.70; physical health, *P*=.97; and psychological health, *P*=.51). Therefore, there was no significant evidence of a difference in variances among the groups at the baseline evaluation.

The characteristics of the participants in the progressive group (n=19), fixed group (n=20), and control group C (n=20) at baseline are summarized in Table 2. The results revealed that no statistically significant differences existed between the 3 groups for any of the variables at baseline.

Table 3 provides a summary of the intergroup comparisons following the intervention. The analysis revealed statistically significant differences between groups as determined by one-way ANOVA for depression ($F_{2,56}$=5.06; *P*=.01; η_p^2=0.15) and GAD-7 ($F_{2,56}$=4.13; *P*=.02; η_p^2=0.12). A Tukey post hoc test revealed significant differences between the progressive group and control group for depression (mean difference −3.27; *P*=.01) and for GAD-7 (mean difference −0.33; *P*=.03). There was no statistically significant difference between the groups for perceived stress ($F_{2,56}$=3.12; *P*=.05), physical health ($F_{2,56}$=3.08; *P*=.05), and psychological health ($F_{2,56}$=1.04; *P*=.36).

Effectiveness of Mobile-Based PA on the Outcomes

Table 4 and Figure 2 illustrate the changes observed in the experiment and control groups from baseline to program completion.

There was a significant positive interaction found between group and time in relation to depression ($F_{2,55}$=3.76; *P*=.03; η_p^2=0.12) and perceived stress ($F_{2,55}$=4.77; *P*=.01; η_p^2=0.15). These results suggest that depression and perceived stress levels changed over time, and the impact of the intervention was dependent on the group assignment. However, no significant interaction was observed for GAD-7 ($F_{2,55}$=2.67; *P*=.08; η_p^2=0.09), physical health ($F_{2,55}$=1.72; *P*=.19; η_p^2=0.06), and psychological health ($F_{2,55}$=1.48; *P*=.24; η_p^2=0.05) between the groups. Specifically, the post hoc analysis showed a significant difference in the change of depression ($F_{1,36}$=6.94; *P*=.01; η_p^2=0.16) and perceived stress ($F_{1,36}$=5.47; *P*=.02; η_p^2=0.13) between progressive group and control group over time. Further, a significant difference in the change of depression ($F_{1,37}$=5.36; *P*=.02; η_p^2=0.12), perceived stress ($F_{1,37}$=7.81; *P*=.01; η_p^2=0.17), and GAD-7 ($F_{1,37}$=5.45; *P*=.02; η_p^2=0.13) between the fixed group and control group was also observed across time.

Table 4. Differences in the outcome variables across time (n=59).

Outcome	Evaluation					
	Baseline, mean (SD)	Posttest, mean (SD)	Difference			
			Values, mean (95% CI)	*t* test (*df*)	*P* value	Cohen *d*

Discussion

Principal Findings

This study investigated the impact of progressive and fixed PA programs delivered through a mobile app on mental health indicators (depression, perceived stress, and anxiety) and quality of life (physical and psychological health) among South Korean adults. Following the intervention, the findings of this study indicated that a significant positive interaction effect existed between group and time for depression and perceived stress, implying that the effectiveness of the interventions in reducing the outcomes may have varied depending on the specific group in which they participated. Thus, we conducted additional statistical analyses to examine the impact of each PA type on the outcome variables in the experimental groups and compare the variables with the control group, leading to the following discussion.

First, we observed that participants in both the progressive and fixed PA groups showed a greater reduction in depression and perceived stress compared with those in the control group. Engaging in PA, including progressive PA, has been shown to stimulate the release of endorphins, which are neurotransmitters associated with feelings of well-being and happiness [17,54]. Furthermore, regular PA promotes neuronal growth and connectivity, particularly in brain regions that are involved in mood regulation, such as the hippocampus and prefrontal cortex [20,21,55]. These alterations in neurochemical and neurobiological processes may help reduce depression symptoms [54,55]. In addition, engaging in PA via a mobile app might function as a diversion from detrimental ideas and excessive contemplation, which are frequently linked to depression [56]. By prioritizing PA at home and attaining specific objectives and significant achievements, individuals can shift their focus away from depressed symptoms and cultivate a more positive mindset. As a result, those who participate in both the progressive and fixed PA groups may observe a more significant decrease in depression and perceived stress compared with those who do not engage in PA. Previous literature has found the significant impact of mobile-based PA programs on mental health [36-41], and this aligns with the findings of this study. Theoretical implications of these findings in academia endorse the use of both regular fixed PA and progressive PA through mobile apps as potential therapies for mitigating depression and stress. These findings contribute to a growing body of research on the effectiveness of mobile-based therapies in enhancing mental well-being.

Along with the finding of significant impact of both progressive and fixed PA on mental health indicators, a critical finding of this study is the superior improvement observed in the outcome variables within the fixed PA group compared with the progressive PA group. This finding is somewhat different from those of the previous literature exploring the impact of progressive and fixed PA on physical health outcomes [57-59]. However, this study found that fixed PA showed better results in terms of mental health indicators. One possible explanation could be related to motivation and adherence to the prescribed PA program. In this study, the fixed group encompassed a relatively higher proportion of men (16/20, 80%) compared with that in the other groups (control and progressive groups: 10/20, 50%), while 2 men from the control group switched to the fixed group, suggesting their high motivation for fixed PA engagement. Previous literature has consistently reported a positive association between motivation and mental well-being [60,61]. For example, a meta-analysis on student motivation [60] identified that amotivation (ie, lack of motivation) was positively associated with depression and anxiety, whereas regulation (ie, self-directed value-driven motivation) and intrinsic motivation were negatively associated with only anxiety. This aligns with the result of this study. Furthermore, Lauderdale et al [62] noted that male college students had more intrinsic motivations than women college students. Thus, it is possible that the fixed group includes participants with higher motivation than the progressive group, which in turn demonstrates better improvement in mental health outcomes, specifically with regard to anxiety.

Another possible explanation may be related to the psychological and physical efforts incurred during the intervention period. The progressive PA group may have faced challenges related to the increasing complexity and intensity of their PA program over time. Some participants might have been reluctant to increase the duration and intensity but felt obligations to adhere to the prescribed protocol due to their commitments to the research protocol. Furthermore, engaging in approximately 30 minutes of PA at weeks 7 and 8 could have induced more physical exertion and stress in the progressive group compared with the fixed group who engaged in approximately 17 minutes of PA. Indeed, grounded upon the reversal theory [63], Kerr and Kuk [64] found that compared with running at a low intensity, running at a high intensity resulted in significantly higher scores for physical stress and exertion among participants who ran 1.7 km. Thus, the gradual progression and high-intensity PA could have led to psychological and physical strain, potentially affecting their mental conditions and generating conflicts with the mental health enhancement. In contrast, participants in the fixed PA group may have experienced less or no psychological strain due to the consistent and predictable nature of their PA protocols. Knowing exactly what to expect in terms of PA duration, intensity, and routine may have provided a sense of structure and control, which may lead to psychological comfort during the intervention phase. Thus, in this context, although progressive PA still had significant impacts on mental health outcomes, the effect may not have been as pronounced as the effect in the fixed group, which did not incur psychological strains and emotional challenges related to engaging in PA at different and higher intensities and durations. It is important to note that this interpretation is only speculative, and further investigation into the psychological mechanisms underlying both progressive and fixed PA protocols on anxiety is warranted. In addition, although the progressive group did not demonstrate statistically significant reductions in anxiety during the 8-week intervention period, it is worth noting that the paired sample *t* test revealed a decrease in the anxiety level from 0.33 to 0.16 (P=.13). This suggests a potential trend toward improvement in anxiety within the progressive group, albeit not reaching statistical significance.

Although this study found that the fixed PA group showed better results in mental health outcomes than the progressive PA group, the main advantage of this study is the demonstration of the efficacy of a mobile-based progressive PA program in diminishing different mental health markers, such as depressive symptoms and perceived stress. Notably, this study is the first to apply the principle of progressive exercise in the mobile PA app context. Prior studies have primarily explored the impact of progressive PA on mental health [42,43] and overall health indicators [57-59] within traditional face-to-face PA contexts. In this study, the researchers expanded the research paradigm by introducing the principles of progressive exercise into the mobile context and specifically investigated the effects of progressive exercise principles in comparison with the control group. Thus, this study contributes significantly to our understanding of the effectiveness of different types of mobile-based PA programs in enhancing mental health. The incorporation of progressive exercise principles into mobile PA programs offers the potential and additional avenues for individuals to experience mental health benefits.

Finally, this study found that neither progressive nor fixed mobile phone–based PA programs had a significant impact on the participants' quality of life (P=.19 for physical health and P=.24 for psychological health), as measured by physical and psychological health. While there was a slight increase in the average scores for both physical and psychological health in both progressive and fixed groups, these increases were not statistically significant. There are several possible explanations for the lack of significant results. First, the duration of the intervention might not have been sufficiently long to produce significant changes in the participants' quality of life. Quality of life is a multifaceted construct that may require a longer period of sustained PA to observe meaningful improvements compared with the negative mental health indicators of depression, stress, and anxiety [65,66]. A meta-analysis of 16 studies examined the impact of PA on the quality of life among patients with cancer [65], and the average duration of each study was 17.18 minutes, ranging from 3 weeks to 16 months. Second, the level of adherence to the prescribed PA programs varied among the participants. Variations in adherence may have influenced the outcomes, as participants who did not consistently engage in PA may not have experienced the full potential benefits.

Limitations and Future Research Directions

Although this study has made valuable findings, it is important to acknowledge its limitations. First, deviation from the initial randomization strategy creates intricacies that may impact the internal validity of the investigation. Although participant choice and ethical responsiveness are prioritized, it is important to acknowledge that these transfers could introduce confounding variables that may affect the results of the study. For example, a higher proportion of men in the fixed group than that in the progressive group, along with the transfer of men to the fixed group, might lead to differences in motivation levels between the groups. This could possibly result in bias in favor of the fixed group over the progressive group. Future research may explore the differential responses of men and women to PA interventions and explore the underlying motivational factors influencing engagement, thus enabling the development of tailored interventions that optimize effectiveness for each gender. Notwithstanding these deviations, measures were implemented to guarantee methodological rigor, such as a meticulous random sampling procedure during the recruitment phase, transparent documentation of the transfers, supplementary analysis to assess their potential impacts, and inclusion of gender as a controlled variable in the statistical analysis. Despite significant efforts to reduce the negative effects of this deviation, it is advisable for readers to consider these complexities while interpreting the study's results.

In a similar vein, if individual differences such as participants' motivational level have the potential to influence the results of PA interventions, it is important to consider individual and contextual differences as moderators in the relationship between PA protocols and mental health outcomes. These individual and contextual differences may include personality traits [67], self-esteem [68], resilience [69], and group dynamics [70], all of which have been shown to significantly impact mental health indicators. Future research may explore these individual differences as moderators or examine the effects of PA interventions on mental health across various individual differences.

Furthermore, potential biases may arise throughout the recruitment process. For example, selection bias may occur if certain groups of individuals are more likely to engage in a study than others [71]. Individuals with a specific interest in mental health or PA may be more inclined to volunteer, leading to a sample that is not representative. In addition, recruitment bias can occur when some recruitment strategies attract specific demographic groups more than others [72]. For example, web-based advertisements might predominantly reach individuals who frequently visit university-related websites, while distributing flyers at community centers may be more accessible to participants who visit such places more often.

In addition, the inability to monitor participant adherence to the assigned PA protocols represents a potential limitation. Although participants were required to capture and submit their PA records generated by the app, the lack of real-time tracking made it challenging to assess the extent to which participants complied with the prescribed PA protocols. Thus, future studies should implement robust adherence tracking mechanisms to provide a more comprehensive understanding of participant engagement and its relationship to intervention effectiveness.

Finally, this study primarily focused on assessing the PA intervention outcomes in a healthy population. Consequently, the protocols and dosages used in this study may not be directly generalizable to populations with preexisting mental health concerns or diagnoses. Individuals with mental health conditions may have unique needs and considerations when engaging in PA interventions, including tailored exercise prescriptions, supervision, and support mechanisms. Therefore, caution should be exercised when extrapolating the findings of this study to clinical populations, and future research should aim to investigate the efficacy of PA interventions specifically tailored to individuals with mental health concerns.

Practical Implications

This study underscores the significance of mobile-based PA in generating positive mental health outcomes in adults. Consequently, it is crucial to actively promote and facilitate the adoption of such programs. This can be achieved through diverse approaches, including awareness campaigns, educational materials, and partnerships with fitness professionals or organizations. By emphasizing the convenience and accessibility of mobile-based programs, individuals can be motivated to incorporate PA routines into their daily lives using smartphones or tablets at their preferred times and locations [73].

In order to encourage mobile-based progressive PA programs, governments must engage in efforts such as providing financing or subsidies for the creation and promotion of mobile PA apps. Engaging in collaboration with app developers, fitness experts, and mental health physicians is vital to guarantee the caliber and efficacy of these programs. Furthermore, governments have the capability to incorporate mobile PA programs into public health campaigns, emphasizing their positive impact on mental health and overall well-being.

Finally, fitness facilities might assume a crucial function by collaborating with mobile app developers or developing their own fitness applications. These centers can grant members access to these apps as a component of their membership packages or provide specific programs that integrate in-person instruction with mobile-based PA. Conducting workshops or events to enlighten persons about the advantages of mobile-based progressive PA and enhance their efficacy can also be advantageous.

Conclusions

This study aimed to fill the existing gap in knowledge regarding the efficacy and application of progressive and fixed PA programs in mobile-based environments, with the ultimate purpose of maximizing mental health advantages. This study produced noteworthy results that provided insights into the influence of this intervention on mental health outcomes. The progressive and fixed PA groups showed a remarkable reduction in depression and perceived stress levels compared with the control group. In addition, only the fixed group showed significant decreases in GAD-7 scores.

These findings offer valuable insights into the potential advantages of engaging in mobile-based PA in enhancing the mental health outcomes of adults. In addition, this study highlights the effectiveness of progressive PA in reducing depressive symptoms and perceived stress, even in mobile-based settings, indicating a specific type of program that yields positive outcomes. Consequently, further development and implementation of innovative strategies that optimize the convenience and effectiveness of mobile-based interventions are warranted to support individuals in achieving better mental health.

Abstract

Background: Digital mental health services are increasingly being provided by employers as health benefit programs that can improve access to and remove barriers to mental health care. Stratified care models, in particular, offer personalized care recommendations that can offer clinically effective interventions while conserving resources. Nonetheless, clinical evaluation is needed to understand their benefits for mental health and their use in a real-world setting.

Objective: This study aimed to examine the changes in clinical outcomes (ie, depressive and anxiety symptoms and well-being) and to evaluate the use of stratified blended care among members of an employer-sponsored digital mental health benefit.

Methods: In a large prospective observational study, we examined the changes in depressive symptoms (9-item Patient Health Questionnaire), anxiety symptoms (7-item Generalized Anxiety Disorder scale), and well-being (5-item World Health Organization Well-Being Index) for 3 months in 509 participants (mean age 33.9, SD 8.7 years; women: n=312, 61.3%; men: n=175, 34.4%; nonbinary: n=22, 4.3%) who were newly enrolled and engaged in care with an employer-sponsored digital mental health platform (Modern Health Inc). We also investigated the extent to which participants followed the recommendations provided to them through a stratified blended care model.

Results: Participants with elevated baseline symptoms of depression and anxiety exhibited significant symptom improvements, with a 37% score improvement in depression and a 29% score improvement in anxiety (*P* values <.001). Participants with baseline scores indicative of poorer well-being also improved over the study period (90% score improvement; *P*=.002). Furthermore, over half exhibited clinical improvement or recovery for depressive symptoms (n=122, 65.2%), anxiety symptoms (n=127, 59.1%), and low well-being (n=82, 64.6%). Among participants with mild or no baseline symptoms, we found high rates of maintenance for low depressive (n=297, 92.2%) and anxiety (n=255, 86.7%) symptoms and high well-being (n=344, 90.1%). In total, two-thirds of the participants (n=343, 67.4%) used their recommended care, 16.9% (n=86) intensified their care beyond their initial recommendation, and 15.7% (n=80) of participants underused care by not engaging with the highest level of care recommended to them.

Conclusions: Participants with elevated baseline depressive or anxiety symptoms improved their mental health significantly from baseline to follow-up, and most participants without symptoms or with mild symptoms at baseline maintained their mental health over time. In addition, engagement patterns indicate that the stratified blended care model was efficient in matching individuals with the most effective and least costly care while also allowing them to self-determine their care and use combinations of services that best fit their needs. Overall, the results of this study support the clinical effectiveness of the platform for improving

and preserving mental health and support the utility and effectiveness of stratified blended care models to improve access to and use of digitally delivered mental health services.

Introduction

Background

The prevalence of mental health needs in the United States has been on an upward trend in recent years, with 21% of adults meeting criteria for a mental, behavioral, or emotional disorder in 2020, up from 18% in 2010 [1]. National data indicate that <50% of people with mental health concerns are able to access mental health services [1]. Traditional models of mental health care are inadequate, as they rely heavily on high-cost providers delivering scheduled, time-limited encounters, and training programs are decades away from adequately closing the provider shortage gaps [2,3]. In addition to a pervasive shortage of mental health professionals to provide needed care [4], issues related to cost, accessibility, and stigma also prevent individuals from accessing evidence-based care to address mental health concerns [1]. Thus, innovative models for mental health care that are scalable, resource sensitive, and acceptable to individuals are needed to sufficiently improve the provision of robust mental health care in the United States.

Innovative and flexible models of mental health care leverage technology and telecommunications to provide more rapid and scalable access to a myriad of mental health services, from self-guided "self-help" techniques to access to providers who deliver secure, remote care [5]. An advantageous feature of digital mental health platforms is their flexibility in offering a variety of care modalities, enabling users to exercise their preferences in accessing care in a way that best fits their needs and comfort level. Stepped care delivery models further accelerate improvements in mental health care access and affordability. There are currently 2 models: progressive and stratified. A progressive model recommends the lowest-intensity intervention first to all individuals and intensifies care if or when symptoms do not improve [6]. This is the prevailing system used by the United Kingdom National Health Service's Talking Therapies program (formerly called Improving Access to Psychological Therapies) [7]. The evidence supporting this model suggests that patients' baseline symptomatology does not impact the efficacy of low-intensity or high-intensity treatments [8,9].

However, recent research suggests the Improving Access to Psychological Therapies program may not adequately support or match the complexity of patients' presenting mental health issues [10]. There are several criticisms [11] of the progressive approach, including (1) low-intensity interventions may not be suitable or acceptable for everyone; (2) patients who do not respond to low-intensity treatment may develop negative attitudes toward treatment or be deterred from undergoing further treatment; (3) engaging in high-intensity treatment after a minimal intervention may be unnecessarily burdensome; and (4) those with greater clinical needs may have to wait longer to receive a more effective level of care and, in the interim, experience an exacerbation of symptoms and additional impairment.

As an alternative, a *stratified* model considers patient characteristics, preferences, and baseline mental health symptoms to identify and deliver the most clinically effective yet least burdensome and least costly initial intervention from a range of care modalities of different intensities [12]. Stratifying care with personalized recommendations is thought to be more patient-centered and is responsive to key drawbacks of the progressive stepped care approach [11]. In some stratified systems, more specifically blended care models, patients can access multiple modalities simultaneously; that is, they can use their recommended treatment modality as well as additional modalities of lower intensity than their recommended starting point (eg, digital tools plus provider sessions, as opposed to digital-only or provider-only session). While advantageous from a delivery perspective and found to be effective [13,14], stratified, blended models can be more difficult to evaluate because of the complexity and variety of care pathways offered to patients and the variability of "blends" that patients may use at different points in time.

Research Questions

Prior findings regarding the clinical superiority of progressive models over stratified models are mixed [15,16]. These mixed results and the criticisms of progressive stepped care suggest that by incorporating patient-level factors to match individuals with the most effective yet least costly mental health services, stratified, blended models can offer more personalized care and increase access while optimizing resources. In this study, we examined the effectiveness of and engagement in a digital mental health platform that uses a stratified blended care approach to deliver therapy, coaching, and self-guided digital services. Specifically, we tested two research questions: (1) Was this approach clinically effective, that is, did participants with elevated baseline mental health symptoms significantly improve their mental health as defined by depression, anxiety, and well-being scores, and did participants without elevated baseline symptoms maintain good mental health from baseline to 3-month follow-up? (2) Was this approach effective in stratifying resources, that is, did people follow, underuse, or overuse mental health services at the levels they were recommended?

Methods

Design and Participants

This investigation was conducted as part of a larger prospective, observational study of individuals who received services through

an employer-sponsored digital mental health benefits platform (Modern Health Inc). The study time frame was September 20, 2021, through May 31, 2022. Participants were eligible if they were aged ≥18 years; were based in the United States; were onboarded with the employer-sponsored mental health benefit; had access to a smartphone, a tablet, or a computer; and had engaged with at least 1 piece of digital content or matched with a coach or therapist (see the Intervention section for more detailed descriptions of the services).

Ethical Considerations

This study protocol was reviewed and approved by the Western Clinical Group Institutional Review Board (protocol no 1316167). Participants provided informed consent to participate in this investigation. The Western Clinical Group Institutional Review Board authorized a waiver of documentation of consent for the team to collect consent through secure electronic methods.

All data were deidentified for the purpose of analyses. Participants were compensated with a US $25 digital gift card upon completion of each of the 3 surveys in this investigation.

Procedures

Participants registered for an account through a mobile app or a website and completed onboarding assessments, including questions designed to assess participants' areas of focus and care modality preferences, as well as validated measures to assess depressive and anxiety symptoms and well-being (described in the Study Measures section). A proprietary algorithm factored in a combination of the participant's clinical acuity, their modality preference, and their topic of focus to recommend an initial care pathway (eg, digital programs, coaching, and therapy). Participants were not required to follow the recommendation; instead, it was offered as an appropriate suggested starting point. Participants who were recommended therapy also had access to coaching and digital content, and those who were recommended coaching also had access to digital content as part of their recommendations (Figure 1). Participants could also self-refer or be referred by a provider to a different combination of care from their recommended combinations.

