Abstract

Background: Some people are less likely to benefit from digital health interventions (DHIs) than others. Culture, along with other factors, contributes to these differences. DHIs that do not address a population's cultural norms or concerns are likely to be less effective. One way to create culturally sensitive DHIs is through cultural adaptations. Yet, there is currently little evidence-based guidance on when and how to adapt DHIs.

Objective: We aimed to capture the experiences of experts to understand the (1) current practices, (2) challenges, and (3) recommendations around culturally adapting DHIs.

Methods: We conducted semistructured interviews (n=15) via Zoom (Zoom Video Communications, Inc) between May and August 2023, with academic experts who have previously undertaken cultural adaptations of DHIs. Experts were identified through publications and snowball sampling. We used a thematic analytical approach, beginning with a preliminary deductive codebook and then following a three-stage analysis. All transcripts were coded with the MAXQDA (VERBI Software GmbH) software. Codes were reviewed, and similar or related codes were categorized into broader themes, consolidating one or multiple codes into a single topic.

Results: Our analysis produced 30 codes, which were categorized into (1) defining culture, (2) justifying the adaptation, (3) choosing the adaptation elements, (4) implementing the adaptation, (5) understanding the challenges, and (6) recommendations. Based on their experiences, experts recommended that (1) the adaptation team is multiprofessional, digitally competent, and culturally sensitive; (2) DHI users and (3) all other relevant stakeholders are continuously involved; and (4) the adaptations incorporate evaluations and knowledge exchange. They further emphasized that culturally adapted DHIs must be understandable, relatable, appealing, and easy to adhere to, ensuring that health technology and content reflect the target population's lived experiences, sociodemographic characteristics, and digital literacy. When asked which elements of cultural DHI adaptations, the most common responses were language, lived experience, and technology. Responses revealed five common DHI-relevant challenges, including (1) technology, (2) uncertainty, (3) user involvement, (4) communication, and (5) evaluation and sustainability.

Conclusions: The cultural adaptation of DHIs was described as an iterative, often unstructured, and resource-intensive process that requires careful justification and a solid understanding of the culture and the specific cultural group for which it is implemented. Our interviews confirmed the absence of technology-specific frameworks to guide the cultural adaptations of DHIs. Based on our findings, such a framework should guide the choice of the correct definition of culture and the criteria for assessing the need to adapt. It should also offer tools to drive stakeholder engagement, prioritize adaptation elements, and address common challenges.

Introduction

Digital health interventions (DHIs) use information and communication technologies (ICTs) to prevent, monitor, manage, and treat health conditions [1]. DHIs are often used to support individuals in developing healthy habits (eg, smoking cessation and healthy eating) and improve outcomes for those living with chronic conditions [1]. A key feature of DHIs is that they can provide access to health information and treatments

XSL•FO
RenderX

without the need for traditional health care intermediaries such as insurance companies and clinicians [1,2]. DHIs are spearheaded by web and mobile apps, social networking platforms, and self-monitoring devices like fitness trackers, sleep monitors, and wearables (electronic health devices work on the body, such as smartwatches) [2]. Recent systematic reviews indicate that DHIs can be effective and cost-effective in reducing risk and enhancing health outcomes across a variety of conditions, such as diabetes, cardiovascular health, mental health, and addictions [3-5].

Despite increasing access to the internet, mobile devices, and other technologies, medically underserved populations are less likely to benefit from DHIs than others [6-9]. The term "medically underserved" describes those (eg, racial or ethnic minorities) who have limited access to primary health care, primarily due to sociocultural, economic, and geographic vulnerabilities [10]. Two recent systematic reviews on DHIs for physical activity and other weight-related behaviors have demonstrated that the use and effectiveness of these interventions vary across several characteristics, including race, ethnicity, and socioeconomic status [11,12]. Other studies found that African American and Hispanic individuals are less likely to engage with DHIs than their White counterparts [13,14]. Together with other factors, culture has been shown to play a role in these differences because most DHIs are most often designed for dominant cultural groups, limiting their appropriateness for marginalized populations. DHIs that do not address a population's cultural norms or concerns, thus, are not culturally sensitive, are likely to be less accepted by that population, and therefore, underused or engaged with [10,13,15]. Although culture can influence how people use and engage with a DHI, very few DHIs are designed to be culturally sensitive [8,15]. This often results in DHIs that inherently exclude certain population groups, further exacerbating the digital and health inequities [8]. Although no single definition of culture exists, Castro et al [16] defined it as a group of people's shared perspectives and practices.

Ensuring that DHIs address the sociocultural norms of a population is challenging. One way to create culturally sensitive DHIs is through adaptations. Cultural adaptations can be defined as interventions that tailor existing, often evidence-based technologies to align with a specific group's cultural identity, including cultural norms, beliefs, values, and practices [16]. In our previous work, we argued that cultural adaptations may increase DHIs' reach, engagement, and outcomes for medically underserved subgroups [17]. However, we emphasized that there is currently little evidence-based guidance on when and how to adapt DHIs [17]. The broader literature on cultural adaptations offers various models designed to guide the adaptation process for evidence-based health care interventions [18,19]. These models specify various steps in the cultural adaptation process, such as (1) assessing the evidence base, (2) creating a preliminary adaptation design, (3) testing preliminary adaptations, and (4) refining them into final adaptations. While many of these models offer broad guidance applicable to the cultural adaptation of DHIs, they do not sufficiently recognize and tackle the unique challenges associated with their use of technology. For example, creating a preliminary adaptation design of a mental health intervention will differ drastically when the intervention is delivered physically compared to it being delivered through a mobile phone app that might require expensive and time-consuming software changes. Nevertheless, there have been many noteworthy attempts to adapt DHIs described in the literature to date, culturally, generating essential knowledge and experience that has the potential to contribute to the development of future guidance [20,21].

In this study, we interviewed researchers who have conducted cultural adaptations of DHIs. Through these interviews, we aimed to capture current practices, challenges, gaps, and recommendations for future adaptations. We specifically asked researchers about (1) why and how they adapted their DHIs and defined culture, (2) how they implemented those adaptations, (3) which elements they chose for adaptation and the criteria for their selection, (4) the challenges they faced during adaptation, and (5) their recommendations for future cultural adaptations of DHIs. We hoped that understanding these experiences might help us identify general principles that could be used to develop broader recommendations to help guide future cultural adaptations of DHIs.

Methods

Study Design

We conducted semistructured 45-minute interviews (n=15) with researchers who have previously undertaken cultural adaptations of DHIs. Researchers (hereafter referred to as experts) were invited to participate in this study if they (1) developed and implemented at least one cultural adaptation of a DHI (globally) and (2) either currently hold an academic appointment or have had a past academic appointment.

Participants and Recruitment

We initially identified eligible experts through academic publications. In March 2023, we searched PubMed and Google Scholar using keywords related to DHIs, culture, and adaptations. We used the following keywords: "digital health," "digital health intervention," "mobile health," "web-based health," "e-health," "culture," "socio-cultural," "cultural tailoring," "cultural adaptation," and "cultural sensitivity." Relevant publications had to address an actual cultural adaptation of a DHI, irrespective of the health field or population. One reviewer (VN) screened and selected all relevant studies. We screened 138 studies, of which 37 were deemed relevant and appropriate and were used for extracting all corresponding authors' names and email addresses. Invitations were emailed to participants, where we briefly introduced the project's aims and participation requirements. In case of nonresponse, we sent reminder emails 2 - 3 weeks after initial contact. Those who expressed interest were emailed a bulleted summary of the project and asked to provide their feedback on availability. We identified additional experts through snowball sampling, which involved asking experts at the end of their interview if they knew of other researchers who may be eligible. Inclusion criteria were verified by screening a recommended expert's publication list to ensure experts had (1) at least one publication specific to the cultural adaptation of a DHI and (2) a past or current academic appointment. We

XSL•FO
RenderX

purposively chose interviews over a literature review because the current DHI literature primarily provides superficial descriptions of the adaptation processes. Instead, interviewing experts allows for a deeper and more nuanced understanding of current practice, challenges, and gaps, and provides experience-based recommendations. Interviews were concluded once we reached thematic saturation. We defined thematic saturation as reaching a state where conducting new research does not provide substantially new information or additional conceptual depth but rather a repetition of themes. We stopped interviewing once we felt that a significant amount of information was repeated, which occurred after 13 interviews. We then conducted two additional interviews to confirm that thematic saturation was reached.

Data Collection

We used a semistructured interview guide developed by the research team and informed by a literature review that we previously conducted (Multimedia Appendix 1) [17]. We used the main topics that emerged in the literature review to develop the interview sections and questions. Interviews were divided into four parts that were specific to DHIs. The first part was an introduction (eg, "tell us about your background and overall experience in cultural adaptations"); the second part focused on the justification of cultural DHI adaptations (eg, what made you decide to adapt?). Furthermore, the third part consisted of questions around adaptation elements (eg, what elements did you adapt and how did you select these elements?), and the fourth part addressed challenges, solutions, and recommendations (eg, what challenges did you face during the adaptation process?"). Based on the first two interviews (pilot), we iteratively adjusted the interview guide. Specifically, the wording of parts three and four was adjusted to be more targeted and more precise, with a series of narrower subquestions.

One interviewer (VN; epidemiologist) with previous experience in qualitative research and interviewing conducted the interviews via Zoom (Zoom Video Communications, Inc) between May and July 2023. Each interview began with a verbal summary of basic information about the study and its objectives. Experts had the opportunity to ask questions. All sessions were recorded and transcribed with Zoom's transcription software. Additional notes were taken by the interviewer during each interview. Each transcription underwent quality checking and was corrected by one of the research team members (VN). Before analyzing the data, we deidentified all transcripts and removed any references to names, institutions, and project names. Each expert was given a unique identification number linked to their transcripts. A week after transcribing, we deleted all recordings.