Figure 1. Stratified blended care model incorporating care preferences and clinical assessments into personalized care recommendations. GAD-7: 7-item Generalized Anxiety Disorder scale; PHQ-9: 9-item Patient Health Questionnaire; WHO-5: 5-item World Health Organization Well-Being Index.

Eligible members were invited to complete a screener for the study via email, which collected their demographic information (age, gender identity, race, and ethnicity). All screeners were sent within 2 weeks of onboarding, with most members receiving the screener approximately 1 week after onboarding. During this time, the members were able to engage with the digital mental health services outlined in the Intervention section. A total of 2 factors determined the length of time it took to send the screener: research staff availability and demographic balancing. Limits were set such that enrolled study participants reflected the current distribution of age, gender, ethnic/racial identity, and mental health symptom acuity observed in the platform's commercial population. Out of the 8786 individuals who were eligible and invited to participate, 950 (10.81%) enrolled, provided informed consent, and completed the baseline survey, hosted by Qualtrics (**Qualtrics** International Inc). They were then emailed a link to complete a follow-up survey 12 weeks after the baseline survey. The baseline and follow-up surveys each took 30 to 45 minutes to complete.

Intervention

Digital Health Services

Participants could engage in all the following digital mental health services. All services were paid for by the participant's employer, at no cost to the individual.

Telecoaching and Teletherapy

Coaches certified by the International Coaching Federation accredited program provided telecoaching services, and therapists who were licensed and had an advanced degree in clinical psychology or a related field (eg, PhD, PsyD, licensed clinical social worker, licensed marriage and family therapist, or licensed professional counselor) provided teletherapy services to participants. All visits were conducted via a secured videoconferencing platform. Participants could also communicate with their therapist or coach through in-app

messaging. All coaches had at least 150 hours of coaching experience, were vetted by a provider management team to ensure their work aligned with evidence-based practices, and completed an additional 6 hours of training from the company clinical strategy team in evidence-based techniques (eg, cognitive behavioral approaches) and culturally centered care. Coaches were also vetted and trained on how to assess for high-risk situations that may require a participant's referral to a therapist or crisis resource.

Therapists were selected for their use of evidence-based practices, such as cognitive behavioral therapy and acceptance and commitment therapy. All coaches and therapists were trained on the company's proprietary model of care. The number of therapy and coaching sessions attended by participants depended on the number of sessions covered by their employer, as well as on personal preferences and their level of need.

Self-Guided Digital Content

All participants had unlimited access to a digital library of mental health programs and resources that they could access at any time. These included short (2 minutes each) daily exercises; interactive programs and podcasts (2 to 15 minutes each); mindfulness exercises such as meditations and breathing exercises (2 to 15 minutes each); and self-paced structured educational lessons (several chapters of content, akin to self-help workbooks, that are paced to be completed over several weeks). Digital programs were developed and designed by an in-house team of clinical psychologists and covered topics such as emotions, relationships, professional life, healthy lifestyles, and finances. Engagement across all digital resources was combined in analyses to represent total digital program engagement.

Study Measures

Demographic Information

Participants self-reported demographic characteristics such as age; gender identity (to select all that applied from a list: agender, genderqueer or genderfluid, Māhū [third gender], man, muxe, nonbinary, questioning or unsure, 2-spirit, woman, prefer to self-describe, and prefer not to say); and race and ethnicity (to select all that applied from a list: American Indian or Alaska Native; Asian; Black or African American; Hawaiian or Pacific Islander; Hispanic, Latinx, or Spanish; White [not Hispanic or Latinx]; multiracial) during the screener. On the basis of participants' demographics, 3 categories were used in analyses: men, women, and nonbinary (all other categories except "prefer to self-describe" or "prefer not to say" collapsed).

Depressive Symptoms

The 9-item Patient Health Questionnaire (PHQ-9) [17] was used to assess the presence of depression symptoms over the past 2 weeks at baseline and follow-up. Participants responded on a 4-point scale (0="not at all" to 3="nearly every day"). Possible ranges for scores include 0-27, with higher scores indicating a higher severity of depression symptomatology. The clinically validated cutoff for probable depression ("high risk") is ≥10 [17], and clinical improvement was indicated when participants' scores decreased by >6 points [18].

Anxiety Symptoms

The 7-item Generalized Anxiety Disorder Questionnaire (GAD-7) [19] was used to assess the presence of anxiety symptoms over the past 2 weeks at baseline and follow-up. Participants responded on a 4-point scale (0="not at all" to 3="nearly every day"). The possible range was 0-21, with higher scores indicating a higher severity of anxiety symptomatology. The clinical cutoff score for probable anxiety disorder ("high risk") is ≥8 [20], and improvement was indicated when participants' scores decreased by >4 points [21].

Well-Being

The 5-item World Health Organization Well-Being Index (WHO-5) [22] was used to assess well-being over the past 2 weeks at baseline and follow-up. Participants responded on a 6-point scale (0="at no time" to 5="all of the time"). Scores are summed and multiplied by 4, giving a total range of 0-100, with higher scores indicating greater subjective well-being. The clinical cutoff indicating low well-being ("high risk") is ≤28; recovery was indicated when the baseline score was <28 and the 3-month score was >28. Prior research has defined clinical improvement in well-being as an increase of at least 10 points [22,23].

Platform Engagement

To operationalize care engagement, we categorized participants based on whether they (1) engaged in care at the level recommended, (2) underused care, or (3) overused care. We defined engaging or following the care recommendation as a participant using their level of recommended care (with the ability to use anything below that level of care). Overusing care occurred when participants used a higher level of care than what they were initially recommended (intensified their care above what was originally recommended, regardless of whether that use step-up was self-referred or referred by a provider). Because participants who were originally recommended therapy as their care modality could not step up their care any higher, only participants who were recommended coaching or digital content or coaching could overuse care. Finally, we defined the underuse of care as participants using a lower level of care than their recommendation and not using any higher care modality. Because participants who were recommended digital content could not use a lower level of care, only participants who were recommended therapy or coaching could underuse it.

Statistical Analysis

Analysis of participant demographics and preliminary analyses were conducted using descriptive statistics and frequencies. We used McNemar χ^2 tests and paired sample 2-tailed *t* tests to examine the clinical effectiveness of the platform, that is, mental health improvement, recovery, or maintenance. Specifically, we used McNemar χ^2 tests to assess whether the percentage of participants categorized as high risk in each mental health outcome significantly decreased from baseline to follow-up. We used paired sample *t* tests to assess whether changes in each outcome (measured continuously) were significantly improved from baseline to follow-up.

We also reported the percentage of participants who reliably improved, recovered, and maintained their mental health. For participants who met the clinical cutoff for outcomes at baseline ("high risk"), we examined improvement or recovery in symptoms from baseline to the 3-month follow-up. Improvement in each measure was indicated when participants' scores changed by established clinical thresholds (see the Study Measures section), and recovery in each measure was indicated when participants met or exceeded the clinical cutoff at baseline (ie, were categorized as "high risk") but did not meet the clinical cutoff at follow-up (ie, were categorized as "low risk"). Maintenance was indicated when participants remained below the clinical cutoff from baseline ("low risk") to follow-up. Continuous variables (ie, depressive and anxiety symptoms and well-being at baseline and follow-up) were examined for kurtosis and skewness; all values were between −1 and 1. Thus, original values were used in analyses.

We assessed our research question regarding use-care recommendations using frequencies and descriptive statistics. We report the percentage of participants who engaged in their recommended services, the percentage who overused services, and the percentage who underused services.

Results

Study Participants and Preliminary Analyses

A total of 950 members completed the baseline survey, of which 696 (73.2%) completed the follow-up survey. Of the 696 with full data, 528 (75.9%) members engaged with the platform (eg, used digital content, had teletherapy, or had a telecoaching visit) at least once between baseline and follow-up. There were 10 (n=528, 1.9%) participants who were not included in data analyses because they were recommended a care modality for which we did not have engagement data (ie, group psychoeducation sessions), and 9 (n=528, 1.7%) participants were not provided with a recommended care plan for reasons unknown. There were no significant baseline clinical differences between people who did not engage with anything on the Modern Health app after baseline (n=168) and those who did engage. As engagement with the app at least once during the analytic time frame was necessary for inclusion in the study, the remaining analyses included the final 509 (53.6% of enrolled) participants for every outcome except for anxiety, for which there were missing data, that yielded a total of 506 (53.2% of enrolled) for anxiety analyses.

The *t* test and χ^2 analyses comparing baseline data from individuals who met final eligibility criteria (509/950, 53.6%) versus those who did not meet eligibility criteria (441/950, 46.4%) revealed no significant differences in age, gender identity, or race and ethnicity at baseline, and the groups were not significantly different on depression, anxiety, or well-being scores when assessed continuously (*P* values >.10). The participants who met the final eligibility criteria were significantly less likely to meet the clinical cutoffs for depressive and anxiety symptoms and low well-being (*P* values <.001).

The descriptive statistics of the sample are provided in Table 1.

Of the 509 participants, 342 (67.2%) engaged with digital content on the app at least once. A total of 159 (31.2%) participants attended at least 1 therapy visit, and 296 (58.2%) participants attended at least 1 coaching visit. The participants that attended therapy or coaching visits typically saw 1 provider over the course of the study (149/159, 93.7% and 283/296, 95.6%, respectively). The maximum number of therapists and coaches seen by any 1 participant were 3 and 2, respectively.

Table 1. Descriptive statistics of sample[a] (n=509).

	Values	Participants at baseline, n (%)	Participants at 3-month follow-up, n (%)
Age (years), mean (SD)	33.9 (8.7)	—[b]	—
Race/ethnicity, n (%)			
Asian	91 (17.9)	—	—
American Indian or Alaska Native	1 (0.2)	—	—
Black	33 (6.5)	—	—
Hispanic, Latinx, or Spanish origin	44 (8.6)	—	—
White (non-Hispanic or Latinx)	305 (59.9)	—	—
Multiracial	33 (6.5)	—	—
Gender identity, n (%)			
Women	312 (61.3)	—	—
Men	175 (34.4)	—	—
Nonbinary	22 (4.3)	—	—
Scores[c]			
Depressive symptoms above clinical cutoff	—	187 (36.7)	106 (20.8)
Anxiety symptoms above clinical cutoff	—	215 (42.2)	156 (30.8)
Well-being below clinical cutoff	—	127 (25)	94 (18.5)

[a]n=509 for depressive symptoms and well-being and n=506 for anxiety symptoms.

[b]—: not available.

[c]Possible ranges for scores include 0 to 27 for depressive symptoms, 0-21 for anxiety symptoms, and 0-100 for well-being. Clinical cutoffs at baseline were ≥10 for depressive symptoms, ≥8 for anxiety symptoms, and ≤28 for well-being.

Improvement and Recovery in Mental Health Symptoms Among Participants at Higher Risk at Baseline

All improvement, recovery, and change in mental health results among participants who met the clinical cutoff on each measure at baseline are presented in Tables 2 and 3.

Participants at a higher risk for depressive symptoms at baseline reported a statistically significant 37% improvement in PHQ-9 scores at follow-up, on average, with 65.2% (122/187) experiencing clinically meaningful improvement or recovery (P<.001). Participants at a higher risk for anxiety symptoms at baseline reported a statistically significant 29% improvement in GAD-7 scores at follow-up, on average, with 59.1% (127/215) experiencing clinically meaningful improvement or recovery (P<.001). Participants at a higher risk for lower well-being at baseline reported a statistically significant 90% improvement in WHO-5 scores at follow-up, on average, with 65.6% (82/127) experiencing clinically meaningful improvement or recovery (P=.002). Post hoc sensitivity analyses revealed that our models among higher-risk participants were sensitive to detect small effect sizes (Cohen d_z=0.20 for depressive symptoms, 0.19 for anxiety symptoms, and 0.25 for well-being), with 80% power and α=.05.

Table 2. Clinical improvement, recovery, and change in mental health from baseline to follow-up among participants at higher risk at baseline (n=509).

Baseline symptoms[a]	Improvement, n (%)	Recovery, n (%)	Improvement and recovery, n (%)	Improvement or recovery, n (%)
Depressive symptoms (n=187)	83 (44.4)	106 (56.7)	67 (35.8)	122 (65.2)
Anxiety symptoms (n=215)	107 (49.8)	98 (45.6)	78 (36.3)	127 (59.1)
Well-being (n=127)	76 (59.8)	71 (55.9)	65 (51.2)	82 (64.6)

[a]Possible ranges for scores include 0-27 for depressive symptoms, 0-21 for anxiety symptoms, and 0-100 for well-being.

Table 3. Change in mental health from baseline to follow-up among participants at higher risk at baseline (n=509).

Baseline symptoms[a]	Baseline, mean (SD)[b]	Follow-up, mean (SD)[c]	Cohen *d*	*t* test (*df*)	*P* value
Depressive symptoms (n=187)	14.13 (3.43)	8.91 (4.25)	1.16	15.81 (186)	<.001
Anxiety symptoms (n=215)	12.68 (3.69)	8.99 (4.76)	0.75	11.02 (214)	<.001
Well-being (n=127)	20.44 (6.80)	38.80 (19.75)	−0.93	−10.50 (126)	<.001

[a]Possible ranges for scores include 0-27 for depressive symptoms, 0-21 for anxiety symptoms, and 0-100 for well-being.

[b]Improvement was indicated when depressive and anxiety symptom scores decreased by ≥6 points, and ≥4 points, respectively, and when well-being scores increased by ≥10 points.

[c]Recovery was indicated when participants met or exceeded the clinical cutoff at baseline, but not at follow-up.

Maintenance of Mental Health Symptoms Among Participants at Lower Risk at Baseline

All maintenance and change in mental health results among participants who had mild or no symptoms on each measure at baseline are presented in Table 4.

Participants at a lower risk for depressive symptoms at baseline reported a small, significant improvement in PHQ-9 scores at follow-up, on average, with 92.2% (297/322) maintaining their low symptom status. Participants at lower risk for anxiety symptoms at baseline reported no significant change (and no escalation) in the GAD-7 scores at follow-up, on average, with 86.7% (255/291) maintaining their low symptom status. Participants at a lower risk for poorer well-being at baseline reported a small, significant improvement in the WHO-5 scores at follow-up, on average, with 90.1% (344/382) maintaining their low symptom status. Post hoc sensitivity analyses revealed that our models among lower-risk participants were sensitive to detect very small effect sizes (Cohen d_z=0.16 for depressive symptoms, 0.16 for anxiety symptoms, and 0.14 for well-being), with 80% power and α=.05.

Table 4. Maintenance and change in mental health from baseline to follow-up among participants at lower risk at baseline (n=509).

Baseline symptoms[a]	Maintenance[b], n (%)	Baseline, mean (SD)	Follow-up, mean (SD)	Cohen *d*	*t* test (*df*)	*P* value
Depressive symptoms (n=322)	297 (92.2)	4.82 (2.88)	4.39 (3.42)	0.13	2.26 (321)	.02
Anxiety symptoms (n=291)	255 (86.7)	3.79 (2.24)	4.00 (3.57)	−0.06	−1.01 (290)	.31
Well-being (n=382)	344 (90.1)	51.84 (14.07)	58.55 (18.83)	−0.40	−7.90 (381)	<.001

[a]Possible ranges for scores include 0-27 for depressive symptoms, 0-21 for anxiety symptoms, and 0-100 for well-being.

[b]Maintenance was indicated when participants did not meet or exceed the clinical cutoff at baseline or follow-up.

Engagement in Recommended Care Plan

Of the 509 participants, 99 (19.4%) were recommended therapy and all lower-level services, 362 (71.1%) were recommended coaching and lower-level services, and 48 (9.4%) were recommended digital content only. Most participants (343/509, 67.4%) engaged with the level of care recommended to them; that is, they engaged at least once with their recommended care modality and did not step up above their recommended care. Specifically, of the 99 participants who were recommended therapy, 84 (85%) met with a therapist at least once; of the 362 participants who were recommended coaching, 224 (61.9%) met at least once with a coach; and of the 48 participants who were recommended digital content, 35 (73%) engaged with at least 1 piece of digital content.

A total of 16.9% (86/509) of the participants overused care beyond their original recommendation; that is, they used a care modality of higher intensity than they were recommended. Of the 362 participants who were recommended coaching, 73 (20.2%) intensified their care to meet with a therapist. Of the 48 participants who were recommended digital content, 13 (27%) intensified their care to access coaching and 2 (4%) participants intensified their care to access a therapist.

In total, 15.7% (80/509) of the participants underused care; that is, they did not engage with the care they were recommended or with a higher-intensity care. Specifically, 15 (15%) of the 99 participants who were recommended therapy declined the invitation to connect with a therapist, and 65 (10.8%) of the 362 participants who were recommended coaching declined the invitation to connect with a coach. A post hoc chi-square analysis comparing the likelihood of clinical improvement or recovery among groups of underusers, overusers, and those who engaged with their recommended level of care found no significant differences in outcomes between groups.

Discussion

Principal Findings

We examined the clinical effectiveness of and engagement in a digital mental health platform that uses a stratified blended care model to deliver mental health services. We found significant improvements in depressive, anxiety, and well-being symptoms among participants with elevated baseline symptoms and high rates of maintaining low symptoms and well-being among participants with lower clinical risk at baseline. Between 60% and 66% of the participants experienced clinically

meaningful improvement or recovery in depressive, anxiety, or well-being symptoms over 3 months. We observed the greatest improvements in well-being (90% score increase), followed by depressive (37% score reduction) and anxiety symptoms (29% score reduction). These results are similar to the published rates of recovery in stepped care systems, which range from 40% to 60% [24].

Among participants with a lower baseline risk (defined as having scores that did not meet the clinical cutoff for that measure), mental health symptoms did not escalate above the clinical threshold or significantly worsen overall; anxiety symptoms remained stable, and depressive symptoms and well-being slightly improved on average. Between 87% and 92% of the participants experienced maintenance of good mental health at follow-up. Given that prevention and well-being promotion are cost-effective for mental health care and provide a positive return on investment for payers [25], our results lend further support to digital mental health services as being helpful for maintaining good mental health. Examining both symptom improvement and prevention of escalating symptoms is crucial to evaluating whether a model of mental health care is improving population health.

Most participants engaged with their personalized care recommendation, with only around one-third overusing or underusing services. Two-thirds (343/509, 67.4%) of the participants used the recommended level of services; that is, they engaged with their recommended care services but did not step up to use higher-intensity care. Rates of meeting the care recommendation were the highest for therapy, with 85% (84/99) of people who were recommended therapy having at least 1 visit with a therapist.

We also found that less than one-fifth (86/509, 16.9%) of the participants overused care; that is, they engaged with a care modality of a higher intensity than the one they were initially recommended. Although we did not have data available on referral pathways, participants could use a higher intensity of care through 2 channels: self-referral by contacting member services through the platform with their request and provider referral where a coach could refer a participant to a therapist if they had a demonstrated clinical need. Interestingly, patterns of overuse matched the intensity hierarchy of services: 20% (73/362) of the people who were recommended coaching moved up 1 level of intensity to therapy, 27% (13/48) of the people who were recommended digital content moved up 1 level to coaching, and only 4.2% (2/48) of the people who were recommended digital content moved up 2 levels to therapy. This further supports the accuracy of the initial care recommendations of this model. In addition, the fairly low rates of overuse are encouraging, considering long-held beliefs about psychotherapy as the gold standard for mental health treatment at all levels of care [26].

Finally, less than one-fifth (80/509, 15.7%) of the participants underused care; that is, they only engaged with lower-intensity care modalities than their recommendation. The rate was slightly higher for those who were recommended therapy (of the 99 participants, 15 (15%) did not have a visit with a therapist), while among those who were recommended coaching, 10.8% (65/362) did not have a visit with a coach or therapist. These rates of treatment nonadherence are consistent with those observed in psychotherapy research [27] and are better than those observed in previous research on digital interventions [28]. A post hoc analysis did not find statistically significant differences in improvement or recovery between people who followed their recommended care and those who overused or underused care. However, the lack of significance could be an artifact of low statistical power, given the skewed proportion of participants in the underuse and overuse categories. Future research that examines reasons for underusing or overusing care qualitatively would provide further insight into why this occurs for some people and may allow programs to stratify individuals into levels of care more appropriately.

It is difficult to compare the effectiveness of stratified blended care approaches in real-world contexts with that of other studies in the literature because most research has been conducted within highly controlled clinical trials, which lack ecological validity (eg, see Andrews et al [13] and Ho et al [29]). However, in one trial comparing stratified and progressive stepped care models, 76% of eligible screened patients engaged in treatment (high intensity or low intensity depending on personalized treatment recommendations) [16]. Thus, the engagement rate observed here is similar to that in research settings with high internal validity, suggesting that this platform is relatively accurate in recommending effective care. Our observational results of stratified blended care engagement patterns indicate that this model was efficient in matching individuals with the most effective and least costly care while also allowing them to self-determine their care and use combinations of services that best fit their needs.

Limitations

Although this investigation demonstrated improvements in depression, anxiety, and well-being over time in a sample of digital mental health platform users, the observational nature of this study presents a limitation. The inclusion of a comparison or control group in an experimental design would confirm the causality of the observed changes. The 3-month time frame of this investigation also limits our conclusions to short-term gains; a longer-term follow-up period is needed to determine the persistence of improvements.

Only 9.25% (950/10,270) of the individuals who were eligible and invited to participate enrolled in this study. The reasons for this are not known but may be due to a combination of factors, such as the time commitment needed, as each survey took between 30 and 45 minutes to complete. In addition, although study materials highlighted the separation between the study and their employer, most invitations to participate were distributed to workplace email addresses, which may have given the impression to participants that their employers would be involved or aware of their participation in this investigation. Although the retention rate of this investigation was 73.26% (696/950) overall, the sample was limited to those who used at least 1 piece of content or sought a provider. More individuals were registered for the platform but did not use any care. This is common in real-world settings, as individuals may register for services without the intention of using them immediately.