Analysis and Synthesis

We applied an iterative, thematic analytical approach [22]. We initially created a preliminary deductive codebook based on our prior work [17]. Specifically, we used the challenges identified in our review to create initial codes (eg, adaptation justification). We then followed a three-stage analysis to ensure themes were understood and developed thoroughly. First, we read and reread all the interviews to familiarize ourselves with the data. That stage led to inductive modifications of the codebook. Second, all transcripts were coded by VN using the MAXQDA software (VERBI Software GmbH). Third, codes were reviewed, and similar or related codes were categorized into broader themes, consolidating one or more codes into a single unit topic. We then described and narratively synthesized these themes. Following standard practice, a second coder (PD) independently coded about 15% (n=2) of our interviews (PD) to ensure that no critical codes were missed [23]. Finally, we synthesized our data and created themes that represented what most experts were stating. Additionally, we elaborated on emerging findings that warrant further investigation.

Ethical Considerations

An ethics approval and informed consent were not required as this study does not meet Brown University's institutional definition of human participant research [24]. An ethics application was submitted and was dismissed as nonhuman participant research. All study data have been anonymized and deidentified. Recordings have been permanently deleted. Each expert received a US $100 voucher.

Results

Overview

We invited 34 researchers to participate in our study. A total of 25 (74%) researchers responded to our email, and 15 (44%) researchers agreed to be interviewed. Of those, 11 (70%) researchers were directly identified through publications, and 4 (30%) were through referrals. In total, 13 of the experts were female. Participant characteristics are listed in Table 1.

XSL•FO
RenderX

Table . Participant characteristics.

ID	Country	Area of expertise	Adapted technology	Target population
1	Brazil	Public health	Mobile app	Pregnant woman
2	United States	Oncology	Web-based decision aid	Latino men
3	Germany	Psychology	Mobile interventions	Low-income setting
4	United Kingdom	Caregiving	eHealth training	Young carers
5	Switzerland	Physical activity	Mobile app	English speakers
6	New Zealand	Public Health	Text-based app	Indigenous
7	Canada	Nursing	Web-based program	Low-income setting
8	United Kingdom	Psychology	eHealth training	Minority carers
9	Sweden	Psychology	Web-based intervention	Minority youth
10	Spain	Caregiving	eHealth training	Informal caregivers
11	Switzerland	Psychology	Mobile app	Migrants
12	Germany	Psychology	Digital intervention	Refugees
13	Germany	Psychology	Mobile app	Refugees
14	Greece	Psychology	Web-based program	Informal caregivers
15	Spain	Public health	Web-based program	Adolescents

Our analysis yielded 30 codes, which we categorized into six broader themes aligned with our interview guide. Table 2 provides a description of all themes and subthemes, which includes: (1) defining culture, (2) justifying the adaptation, (3) choosing the adaptation elements, (4) implementing the adaptation, (5) understanding the challenges, and (6) recommendations. The first theme addresses topics related to all preparatory steps before a cultural adaptation is implemented. Themes 2 to 5 address issues directly related to implementation.

XSL•FO
RenderX

Table . Definitions of themes and subthemes.

Themes and subthemes	Description
1. Defining culture	Main theme that includes all statements referring to the definition, perception, and conceptualization of culture.
2. Justifying the adaptation	Main theme that includes all statements referring to reasons for culturally adapting DHIs[a].
2.1. Pragmatic reasons	Subtheme that includes all opportunity-driven reasons to culturally adapt DHIs.
2.2. Equal access	Subtheme that includes reasons to culturally adapt DHIs that refer to equal access to technology.
2.3. Other ethical reasons	Subtheme that includes all other ethical reasons to culturally adapt DHIs.
3. Implementing the adaptation	Main theme that includes all statements referring to implementing cultural adaptations of DHIs.
3.1. The adaptation team	Subtheme that describes the role of adaptation team members in the implementation of adaptations.
3.2. User involvement	Subtheme that describes the role of user involvement in the implementation of adaptations.
3.3. Expert or stakeholder involvement	Subtheme that describes the consulting role of experts or stakeholders in the implementation of adaptations.
4. Choosing the adaptation elements	Main theme that includes all statements referring to selecting and prioritizing what DHI elements to adapt.
4.1. Language	Subtheme that describes language as a critical adaptation element.
4.2. Lived experience	Subtheme that describes lived experience as a critical adaptation element.
4.3. Technology	Subtheme that describes technology as a critical adaptation element.
5. Understanding the challenges	Main theme that includes all statements referring to challenges when adapting DHIs.
5.1. Technology	Subtheme that describes adaptation challenges related to technology and its functions.
5.2. Uncertainty	Subtheme that describes adaptation challenges related to missing knowledge or evidence and uncertainty
5.3. User involvement	Subtheme that describes challenges related to involving and engaging users in the adaptation process.
5.4. Communication	Subtheme that describes challenges related to communication during the adaptation process.
5.5. Evaluation and sustainability	Subtheme that describes challenges related to evaluating and sustainably maintaining an adapted DHI.
6. Recommendations	Main theme that includes all statements referring to expert recommendations for future cultural adaptations of DHIs.

[a]DHI: digital health intervention.