There were no significant differences on key demographic characteristics and baseline symptoms between the sample who met eligibility criteria and those who did not, which helps to bolster the generalizability of our findings.

In addition, we were unable to discern between self-referrals and provider referrals for the 16.9% (86/509) of the members who sought more intensive services beyond their initial care recommendation. It is possible that the 17% include some individuals who were appropriately identified for intensification of services (ie, a coach detected additional symptoms, or a member disclosed additional pertinent information that was not detected in the assessment algorithm that determines care recommendations).

Finally, most of the sample (312/509, 61.3%) identified as women, and only 34.4% (175/509) identified as men. Furthermore, the percentage of nonbinary people in this sample was higher than the overall US population [30] at 4.3%. There are several possibilities for the disproportionate numbers of women and nonbinary people enrolling in this study. First, the disproportionate number of nonbinary people in the sample may reflect a younger population, who are more likely to identify as transgender or nonbinary than older populations (5% vs 1.6% overall) [30]. In addition, we provided multiple nonbinary options for participants as opposed to a single all-encompassing option (eg, “nonbinary”), which may have encouraged identification. Finally, women and people who are lesbian, gay, bisexual, transgender, or questioning, including people who identify as nonbinary, are more likely to experience mental illness [31,32]. Women are more likely to seek help than men (due in part to societal expectations of stoicism and self-reliance for men, as well as mental health stigma), which might have affected their likelihood of signing up for the Modern Health app and participating in research [33]. Regardless of the reason for the lack of men in this sample, it is possible that the results here may be different among other populations, and we encourage future research to examine these potential differences.

Conclusions

Overall, the results of this study lend support to the utility and effectiveness of the stratified blended care model used in this study to improve access to and use of mental health services. In a resource-constrained ecosystem, using a stratified blended model, such as the one evaluated, can make efficient use of limited and costly services while centering the individual’s needs, preferences, and receptivity to mental health care. The deliberate allocation of resources preserved the more intensive and costly resources for those who are most likely to benefit from them while providing beneficial care at all levels. As our results indicate, meaningful clinical improvements can be gained through stratified blended care while honoring the individual’s personal preference for how they want to engage in care.

Research continues throughout the field of mental health to determine the therapeutic approaches, techniques, and tools that can be adapted and disseminated for digital delivery while preserving safety, quality, validity, and efficacy [34]. As progress continues, the constraints of the traditional tertiary care model of mental health will eventually give way to a more comprehensive approach that can serve the full spectrum of mental health from primary prevention to treatment.

Acknowledgments

The authors would like to thank Dr Myra Altman, the Modern Health Clinical Strategy and Research team, the larger Modern Health organization, as well as the members and providers for their contributions to this work. The authors declare that no funds, grants, or other support was received to support the preparation of this manuscript.

Data Availability

The data sets generated during and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

This study was conceived and designed by LGR, SJS-H, CCS, and CEWC. Data were acquired by SJS-H, CEWC, and BJS. LGR contributed to data analysis, while LGR, SJS-H, CCS, and BJS interpreted the data. The manuscript was drafted by LGR, SJS-H, CCS, and CEWC and critically revised by LGR, SJS-H, CCS, CEWC, and BJS. All authors provided critical feedback and edits to each version of the manuscript. All authors read and approved the final manuscript and agreed to be accountable for all aspects of the work.

Conflicts of Interest

SJS-H, CCS, CEWC, and BJS are employed by Modern Health and receive salary and stock options. LGR declares no conflict of interest.

Abstract

Background: Rising rates of psychological distress (symptoms of depression, anxiety, and stress) among adults in the United States necessitate effective mental wellness interventions. Despite the prevalence of smartphone app–based programs, research on their efficacy is limited, with only 14% showing clinically validated evidence. Our study evaluates Noom Mood, a commercially available smartphone-based app that uses cognitive behavioral therapy and mindfulness-based programming. In this study, we address gaps in the existing literature by examining postintervention outcomes and the broader impact on mental wellness.

Objective: Noom Mood is a smartphone-based mental wellness program designed to be used by the general population. This prospective study evaluates the efficacy and postintervention outcomes of Noom Mood. We aim to address the rising psychological distress among adults in the United States.

Methods: A 1-arm study design was used, with participants having access to the Noom Mood program for 16 weeks (N=273). Surveys were conducted at baseline, week 4, week 8, week 12, week 16, and week 32 (16 weeks' postprogram follow-up). This study assessed a range of mental health outcomes, including anxiety symptoms, depressive symptoms, perceived stress, well-being, quality of life, coping, emotion regulation, sleep, and workplace productivity (absenteeism or presenteeism).

Results: The mean age of participants was 40.5 (SD 11.7) years. Statistically significant improvements in anxiety symptoms, depressive symptoms, and perceived stress were observed by week 4 and maintained through the 16-week intervention and the 32-week follow-up. The largest changes were observed in the first 4 weeks (29% lower, 25% lower, and 15% lower for anxiety symptoms, depressive symptoms, and perceived stress, respectively), and only small improvements were observed afterward. Reductions in clinically relevant anxiety (7-item generalized anxiety disorder scale) and depression (8-item Patient Health Questionnaire depression scale) criteria were also maintained from program initiation through the 16-week intervention and the 32-week follow-up. Work productivity also showed statistically significant results, with participants gaining 2.57 productive work days from baseline at 16 weeks, and remaining relatively stable (2.23 productive work days gained) at follow-up (32 weeks). Additionally, effects across all coping, sleep disturbance (23% lower at 32 weeks), and emotion dysregulation variables exhibited positive and significant trends at all time points (15% higher, 23% lower, and 25% higher respectively at 32 weeks).

Conclusions: This study contributes insights into the promising positive impact of Noom Mood on mental health and well-being outcomes, extending beyond the intervention phase. Though more rigorous studies are necessary to understand the mechanism of action at play, this exploratory study addresses critical gaps in the literature, highlighting the potential of smartphone-based mental wellness programs to lessen barriers to mental health support and improve diverse dimensions of well-being. Future research should explore the scalability, feasibility, and long-term adherence of such interventions across diverse populations.

KEYWORDS

mHealth; psychological distress; Noom Mood; digital mental wellness programs; mobile phone

Introduction

Psychological distress, encompassing nonspecific symptoms of stress, anxiety, and depression, has been on the rise in the United States since 1999. More specifically, a 40% increase in prevalence was found from 2000 to 2018 [1-4] and was exacerbated by the COVID-19 pandemic [5-9]. One 2020 meta-analysis found the prevalence of stress in the general population to be between 29.6% and 33.7% [5]. This distress correlates with personal and occupational impairment, chronic medical disorders, adverse health behaviors, and increased mortality risk from diseases such as cardiovascular disease, cancer, and liver disease [10-12]. Depression and anxiety symptoms also predict absenteeism (missed work days) and presenteeism (low productivity days), costing an estimated 3% to 4% of the gross national product [13-16].

Despite the high prevalence, a large portion of affected adults do not receive necessary mental health support. Common barriers to mental health support in the United States include a desire for autonomy in the process, fear of social stigma, and lack of access (financially and structurally) [17-19]. Smartphone app–based mental wellness programs offer a promising solution, and the benefits of mobile mental wellness programs include increased convenience, adherence, personalization, social support, and cost-effectiveness [20-22]. However, research on their effectiveness is lacking [23], with only 14% showing clinically validated evidence of effectiveness [18], particularly among commercially available programs.

In response to the scarcity of clinical validation among these programs, we previously evaluated the feasibility and short-term efficacy of Noom Mood [24], a commercially available, smartphone-based mental wellness program that provides educational content, skills-based activities, and nonclinical coaching support to help users manage stress and symptoms of anxiety. In this study, we extend our initial findings (at 4 weeks) to the full length of the intervention (at 16 weeks) and postintervention (at 32 weeks) in a larger sample. We also aim to contribute to important gaps within the literature by increasing our understanding of the efficacy and outcome maintenance associated with mobile mental wellness programs.

Research on the maintenance of outcomes after completing mobile mental wellness programs is currently scarce and is essential to inform postintervention support and establish long-term efficacy. Economides and colleagues [25] provide some evidence that a reduction in anxiety and depressive symptoms can be maintained at 6 months post intervention. However, their analysis was retrospective, and follow-up assessments were limited. High-quality, long-term postintervention data are needed to better understand the full clinical utility of mobile mental wellness programming for the general population [26]. In addition, there are gaps in the existing literature looking at overall mental wellness, beyond mental health-related symptoms (eg, emotion regulation, coping, or quality of life). Despite theoretical and empirical assertions that smartphone-based programs can indirectly help improve mental wellness, such outcomes have not been widely studied [27,28].

This 1-arm prospective study examines the efficacy and postintervention outcomes of a commercially available mental wellness program on a broad range of mental health outcomes: symptoms of anxiety, stress, and depression, as well as well-being, quality of life, coping skills, emotion regulation, sleep, and workplace presenteeism and absenteeism. In doing so, this study contributes to the empirical foundation and clinical utility of such programming for the general population.

Methods

Participants

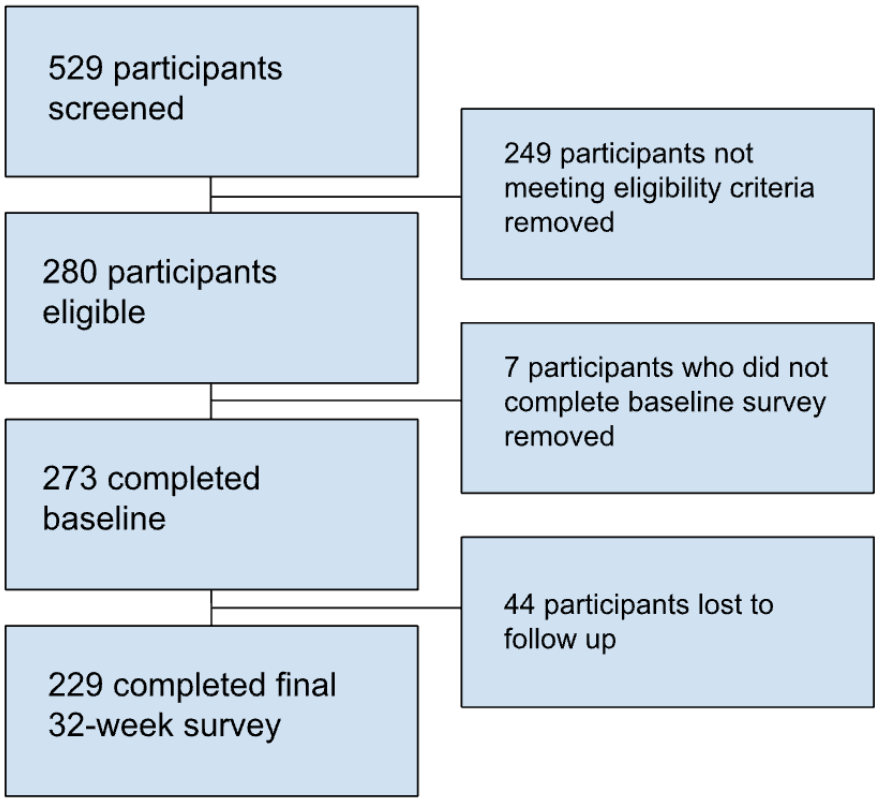
A total of 273 adults participated in this study. All participants were recruited from social media (ie, Facebook and Instagram) between May and September 2022, with advertisements targeting a 50% (50/100) female audience. Before enrollment, an online screening questionnaire confirmed eligibility. A total of 529 participants were recruited and screened for this study.

Participants were eligible for participation in this study if they were located in the United States, English-speaking, aged older than 18 years, used an Apple operating system mobile device, and agreed to not alter current mental health treatment, if any. Given the online nature of this study, they were required to verify their identity by uploading a photo of their state-issued identification card. They were also required to complete a decisional balance exercise to ensure a thorough understanding of and willingness to participate in this study. This exercise, based on the work of Goldberg and Kiernan [29], aimed to increase study retention rates by discussing the nature, design, and importance of this study and required potential participants to consider all the pros and cons of participation before deciding whether or not to participate.

Participants were excluded if they had a current or past diagnosis of psychotic disorder or bipolar disorder; if they had started, stopped, or changed doses of psychotropic medication in the past 2 months; or had started or stopped psychotherapy within the past 2 months. They were excluded if they had used the Noom Mood program previously, or were currently using the Noom Weight program.

In total, 351 participants were eligible for participation. Eligible participants were provided informed consent forms and were required to download the app within 14 days to be considered fully enrolled. The final sample included 273 participants who downloaded the program and provided consent (see Figure 1).

Figure 1. Study flow CONSORT diagram. CONSORT: Consolidated Standards of Reporting Trials.



Ethical Considerations

This study was approved by the Advarra Institutional Review Board (Pro00062644).

Power Analysis and Sample Size Calculation

The sample size was determined based on an estimated medium effect on postintervention scores on our primary outcome, the 7-item generalized anxiety disorder scale (GAD-7), from baseline to end of the program, 95% power, and α set at .05. The effect size is based on an ITT analysis of the GAD-7 (d=0.70) from a previous Noom Mood feasibility study [24]. The sample size calculation was conducted using G*Power [30] matched pairs t tests (2-tailed). Our recruitment target also accounted for 48% attrition, based on a recent meta-analysis of dropout rates in clinical trials with smartphone apps [31]. Therefore, this study aimed to recruit at least 247 participants in total.

Recruitment and Eligibility

The eligibility criteria of this study included the ability to understand and provide informed consent, willingness to not alter current mental health treatment (ie, psychotropic medications or psychotherapy), aged at least 18 years, English speaking, located in the United States, iOS user (because certain program features were only available on iPhones at the time of study launch), and successful identity verification. The ineligibility criteria included current or past diagnosis of psychotic disorder or bipolar disorder, past use of the Noom Mood program, starting, changing dose, or stopping psychotropic medication within the past 2 months, starting or stopping psychotherapy within the last 2 months, or current use of the Noom Weight program.

Procedure

Participants were invited to complete the baseline questionnaire after consenting to participate in this study. As part of this study, participants were required to redeem a unique code and download the Noom Mood app within 14 days of consent, however, there were no further stipulations on participants' level of engagement with the app. As part of this study, all participants had access to the full Noom Mood program, which consists of 16 weeks of content, at no cost. Participants were surveyed 4, 8, 12, 16, and 32 weeks after baseline. All surveys were administered online via OpenClinica, a HIPAA (Health Insurance Portability and Accountability Act)-compliant electronic data capture platform [32].

Program

Noom Mood is a commercially available, mobile app–based, mobile mental wellness program that focuses on stress and anxiety management as well as improving overall mental wellness. The program is based on cognitive behavioral therapy, dialectical behavior therapy, acceptance and commitment therapy, and mindfulness-based stress reduction with an emphasis on building a toolkit of coping skills that can be applied to daily life. Participants have access to several program features, including a daily curriculum consisting of psychoeducational articles for users to read, personalized coaching offered through in-app messaging, weekly skills-based activities, and a mood-logging feature. In a previous study of feasibility, acceptability, and preliminary outcomes, significant improvements in anxiety symptoms, perceived stress, depressive

feelings, emotion regulation, and optimism were found from baseline to 4-week follow-up. Additionally, learning coping skills (eg, breathing and cognitive reframing techniques), interacting with the program features, and gaining awareness of personal emotions and thought patterns were the features of the program that participants reported benefiting most from [24].

Measures

Overview

The primary outcomes of this study were self-reported measures of symptoms of anxiety, stress, depression, perceived health and quality of life, and mental wellness, detailed below.

Anxiety Symptoms (GAD 7)

The GAD-7 [33] assesses the extent to which individuals experience symptoms of anxiety (eg, "feeling nervous, anxious, or on edge") on a scale of 0 ("not at all") to 3 ("nearly every day"). Clinical severity was determined using a normed cutoff of 10 for this measure.

Depressive Symptoms (8-Item Patient Health Questionnaire Depression Scale)

The 8-item Patient Health Questionnaire depression scale [34] assesses the extent to which participants experience feelings of depression (eg, "feeling down, depressed, or hopeless" or "little interest or pleasure in doing things") on a scale of 0 ("not at all") to 3 ("nearly every day"). Clinical severity was determined using a normed cutoff of 10 for this measure.

Perceived Stress (10-Item Perceived Stress Scale)

The 10-item Perceived Stress Scale [35] assesses the frequency with which individuals experience various symptoms of stress (eg, "how often have you felt that you were unable to control the important things in your life?") on a scale of 0 ("never") to 4 ("very often").

Mental Wellness (14-Item Warwick Edinburgh Mental Well-Being Scale)

The 14-Item Warwick Edinburgh Mental Well-Being scale [36] measures mental wellness. The questions (eg, I have been feeling "optimistic, useful, relaxed") are answered using a scale of 0 ("none of the time") to 5 ("all of the time").

Absenteeism, Presenteeism, and Productivity Loss (Sheehan Disability Scale, Modified)

The Sheehan Disability Scale [37] is a scale that measures impairment in functioning ("how many days in the last week did your symptoms cause you to miss school or work or leave you unable to carry out normal daily responsibilities?"). Further, 2 items in particular were used for this study. Absenteeism was measured with the days lost item ("on how many days in the last month did your symptoms cause you to miss school or work or leave you unable to carry out your normal daily responsibilities?"); participants provided a number from 0 to 30. Presenteeism was measured with the days unproductive item ("on how many days in the last month did you feel so impaired by your symptoms, that even though you went to school or work, your productivity was reduced?") Participants provided a number from 0 to 30. Productivity loss was calculated as the sum of absenteeism and presenteeism, similar to previous work [38,39].

Quality of Life (10-Item Patient-Reported Outcomes Measurement Information System Global)

The 10-item Patient-Reported Outcomes Measurement Information System Global scale [40] measures general health care–related quality of life (eg, "how would you rate your physical health?") on a scale of 1 ("poor") to 5 ("excellent").

Sleep (Pittsburgh Sleep Quality Index)

The Pittsburgh Sleep Quality Index [41] is a 9-item scale used to measure sleep quality and patterns in adults. The first 4 questions (for instance, "when have you usually gone to bed?") are free-response questions. The following 4 questions (eg, "during the past month, how often have you taken medicine [prescribed or 'over the counter'] to help you sleep?") use a scale of 0 ("not during the past month") to 3 ("three or more times per week"). The final question ("during the past month, how would you rate your sleep quality overall?") uses a scale of 0 "very good" to 3 "very bad."

Emotion Regulation (Difficulties in Emotion Regulation Scale)

The Difficulties in Emotion Regulation Scale [42] is an 18-item scale that measures emotional dysregulation (eg, "I pay attention to how I feel") and uses a scale of 1 "almost never" to 5 "almost always."

Statistical Analysis

All analyses were linear mixed-effects models. Dummy codes reflecting comparisons between baseline and all other time points were included as predictors of each primary outcome. Random intercepts were specified for all models. For count data (eg, absenteeism or presenteeism), a Poisson mixed-effects model was used. For categorical outcomes (eg, clinical cutoffs), logistic mixed-effects models were used. Maximum-likelihood estimation was used to account for missing data, which was relatively low (see below).

Results

Demographics and Participation

Participant demographic characteristics are presented in Table 1. Of the 273 participants, the mean age was 40.5 (SD 11.7) years. Nearly half (124/273, 45.4%) identified as female, 53.8% (147/273) as male, and 0.7% (2/273) as other, within a predominantly White, non-Hispanic sample (85%). A substantial portion of the sample possessed a college degree (103/273, 37.7%) or graduate degree (81/273, 29.7%). Income distribution spanned a wide range, with the majority reporting annual incomes of US $25,000-$50,000 (44/273, 16.1%), US $50,000-$100,000 (98/273, 35.9%), or US $100,000-$200,000 (70/273, 25.6%). Attrition was minimal and unlikely to introduce bias, with a maximum of 7% missing data reported at all time points.

Retention

Of the 273 participants who on a baseline survey with retention rates at the 4-week, 8-week, 12-week, 16-week, and 32-week surveys, respectively, were 266/273 (97.4% retention rate from baseline), 255/273 (93.4% retention rate from baseline), 245/273 (89.7% retention rate from baseline), 250/273 (91.6% retention rate from baseline), and 229/273 (83.9% retention rate from baseline).

Psychological Distress

Statistically significant changes in anxiety symptoms, depression symptoms, perceived stress, well-being, and quality of life were observed by week 4 and maintained through program end (16 weeks) and follow-up (32 weeks, $P<.001$). The largest changes occurred between baseline and 4 weeks, with only small incremental improvements afterward, as shown in Figure 2. Mixed-effects regression models, using random intercepts, were used to assess the impact of time on the aforementioned variables, as depicted in Figure 2 and Tables 2 and 3. All comparisons between program end (16-weeks) and follow-up (32-weeks) were not statistically significant ($.29\leq P$ values $\leq.99$).

Clinical Severity

At baseline, nearly half of all participants met clinically relevant criteria for anxiety (130/273, 47.6%) and depression (130/273, 47.6%) symptoms. A mixed-effects binomial logistic regression with a random intercept was conducted to analyze changes in clinical severity. Reductions in the probability of meeting clinically relevant criteria for anxiety or depression were significant across all time points (P<.001), as shown in Tables 4 and 5. By week 4, the model estimates that only 10% and 12% met the criteria for anxiety or depression, respectively. By week 8, these estimated percentages further decreased to 8% and 9%. The substantial reduction in participants meeting clinical criteria for anxiety or depression was maintained on average through program end (16 weeks) and follow-up (32 weeks), as illustrated in Figure 3.

Overall Well-Being

Secondary effects of the intervention on coping, emotion regulation, sleep, and workplace absenteeism or presenteeism were examined via separate models for each variable. Absenteeism and presenteeism days were aggregated to form a comprehensive productivity loss outcome. A 0-inflated Poisson mixed-effects model with a random intercept was used for absenteeism and presenteeism. By program end (16 weeks), participants gained 2.57 productive work days from baseline, with this number remaining relatively stable (2.23 days) at follow-up (32 weeks). Effects across all well-being variables exhibited positive and significant trends at all time points (P<.001), as summarized in Tables 6 and 7 and displayed in Figure 4.

Discussion

Principal Findings

This study contributes to research on mobile mental wellness interventions by examining the efficacy and postintervention outcomes of the Noom Mood program for the general population. The investigation addresses gaps in the existing literature by examining the impact of this type of intervention on mental health and well-being outcomes both postintervention and after a 16-week maintenance period. Using a prospective 1-arm design, our study evaluated the effects of Noom Mood on an array of mental health indicators and well-being measures, spanning from baseline assessment to a follow-up assessment 32 weeks later (16 weeks after the conclusion of the intervention phase). Promising results were seen in terms of improvements in mental health, workplace productivity, and well-being outcomes.

Our study benefited from several notable strengths. First, a major strength of this study was the achievement of retention rates ranging from 85% to 98%. Low retention rates are a widely acknowledged barrier to understanding and applying the results of digital health research. Other digital studies have often found the most successful retention rates (48%-56%) to still remain suboptimal [31,43]. The higher retention rates observed within this study are likely related to the screening practices used, such as the decisional balance exercise, which are designed to both select for and enhance participant motivation and commitment at this study's start [29]. An additional strength of this study is the generalizability of the results. Given that we did not select individuals with a certain score on mental health measures, the results support the intervention's ability to reduce distress and enhance well-being for this quite large group of individuals. Furthermore, we did not use a certain engagement threshold for this study, meaning that participants were able to use the app as much or as little as they liked, and the results remained promising. Finally, this type of mobile app–based intervention has a large potential for scalability.

Mental Health

Mobile mental wellness apps have shown promising potential in providing support and resources for individuals experiencing stress, symptoms of depression, and symptoms of anxiety [21,44,45]. Further, a study by Economides et al [25] reported substantial and sustained improvements in depression and anxiety symptoms 6 months after an 8-week therapist-led smartphone-based intervention for elevated symptoms of anxiety and depression. Likewise, a recent systematic review and meta-analysis of mobile mental wellness interventions suggested the high potential of these interventions to improve (or significantly support the improvement of) mental health challenges such as depression and anxiety [28]. These findings underscore the potential for a prolonged positive impact of mental wellness interventions on major mental health dimensions.

Similarly, a recent systematic review and meta-analysis of 9 randomized controlled trials (RCTs) including 1837 participants also found small to medium effect sizes of mobile mental wellness apps on anxious symptoms, though when compared

with an active control only small effect sizes were found [21]. Similarly, a meta-analysis of 18 RCTs including 3414 participants found that depressive symptoms were reduced significantly following a digital mental health intervention when compared with a control condition; effect sizes were small, however, when compared to active control conditions [45].

Our findings showed statistically significant reductions within 4 weeks of program initiation for both anxiety and depression symptoms, assessed using the GAD-7 and 8-item Patient Health Questionnaire depression scales respectively. These initial improvements are maintained throughout the program, from the intervention's conclusion at 16 weeks to the 32-week follow-up assessment. Outside of symptom reduction, we observed a significant reduction in the proportion of participants meeting clinically relevant anxiety and depression symptom criteria at all assessment points. Our findings align with other published results, however, the outcomes of the meta-analyses highlight the need for a study comparing Noom Mood with an active control condition.

Workplace Productivity and Accessibility

Previous studies have shown a clear connection between mental health and workplace productivity [13,46-49]. Further, a cross-sectional study found the mean days of absenteeism and presenteeism were significantly higher among participants with moderate or high psychological distress compared to low distress [47], and a recent multi-arm, pilot RCT examining the outcome of digital interventions among working adults showed promising preliminary findings indicating improved depressive symptoms, well-being, and functioning following a digital intervention [48].

In parallel, this study showed the potential of a mental wellness intervention to reduce both symptoms of depression and decreased workplace absences along with improved workplace focus. The personalized nature and convenience of mobile interventions allow them to be positioned as promising tools for reaching individuals with limited access to conventional mental health services.

Furthermore, to rationalize employer investment in mobile mental wellness programs, it is necessary to demonstrate their effectiveness in not only improving employee health and well-being but also in saving money. Previous studies have indicated that digital mental wellness interventions can reduce weekly costs by US $155.82 over 8 weeks [49]. Given the anticipated costs to employers associated with anxiety, stress, and depressive symptoms, there is a clear indication that scalable digital interventions such as Noom Mood have the potential to demonstrate significant cost savings within the workplace.

Well-Being

Several studies have cited the scarcity of research looking at various dimensions of well-being within the context of self-guided mobile mental wellness interventions [27,28]. The literature that does exist is somewhat ambivalent, with some studies finding improvements in well-being as a result of a digital mental wellness intervention and some not. For instance, a recent systematic review and meta-analysis found that digital mental wellness apps, when compared to controls, showed small effects for reducing mental health symptoms and improving well-being, but a medium effect for emotion regulation [28]. Another recent RCT found that the group using a mindfulness app for 4 weeks saw small reductions in stress and depression, but students who practiced more did not experience additional improvement in well-being [50].

Our study reveals enhancements in well-being dimensions including coping skills, emotion regulation, and sleep quality, and suggests that mobile mental wellness programs are not only beneficial in terms of symptom reduction but also support a variety of well-being dimensions. However, given the existing literature, and the limitations of this study's design, more rigorous testing is needed to better understand this association.

Limitations

Limitations of this study include the absence of a control group, lack of sample diversity, reliance on self-report measures, potential selection bias from recruitment via social media ads, and the potential impact of high retention rates on outcomes' representativeness. Importantly, results should be interpreted with caution as this study's design did not use a control group, meaning results could in part be due to the passage of time alone. This study advances understanding of the effects of a commercially available mental wellness program on various mental health outcomes and contributes potential insights into the program's utility for the general population; however, robust research is needed to affirm the program's efficacy, particularly across diverse populations.

Conclusions

In conclusion, this single-arm prospective study examined 16-week and 32-week outcomes of the Noom Mood self-guided smartphone-based mental wellness program, including a 16-week maintenance period. Our outcomes showed positive impacts on mental health and well-being dimensions, both in terms of symptom reduction and broader psychosocial aspects, though outcomes are limited in scope due to the lack of a control arm in this study's design. The results highlight significant improvements across all mental health and well-being outcomes at program end (16 weeks), which extend to postprogram follow-up (32 weeks). Significant improvements emerge as early as the first follow-up assessment, conducted 4 weeks after program initiation. These findings contribute to the evidence base of mental wellness programs and address gaps in the literature concerning maintenance and the comprehensive effects of a digital self-guided mental wellness intervention.

Future studies must include an RCT study design and a study population spanning diverse groups, accounting for race and ethnicity, education level, and income level. Additionally, future research should aim to understand the specific mechanisms underlying the observed improvements as well as explore the program's scalability and feasibility within real-world settings. Further research investigating the program's potential for long-term adherence and sustained outcomes may additionally provide valuable insights for both practitioners and researchers. Lastly, a direct comparison of the effectiveness of the Noom Mood program with similar interventions may shed light on the

relative advantages and disadvantages of different approaches in the field of mobile mental wellness.

Acknowledgments

MM and ESM conceived this study. MM, PT, KB, and MCA carried out study management. MB analyzed data. PT, MF, and AH wrote this paper. AM and CNM provided supervision. All authors were involved in revising this paper and had final approval of the submitted version.

Conflicts of Interest

Authors MM, MB, PT, KB, MCA, and AM are employees at Noom Inc in the academic research department and have received salary and stock options for their employment. Authors MF, AH, ESM, and CNM were employees at Noom at the time of this study. This study was funded by Noom, which did not (other than the specific authors listed above) play a role in this study's design, execution, analyses, interpretation of the data, or the decision to publish the results.

Abstract

Background: Lifestyle behaviors including exercise, sleep, diet, stress, mental stimulation, and social interaction significantly impact the likelihood of developing dementia. Mobile health (mHealth) apps have been valuable tools in addressing these lifestyle behaviors for general health and well-being, and there is growing recognition of their potential use for brain health and dementia prevention. Effective apps must be evidence-based and safeguard user data, addressing gaps in the current state of dementia-related mHealth apps.

Objective: This study aims to describe the scope of available apps for dementia prevention and risk factors, highlighting gaps and suggesting a path forward for future development.

Methods: A systematic search of mobile app stores, peer-reviewed literature, dementia and Alzheimer association websites, and browser searches was conducted from October 19, 2022, to November 2, 2022. A total of 1044 mHealth apps were retrieved. After screening, 152 apps met the inclusion criteria and were coded by paired, independent reviewers using an extraction framework. The framework was adapted from the Silberg scale, other scoping reviews of mHealth apps for similar populations, and background research on modifiable dementia risk factors. Coded elements included evidence-based and expert credibility, app features, lifestyle elements of focus, and privacy and security.

Results: Of the 152 apps that met the final selection criteria, 88 (57.9%) addressed modifiable lifestyle behaviors associated with reducing dementia risk. However, many of these apps (59/152, 38.8%) only addressed one lifestyle behavior, with mental stimulation being the most frequently addressed. More than half (84/152, 55.2%) scored 2 points out of 9 on the Silberg scale, with a mean score of 2.4 (SD 1.0) points. Most of the 152 apps did not disclose essential information: 120 (78.9%) did not disclose expert consultation, 125 (82.2%) did not disclose evidence-based information, 146 (96.1%) did not disclose author credentials, and 134 (88.2%) did not disclose their information sources. In addition, 105 (69.2%) apps did not disclose adherence to data privacy and security practices.

Conclusions: There is an opportunity for mHealth apps to support individuals in engaging in behaviors linked to reducing dementia risk. While there is a market for these products, there is a lack of dementia-related apps focused on multiple lifestyle behaviors. Gaps in the rigor of app development regarding evidence base, credibility, and adherence to data privacy and security standards must be addressed. Following established and validated guidelines will be necessary for dementia-related apps to be effective and advance successfully.

KEYWORDS

dementia; Alzheimer disease; mHealth; mobile health; apps; lifestyle behaviors; mobile phone

Introduction

Background

Dementia, a condition with global impact and no current cure, has led to a rise in mobile health (mHealth) apps catering to individuals and caregivers [1-3]. These apps offer features such as location tracking [4], medication reminders [4], education [3], support for caregivers [3], and planning and information sharing across one's circle of care including with health care providers [5]. Some also focus on screening and diagnostic capabilities, with the ability to analyze large amounts of personal data (eg, changes in voice) that would not have been possible to collect previously [6].

At the same time, research suggests that lifestyle behaviors such as physical activity, sleep, stress, mental stimulation, diet, and social interaction play a crucial role in dementia prevention [7]. Research shows that engaging in these behaviors can significantly decrease the risk of dementia. A recent meta-analysis showed that adults in their 40s who participated in physical activities had a considerably decreased risk of dementia years later [8]. One study found that increased levels of stress and exposure to >2 stressful life events significantly increased the risk of all-cause dementia, while levels of neuroticism caused a higher risk of dementia and Alzheimer disease [9]. Another study found that adults participating in mentally stimulating leisure activities had a significantly decreased risk of developing dementia and other cognitive impairments later in life [10]. According to a random-effect model, individuals with sleep disorders had a higher likelihood of having dementia than those with regular sleep participants [11]. Diet has also been found to be a lifestyle behavior of significance, with one study finding that higher adherence to a Mediterranean diet is adversely related to cognitive decline, dementia, or Alzheimer disease [12]. Similarly, a meta-analysis evaluating social relationships and their impact on the risk of dementia found that social engagement helps prevent dementia. These relationships act as a stress buffer and source of information that help develop positive health behaviors and optimal use of health services [13].

In addition, there is a mounting body of research associating sensory loss and dementia, recognizing a connection between an individual's vision, hearing, dual sensory (vision and hearing) impairment, smell, and touch with their cognitive health [14,15]. Fischer et al [16] have observed an association between the impairment of the auditory, visual, and olfactory faculties and cognitive decline in older adults. This study suggests that hearing loss and cognitive decline may be magnified by several probable mechanisms including social isolation, a lifestyle behavior associated with dementia risk [16,17]. mHealth apps show potential in supporting the maintenance of users' sensory health, as observed in a successful pilot that used a mobile app to support electronic devices in the implementation of a home-based cognitive-multisensory-physical exercise program for participants with dementia [18]. These findings demonstrate the potential of exploring if and how dementia-related apps address sensory decline to maintain users' brain health and prevent cognitive decline.

Currently, there are many popular apps that focus on these lifestyle behaviors and have gained tremendous popularity including MapMyRun that focuses on tracking physical activity and MyFitnessPal, another fitness app focused on tracking diet and calorie intake [19,20]. Although these apps address a number of the lifestyle behaviors (mentioned in the previous paragraphs) that have been linked to the likelihood of developing dementia, few apps have been designed to target these functions specifically for persons with or at risk of developing dementia. Given the movement toward designing mHealth apps to promote healthy lifestyle behaviors (eg, improved diet, exercise habits, and memory-training games), these apps could be leveraged to promote such behaviors earlier in life, with the hopes that this can prevent or delay the onset of dementia or manage symptoms once they present [21,22]. Understanding the breadth of what is available in terms of which lifestyle behavior or combination of behaviors that currently available mHealth apps leverage presents an opportunity to create mHealth apps to address existing gaps and needs for targeted populations.

However, as commercially available smartphone apps can be developed and published by anyone, it is essential to understand which of these are evidence-based so that the public may safely use these apps as a tool for dementia education, prevention, or overall well-being promotion [23]. Since these products may also be eligible for medical device accreditation, or at the very least are considered mHealth or wellness products, we need to understand how they are being marketed, what security and privacy measures are in place to protect their users, and whether the information or tools provided are evidence-based [23]. In particular, these privacy and transparency factors must be strongly considered when leveraging existing or new health apps for persons with dementia or when marketing a certain app as a tool for the prevention of dementia or promotion of well-being. Older adults were found to express concern for their personal information getting hacked while using technology, leading to a hesitancy toward its use [24]. In the case of people with dementia, their personal health information gathered by mHealth apps is at greater risk of being breached [25]. Specifically, many app users with dementia live with impaired cognitive capacity that may interfere with their ability to understand the details of an app's privacy policies, which are usually presented in confusing or complex language [25].

Objective

Our objective with this systematic search and environmental scan was to map out the landscape of smartphone apps intended for use by the general public relating to dementia prevention and its risk factors. We have reported on the breadth and depth of available dementia-related mHealth apps and importantly identified gaps that could be addressed by future apps.

Methods

Systematic Search and Environmental Scan

This study was conducted according to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [26]. Using selected search terms, available mHealth apps directed at dementia and Alzheimer disease and other neurocognitive symptoms were searched for through a systematic search of mobile app stores and supplemented by an environmental scan of peer-reviewed and gray literature. The environmental scan allowed for the identification of a larger subset of relevant apps from external resources to examine the current state of existing mHealth apps directed at dementia and Alzheimer disease and other neurocognitive symptoms [27]. Apps were then screened for eligibility using inclusion and exclusion criteria. Those apps that met the inclusion criteria were then systematically evaluated using an extraction framework developed for this study, available in Multimedia Appendix 1.

Search Strategies

A systematic search of mHealth apps was conducted by the research team from October 19, 2022, to November 2, 2022. The search terms *Dementia*, *Alzheimer's*, and *Mild Cognitive Impairment* OR *Cognitive Decline* were entered into the 4 most popular mobile app stores in North America: App Store (Apple), Google Play store, Samsung store, and Microsoft store. These terms were used to identify apps available in these stores that were directed at dementia and Alzheimer disease and other neurocognitive symptoms, with the research team recording up to the first 100 app results as they were generated.

In addition to app stores, the following 3 data sources were searched:

1. The websites of recognized dementia and Alzheimer associations and advocacy groups across North America that listed any recommended or advertised mobile apps: Alzheimer's Association, Alzheimer's Family Association, Alzheimer's Disease International, Alzheimer Society of Canada, Alzheimer Society of Simcoe County, Dementia Society of Canada, National Aphasia Association, and The Ontario Caregiver Association
2. The top 100 article results and listed relevant mobile apps for the search query "Top <dementia/ Alzheimers/ MCI/MCD> apps" on the Google search engine
3. Peer-reviewed meta-analyses, systematic reviews, and scoping reviews on the topic of "Dementia OR Alzheimers OR MCI/MCD and mobile app"

Once duplicates were removed, HA, DJH, SRR, DC, PSJ, and VAS independently screened the apps in pairs based on our inclusion and exclusion criteria, and conflicts were resolved by a third reviewer among them.

Eligibility Criteria

Apps that indicated any relation to dementia and Alzheimer disease or other neurocognitive symptoms in either title or description were included (eg, dementia-related news, tips for caregivers, and reminder systems). Furthermore, apps available on either the App Store, Google Play, Samsung Galaxy, or Microsoft app stores or a combination of any of the above were included. Textbox 1 defines the inclusion and exclusion criteria for this study in detail.

Textbox 1. App eligibility criteria.

Inclusion criteria

- Available in English
- Title or description of app indicated the purpose or audience related to dementia and Alzheimer disease or other neurocognitive symptoms, using information available on app stores, developer websites, or other web sources

Exclusion criteria

- Not available in English
- Title, app store description, or other information available on other app stores, developer website, or other web sources did not indicate that app purpose or audience is related to dementia and Alzheimer disease or other neurocognitive symptoms
- Unavailable on an app store during screening phase

Data Extraction and Charting Framework

A data extraction framework was developed, partially drawing from the study by Giunti et al [28], where the authors conducted a systematic search of app stores for mHealth apps focused on multiple sclerosis, another neurodegenerative condition. Several elements were modified to fit the context of the nature of dementia risk and lived experience with the condition, which both cope with declining cognitive function. This included the addition of lifestyle behaviors associated with dementia risk as a major coding theme, following background research into the area. The data extraction framework was also designed to set a focus on the credibility of reviewed apps, incorporating coding themes to assess sources consulted, currency, and transparency.

Included apps were independently coded by SA, HA, DJH, SRR, DC, PSJ, and VAS in pairs using the extraction framework described in Multimedia Appendix 1, which included elements such as evidence-based and expert credibility, app features, purpose, lifestyle elements of focus, and privacy and security. In addition, the Silberg scale was incorporated into the data extraction framework, serving as an established evaluation scale designed to assess the accountability of web-based health information, which in this study applies to mHealth apps [29,30]. The Silberg scale was also chosen as it allowed for screening

mHealth apps without downloading them and instead used information available through app store descriptions, which included intended use and audiences, available features, and privacy practices, along with information from developer websites when available. While all 9 of the Silberg scale's evaluation points were adapted from the framework by Jeon et al [29], they were separated from their originally assigned categories and reassigned to an appropriate theme under the new framework.

Data Analysis

The coding process was performed independently by SA, HA, DJH, SRR, DC, PSJ, and VAS in pairs over multiple iterations, with the researchers meeting to discuss connections between the codes and agree on emerging themes at each stage. The final data set was analyzed by examining the responses of the paired coders or, in some instances, the response of a third coder when present to resolve any conflicts. The consolidated extracted data are available in Multimedia Appendix 2. Descriptive statistics were calculated for numeric responses, which included number of downloads and app store rating. Qualitative data were analyzed using thematic analysis.

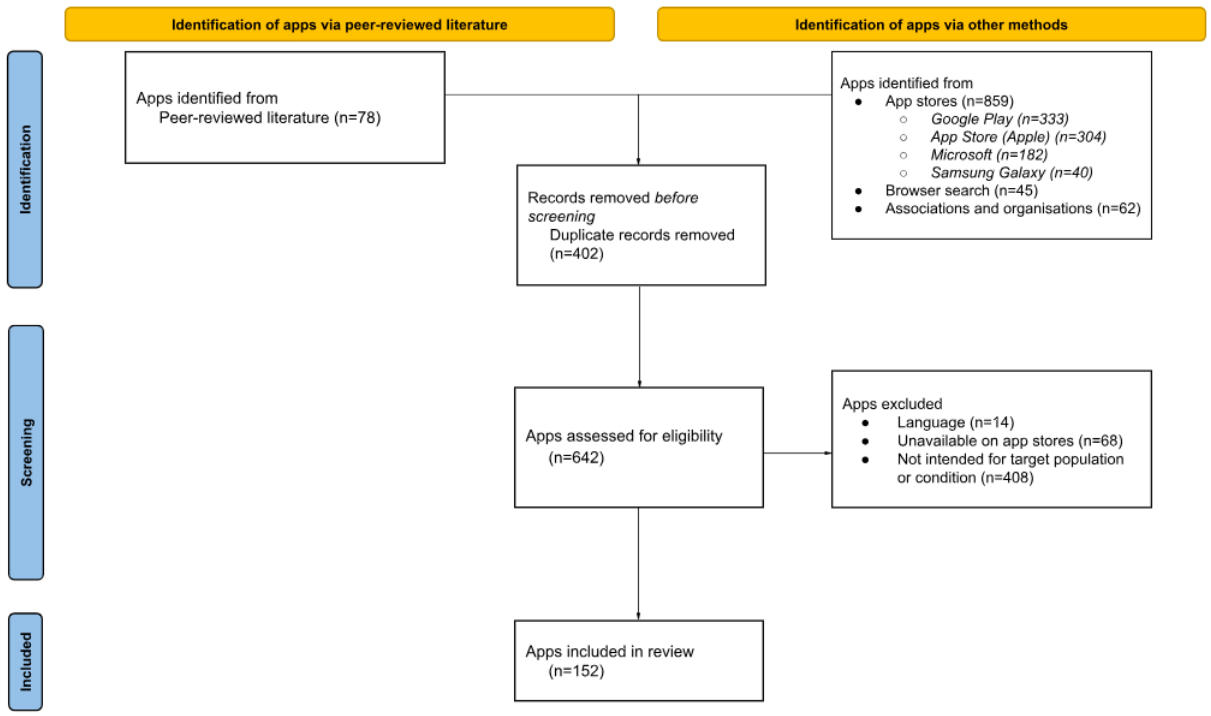
Results

Overview

A total of 1044 apps were found after the initial search for mHealth apps in 4 popular mobile app stores (n=859, 82.27%) and in peer-reviewed literature (n=78, 7.47%). Apps were also found from nonscholarly sources (dementia and Alzheimer association and advocacy websites: n=62, 5.9%; websites accessed through a browser search: n=45, 4.3%). Following this, 402 (38.5%) duplicates were removed, and 642 (61.5%) apps were screened by HA, DJH, SRR, DC, PSJ, and VAS based on our inclusion and exclusion criteria.