Defining Culture

We asked participants how they define culture, primarily in the context of their work. Most describe culture as a complex concept beyond ethnicity and place of origin. Instead, they emphasized (1) community, (2) shared experience, (3) shared values, (4) family, and (5) sociodemographics, as well as (6) shared context and living conditions. Of those experts who provided more details, defining culture (in the context of DHI adaptations) was described as an intuitive and pragmatic process often grounded in common knowledge (eg, what people think they know about culture) or the adaptation team's expertise of the target culture (eg, the culture of the focal population that a DHI is adapted for). Overall, many experts described culture as an influencer of one's perception of the world, which includes the perception of health and technology. One expert summarized that as "cultural and context," and described cultural adaptations as "contextual adaptations." One expert who has adapted a mobile mental health app for refugees described:

> *But what you have to do is you have to do contextual adaptation, you have to understand the context in which the people grew up in which they live now, and in which they will use the app.* [ID13]

XSL•FO
RenderX

Justifying the Adaptation

Overview

We asked participants about valid reasons to culturally adapt to a DHI, as well as the reasons for their adaptations. Replies led to three subthemes: (1) pragmatic reasons, (2) providing equal access to DHIs for underserved populations, and (3) other ethical reasons.

Pragmatic Reasons

Some experts mainly mentioned the lack of guidance specific to cultural adaptations of DHIs. A participant (ID9) who has previously adapted a web-based health intervention for minority youth confirmed: "I don't think there is much in the existing research that can guide us in that." Therefore, their decisions to adapt were often described as intuitive and common sense–based (eg, they believed they were needed and they made sense), as well as the result of arising opportunities, such as available funding for transferring a DHI to another community. One expert (ID8) who has worked on the adaptation of an eHealth training for young carers in the United Kingdom said: "Our adaptation came about through a recommendation from our funders."

Equal Access

One consistent theme that arose when justifying their adaptations was the provision of equal access. It was described as making digital health resources available to people who are expected to benefit but tend to be medically underserved and would not be reached otherwise. This was described as the case either because the nonadapted DHI is (1) not relevant or appealing, (2) not understandable, (3) offensive, (4) incompatible with prevailing norms and values, and (5) not aligned with the context and lived experiences. An expert who has adapted an eHealth training for minority young carers described:

> *There was very, very little in terms of resources for them, support in the caring world [...] there is a lot of evidence south Asian minorities, communities in the UK have a different look at what caring means, and because their family context is quite different, their openness or the way they like to receive the help is quite specific.* [ID4]

Other Ethical Reasons

One expert emphasized the ethical reasons for adaptation, including (1) eliminating Western biases from DHIs before implementing them in more culturally diverse environments and (2) enhancing the visibility of individuals who are otherwise socially excluded groups. One expert said:

> *But we knew there wasn't anything for younger carers of people living with dementia [...] we could do something that at least was going to help increase the visibility of the group.* [ID4]

Another common theme was the improvement of DHI engagement and adherence, specifically for people who have otherwise previously shown low engagement intervention rates. Here, adaptations were described as synonymous with an elevated user experience, which ensures that people interact with a DHI long enough for it to have an effect. An expert who had previously adapted a mental health app for refugees described:

> *So, the ultimate goal for cultural adaptation is really to make sure that the core of the intervention can even take effect. And people do not drop out before they get to the point.* [ID13]

Two additional adaptation reasons that experts gave were (1) to understand whether a DHI is suitable for implementation across sociocultural settings and (2) to implement a DHI that is initially generic. For instance, a DHI that has been successfully adapted at least once indicates that it is transferable and potentially scalable across sociocultural contexts. Similarly, many DHIs were designed to be adapted (eg, some generic interventions developed by the World Health Organization [WHO]), which was the case for many of our experts. One mental health expert said:

> *The intervention in itself is set up to be adapted. So it is developed by the World Health Organization that is recommending that researchers and research groups pick this up and adapt it.* [ID8]

Implementing the Adaptation

Overview

Experts' views and experiences on the implementation of the cultural adaptation focused on (1) the adaptation team, (2) user involvement, and (3) expert and stakeholder involvement. The adaptation process of DHIs was described as dynamic, iterative, often unstructured, and trial-and-error-based.

The Adaptation Team

Overall, responses revealed two critical characteristics of a good cultural adaptation team. First, a multiprofessional background, which was described as a team with a diverse skill set and professional expertise, including experts in health and technology, such as hardware and software designers. An expert who adapted a mobile health intervention for refugees described:

> *So, you need lots of people with very different backgrounds, and you need them to work together efficiently [...] If you want to have a proper user experience, you need a designer. You need people who know something about user interfaces.* [ID13]

Second, cross-cultural competence, which includes language skills (written and verbal), is another factor in successful DHI adaptations. Experts described that this could be experts (eg, researchers, citizens, or community members) with the same cultural background (eg, lived experience) as the focal population. Cross-cultural competence was described as enhancing cultural credibility, which facilitates the reach and engagement of the target population in the adaptation process. Additional specific roles and expertise requirements were unclear, aside from providing cultural expertise and facilitating communication with the focal point population. Some experts highlighted that cultural adaptation teams often lack these characteristics due to a lack of time and resources.

XSL•FO
RenderX

User Involvement

Overall, experts viewed user involvement (of the focal cultural group) as the gold standard approach to culturally adapting DHIs. Good user involvement was described as (1) timely (from the start of the adaptation), (2) iterative and stepwise (allowing for multiple rounds of feedback), and (3) continuous (throughout the adaptation process). Yet it was also mentioned that there are no clear guidelines on how to involve users. An expert (ID12) who worked on the adaptation of the DHI for refugees mentioned:

> *The field is new ... there is no blueprint, so you have to make it participatively and try to see what really works within that culture in the sense of what is their understanding.* [ID12]

Responses highlighted several benefits of user involvement, including (1) a deeper understanding of technology use within a specific culture, (2) capturing lived experiences and comprehending the extent of necessary adaptation, (3) identifying and recognizing diversity within cultural groups (eg, subcultures) and adjusting accordingly, (4) increased chances that the adapted DHI aligns culturally with the target group, (5) a higher likelihood of ongoing use, and (6) fewer errors (eg, adapting something that requires no change). Avoiding mistakes was highlighted as particularly relevant to DHIs by one of our experts, who adapted an eHealth training for informal caregivers, primarily because changing software or hardware is associated with lower cost-effectiveness of the adaptation process. They mentioned:

> *Well, advantages, many in terms of that you probably will get a product that is going to be hopefully used [...] you will reduce or limit the amount of mistakes that you will have if you don't do it. And that is important for cost-effectiveness.* [ID10]

Another expert highlighted that recruiting must be culturally tailored and supported by relevant community groups and organizations to reach and engage users in the adaptation process.

Responses revealed three methods for user involvement, primarily through interviews and focus groups. The first approach was expert-centered, in which the adaptation team and consulted experts made all initial decisions on which DHI elements must be adapted and how (top-down approach). The second approach included simultaneous expert and user feedback, mainly in the form of interviews and focus groups (hybrid top-down and bottom-up approach). The third approach was user-centered, commonly agreed to be best practice, in which users were continuously involved in the adaptation process (through surveys, interviews, and focus groups), and expert opinions were mainly confirmatory (bottom-up approach). An expert who adapted a text-based app for Indigenous communities in New Zealand said:

> *Always start with the people. So, we generally always start with some formative research, focus groups, or other kind of qualitative research with that group you know, kind of representing the target population.* [ID6]

Overall, this approach was often described as the most resource-intensive.

One expert highlighted that even if the adaptation of the technology is behind (eg, the software has not been adapted yet), it is essential to ensure users are provided with regular input (mock-up versions, examples) to ensure that user feedback is as helpful as possible. Yet, experts highlighted that due to a lack of time and resources, in practice, user involvement often plays a more minor role than it should in cultural adaptations of DHIs. One expert in the cultural adaptation of DHIs in middle and low-income settings mentioned:

> *I didn't have a lot of money. So, it would be nice to include more participants [...]. So, like If I had more time, I definitely would have done a qualitative study to get feedback on the adapted version before conducting the pilot's study.* [ID3]

Overall, involving DHI users, the adaptation process was described as iterative.

Expert and Stakeholder Involvement

Our participants also addressed the integration of experts and other stakeholders (eg, health care professionals and software designers) into the adaptation process, in addition to user involvement. This was distinguished from having experts or stakeholders within the adaptation team, and it mostly referred to consulting additional ones throughout the adaptation process. An expert said:

> *So all the right stakeholders, the funders, the referrers, the service providers in that kind of area that you're in [...] just try and think of them all up front and then include them in your project, if you can.* [ID6]

Overall, responses highlighted that experts and stakeholders can provide critical knowledge (eg, technical), facilitate user involvement in the adaptation process (eg, doctors referring patients), and contribute to an adaptation's long-term success. One expert described the role of experts and stakeholders as supportive, by reducing the overall uncertainty around cultural adaptations.

Choosing the Adaptation Elements

When asked which elements of cultural DHI require adaptations, the most common responses were: (1) language, (2) lived experience, and (3) technology.

Language

First, experts explained that the language of a DHI, including its tone, narrative, and complexity, must be clear and relatable to the focal population. One expert in cultural adaptations for young carers described:

> *[...] just the language and not necessarily meaning translation. Just the whole tone of the language, the simplicity, clarity of the language.* [ID4]

Lived Experience

Second, they viewed that adapted DHI content must reflect the lived experience of the focal cultural group, which includes

XSL•FO
RenderX

their reality, past and current living conditions, values, beliefs, and preferences. An expert in caregiver DHIs described:

> *We then definitely wanted to collect a number of lived experiences that we could then use to create test case scenarios.* [ID4]

Technology

Third, experts noted that culturally sensitive changes in technology and its functions must take into account the focal group's digital literacy and skills, particularly if the group's cultural influences play a role. An expert on the adaptation of mobile mental health interventions for refugees said:

> *We made sure that it looks and works similar to what people are already using [...]. So people are already familiar with the interfaces and how it works to support those with low tech literacy.* [ID3]

That ensures that the adapted DHI is easy to adhere to. Experts also mentioned that it is essential to carefully consider the sociodemographic characteristics of the focal population, such as age and gender, as these often interact with one's cultural background, influencing how health technologies are perceived and used.