Of these 642 screened apps, 14 (2.2%) were not offered in English, 408 (63.6%) of the apps were determined to not be intended for the target populations or condition, and 68 (10.6%) were unavailable on any of the 4 app stores. With the application of these exclusion criteria, 152 (23.7%) apps remained for full data extraction and charting. The PRISMA flow diagram represented in Figure 1 shows this process at each stage.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of study process.



Themes

The following results are presented thematically using the extraction framework details provided in Multimedia Appendix 1, which includes a breakdown of each theme and its objective, along with the operational definition of each variable used within each theme.

Evidence-Based and Expert Credibility

At minimum, 120 (78.9%) of the 152 apps assessed did not disclose any expert credibility or use of evidence, such as providing references, citing information sources used, or disclosing that in the process of the app's development, there was consultation with at least 1 expert, which includes people with lived experience and caregivers. Table 1 illustrates the number of apps that have disclosed these elements.

Table 1. Number of apps that satisfy app elements (n=152).

App element	Apps, n (%)
Variables related to evidence-based and expert credibility disclosed	
Consulted with at least one expert	32 (21.1)
Evidence-based information	27 (17.8)
Information sources	18 (11.8)
Funding from a medical or health organization	16 (10.5)
References	8 (5.3)
Author credentials	6 (3.9)
Common mHealth app purposes supported	
Education	53 (34.9)
Reminder features	28 (18.4)
Diagnostic tools	25 (16.4)
Habit tracking	13 (8.6)
Progress tracking	7 (4.6)
Goal setting	6 (3.9)
Professional supervision	4 (2.6)
Lifestyle elements associated with reducing dementia risk	
Mental stimulation	59 (38.8)
Social stimulation	26 (17.1)
Exercise	10 (6.6)
Stress management	10 (6.6)
Eating and nutrition	7 (4.6)
Sleep	3 (2.0)
Various elements of transparency disclosed	
Application ownership	143 (94.1)
Author affiliation	20 (13.2)
Authors credited	11 (7.2)
Sponsorship	8 (5.3)

Out of the 152 apps, most apps (n=114, 75%) were created by miscellaneous app developers, in other words, developers who were not stated to be associated with any organization or institution. Researchers and health care organizations made up the next 2 largest categories of app creators, observed in 12 (7.9%) and 11 (7.2%) apps, respectively. Members of the public created 8 (5.3%) apps, while medical app developers created 5 (3.3%) apps. Nonprofit non-health care organizations created 2 (1.3%) apps.

Purpose

Of the 152 apps, approximately one-third (n=53, 34.9%) were categorized under “Health & Fitness” by app stores. Following this, “Medical” and “Educational” comprised the next 2 largest categories at 40 (26.3%) and 18 (11.8%) apps, respectively. Multimedia Appendix 3 presents the wide range of categories assigned by 4 app stores and the number of apps tagged under each category.

Table 2 illustrates the wide range of intended users of the assessed apps. Note that some apps were observed to have targeted >1 group of users. Of the 152 apps, 105 (69%) apps were intended for people with dementia, making them the most frequently targeted audience. Informal caregivers at 79 (52%) apps and the general public (ie, people without neurocognitive symptoms) at 65 (42.8%) apps comprised the next 2 largest groups.

Table 2. Intended app users, up to 3 groups per app (n=152).

Intended user group	Apps, n (%)
People with dementia	105 (69.1)
Informal caregivers	79 (52)
General public	65 (42.8)
Friends or family (noncaregivers)	38 (25)
Clinicians or other providers	27 (17.8)
Dementia Advocates	3 (1.9)
Not stated	2 (1.3)

Of the common mHealth app purposes, the most common was providing education on the health topic (ie, dementia), applicable among 53 (34.9%) out of the total 152 apps assessed. As illustrated in Table 1, the least common was providing professional supervision to users, applicable among 4 (2.6%) apps.

Lifestyle Elements of Focus

Of the lifestyle elements important for the prevention of dementia, the most common category was mental stimulation, addressed by 59 (38.8%) out of the total 152 apps assessed. The least common element was sleep, addressed by 3 (2%) apps. Table 1 illustrates these findings. Meanwhile, 65 (42.8%) apps did not focus on any of the lifestyle elements. In addition, only 6 (3.9%) apps addressed sensory health. Table 3 also presents the number of modifiable lifestyle behaviors addressed by the included mHealth apps.

Table 3. Number of lifestyle behaviors of focus per app (n=152).

How many lifestyle behaviors does an app focus on?	Apps, n (%)
0	65 (42.8)
1	67 (44)
2	12 (7.9)
3	4 (2.6)
4	2 (1.3)
5	1 (0.6)
6	1 (0.6)
7	0 (0)

App Features

Observed in 57 (37.5%) out of the 152 assessed apps, providing communication avenues with various parties was the most frequently observed app feature, while 45 (29.6%) apps incorporated game-based elements. The least embraced feature, found in only 2 (1.3%) apps, was the ability to link to social media.

In addition, there was a lack of mention of features designed for people with dementia such as visuals supplementing texts, voice recognition, and customized accessibility features in the app descriptions.

Currency of Apps (as of April 2023)

Of the 152 apps, 136 (89.5%) apps specified their creation date or year and the date of their last update. At the time of analysis in April 2023, only 14 (9.2%) were modified within the previous month.

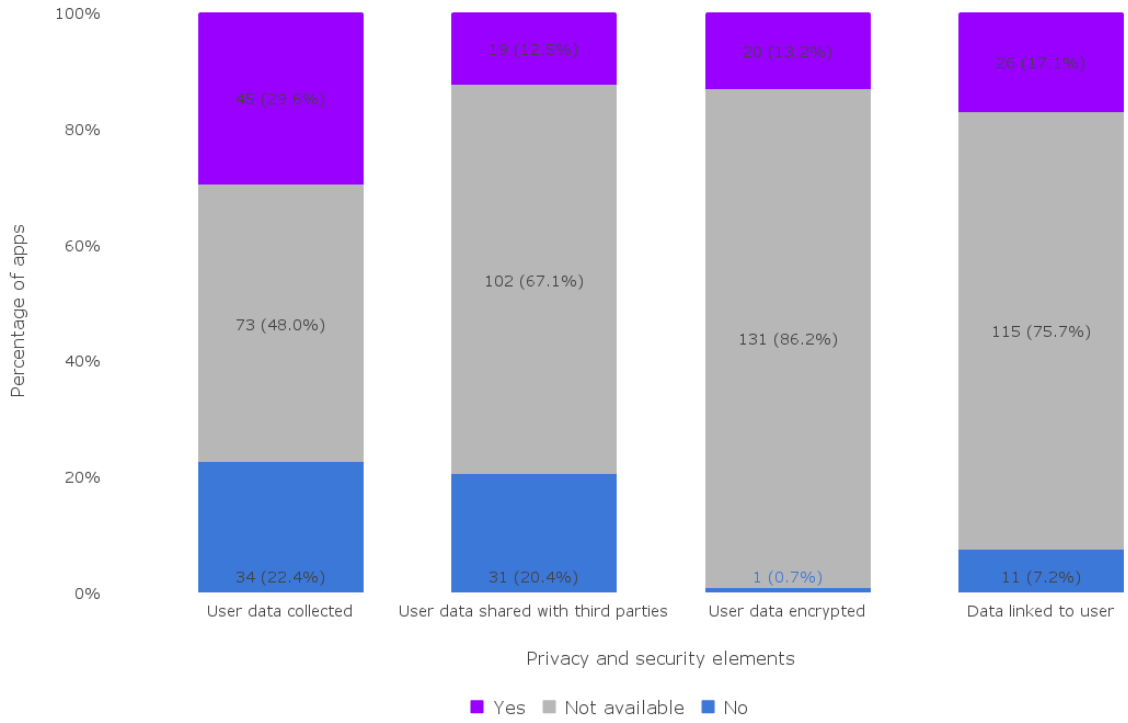
Transparency

Most apps (143/152, 94.1%) had disclosed app ownership, as seen in Table 1, and most apps (132/152, 86.8%) did not disclose any author affiliations or sponsorships or credited any authors or lack thereof.

Privacy and Security

The most disclosed facet of user privacy and security was whether user data were being collected. This was disclosed by 79 (52%) out of 152 apps, of which 45 (57%) apps collected user data. The vast majority of apps (131/152, 86.2%), however, did not disclose if any user data were encrypted at all, with an average median of 105 (69.2%) apps that did not disclose the privacy and security of their apps. Figure 2 visualizes these observations.

Figure 2. Privacy and security of the assessed apps (n=152).

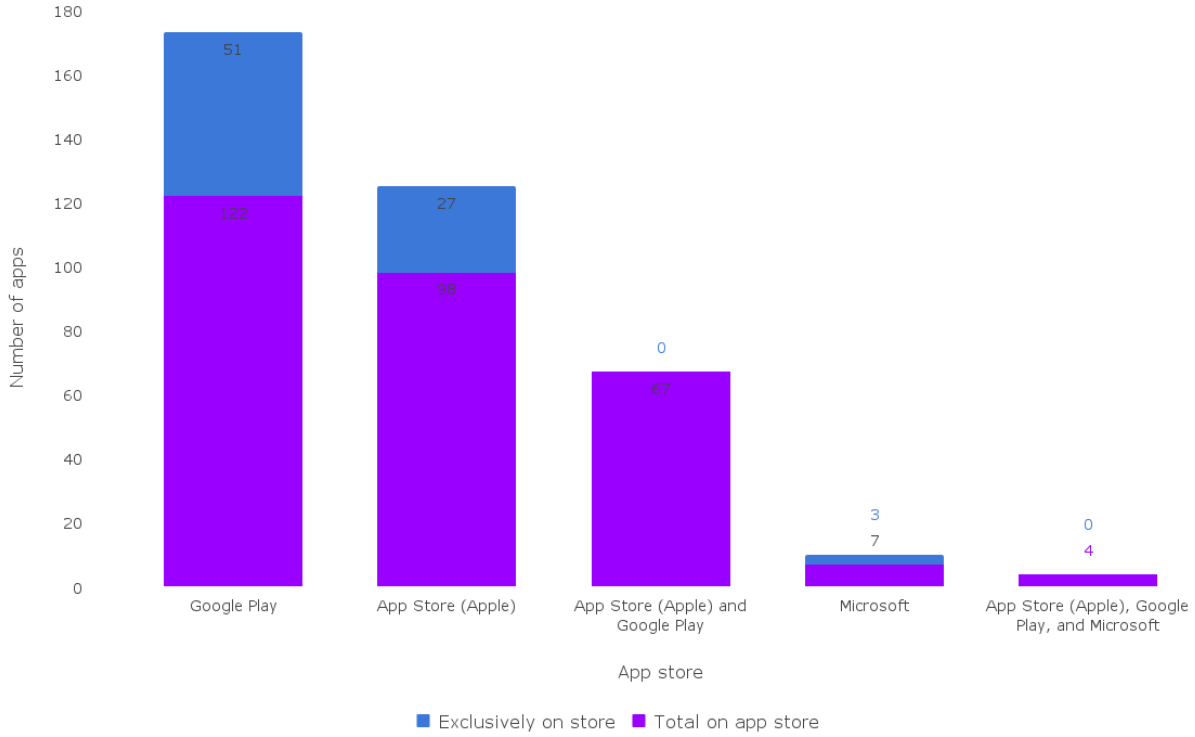


App Availability

Of the 152 apps, most apps (n=111, 73%) were free. Free with in-app purchases was the second largest category at 25 (16.4%) apps, followed by 13 (8.6%) premium or paid apps. The smallest category stood with 3 (2%) “freemium” apps, referring to those with basic or limited features available for free download but offering a paid subscription for premium features once installed.

Many apps were available on >1 app store. Figure 3 presents the number of apps available by store, which include the Google Play store, App Store, Microsoft app store, Samsung Galaxy store, and combinations of these.

Figure 3. App availability by app store (n=152).



User Reception

Due to the structure of some app stores (ie, certain elements of app information are or are not made available and provided by app stores), 120 (78.9%) out of the 152 assessed apps had no ratings available. The next highest group of app ratings was 4 to 4.9 stars, given to 14 (9.2%) apps. Only 7 (4.6%) assessed apps received a rating of 5 stars.

A total of 77 (50.7%) apps had no download information available due to the structure of some app stores (eg, the App Store did not present this element of app information at the time of charting), while 20 (13.2%) had between 100 and 999 downloads. The next highest number of downloads were those apps with <100 downloads as observed in 19 (12.5%) apps, then between 1000 and 4999 downloads observed in 18 (11.8%) apps. Only 4 (2.6%) apps had between 5000 and 9999 downloads, while 10 (6.6%) apps had between 10,000 and 49,999 downloads. Another 4 (2.6%) apps had between 50,000 and 999,999 downloads.

Silberg Scale

As the Silberg scale aims to assess the accountability of web-based health information, with each point representing 1 of 9 elements of accountability disclosed [29,30], a low score suggests that these apps possess gaps in accountability to users. More than half of the apps (84/152, 55.3%) evaluated scored 2 out of 9 Silberg scale points (mean score 2.4, SD 1.0 points), as visualized in Table 4.

Table 4. Silberg scale points accrued by apps (n=152).

Silberg scale points	Apps, n (%)
0	4 (2.6)
1	12 (7.9)
2	84 (55.2)
3	33 (21.7)
4	13 (8.6)
5	4 (2.6)
6	1 (0.7)
7	1 (0.7)
8	0 (0)
9	0 (0)

Of the 152 apps, 4 (2.6%) apps did not score any Silberg scale points (ie, received total scores of 0), and none of the included apps achieved a perfect score. The Care4Dementia app totaled to 7 points, forgoing 2 elements of app accountability: crediting the app's authors and indicating whether an update had been made within the last month (as of the screening and review stages). Meanwhile, the Memory Lane Games app received a score of 6, forgoing the same elements as the Care4Dementia app along with failing to disclose author credentials.

Discussion

Principal Findings

This study aimed to assess the scope of mHealth apps intended for use by the general public relating to dementia prevention and its risk factors and to determine any gaps pertaining to factors including accountability of information, addressing modifiable lifestyle behaviors, and privacy and security. The findings of this systematic search and environmental scan of mHealth apps have found that most lack sufficient accountability of information, particularly for products that target health and can store sensitive user information. Most apps assessed did not satisfactorily disclose their evidence base, lacked comprehensive focus on >1 modifiable lifestyle behavior related to reducing dementia risk, and did not disclose adherence to privacy and security measures or established privacy guidelines. However, apps did show promising diversity in its target audiences, as a number of apps were designed for caregivers of people with dementia (and more broadly, people with neurocognitive symptoms); friends and family; clinicians; or the general public (ie, people without neurocognitive symptoms). These gaps highlight opportunities for researchers and clinicians to establish participatory design frameworks for developing rigorous mHealth apps, as the interest in dementia prevention grows and is projected to continue to grow.

In this study, our goal was to describe the breadth and depth of dementia-related mHealth apps to understand whether these apps demonstrate factors such as credibility, privacy, and transparency in order to be leveraged as a tool for the prevention of dementia. In addition, this study sought to explore whether dementia-related apps specifically addressed any of the above-discussed lifestyle behaviors attributed to maintaining brain health. In the following sections, we will report on the state of apps intended for the public relating to the prevention of dementia by the themes identified above.

Themes

Evidence-Based and Expert Credibility

Most apps did not report author credentials, give information on whether peer-reviewed papers or other sources were used, or provide references. When creating apps that address people with dementia, there should be clear guidelines for developers to follow to ensure that a minimum standard is met in terms of how credible the information in the app is, such as including the source of evidence-based information presented [31]. The absence of these factors could impact the overall effectiveness of the app and its uptake by patients or could mislead and misinform individuals looking to use apps to improve their brain health.

Similarly, most assessed apps (114/152, 75%) did not specify the app developer association, meaning their affiliations were not clearly defined. Meanwhile, only a small subset of assessed apps (23/152, 15.1%) had been created by developers categorized as researchers or health care organizations. This reinforces the need for more credibility and reporting of evidence-based information that could benefit users. Furthermore, only a few indicated having consultations with an expert, which included people with dementia or caretakers of people with dementia, whose lived experiences could be strongly leveraged to take input from, as apps are developed to influence behaviors and habits [32]. The lack of consultation with experts [33] or people with lived experience could impact the quality of the app and the information delivered, making these apps less relevant to those who could best benefit from it. These gaps may mislead consumers in the target populations or provide them with misinformation that could further affect their condition onset or prognosis.

Purpose

Of the 152 apps assessed, 96 (62.5%) were categorized under "Health & Fitness," "Medical," and "Educational," with most apps intended for persons with neurocognitive symptoms, informal caregivers, and the general public (ie, people without neurocognitive symptoms). Meanwhile, only a small subset of these apps actually provides information pertaining to dementia; offers diagnostics tools; and provides reminder, goal-setting, progress-tracking, or habit-tracking features. The lack of diagnostic tools and ability for professionals to remotely monitor users align with the minimal evidence-based information or clinical credibility available in these apps. There appears to be a gap in what these apps that claim to target persons with dementia (and more broadly, people with neurocognitive symptoms) realistically provide to benefit this population. Education, reminder features, goal setting, and tracking would be beneficial tools to provide through apps not only for the target population but also for informal and formal caregivers as well (ie, apps could help set reminders for medications while providing education on certain habits that individuals can commit to improving their condition) [34].

Lifestyle Elements of Focus

Apps were screened for whether they focused on one of the modifiable lifestyle behaviors associated with reducing the risk of developing dementia, which include exercise, sleep, stress management, mental stimulation, eating and nutrition, and social stimulation. More than 2 in 5 apps did not address any lifestyle behavior, while 57.2% (87/152) addressed at least 1. When apps did address modifiable lifestyle behaviors, it was most common to focus on 1 behavior at a time while few addressed a combination of 2 behaviors per app, as demonstrated in Table 1. The lifestyle behavior of focus was mental stimulation; a greater focus on mental stimulation in these apps is in line with the number of apps that had contained game-based elements. This complements the observations of many studies that dementia prevention mHealth apps focused on mental stimulation in maintaining cognitive vitality in healthy

individuals and those with mildly impaired cognition, including improved memory and enhanced quality of life [35].

Research suggests that activities addressing these lifestyle behaviors could in fact improve brain health and lower the chances of developing dementia. In a study exploring physical exercise, diet, smoking, alcohol consumption, cognitive stimulation, and social stimulation, Jia et al [36] observed that positively maintaining any one of these lifestyle behaviors contributes to slowing memory decline. Mamalaki et al [37] also observed the individual impacts of diet, physical activity, sleep, and engagement in activities of daily living (including social stimulation) in maintaining cognitive vitality and reducing the risk of developing dementia. Both studies highlighted the combined effects of addressing multiple lifestyle behaviors to further slow cognitive decline, with the upkeep of more behaviors resulting in stronger prevention [36,37]. It is noteworthy to mention that both studies found diet as the modifiable lifestyle behavior with the largest associated effect on maintaining cognitive vitality and reducing the risk of decline. Thus, if apps are to target patients and their caregivers, it would be most useful to use this evidence-based information to allow for habit development and tracking in activities related to exercise, reminders to maintain sensory well-being, or prompts that could structure stress management. In particular, delivering interventions related to the prevention of dementia using the mHealth app format can expand the availability of these products to hard-to-reach populations [38].

App Features

Apps were also categorized based on whether they offered game-based elements, communication avenues, and links to social media. These features are attractive and can address feelings of loneliness for patients. While game-based apps can be a therapeutic experience, this population may have difficulty in carrying out the tasks or activities required by some of these game apps. Apps may also be a promising way to address social isolation and loneliness [39], providing a channel for in-app users to connect among themselves or presenting features to link with family, friends [40], or the general public for connection or support.

One subset of the intended users of these apps, that is, persons with dementia, requires specific design features for these apps to be beneficial and accessible. Such features include prompts (eg, redirection prompts while completing an activity), visuals supplementing the text, reminder systems, and voice recognition, along with the option to customize accessibility features because dementia affects each of those with the condition differently [41,42]. If these game-based apps are targeted at patients, they may be inaccessible for them due to impaired cognitive abilities where they cannot complete multistep cognitive tasks, remember information, or answer questions in a short time span as they may be cognitively demanding. These features are clearly lacking, making them less accessible to the target users. Thus, the gap remains that consulting the target populations during the development of these apps to identify useful elements would likely serve as the best use of time and resources to yield a positive impact on patients.

Currency of Apps (as of April 2023)

Information on currency, year of creation, and last update date were available for most of the apps. This practice of transparency around app currency is important as new research is released regularly and thus would be important for the consumer to understand when the app itself was created along with the date of the information that the app is based on.

Transparency

A minority of apps credited authors to acknowledge their work, reported author affiliation to demonstrate connection to an organization or academic center, or disclosed sponsorship on whether a specific organization provided funding for the development of the app. This results in poor transparency, as it does not provide consumers with the necessary information to identify the basis of the app or disclose whether there is a possible conflict of interest because of a sponsorship, author, or organization affiliations. Moreover, it is crucial to disclose all these pieces of information, as simply reporting sources or authors while failing to report sponsoring organizations obscures acknowledgment of possible bias embedded in the information presented and the intention behind mHealth apps [43,44]. Providing this information to users could add credibility to the app, which could help an individual decide whether or not such an app will serve their needs and whether it is trustworthy and safe to use [23,45]. Furthermore, the availability of this information is crucial to ensure patient safety and suitability on part of professionals who may recommend such mHealth apps for clinical use [23,45]. By contrast, users are less aware of and less preoccupied with considering an app's evidence base and instead emphasize the quality of its consumer-oriented, practical use such as data use, battery drainage, loading speed, and presence of advertisements when deciding whether to continue its use [43].