When asked how to choose what to adapt, responses varied and did not suggest any specific models or frameworks to help prioritize which DHI elements to adapt, except for those who conducted implementations of generic DHIs, where the developers of the initial intervention provided some adaptation guidance.

Understanding the Challenges

Responses identified five common DHI-relevant challenges, including (1) technology, (2) uncertainty, (3) user involvement, (4) communication, and (5) evaluation and sustainability.

Technology

DHIs were described as more complex to adapt than non-DHIs because changing hardware and software often requires more resources (expertise, time, and money), including higher up-front investments than usually expected or available. An expert described:

> *So a couple of months ago, we needed to update one of our digital tools. You swear we were trying to put somebody on the moon. We're changing something that's very basic. But it's going to be $6000. It is taking so much longer. It was just changing a few words.* [ID7]

Experts also described that if resources are limited, the cultural adaptation risks being insufficient or superficial, which was the case for many of the examples mentioned during the interviews. One expert said:

> *We were very limited in budget, so ideally, the adaptation would have been a lot more radical, and it would have had animations.* [ID4]

Also, two experts emphasized that current health technologies are based on, and therefore biased toward, Western cultures. Adapting these technologies without any influence of these biases and preconceptions was described as a complex yet crucial task.

Uncertainty

Uncertainty was implied in most interviews and primarily referred to missing knowledge of the required cultural adaptation. Experts often described not knowing the right balance between adapting a DHI, keeping costs contained, and ensuring that the adapted DHI is effective. An expert in text-based DHIs for Indigenous communities mentioned:

> *You can never fully account for everything that you need to in terms of cultural adaptation. So there are always things that you don't know.* [ID6]

Adapting too much was described as too costly, leading to DHIs that are too specific, and thus, exclude some people who might otherwise have benefited. Adapting too little was described as being insufficiently targeted, which may result in ineffective adaptations and wasted effort and resources. Many aspects outlined in the previous paragraphs (eg, ensuring that the adaptation team is multiprofessional and culturally competent, involving users, experts, and other stakeholders, and evaluating adapted DHIs) were mentioned as potentially reducing some of that uncertainty. Ultimately, one expert described that uncertainty is inherent and cannot be avoided entirely.

User Involvement

Overall, responses highlighted that user involvement in the adaptation process can be challenging, mainly when conducted digitally and remotely (often in DHIs). Experts mentioned that it is difficult to (1) reach people and get them engaged, (2) bring experts and users to collaborate, and (3) secure enough time and money for thorough user involvement. An expert in the adaptation of maternity mobile health apps in Brazil said:

> *I tried it, but there are categories of power, and I was less powerful. So, to get these people (experts) together and convince them that this was important was already very difficult. Imagine having the users involved.* [ID1]

As explained by the experts, these challenges, in addition to limited resources (money and time), often lead to cultural adaptations that have minimal to moderate (eg, small sample sizes and few feedback loops) user involvement, often after the adaptation team and experts have decided on what and how much needs to be adapted.

Communication

Experts emphasized that cultural adaptations, especially of DHIs, are a multidisciplinary effort and rely on feedback from various stakeholders across disciplines (eg, technology, medicine, and public health). According to their experience, communication was viewed as a common challenge. This primarily involved communication among IT experts, the rest of the adaptation team (eg, health researchers), and other stakeholders, including users. For example, one expert in informal caregiver DHIs mentioned that translating user and expert feedback in understandable ways for hardware and software designers was described as particularly challenging, saying:

XSL•FO
RenderX

> *So, I was in between the target population and the engineering developers of the platform. And it's very difficult to have a communication with both and try to put them together.* [ID10]

Maintaining transparency and including team members with interprofessional skills (eg, health and engineering knowledge) were mentioned as potential solutions to communication problems. Yet, some responses indicated that the lack of resources and time does not always allow for that.

Evaluation and Sustainability

Experts mentioned that robust evaluations (eg, randomized controlled trials) of how well culturally adapted DHIs perform are rare. Two common themes that arose were (1) the scarcity of additional resources to conduct evaluations and (2) the difficulty of engaging often hard-to-reach individuals in evaluations (eg, in longitudinal studies). Finally, culturally adapted DHIs were described as dynamic and may need to be regularly updated to remain relevant. Our participants described that as a challenge because (1) technology or software changes can be complex and costly, (2) lacking postadaptation funding, and (3) lacking evaluations that prove the initial cultural adaptation was effective. Overall, responses suggested evidence of the effectiveness of cultural adaptations of DHIs is currently lacking, which explains the lack of systematic guidance (eg, DHI-specific models or frameworks). An expert (ID6) in text-based DHIs described:

> *[...] they generally don't even put enough money into maintaining it because they just think once you've done a digital program, it's there. And so then they tend to put funding in for things like upgrades of digital systems.* [ID6]

Recommendations

Based on all our findings, we have compiled a list of recommendations for future cultural adaptations of DHIs. All stem from the experiences, mistakes, and lessons learned by the interviewed experts. We summarized all recommendations in Textbox 1.