Privacy and Security

In regard to privacy and security of these apps, most apps did not provide information regarding the collection of user data, data sharing with third parties, user data encryption, or data linking to users. This demonstrates a gap in the security of app-user data, which may be at risk of being compromised due to weak data governance guidelines that are not disclosed clearly or at all. Close attention should be paid to ensuring the privacy and security of mHealth apps, especially when dealing with susceptible target groups such as people living with mild cognitive impairment [46]. One relevant guideline that can be followed is the *mHealth Data Security, Privacy, and Confidentiality: Guidelines for Program Implementers and Policy Makers*, which details best practices and considerations for mHealth app development. These best practices cover the data life cycle stages of data capture and storage, access, transfer, and disposal, as well as address risks associated with operating systems, mobile devices, networks, and mHealth data storage [47]. The *Privacy and Code of Conduct on Mobile Health Apps* developed by the European Commission [48] lays out principles for mHealth app development and function, including considerations for user consent, app security measures, and use of user data for secondary purposes such as research and third-party sharing among others. While these guidelines

are not official law or policy, they provide detailed considerations that will assist mHealth app developers in creating and sustaining responsible data governance.

App Availability

For apps to be useful, they should be accessible to the targeted population. Commercialization of the apps significantly impacts this, as almost three-quarters of assessed apps were offered for free, while about one-tenth involved a purchase for the basic or the full version of the app. Furthermore, 44.1% (67/152) of the apps were offered both on the App Store and Google Play app store, whereas an exclusive 33.5% (51/152) were offered only on Google Play as opposed to 17.8% (27/152) of apps that were exclusively available on the App Store. Interestingly, only a small number of the apps (7/152, 4.6%) were available on the Microsoft app store, and none were offered on the Samsung Galaxy app store. A needs-based analysis to identify which app features are most useful for patients and caregivers would be appropriately supplemented by identifying the type of smartphones that are accessible to this population.

User Reception

Measured by the number of downloads, user reception is important when it comes to measuring meaningful use of apps. While not all apps had information pertaining to their exact number of downloads, 39 (25.7%) out of the 152 assessed apps had <999 downloads, of which 19 (49%) had <100 downloads per app. This illustrates a very low use or download rate of apps that are categorized and are targeted for persons with neurocognitive symptoms.

Silberg Scale

Apps were also scored using the Silberg scale, which is an established validated measure to capture the extent of accountability of health information presented on the web, including through mHealth apps [29,30]. An app can score up to a total of 9 Silberg scale points, wherein the higher the total Silberg score, the more the accountability of the information presented by or used to create the app is communicated [49,50]. Meanwhile, a low total Silberg score implies the opposite, suggesting that the app in question does not transparently disclose the credibility of the app's information, which may therefore lack accountability toward users and the public. Within this study, the mean Silberg scale score of 2.4 (SD 1.0) across all reviewed apps points toward a trend skewed toward low accountability of information used and presented by the apps (ie, in communicating the authorship, attribution, disclosure, and currency of their information). The observed skewed trend of apps with low Silberg scale scores raises concern for a lack of accountability these apps take in disclosing the credibility of their foundations, their reliability, usefulness to targeted users, and the efficacy and effectiveness of their results, if any.

While the apps assessed in this study produced low Silberg scale scores, this does not appear to be unique in this regard, as other nondementia mHealth apps have observed similar findings. Several studies assessing mHealth apps using the Silberg scale found that most apps scored <5 points [29,51-53]. In the case of a study assessing the (then) current state of mHealth apps that addressed postnatal depression, the authors observed a mean Silberg score of 3.0 points and suggested the need for the involvement of health care professionals in developing mHealth apps [51]. In another study, an analysis of obesity management mHealth apps observed a mean score of 4.55 points along with a low percentage of apps disclosing information sources and references [29]. The assessed obesity management apps were found to present poor accountability of the information, highlighting the need to improve the current state of mHealth app information quality. The systematic review of mHealth apps by Feldman et al [53] that had addressed peripartum mood disorders reached a similar conclusion, finding <30% of the assessed apps indicated the use of research for app development. Overall, the authors found that most apps reviewed in their study were of poor quality, as indicated by low Silberg scores, and suggested their poor accountability of information as a hindrance to users in making an informed decision about their quality [53]. Overall, there is a general trend of low Silberg scale scores observed across mHealth apps, which is a gap that requires addressing by developers.

The observations noted in this section point toward the need for app developers and app stores to fill in the gaps when presenting descriptions of the products they are offering. The most significant gaps observed in targeted apps included (1) a lack of prevention-oriented apps addressing >1 modifiable lifestyle behavior (diet, sleep, exercise, stress management, mental stimulation, social stimulation, and sensory health) associated with dementia risk; (2) an absence of apps created using evidence-based information and credible authors and an absence of transparent disclosure of these sources; (3) inadequate rigor of general mHealth data privacy and security procedures and a complete lack of disclosed specific guidelines created for people with cognitive impairment; and (4) a lack of evidence-based, usable app features designed for the needs of people with declining or limited cognitive abilities.

Limitations

While efforts were made to make this study systematic and comprehensive, several limitations should be acknowledged. This study used PRISMA with the goal of adhering to rigorous standards and to thoroughly structure its data search, screening, and extraction. However, PRISMA guidelines are intended for systematic reviews and meta-analyses evaluating peer-reviewed literature, contrasting with this study's environmental scan component along with its evaluation of mobile apps. In addition, a limited selection of app stores were searched from the available pool of North American app stores, and reviewed apps had to be available in English, and thus, this study may not have captured the entirety of dementia-related apps available on the global market. While peer-reviewed journal articles, browser searches, and dementia and Alzheimer association and organization websites were initial sources for identifying available apps, the search using these sources was not exhaustive. There are also additional search terms that could have been used to widen the search results such as "memory," "brain training," and "cognit*." As a result, there is a possibility that some potential apps for identification may have been missed, and we recommend taking this into account for future research.

Due to the dynamic nature of app stores, some apps included in this study's final review have been pulled out of app stores since the time of analysis. In addition, the structural differences among the 4 app stores resulted in some details being available on 1 or some app stores (ie, number of app downloads, user data collection, sharing of user data with third parties, user data encryption, and linking data to user) and not on other app stores. Because of this, some data points were extracted as "N/A" and do not present a full picture of the variable.

Apps were not downloaded, meaning that features and functionality could not be assessed to the fullest extent. Thus, relying on app store descriptions as the primary source for information, supplemented with other sources available on the web, we could not extract the data regarding the full extent of app features, purposes, audiences, and other elements in the screening and data extraction phases. Furthermore, some descriptions encountered provided only scarce information, impacting the scope of data extraction for individual app screeners at times. However, second- and third-screener corroboration was conducted in response to this and ensured complete data extraction.

Finally, in the process of screening for mHealth apps, we encountered a challenge in accurately distinguishing between those targeted for users with mild cognitive impairment and dementia due to the inherent complexities and overlapping characteristics of these conditions. Recognizing the importance of this distinction in clinical contexts, it is crucial to acknowledge that our screening criteria erred on the side of inclusivity, resulting in a broader scope of apps included in our review. While this may initially seem to widen the spectrum of included apps, it inherently contributes to a more comprehensive and nuanced report of the current landscape of available apps. By encompassing a broader range of users experiencing neurocognitive symptoms, our study provides a holistic view of the mHealth app landscape, offering valuable insights into potential digital interventions for individuals at varying stages of cognitive decline. This approach enhances the practical relevance of our findings and acknowledges the diverse needs of users in the evolving field of digital therapeutics.

Conclusions

As the prevalence of dementia continues to grow, so does the burden of disease on patients, caregivers, the health system, and the greater community. This could be combated by leveraging mHealth apps to address and mediate the symptoms and effects of these diseases. Specifically, the literature suggests addressing a number of modifiable lifestyle behaviors as an effective way to improve brain health. In order to address these behaviors through mHealth apps, the apps should not only be accessible in terms of availability but also offer features suited for individuals living with declining or impaired cognitive vitality. Furthermore, these apps should be transparent in the foundation of information, its evidence base, and the involvement of professionals or people with lived experience in its development. Thus, providing app designers and developers with a guideline for what is required and necessary to fulfill the needs of patients and caregivers, along with minimal standards for what an app must have to be appropriate for this susceptible population, would be ideal. Such a guideline would be instrumental in leveraging mHealth apps to maintain cognitive vitality, socially connect, and provide therapeutic avenues for persons with dementia (and more broadly, those with neurocognitive symptoms) or their caregivers.

Acknowledgments

This study was supported by the funding (2122-HQ-000257) from the Public Health Agency of Canada. The authors would like to thank Thuraya Marjan for her contributions to the data analysis and peer-review stages. The authors also thank the Women's Brain Health Initiative for their input and support throughout this study. The views expressed in this study are those of the authors and do not necessarily reflect the official views of the Public Health Agency of Canada or the Government of Canada.

Authors' Contributions

LA conceived the study and designed the protocol. DC, DJH, HA, PSJ, SRR, and VAS screened the apps. DC, DJH, HA, PSJ, SA, SRR, and VAS conducted data extraction as first and second coders and resolved conflicts emerging in coded data as third reviewers. SA, HA, DJH, and SRR wrote the first draft of the manuscript. LA, SA, and HA edited and revised the final manuscript.

Abstract

Background: Interventions are required that address delays in treatment-seeking and low treatment coverage among people consuming methamphetamine.

Objective: We aim to determine whether a self-administered smartphone-based intervention, the "S-Check app" can increase help-seeking and motivation to change methamphetamine use, and determine factors associated with app engagement.

Methods: This study is a randomized, 28-day waitlist-controlled trial. Consenting adults residing in Australia who reported using methamphetamine at least once in the last month were eligible to download the app for free from Android or iOS app stores. Those randomized to the intervention group had immediate access to the S-Check app, the control group was wait-listed for 28 days before gaining access, and then all had access until day 56. Actual help-seeking and intention to seek help were assessed by the modified Actual Help Seeking Questionnaire (mAHSQ), modified General Help Seeking Questionnaire, and motivation to

change methamphetamine use by the modified readiness ruler. χ^2 comparisons of the proportion of positive responses to the mAHSQ, modified General Help Seeking Questionnaire, and modified readiness ruler were conducted between the 2 groups. Logistic regression models compared the odds of actual help-seeking, intention to seek help, and motivation to change at day 28 between the 2 groups. Secondary outcomes were the most commonly accessed features of the app, methamphetamine use, feasibility and acceptability of the app, and associations between S-Check app engagement and participant demographic and methamphetamine use characteristics.

Results: In total, 560 participants downloaded the app; 259 (46.3%) completed eConsent and baseline; and 84 (32.4%) provided data on day 28. Participants in the immediate access group were more likely to seek professional help (mAHSQ) at day 28 than those in the control group (n=15, 45.5% vs n=12, 23.5%; χ^2_1=4.42, *P*=.04). There was no significant difference in the odds of actual help-seeking, intention to seek help, or motivation to change methamphetamine use between the 2 groups on the primary logistic regression analyses, while in the ancillary analyses, the imputed data set showed a significant difference in the odds of seeking professional help between participants in the immediate access group compared to the waitlist control group (adjusted odds ratio 2.64, 95% CI 1.19-5.83, *P*=.02). For participants not seeking help at baseline, each minute in the app increased the likelihood of seeking professional help by day 28 by 8% (ratio 1.08, 95% CI 1.02-1.22, *P*=.04). Among the intervention group, a 10-minute increase in app engagement time was associated with a decrease in days of methamphetamine use by 0.4 days (regression coefficient [β] –0.04, *P*=.02).

Conclusions: The S-Check app is a feasible low-resource self-administered intervention for adults in Australia who consume methamphetamine. Study attrition was high and, while common in mobile health interventions, warrants larger studies of the S-Check app.

Introduction

Frequent use of methamphetamines is associated with adverse physical and mental health consequences [1,2], and Australia reports one of the highest rates of methamphetamine use and dependence in the world [2]. Since 2010, associated harms have been steadily increasing [3]. Psychosocial therapies are the primary mode of treatment for methamphetamine use disorder [4], especially as no pharmacotherapy has yet been shown to be effective [5]. Interventions such as cognitive behavioral therapy show modest effects [6], while contingency management has been demonstrated to be effective for outcomes associated both with methamphetamine use and with harm reduction for the duration of the intervention, but lacks widespread uptake [7]. Access to treatment is associated with more positive outcomes [8], but despite this, a gap of up to 10 years has been shown between the onset of problems related to methamphetamine use and presentation to health services for assistance [9].

Delays in access to health services can be due to a perception of "nonproblematic" methamphetamine use among people with methamphetamine use disorder [10,11]. Mental, physical, and social consequences can result from untreated persistent methamphetamine use disorder [9]. The development of a low-threshold intervention to encourage awareness of problems related to methamphetamine use could potentially change behavior and reduce the gaps between use, problems related to use, and treatment access. Health interventions supported by mobile devices (mHealth) are a promising mode of delivering early interventions to people who use drugs. As demonstrated in other mental health and substance use disorders, mHealth offers advantages in privacy and access over traditional face-to-face services and may facilitate help-seeking [12-16]. There are no mHealth interventions such as smartphone apps that have been shown to be effective in encouraging behavioral changes in people who use methamphetamine [17].

The S-Check intervention is targeted toward people who use methamphetamine, who do not necessarily identify problems related to its use [18], and are curious about the relationship between their use and other aspects of their health and well-being. Developed in 2011, the S-Check intervention consists of 4 sessions: a psychosocial assessment with a counsellor (based on Smout et al [19]); a physical health assessment with a medical officer; physical health feedback from a medical officer; and a biopsychosocial feedback, goal setting, and care planning session with a counsellor. The S-Check intervention aims to reduce harms associated with methamphetamine use, support behavior change, and encourage treatment seeking where indicated. When evaluated in 2018 [11], a majority of participants reported that the S-Check intervention was their first contact with general health services for issues related to methamphetamine use. Participants identified harm reduction, including education and advice about safer consumption practices, and the accessible and approachable environment to track their methamphetamine use patterns, as benefits of the model [11].

The S-Check intervention was translated into a smartphone app ("the S-Check app") that uses the eHealth Behavior Management Model [20] to encourage help-seeking for methamphetamine use. The eHealth Behavior Management Model incorporates the transtheoretical model [20] and the behavioral intent aspect of the theory of planned behavior [21] to create systems that tailor health communication to meet the needs of individual app users through a set of predeveloped messages based on readiness to change. The S-Check app allows app users to assess the risks and harms associated with their methamphetamine use in 5 domains (sexual, lifestyle, physical, psychological, and cognitive health), track their use of methamphetamine and other health measures with an Ecological Momentary Intervention [22], and receive tailored feedback based on persuasive communication principles [20,23,24]. The S-Check app incorporates principles of efficacious behavioral change models [25,26] to reinforce engagement and positive change by encouraging S-Check app users to attend to messages; requesting further inputs from app users; and motivating app users toward change. The S-Check app was piloted with 10 consumers and found to be acceptable and usable by participants [27].

Following the development of the S-Check intervention and the translation to a usable smartphone app, we aimed to assess the effectiveness of the S-Check app to motivate help-seeking among people who use methamphetamine and its effect on motivation to change methamphetamine use. To do this, we undertook a randomized waitlist-controlled trial of the S-Check app.

Methods

Trial Design

This study was a digital randomized 28-day waitlist-controlled trial. Participants were allocated 1:1 to one of two study arms: immediate access to the S-Check app (intervention group) or access after a 28-day waitlist period (waitlist control group). The primary end point was day 28, and the primary outcome was between-group differences in help-seeking. Both groups had the option to use the S-Check app through to day 56. Optional qualitative interviews were conducted with consenting participants and will be reported elsewhere. This study is reported in line with the CONSORT (Consolidated Standards of Reporting Trials) guidelines [28], a checklist is available in Table S1 in Multimedia Appendix 1.

Ethical Considerations

This study was approved by the Human Research Ethics Committee of St Vincent's Hospital, Sydney, Australia (HREC/18/SVH/196).

Participants

Inclusion criteria were adults (aged ≥18 years) living in Australia, who had self-reported methamphetamine use at least once in the month before study enrollment and private access to a smartphone (Android or Apple) to day 56 of follow-up. There were no exclusion criteria. Participants were recruited anonymously. This study was promoted through posters and leaflets at community (eg, people who use drugs) and partnering (eg, needle and syringe programs [NSP], medically supervised injecting center, sexual health clinics) organizations, alcohol and other drug service websites, and social media (including location-based dating apps).

Intervention

The S-Check app was available to download free of charge from Android and iOS app stores. Eligibility screening and provision of the participant information sheet and consent form were completed electronically within the app as an anonymous automated consent procedure [29].

Once accessed, the S-Check app home screen presented a dashboard (Figure 1) to access the S-Check app resources. These included 6 structured self-assessment tools (methamphetamine use, sexual health, social health, psychological well-being, physical health, and cognitive health; Table 1), provision of automated feedback (Figure 2), generation of a referral letter when appropriate to services or further support, relevant up-to-date information and resources about methamphetamine use, and a tool to track methamphetamine use and health impacts of methamphetamine over time (Figure 3).

Data were stored on a secure, encrypted password-protected Customer Relationships Management database integrated into the S-Check app's unique Application Programming Interface.

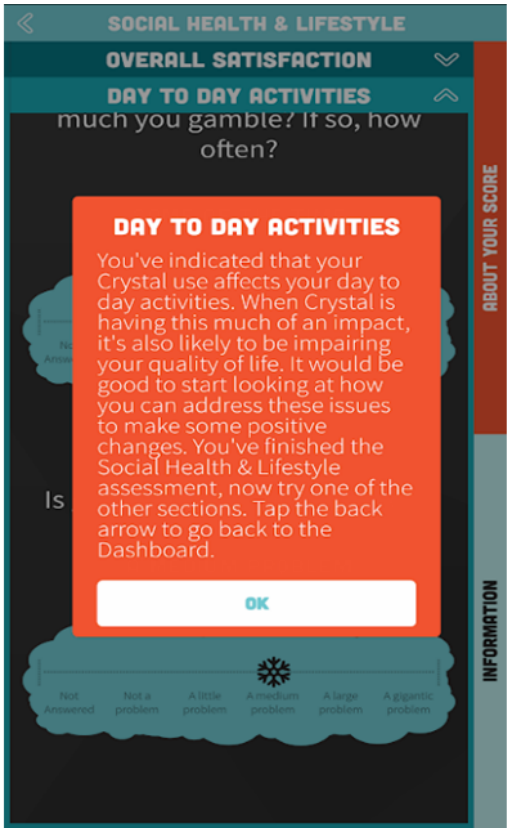

Figure 3. Tracking health over time.

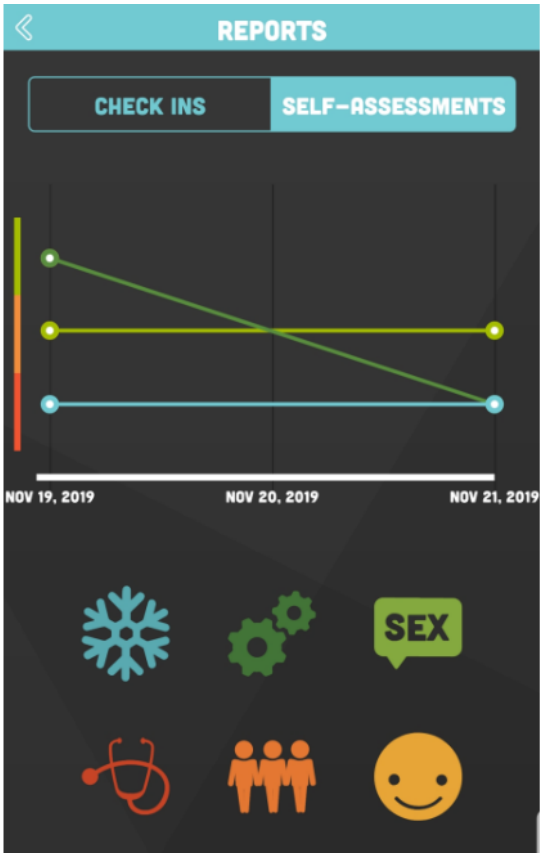

Outcomes and Measures

Help-seeking was measured by (1) the modified Actual Help Seeking Questionnaire (mAHSQ; recent help-seeking) [40], (2) the modified General Help Seeking Questionnaire (mGHSQ; intention to seek help) [40], and (3) the modified readiness ruler (mRR; motivation to change behavior). AHSQ and GHSQ are validated to measure intention for and actual help-seeking in mHealth interventions addressing substance use [41] and mental health [42-45]. Both problem-type and the help-source for AHSQ and GHSQ were modified for methamphetamine use [40] over 4 weeks, and for ease of use in the app, response options were collapsed into "professional" and "nonprofessional" help sources. The mAHSQ has 2 binary measures (yes or no) for help-seeking for a problem related to the use of methamphetamine in the past 4 weeks from (1) a professional source (eg, doctor, counsellor, psychologist, specialist, telephone or web-based counseling, etc) and (2) a nonprofessional source (eg, partner, friends, parents, other family members, colleagues, internet) [41,46]. The mGHSQ scale captures intent to seek professional and nonprofessional help in the next 4 weeks, rating each source of help on a 7-point Likert-type scale ranging from 1 (extremely unlikely) to 7 (extremely likely). The mRR is a measure that has demonstrated higher predictive validity than longer measures for readiness to change among people with substance use disorder [47-49]. Participants were asked: "how ready are you to change your use of [nickname of methamphetamine]?" with responses rated and scored on a 10-point Likert-type scale ranging from 1 (not ready) to 10 (trying hard to change). Primary outcomes were measured at baseline (day 0), day 28 (primary end point), and repeated at day 56 for both intervention and control groups.