Textbox 1. Recommendations for future cultural adaptations of digital health interventions (DHIs).

- Define the focal culture or cultural group clearly from the start
- Learn from the experience of those who have previously culturally adapted DHIs
- Involve users continuously, adapt only what is relevant to them, and consider their digital literacy
- Think about the DHI design and functionality from the start, and prioritize what users want
- Do not underestimate the money and time needed to adapt technology and expect setbacks
- Stay open-minded and free of assumptions (ie, do not assume what the focal population wants)

The first recommendation highlights the importance of a clear, appropriate definition, chosen well before an adaptation starts. An expert on mobile mental health intervention mentioned:

> *You really need to define culture as something trans-cultural, something diverse, and you have different categories that you have to keep in mind.* [ID11]

The second recommendation addresses current evidence gaps and urges future adaptations to learn from existing knowledge, either through reviews or by talking to people who have adapted DHIs. One expert in the cultural adaptation of DHIs in middle and low-income settings said:

> *There are some projects doing cultural adaptations of the digital interventions and like in a in a very systematic way. So, I think it's good to talk to them to get their experiences.* [ID3]

The third recommendation emphasizes the need to involve users throughout the adaptation and ensure that all changes to a DHI reflect their needs and preferences. While involving users in the adaptation process, it is important to understand and address their digital support needs. One expert highlighted: "But I mean, even involve them at the very, very earlier stage of the research. I think that would be the best thing." Related to that, thinking early about technological changes (eg, changing certain functionalities for better cultural fit) is the fourth recommendation. One mental health expert (ID8) said:

> *So thinking about the web build and the functionality from the outset rather than as a second thought. Because, yeah, it's kind of the cultural adaptation, the content, and like I said that it could work.* [ID8]

The fifth recommendation urges adaptors to consider the time and money that adaptations require before adapting. One expert (ID13) who has adapted a mobile mental health app for refugees mentioned:

> *And then, another thing is, it is really important not to underestimate the money and time it takes to create software.* [ID13]

The final recommendation refers to adapting without assuming what the focal population wants, but listening carefully and only acting on that. An expert who has adapted an eHealth training for minority young carers described:

> *I just think it's getting rid of your preconceptions and your assumptions about the cultural group that you are targeting.* [ID4]

Discussion

Principal Results

Cultural adaptations are emerging and have the potential to improve DHI access for medically underserved population groups [25]. This work represents one of the first attempts to learn from the experiences of academic experts who have

XSL•FO
RenderX

previously culturally adapted DHIs. Our findings outline current practice and underline existing gaps. Overall, the current practice emphasizes culturally competent and multiprofessional adaptation teams that involve IT experts (eg, hardware and software designers), and user, expert, and other stakeholder involvement in the adaptation process. There is also an emphasis on three core adaptation elements, highlighting that a culturally adapted DHI must be understandable (eg, using appropriate language, tone, and narrative), relatable (eg, reflecting lived experience and sociodemographics), and appealing and easy to adhere to (eg, functions, design, and layout that consider digital literacy and preferences). However, many challenges remain, and although the field is emerging, responses have not revealed any systematic ways for the cultural adaptations of DHIs.

Comparison With Prior Work

Our findings are partially aligned with general adaptation frameworks, such as FRAME (framework for reporting adaptations and modifications to evidence-based interventions) [26]. Our findings, and FRAME, highlight the importance of justifying adaptations, clearly outlining adaptation elements, involving a broad range of stakeholders (from experts to community members), and conducting evaluations [26]. Our findings also align with the 17 cultural adaptation considerations provided by the systematic review of Spanhel et al [27] for internet- and mobile-based mental health interventions [26]. In particular, they confirm the importance of adapting in ways that reflect the lived experience of the target population. That includes, as also identified by Spanhel et al [27], habits, gender norms, religious beliefs, values and traditions, stressors, and socioeconomic factors (eg, education and political context) [27]. Spanhel et al [27] also underlined the importance of language tailoring and visualization, ensuring that text is simple, culture-specific, and accompanied by visual cues [27]. This aligns well with our findings, highlighting that adaptation goes well beyond simple translations. Experts described that language, including its tone, needs to be understandable, providing a relatable and culturally familiar narrative. Our work contributes beyond that and provides insights into implementers' challenges when adapting digital interventions. Securing enough resources to conduct thorough hardware and software adjustments, reaching and engaging users of the focal cultural group (digitally or remotely) throughout the adaptation process, and ensuring good communication between ICT and non-ICT members of the adaptation team were some of the technology-specific challenges that experts described.