Secondary outcomes were the most commonly accessed features of the S-Check app (number of times participants accessed each section); number of days of methamphetamine use in the past 28 days (collected at baseline, day 28, and day 56); feasibility and acceptability assessed by the number of participants retained to days 28 and 56 and a qualitative substudy (to be reported elsewhere). Associations were examined between S-Check app engagement over this study's period (total minutes in-app use) and participant characteristics collected within the S-Check app: age, gender, sexual orientation, education, age of first use of methamphetamine, injection of methamphetamine in the last 4 weeks, treatment history, days of methamphetamine use in the past 28 days, and recent treatment.

For completion of the day 28 and day 56 surveys, participants in both the waitlist and control group were reimbursed with an AUS $25 (approximately US $19 at the time of enrollment) digital grocery voucher, redeemable through the S-Check app.

Sample Size

We determined the sample size required to evaluate the outcome of actual help-seeking at a power of 0.8 to detect a small to medium effect size (d=0.25), and α set at .05. A minimum of 510 participants was required [50] as we anticipated 50% attrition, and 255 participants to remain enrolled to the primary end point (day 28).

Randomization and Blinding

Randomization was automated within the S-Check app using a JavaScript (Refsnes Data) function whereby a random-access token was generated and participants were allocated to either immediate access to the S-Check app or a waitlist control group. Since participants were automatically enrolled and consented within the app, there was no risk of unblinding to the investigators.

Statistical Methods

We compared baseline characteristics between the 2 groups using χ^2 for categorical variables, and the t test (2-tailed) or Mann-Whitney U test for continuous variables.

χ^2 comparisons for the proportion of positive responses to the mAHSQ, mGHSQ (dichotomized to <5 being no intention to seek help and ≥5 being intention to seek help), and mRR (dichotomized to >8 indicating motivation to change) were conducted between the 2 groups at baseline and day 28.

For the mAHSQ, a logistic regression model compared the odds of recent help-seeking at day 28 between the intervention and the control groups, adjusted with the recent help-seeking status at baseline included as a covariate in the model. For the mGHSQ a logistic regression compared the intention of help-seeking score (derived from the mGHSQ dichotomized to <5 being no intention to seek help and ≥5 being intention to seek help) at day 28 between the intervention and control groups, adjusted with the intention to seek help status at baseline included as a covariate in the model. For the mRR, a logistic regression compared the motivation to change behavior (derived from the mRR with a score >8 indicating motivation to change) at day 28 between the 2 groups, adjusted for the corresponding baseline score, by including it as a covariate in the model.

Descriptive statistics were used to report participant access to layers within the app, methamphetamine use, and study retention at days 28 and 56. To analyze the association between demographics and methamphetamine use characteristics and S-Check app use, total engagement time for the intervention group was aggregated from the range of S-Check app use activities (from time of download to day 28). Multiple linear regression was applied to examine which baseline characteristics were predictive of more time engaged with the S-Check app, where engagement time as a dependent variable was log-transformed. The effect of time engaged with the S-Check app on help-seeking (mAHSQ and mGHSQ) and motivation to change (mRR) at day 28 were also examined. Dashboard activity time greater than 60 minutes was treated as outliers, as they were unlikely to accurately reflect true app engagement duration and be imputed with the sample median.

To handle missing data at follow-up, the analysis was conducted initially and primarily based on the retained cohort of observed data, following the recommendation of Jakobson et al [51]. Ancillary analysis based on the full intention-to-treat (ITT) cohort using multiple imputations by chained equations was performed under the missing at-random assumption. Variables in the multiple imputation model included the response to the primary outcome measure at baseline, as well as demographic

and methamphetamine use variables in the collected data. The statistical significance level was set at 2-sided .05. Analyses were performed using SAS (SAS Institute) and R (R Foundation for Statistical Computing).

Results

Participants

In total, 560 participants downloaded the app, of which 259 (46.3%) completed the eConsent process and baseline survey. Of these, 84 (32.4%) provided data on day 28. Further, 175 did not provide data at day 28, resulting in a 68% attrition from baseline. A participant flow diagram is presented in Figure 4.

Baseline participant features, summarized by intervention group or control group, are presented in Table 2. There was no significant difference observed between the 2 groups. The majority of the sample (n=159, 61.6%) had not previously accessed treatment services for methamphetamine use, while 55.8% (n=144) had injected methamphetamine in the prior 4 weeks.

Figure 4. Participant flow diagram.

[a]Baseline and day 28 demographic data on age, gender identity, sexuality, sex assigned at birth, intersex status, education, and days of methamphetamine use in the previous 28 days is missing for 1 participant.

[b]MA: methamphetamine.

[c]Not applicable.

Primary Outcomes

The primary outcomes for help-seeking were assessed using the 84 participants retained to day 28 including 33 (39.2%) participants in the intervention group and 51 (60.7%) participants in the control group.

Table 3 compares actual help-seeking (mAHSQ), intention to seek help (mGHSQ), and motivation to change (mRR) between the 2 groups at baseline and day 28. A greater proportion of participants in the intervention group recently sought

professional help (mAHSQ) at day 28 than in the control group (n=15, 45.5% vs n=12, 23.5%; χ^2_1=4.42; *P*=.04).

Regression analyses for mAHSQ, mGHSQ, and mRR are presented in Table 4. In the primary regression analyses, there was no statistically significant difference in the odds of actual help-seeking, intention to seek help, or motivation to change between the immediate access group and the waitlist control group on day 28.

Table 3. Help-seeking, intention to seek help, and motivation to change.

	Actual help-seeking (mAHSQ[a])				Intention to seek help (mGHSQ[b])[c]				Motivation to change (mRR[d])[e]	
	Professional	*P* value	Nonprofes-sional	*P* value	Professional	*P* value	Nonprofes-sional	*P* value	Motivation to change	*P* value
Baseline, n (%)		.23		.22		.19		.43		≥.99
Control	11 (21.6)		15 (29.4)		30 (58.8)		23 (45.1)		17 (33.3)

Table 4. Logistic regression for mAHSQ[a], mGHSQ[b], and mRR[c].

Outcome measure and outcome response set	Adjusted odds ratio[d] (95% CI)	*P* value
mAHSQ		
Professional help-seeking–actual	2.72 (0.86-8.64)	.09
Nonprofessional help-seeking–actual	1.21 (0.44-3.67)	.71
mGHSQ[e]		
Professional help-seeking–intention	0.49 (0.17-1.32)	.17
Nonprofessional help-seeking–intention	1.04 (0.42-2.64)	.93
mRR[f]		
Motivation to change	2.4 (0.89-6.47)	.08

[a]mAHSQ: modified Actual Help Seeking Questionnaire.

[b]mGHSQ: modified General Help Seeking Questionnaire.

[c]mRR: modified readiness ruler.

[d]Adjusted for baseline response.

[e]Score on a 7-point Likert scale categorized as 1-4, no intention to seek help; 5-7, intending to seek help.

[f]mRR scored as <8, not motivated to change; ≥8, motivated to change.

Ancillary Analysis

Based on the multiple imputed data set, consisting of 10 baseline characteristics, an ancillary analysis was conducted. While overall the results were consistent with our observed case analysis, there was a significant difference in the odds of recent professional help-seeking between the immediate access group compared to the waitlist control group on this analysis (adjusted odds ratio [aOR] 2.64, 95% CI 1.19-5.83, *P*=.02; Table S2 in Multimedia Appendix 1).

Secondary Outcomes

The most commonly accessed features of the app over this study's period are presented in Table S3 in Multimedia Appendix 1. The most accessed features were the dashboard feature, information, and methamphetamine tracking resources.

There were no between-group changes in days of methamphetamine use at day 28, as presented in Table S4 in Multimedia Appendix 1.

In a multivariable regression analysis with app engagement time as the response variable, participants who identified as gay

males had 68% more app engagement time than all other participants (ratio 1.68, 95% CI 1.04-2.98, *P*=.03). It was not possible to analyze S-Check app engagement by other sexualities and gender identities due to small numbers. Greater days of methamphetamine use at baseline was also found to be a predictor of S-Check app engagement, with 3% more app engagement time for each additional day of methamphetamine use (ratio 1.03, 95% CI 1.00-1.06, *P*=.03). Participants who intended to seek professional help (mGHSQ) at baseline had 17% more S-Check app engagement than those who did not (ratio 1.17, 95% CI 1.03-1.32, *P*=.01). After adjusting for baseline days of methamphetamine use, a 10-minute increase in app engagement time over the 28-day intervention was associated with a decrease in days of methamphetamine use by 0.4 days (regression coefficient [β] –0.04, *P*=.02; intervention group: n=33). In a subgroup analysis of participants who were not seeking help at baseline, for every additional minute of S-Check app use, there was an 8% increase in the likelihood of seeking professional help at day 28 (ratio 1.08, 95% CI 1.02-1.22, *P*=.04).

Discussion

Principal Findings

This study demonstrated that compared to waitlist controls, almost twice the proportion of participants with immediate access to the S-Check app sought professional help by day 28. Importantly, among participants not seeking help at baseline, each minute in the app was associated with seeking professional help by day 28, and there was an association between increased S-Check app use and decreased methamphetamine use over the 28 days among those in the immediate access group.

This study has limitations. We aimed to recruit 510 participants but we were only able to achieve a sample of 259. Retention to the primary end point was 32%, less than the expected 50%, which was likely unrealistic, given emerging evidence for this type of study suggests that when participants are enrolled in mHealth studies after downloading an app, retention is generally <30% [52]. Future research may include methods whereby participants are recruited before downloading the app; however, this design would affect the generalizability of the results to the population recruited. We learned important lessons about implementing an app-based trial. We underestimated the resources required to support a study of this nature. Keeping this study open longer may have increased our sample size. Budgeting for longer periods of recruitment and advertising may support higher enrollment in future trials. Apps to address substance use disorder should be co-designed with the community anticipated to benefit from their use. To this end, the stepped process of consultation with affected populations in transitioning from a clinical intervention to a smartphone app is a strength of the S-Check app. Further refinement of this resource or subsequent apps to address methamphetamine use should include active engagement with people who will use the app, to ensure alignment of what will benefit this population and what research and developers are delivering.

There is a possibility that this sample was already motivated toward change. Given the design of the app encourages people to understand more about their methamphetamine use and its impact, those who downloaded it likely had some interest in how their methamphetamine use was affecting them. In selecting a primary outcome, future studies of the S-Check app may therefore seek to examine how people use the app to better understand their methamphetamine use, identify which aspects of their use may be problematic for them, and how the app provides earlier insights into the relationships between methamphetamine use and aspects of their life. In the present study, assessing help-seeking and motivation to change is difficult given fixed time points and in binary measures as is demanded of a randomized controlled trial, while change is a fluid process. Engaging with the app may in itself have addressed concerns for participants, reducing the need or motivation to seek external help. Further exploration of the place of a self-administered information app such as the S-Check app within the broader treatment landscape in support of people who consume methamphetamine is warranted. A nuanced understanding of progress along the change continuum, an aim of the app, is required in future studies.

Sample characteristics limit the generalizability of the results to the broader Australian population of people who use methamphetamine. The majority of participants recruited to our study identified as male (69.9%) while 64% of past-month methamphetamine use occurs among men in Australia [53]. Our sample had a large proportion of participants who had undertaken higher level education (35.9% had a University degree), as compared to underlying population data (24%) [53]. In our study, neither ethnicity nor employment data were collected, therefore we cannot comment on the generalizability of these findings to a range of communities affected by methamphetamine use. This study recruited a large proportion of participants identifying as gay men (n=131, 50.8% of the sample), reflecting the recruitment strategy through targeted social media channels. The underrepresentation of women, transgender people, or other populations may be attributed to our recruitment strategy, but we do not have any way of knowing whether this is due to the design or content of the app. It is also possible that people did not want to use an app that would be associated with their drug use, particularly given the legal implications of drug use. Nevertheless, the anonymous nature of the S-Check app may reach participants who are reluctant to seek traditional or face-to-face treatment services due to barriers such as high cost, treatment access delays (eg, long waitlists), travel time to services, or fear of stigma.

The S-Check app recruited participants who had predominantly never sought treatment for methamphetamine use previously, and who reported injecting methamphetamine in the 4 weeks to baseline, a potential surrogate for severity of dependence. Furthermore, a higher proportion of those who were retained in the intervention group were people who injected methamphetamine. Previous studies have demonstrated greater methamphetamine-related service use among people who inject methamphetamine [54,55]. This may be due to the lack of treatment options for methamphetamine use disorders, whereas harm reduction services are more accessible, such as NSPs to reduce injection-related harms [56]. Our recruitment strategy included advertising through NSPs, and this may reflect that.

However, our results suggest that the S-Check app can act as a feasible low-resource, early intervention for participants who may be reluctant to seek traditional or face-to-face services, or are not linked to services such as those by referral points that may be made available at NSPs.

While it was not designed to be a motivator for reducing methamphetamine use, participants who spent more time engaged with the S-Check app demonstrated a reduction in methamphetamine use from baseline to day 28. This finding is consistent with other mHealth apps that included self-monitoring for alcohol and other substance use [57], reinforcing the theory that supportive self-monitoring influences behavior change [58,59]. Importantly, participants who had more frequent methamphetamine use engaged for longer with the S-Check app than those with less frequent use; and those participants who reported injecting methamphetamine were more likely to be retained to day 28 if they were randomized to the intervention group than those who did not report injecting. These findings highlight a potential treatment gap that could be filled by an mHealth intervention such as the S-Check app, or at the very least the potential of the S-Check app to be an adjunct to other treatment and harm reduction services and an important and accessible resource for when those are not available. The S-Check app was intended as an early intervention but may be an attractive resource for those people who are more frequent or injecting consumers of methamphetamine as well.

Previous research has highlighted a need for targeted interventions to improve pathways to professional support among people who use methamphetamine [55]. While we collected baseline data on 259 participants, 560 people downloaded the app. Of those who completed screening, only 10 were ineligible. This suggests that the S-Check app was highly accessible, while perhaps recruitment into the research study was not favorable; for example, it is unknown if potential participants did not proceed due to the chance of being randomized to the waitlist control. While not statistically significant, a higher proportion of those randomized to the waitlist went on to complete the day 28 assessment. It cannot be inferred from our data whether this is related to satisfaction of those randomized to immediately access the app, or perhaps reflecting the context of the waitlist group wanting to access the app.

Future directions include exploring the incorporation of the S-Check app as part of a stepped-care approach to clinical treatment, within a range of clinical settings, or as a motivational and self-awareness tool to be provided to people waiting for care. Primary care and sexual health service use is high among people who use methamphetamine, but opportunities to intervene are often missed. A health economic analysis was not part of the scope of this project and as such more work is required to test and analyze the costing and implementation of the app. Further development of the S-Check app and dissemination more broadly as a freely accessible resource to support people in understanding their methamphetamine use is planned.

Conclusions

This study demonstrates the effectiveness of the S-Check app in motivating help-seeking, particularly among treatment-naïve populations. The S-Check app was shown to be a feasible, low-resource, self-administered intervention for adults in Australia who use methamphetamine. Using supportive self-monitoring, the S-Check app assists people who use methamphetamine to identify problem use, shifting people along the motivational pathway, and promoting treatment seeking. As an early intervention, the S-Check app has the potential to facilitate the first step in a stepped-care approach to treatment, reducing treatment delays and avoiding more serious adverse health outcomes. Further work is required to demonstrate the generalizability of the S-Check app among people who use methamphetamine in Australia and to increase access to other internet-enabled devices.

Acknowledgments

The authors wish to thank all participants who took part in this study. In addition, we wish to acknowledge contributions from the investigators and research team (Ms Jessica Wilson, Mr Duncan Graham, Dr Emily Li, Ms Victoria Malone, Mr Quoc Nguyen, Ms Lauren Rogers, Dr Samineh Sanatkar) and the S-Check study advisory group (Mr Thomas Capell-Hattam, Dr Hila Haskelberg, Ms Ruth Hennessy, Dr Suzie Hudson, Ms Debbie Kaplan, Ms Chris Keyes, Associate Professor Anna McNulty). This study was funded by a New South Wales Health Early Intervention and Innovation Fund Grant (number A280560), the National Centre for Clinical Research on Emerging Drugs (which is funded by the Australian Department of Health and Aged Care), and the St Vincent's Hospital Sydney Inclusive Health Program.

Abstract

Background: Wearable activity trackers have become key players in mobile health practice as they offer various behavior change techniques (BCTs) to help improve physical activity (PA). Typically, multiple BCTs are implemented simultaneously in a device, making it difficult to identify which BCTs specifically improve PA.

Objective: We investigated the effects of BCTs implemented on a smartwatch, the Fitbit, to determine how each technique promoted PA.

Methods: This study was a single-blind, pilot randomized controlled trial, in which 70 adults (n=44, 63% women; mean age 40.5, SD 12.56 years; closed user group) were allocated to 1 of 3 BCT conditions: self-monitoring (feedback on participants' own steps), goal setting (providing daily step goals), and social comparison (displaying daily steps achieved by peers). Each intervention lasted for 4 weeks (fully automated), during which participants wore a Fitbit and responded to day-to-day questionnaires regarding motivation. At pre- and postintervention time points (in-person sessions), levels and readiness for PA as well as different aspects of motivation were assessed.

Results: Participants showed excellent adherence (mean valid-wear time of Fitbit=26.43/28 days, 94%), and no dropout was recorded. No significant changes were found in self-reported total PA (dz<0.28, P=.40 for the self-monitoring group, P=.58 for the goal setting group, and P=.19 for the social comparison group). Fitbit-assessed step count during the intervention period was slightly higher in the goal setting and social comparison groups than in the self-monitoring group, although the effects did not reach statistical significance (P=.052 and P=.06). However, more than half (27/46, 59%) of the participants in the precontemplation stage reported progress to a higher stage across the 3 conditions. Additionally, significant increases were detected for several aspects of motivation (ie, integrated and external regulation), and significant group differences were identified for the day-to-day changes in external regulation; that is, the self-monitoring group showed a significantly larger increase in the sense of pressure and tension (as part of external regulation) than the goal setting group (P=.04).

Conclusions: Fitbit-implemented BCTs promote readiness and motivation for PA, although their effects on PA levels are marginal. The BCT-specific effects were unclear, but preliminary evidence showed that self-monitoring alone may be perceived demanding. Combining self-monitoring with another BCT (or goal setting, at least) may be important for enhancing continuous engagement in PA.

Introduction

Background

Promoting physical activity (PA) is an urgent mission in modern society, as physical inactivity is a known risk factor for a wide range of illnesses such as diabetes, cardiovascular diseases, and depression [1,2]. Behavior change techniques (BCTs) and lifestyle interventions have been studied extensively, and systematic reviews and meta-analyses have found that, overall, behavioral interventions are effective in promoting PA [3-5]. Notably, many behavioral interventions have been delivered digitally through web applications or smartphone apps (or augmented by online support tools) for recording, giving feedback on, or coaching to promote PA. Thus, eHealth and mobile health (mHealth) interventions are expected to play an important role in promoting PA, especially during and after the COVID-19 pandemic [6,7].

Key players in digital health care research and business are wearable activity trackers, which are (consumer) devices that monitor PA and provide feedback to the wearer. These devices include pedometers, fitness trackers, smartwatches, and smart rings, which are often linked to web applications or smartphone apps that offer individualized dashboards, health messages, social support, and tips to continue exercising regularly (eg, [8,9]). Meta-analyses [10-12] have suggested that activity trackers significantly improve PA with standardized mean difference (SMD)=0.3-0.6, equating to approximately 1800-1850 extra steps per day.

Wearable activity trackers have been found to be well accepted by various populations, including adolescents [13], older adults with chronic diseases [14,15], and cancer survivors [16]. Users typically report positive experiences with activity trackers, which are perceived to be easy to use and useful to track daily (physical) activity. Thematic analyses highlighted enhanced self-awareness among users, which increases motivation to improve or maintain PA [14,15]. Indeed, a pilot trial showed that activity trackers help improve cardiometabolic risk variables in patients with diabetes and could potentially be a motivation tool to increase PA [17,18], particularly with appropriate features and implementations [19].

Fitbit devices are some of the most widely used wearable activity trackers in health care research. A recent narrative review [20] identified 75 published trials using Fitbit, in which a variety of behavior change strategies (eg, competition or challenges, self-monitoring, social support, and goal setting) were implemented. Through these trials, considerable heterogeneity was found in the use of Fitbit. Typically, these trials were designed to investigate the overall effect of a Fitbit-based intervention versus an intervention without Fitbit (or treatment as usual). If not limited to Fitbit, it is often the case with behavioral interventions in which multiple BCTs (ie, 5-10 different techniques [9]) are implemented simultaneously, which makes it difficult to identify which BCTs are active components to improve PA and motivation for PA. Therefore, we aimed to investigate the effects of different BCTs implemented using the Fitbit Sense smartwatch to determine how each technique would improve PA and motivation for PA through a mobile intervention.

The following three BCTs (indexed by the BCT taxonomy v1 [5]) were targeted in this study: (1) self-monitoring, which encouraged participants to monitor and record their step counts each day (*2. Feedback and monitoring* and *2.3 Self-monitoring of behavior*); (2) goal setting, which provided participants with an explicit daily step count goal and feedback on the goal progress (*1.1 Goal setting* and *2.7 Feedback on outcomes of behavior*); and (3) social comparison, which drew the participants' attention to their peers' step counts to allow comparison with their own performance (*6.2 Social comparison*). Note that the latter 2 conditions included self-monitoring by nature; without self-monitoring, feedback on goal progress or social comparisons could not be implemented.

We regarded self-monitoring as the control condition (or treatment as usual) because it is the most prevalent BCT implemented in mHealth interventions, and there is robust evidence that self-monitoring increases PA and improves dietary behavior [21,22]. A systematic review on digital implementations of self-monitoring [23] distinguished active self-monitoring, which requires users to reflect on the current state and physical functioning, from passive self-monitoring, which relies on sensors automatically recording (locomotor) acceleration, heart rate, and other physical or environmental information. In this study, we used active self-monitoring (ie, participants manually entered their step count of the day on an online questionnaire platform). This decision was made because (1) we wanted to be sure that each participant consciously checked their steps of the day and (2) the systematic review [23] identified in the literature no intervention study that included wearables to combine active self-monitoring with passive self-monitoring of additional physical information.

Furthermore, a meta-analysis [24] suggested that interventions combining self-monitoring with at least 1 other self-regulatory technique (eg, goal setting or feedback) are more effective than other interventions. A goal setting BCT is implemented in most commercial PA apps—95% set specific and measurable goals, which allow users to evaluate whether and to what extent they achieved the goal [25]. We followed this basic, core implementation, although other components of goal settings (eg, tailoring goal difficulty, scheduling, and action planning) were not considered in this study.

A systematic review [26] found that most of the social features implemented in mHealth interventions involve the delivery of social support or social comparison, which are often combined with the self-monitoring of behavior. The researchers also meta-analyzed the efficiency of mHealth interventions with social features, showing a moderate-to-large size effect, albeit

with large heterogeneity (SMD=0.96; I^2=99.6%). A recent analysis of the use patterns of commercial PA apps in a community sample suggested that people typically use only 2 functions within an app, often a combination of self-monitoring and one other function [27]. Given that users highly appreciate the simplicity of an app [28], it is of theoretical and practical importance to clarify how large the additive values of goal setting and social comparison are compared with self-monitoring alone.

Objectives

In summary, we aimed to test the effects of the 3 BCTs implemented using the Fitbit smartwatch to resolve an answered question in the literature, that is, how each BCT would contribute to improvement in PA levels and motivation in the form of mHealth intervention. A 2 × 3 factorial design was used, with assessment occasions (pre- vs postintervention time points) as the within-person factor and groups (self-monitoring vs goal setting vs social comparison) as the between-person factor. During the 4-week intervention, participants wore a Fitbit Sense to receive 1 of the 3 interventions (ie, self-monitoring, goal setting, or social comparison) and assess their levels of PA (in the form of step count) for 24 hours. They also responded to daily online questionnaires asking how motivated they were regarding PA. The primary outcome was self-reported PA levels assessed before and after the intervention. The secondary outcomes included (1) the stage of change for PA [29], (2) intrinsic and extrinsic motivations for PA, (3) Fitbit-assessed step count, and (4) day-to-day motivations for PA [30]. We expected that the goal setting and social comparison groups would show larger increases in the levels and motivations for PA compared with the self-monitoring group. We did not have a clear hypothesis for a direct comparison between goal setting and social comparison, which was tested in an exploratory manner.

Methods

Participants

Invitations were spread to local inhabitants in and around Ibaraki Prefecture (a middle-north region in Japan; February 2023) who had been registered in a database of potential participants. The study was advertised (online) as one that assessed psychological and behavioral data in daily life. The advertisement explicitly stated that participants would be asked to wear the Fitbit for 1 month, but they were blinded to the intervention conditions. In total, 140 individuals were assessed for eligibility, and 70 (50%) met the following inclusion criteria: (1) being aged 18-64 years; (2) expecting no major life change (eg, in a living place or job) before or during the study; (3) being not pregnant or not lactating; (4) being in good health (ie, having no medical, neurological, psychiatric, or other physical illnesses); (5) having not been diagnosed with dysautonomia, depression, mania, bipolar disorder, or facial paralysis in the past; (6) not taking tranquilizers or antihypertensive drugs regularly; (7) not taking hormone replacement therapy or not taking oral contraceptives; and (8) not exercising regularly. Regular PA levels (criterion 8) were assessed using the Stage of Change (SoC) questionnaire for PA (see the *Measures* section), and those who identified themselves as being at the precontemplation, contemplation, or preparation stages were eligible for participation. We assessed SoC instead of PA levels because we targeted motivation and readiness for PA, not only the actual engagement in PA behavior. Among the 70 excluded participants, 60 (86%) were physically more active than criterion 8 (belonging to the action or higher stages of change), and 10 (14%) could not find time for the briefing session of the study. All participants were assumed to have good internet literacy (necessary support was provided at the briefing session by an experimenter).

The sample size was determined after the recommendations of a pilot randomized controlled trial (eg, [31]). We did not perform a rigorous power analysis because we regarded this study as a pilot trial, and there was no good way to determine an expected effect size that could be used for a priori power analysis, particularly for the comparison of goal setting and social comparison. However, the current sample size (n=23 or 24 per group) allowed for the detection of an effect of Cohen d=0.87 with α=.05, and power=0.80. A meta-analysis [26] reported SMD=0.96 as the effect of social features implemented in mobile interventions on PA levels albeit high heterogeneity being documented.

Interventions

Participants were randomly allocated to 1 of 3 groups and received a smartphone and a Fitbit Sense at the beginning of the study (briefing session). The Fitbit app was installed on the smartphones with varying settings for each intervention condition.

In the self-monitoring group, participants received a smartphone with the Fitbit app, with all notification functions turned off, except for low battery warnings. Participants were allowed to see the home display, showing the step count of the day and other physiological information, including sleep, heart rate, and skin temperature. However, the app indicated no step goals to achieve, social functions were disabled, and no push notifications were sent to the devices during the intervention period. Participants received a chat message on their smartphone each evening (at 9 PM) asking them to read the step count of the day displayed on the Fitbit and manually record it on an online questionnaire platform.

Participants in the goal setting group were explicitly informed of the goal to be achieved each day (ie, 9000 and 8500 steps for men and women, respectively) by an experimenter during the briefing session. These goals were set according to the Japanese national health recommendations [32]. During the briefing session, the experimenter instructed the participants to enter the step goal into their Fitbit app to monitor their progress at any time, and the Fitbit Sense notified each participant of their daily goal achievement using vibration.

The participants in the social comparison group were explicitly instructed to read and record the step counts of their peers on the Fitbit app each evening. On the Fitbit app, 5 peers (called “friends”) had been registered before distribution. Participants were not explicitly told who these friends were, but each friend was displayed on the app with a unique participant ID (eg, AIST_01 and AIST_02). These 5 friends were the researchers

and research assistants of this project, who wore the Fitbit Sense throughout the period of data collection. The average step count for the 5 friends was 6405-11,449 steps per day. Each participant was paired with the same 5 friends so that there was no variability in the friends' activity levels between participants. We asked participants to check their friends' steps each day but did not explicitly ask participants to outperform their friends.

Measures

We administered the following three types of assessments: (1) pre- and postintervention assessments in the lab, (2) daily in-intervention assessments at home using self-report scales for motivation, and (3) accelerometry (implemented in Fitbit) for step counts (Table 1).

Table 1. Overview of the measures and response items.

Type and timing of assessment and measure	Variable and description
Self-report (in the lab, at pre- and postintervention time points)	
Stage of Change questionnaire (at the eligibility screening)	Stage of change, readiness for PA[a]
International Physical Activity Questionnaire—Short Form	Levels of total PA
Self-determined Motivation Scale for Exercise	Different motivations for regular PA (intrinsic motivation, external regulation, introjected regulation, identified regulation, integrated regulation, and amotivation)
Self-report (at home, each evening)	
Modified Situational Motivational Scale	Identified regulation, intrinsic motivation, and external regulation
Step count of the day (all 3 groups)	Read and record the step count of the day, displayed on Fitbit
Goal achievement of the day (goal setting group only)	Record whether the goal (9000 or 8500 steps) was achieved
Step count of a peer (social comparison group only)	Record the step count of the Fitbit friend whose count was the highest among the friend group
Fitbit (at home, at any time)	
Step count	Accelerometer based

[a]PA: physical activity.

SoC Questionnaire

Readiness for PA was assessed using the Japanese version [33,34] of the SoC questionnaire [29,35]. Participants were classified into 1 of 5 stages (ie, precontemplation, contemplation, preparation, action, and maintenance), selecting the most applicable statement among the following: "I currently do not exercise and do not intend to start exercising in the future" (pre-contemplation); "I currently do not exercise but I am thinking about starting to exercise in the next six months" (contemplation); "I currently exercise some, but not regularly" (preparation); "I currently exercise regularly, but have only begun doing so within the last six months" (action); and "I currently exercise regularly and have done so for longer than six months" (maintenance). We instructed the participants to consider regular exercise as exercising twice or more per week for 20 minutes or longer.

International Physical Activity Questionnaire—Short Form

Total PA was assessed using the International Physical Activity Questionnaire—Short Form (IPAQ-SF) [36,37]. The IPAQ-SF includes three dimensions: (1) walking, (2) moderate-intensity activity, and (3) vigorous-intensity activity. Sedentary time was not included in the analyses. Participants reported the number of days and duration spent on each dimension of PA over an average week. The reported weekly minutes of PA (duration×days for each PA dimension) were transformed into hourly metabolic equivalents per week (METs-h/w). This scaling allowed us to explore how many participants adhered to the Japanese public health guidelines for PA, which is 23 METs-h/w for adults [32].

Self-determined Motivation Scale for Exercise

The baseline and postintervention levels of motivation for PA were assessed using the revised version of the Self-determined Motivation Scale for Exercise [38], which was developed based on self-determination theory [39]. This 22-item self-report questionnaire covers the following six types of motivations or regulatory styles concerning PA: (1) intrinsic motivation (eg, "Exercising itself is fun"), (2) external regulation (eg, "I exercise because other people will be pleased with me"), (3) introjected regulation (eg, "I feel guilty if I do not exercise"), (4) identified regulation (eg, "I think it is a good way to improve myself"), (5) integrated regulation (eg, "It is essential to my identity and sense of self"), and (6) amotivation (eg, "I do not know why I exercise"). Each construct is assessed using 3- or 4-item subscales, and each item is rated on a 5-point scale (1=not at all true and 5=very true). Cronbach α was >.73 for each subscale.

Daily Measures: Motivation

A chat message was sent to the participants' smartphones in the evening (at 9 PM). The message included a link to an online survey platform (Exkuma [40]) where participants rated their motivation for PA. The link was to expire at 2 AM, but because of a technical problem, responses were erroneously accepted even after this due time. All such delayed responses were

excluded from analyses. The evening questionnaire included the following 3 items: identified regulation ("I'm feeling that exercising is important for me"), intrinsic motivation ("I'm feeling that exercising is fun"), and external motivation ("I'm feeling that I have to exercise"). Each item is rated on a 7-point scale (1=not at all and 7=very much). Motivation items were adapted from the Situational Motivational Scale [41] for physical exercise [42]. We adjusted the wording for daily or momentary assessments (ie, asking how one is feeling right now) and selected the items with the highest factor loadings in each dimension to minimize the burden on the participants [30]. In addition, we did not include items on amotivation, as our focus was on a pro-PA psychological state, not on the barriers to PA.

Procedure

Interested participants completed an online screening survey for eligibility. Those identified as eligible were then invited to an online system to schedule an in-person briefing session, where groups of 1-4 participants were formed arbitrarily. These groups were randomly allocated to 1 of the 3 intervention conditions (1:1:1) following a random sequence generated by a trial analyst using R (version 4; R Foundation for Statistical Computing). Experimenters (who conducted the recruitment and assessments) were not involved in this process. Block randomization (batch per group size) was used to prevent imbalances in group allocation. Single blinding was used; participants were not aware of whether they were in an active or control condition or what interventions other participants received. During the briefing session, the participants received instructions about the study, provided informed consent, and completed baseline questionnaires. At the end of this session, the participants received a smartphone (Android OS) paired with a Fitbit Sense. As the data collected via these devices were tagged with participant IDs (but not with their real names), there was no security concerns about personal information.

During the 4-week intervention period, participants were asked to wear a Fitbit Sense on their nondominant wrist for 24 hours. Participants were instructed not to change the settings of the Fitbit app. Each evening, all participants recorded their daily step count on an online questionnaire platform. Those in the social comparison group were also asked to record the highest step count of the day among their friends on the Fitbit app. There was no in-person component in the interventions although technical support (eg, for app login and online questionnaires) was provided by an experimenter at any point of the interventions.

Immediately after the 4-week interventions, the participants were invited to the lab again, returned their smartphones and Fitbit, and completed the postintervention questionnaires. They also took part in a brief in-person interview asking whether participants experienced any adverse events during the intervention period and how they liked Fitbit and each intervention component (ie, self-monitoring, goal setting, or social comparison). At the end of the debriefing session, the participants received 49,000 JPY (US $350) as compensation. Postintervention checks were conducted on the devices right after the interventions were completed. These checks reassured us that (1) the step goals were not changed on the system (8500 or 9000 steps in the goal setting group and no goals in the other 2 groups), and similarly, (2) the friend list was not changed (5 peers in the social comparison group, and no peers in the other 2 groups). The data collection was ended in May 2023.

Ethical Considerations

The study protocol was approved by the Ethics Committee of the National Institute of Advanced Industrial Science and Technology (approval ID: 2022-1240). The protocol was preregistered with the Open Science Framework before data collection.

Statistical Analyses

The primary outcome (ie, self-reported PA level) was analyzed using a 2-level multilevel model with the groups as between-person predictors, time (pre- vs postintervention time points) as the within-person predictor, and cross-level interactions. Groups were dummy coded, with the self-monitoring group as the reference level. Random intercepts and slopes were assumed, which allowed the baseline level of PA and rate of change in PA to vary across individuals. No correlation was assumed between the intercept and the slope. Each model was estimated using the restricted maximum likelihood estimation method. The same or similar models were used for the secondary outcomes. An exception is that the analyses of day-level variables (ie, daily step count and motivations reported each evening) had a continuous time predictor (ie, days since the start of the intervention) instead of pre- and postintervention time points. All randomized participants were included in the analyses on an intention-to-treat basis. The effect sizes (Cohen *d* for between-group differences and *dz* for within-group changes) were calculated [43]. All analyses were performed using R (version 4; R Foundation for Statistical Computing) with the specific packages *lme4* [44], *lmerTest* [45], and *fitbitr* [46].

Sensitivity analyses were planned to examine the influences of missingness on (1) the Fitbit-assessed step count and (2) evening levels of motivation for PA. First, for the main analysis on step count, we excluded days with steps <2000 as outliers. This cutoff was determined on the distribution observed in the current data (5.6% [110/1960] of records met <2000 steps). Also, 2000 steps can be reliably regarded as too few given that a daily step count of 5000 is operationalized as a sedentary lifestyle [47], and thus, measurement issues were suspected (eg, Fitbit was not worn appropriately). Second, as a sensitivity analysis, we reran the analysis while filtering out the days with missing heart rate (ie, days with <50% of valid heart rate records) instead of days with <2000 steps. Note that heart rate was not a target of our analyses but was measured by Fitbit; also, missingness in heart rate does not always indicate invalid wearing as temporary dysfunctions in the device or sensor may result in missingness. Third, we checked compliance in responding to daily questionnaires to see whether any participants should be excluded because of too few valid responses. However, we found excellent compliance in the current data (24.96/28 days, 89%, 1747/1960; see the *Results* section for details), and thus, data from all participants were used for statistical analyses.

Results

Demographics and Descriptive Statistics at the Baseline

The demographic characteristics of the participants are shown in Table 2. At the baseline assessment, the 70 participants were physically inactive: 46 (66%) in the precontemplation stage, 15 (21%) in the contemplation stage, and 9 (13%) in the preparation stage. In the IPAQ-SF, 46 (66%) participants did not meet the national health guidelines for PA (23 METs-h/w). Among the remaining participants (n=24), 10 (42%) were classified under category 3 (health-enhancing PA). As these highly active individuals were not the target of this study (and responded inconsistently to the SoC questionnaire and IPAQ-SF), we performed sensitivity analyses after excluding them at baseline (see Tables S4 and S5 in Multimedia Appendix 1 for details; overall, we identified no significant changes in the results that influenced the conclusion). No significant group differences were found in age, gender, education level, or other socioeconomic factors.

Table 2. Demographics and descriptives at baseline.

Variable	Self-monitoring (n=23)	Goal setting (n=23)	Social comparison (n=24)	Test on group differences, *F* test (*df*) or chi-square (*df*)	*P* value

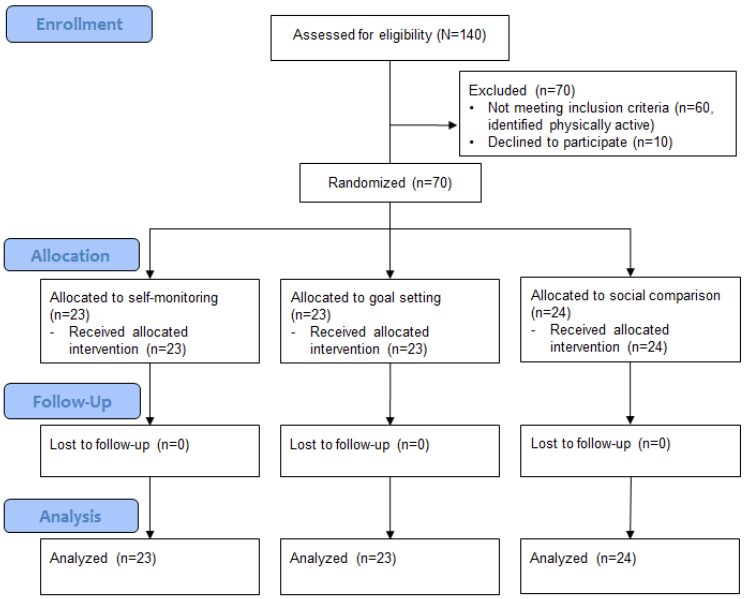
[a]Total PA: total physical activity in metabolic equivalents for hours per week, as assessed using the International Physical Activity Questionnaire—Short Form.

[b]SMSE-2: Self-determined Motivation Scale for Exercise 2.

Compliance and Adherence

All participants completed the pre- and postintervention assessments and received the intended interventions (see Figure 1 for the Consolidated Standards of Reporting Trials flow diagram). The compliance rate was 89% (mean 24.96, SD 5.75 out of 28 days) for the daily online questionnaires. The mean valid-wear time of Fitbit was 26.43 days (94%) out of the entire assessment period (28 days) after the invalid days (when <2000 steps were recorded) were left out. As another measure of adherence to wearing Fitbit, we checked the presence of heart rate signals in the data. This check identified 30 days to be excluded across 70 participants, and the remaining mean 27.57 (SD 1.04; 99%) days were submitted to the sensitivity analysis. No adverse event was recorded.

Figure 1. Consolidated Standards of Reporting Trials flow diagram.



We examined the correlations between compliance and baseline variables (Table S1 in Multimedia Appendix 1). The older participants showed higher compliance (day-to-day assessments; r=0.30) and adherence (Fitbit wear time; r=0.39). Those with children or jobs showed higher adherence (r=0.35 and 0.31, respectively). Individuals with higher baseline levels of integrated regulations had a lower compliance rate (r=–0.35).

Changes From the Pre- to Postintervention Assessments

The results of a 2 × 3 multilevel model (pre- vs postintervention time point; self-monitoring vs goal setting vs social comparison) of self-reported total PA revealed neither a significant main effect of time nor a significant interaction effect between time and group (Table 3). The same multilevel model analyses were repeated for SoC and motivation variables as outcomes, which showed no significant time-group interaction effects. However, significant effects of time were observed for the following secondary outcomes (Table S2 in Multimedia Appendix 1): SoC (dz=0.50, 95% CI 0.25-0.75, P=.006), integrated regulation (dz=0.35, 95% CI 0.11-0.59, P=.03), and external regulation (dz=0.42, 95% CI 0.17-0.66, P=.003). These time effects suggest that participants reported progress to higher stages at the end of the interventions; typically, people who had been in the precontemplation stage progressed toward the contemplation stage (see Table S3 in Multimedia Appendix 1). Similarly, participants experienced increases in integrated regulation (ie, they recognized more personal values and sense of self in PA) and external regulation (ie, they gained more motivation that was controlled by external sources and actions such as pleasing their family), but these effects did not differ between the BCT conditions.

Table 3. Changes in the levels of physical activity and other outcomes from the pre- to postintervention assessment.

Outcome and group[a]	Value, mean (SD)	Standardized within-group change (*dz*)	Standardized mean group difference (vs self-monitoring)	
			Cohen *d*	*P* value
Total PA[b] (METs-h/w)[c]				
Self-monitoring	–4.97 (27.82)	–0.18	__[d]	—
Goal	5.48 (46.49)	0.12	0.28	.33
Social	22.12 (80.80)	0.27	0.45	.15
All groups	7.75 (56.91)	0.14	—	—

Goal	–0.57 (2.64)	0.21	–0.05	.87
Social	0.63 (2.60)	0.24	0.42	.17
All groups	–0.11 (2.63)	0.04	—	—

[a]n=23, 23, and 24 for the self-monitoring, goal setting (goal), and social comparison (social) conditions, respectively. Stage of change coded as follows: precontemplation=1, contemplation=2, preparation=3. *P* values for group differences were calculated using multilevel modeling (ie, group-time interaction effects; see Table S2 in Multimedia Appendix 1 for details).

[b]PA: physical activity.

[c]METs-h/w: metabolic equivalents for hours per week

[d]Not available.

[e]SoC: Stage of Change.

Day-Level Outcomes

We performed multilevel modeling with days, groups, and their interactions as predictors. The results showed no significant day-group interactions in predicting Fitbit-assessed step count, identified regulation, or intrinsic motivation (Figure 2; Table 4). However, external motivation was significantly predicted by the interaction between the day and group dummy of self-monitoring versus goal setting. This interaction effect implies that the self-monitoring group experienced a significant increase in external motivation (*b*=0.019, SE=0.008; $t_{68.24}$=2.436, *P*=.02), whereas the goal setting group showed no change over time (*b*=–0.003, SE=0.011; $t_{66.51}$=–0.516, *P*=.61). Over the intervention period, the Fitbit-assessed step count remained slightly higher in the goal setting and social comparison conditions than in the self-monitoring condition (Figure 2D), although these main effects of the condition did not reach statistical significance (*P*=.051 and *P*=.06; Table 4). The results were unchanged when heart rate was used to define invalid wearing time (the main effects were not significant; *P*=.053 for goal setting and *P*=.17 for social comparison).

Figure 2. Levels of motivations and Fitbit-assessed step count as a function of day.