Uncertainty was emphasized as one of the most prominent and cross-cutting adaptation challenges. That means adaptations often start with little knowledge of how much to adapt to ensure DHI effectiveness without wasting time and resources. Uncertainty is not exclusive to DHIs but to cultural adaptations in general [28]. Several well-described challenges might lead to uncertainty. Castro et al [16] describe some of these and include (1) defining culture, (2) segmenting and understanding the population for which the adaptation is conducted, and (3) understanding heterogeneity and subcultures within that population. Although experts provided recommendations to mitigate uncertainty when adapting DHIs (eg, continuously involving the user and expert feedback), the lack of evidence, guidance, frameworks, and systematic practice makes uncertainty inherent. That uncertainty was repeatedly voiced during the interviews and is reflected in our findings overall.

When asked how to choose or prioritize what to adapt, responses varied and did not provide any systematic approach. User-centeredness, although not always possible if resources are lacking or the target population is hard to reach, was highlighted as the best approach for identifying (or prioritizing) which DHI elements are culturally relevant and worth adapting. This aligns with previous work highlighting the value of user-centered adaptations, particularly when adapting DHIs [29]. The acceptance and use of health technologies depend on many factors, such as self-efficacy, prevailing norms and values, and trust [30]. These factors are often related to culture, and therefore, highly relevant to the adaptation process. Without direct feedback from prospective users and members of the focal cultural group, these factors cannot be fully captured. Based on the experience of these experts, engaging users should start early in the adaptation process, be iterative, allow for flexibility, be continuous yet stepwise, and allow for feedback loops. However, there is still little systematic guidance on how to involve DHI users in the cultural adaptation process, especially if conducted digitally or remotely.

Implications, Current Practice, and Existing Gaps

Our findings highlight the importance of cultural adaptations for reaching and engaging systematically underserved communities. Despite overall agreement on their value, current practice often lags, and the needed support to advance the field has not been prioritized yet. First, there seems to be a lack of dedication to resources to complete well-designed and thorough adaptations, which leads to adapted DHIs that are only partially adapted and not adequately evaluated. This is aligned with the findings of a recent literature review by Naderbagi et al [31], which highlights the lack of rigorous DHI adaptations, arguing that budgets and timelines should facilitate instead of limiting the adaptation process.

Second, the lack of thorough evaluations likely has a negative impact on the field as it limits available evidence on which future DHI adaptations could be built. Existing frameworks, such as the Ecological Validity Framework, the Cultural Accommodation Model, and the circular model of cultural tailoring, offer valuable higher-level guidance on cultural adaptations, yet do not sufficiently cover aspects specific to DHIs, such as technological and digital literacy barriers [32,33]. Recent work, such as the systematic review on the cultural adaptation of internet- and mobile-based interventions for mental disorders by Spanhel et al [27] and the related editorial by Marwaha and Kvedar [25], provides valuable steps toward filling that gap. However, a comprehensive framework focusing on the cultural adaptation of DHIs is still lacking. That feeds an uncertainty on what to prioritize to maintain a balance between available resources and addressing the population's needs, the adaptations are aimed at. Our findings contribute to closing the practice gaps by (1) highlighting actual practice gaps and DHI-specific challenges, (2) providing examples of commonly agreed-upon good practices, (3) identifying core adaptation

XSL•FO
RenderX

elements, and (4) highlighting the need for DHI-specific cultural adaptation frameworks.

Toward DHI-Specific Cultural Adaptation Frameworks

Our methodological approach does not allow for the development of a DHI-specific cultural adaptation framework because it is a single qualitative study with a limited range of participant perspectives. Developing a robust and transferable framework typically requires insights from multiple studies and across a diverse range of participants, as well as data triangulation [34]. However, our findings contribute toward a future DHI-specific cultural adaptation framework. First, our findings highlight the importance of defining culture and justifying the adaptation early on. A future framework should provide stepwise guidance on how to identify relevant cultural elements in ways that align with a specific DHI and the targeted cultural group, as well as tools to identify cultural nuances beyond ethnicity and place of origin. It should also, as our findings highlight, provide criteria for assessing the need to adapt.

Second, our findings indicate the importance of diverse adaptation teams, as well as user and stakeholder engagement. This is aligned with prior work for nondigital interventions that emphasize the role of community and stakeholder involvement in sustainable and efficient adaptations [35]. A DHI-specific framework should (1) guide the creation of adaptation teams with adequate digital expertise, and (2) provide digital approaches to reach and engage users and other stakeholders. This would complement existing work, which highlights the importance of involving the target group in the adaptation process but offers little guidance on digital ways to do so [27].

Third, our findings present essential elements of adaptation but emphasize that these decisions are context-specific. A future framework should offer support for decision-making related to prioritizing which elements need adaptation, including both technical and user-centered aspects. Finally, we identified the core DHI-specific challenges. Based on these, a framework should guide overcoming technological limitations and offer strategies for effective communication, resource allocation, and evaluations.

Limitations

This study has some limitations. First, because this is an emerging field, we only interviewed academic experts since they were easy to identify (through publications). Thus, our findings might not be fully transferable to cultural adaptations of DHIs in nonacademic settings. The wealth of knowledge outside of academia (eg, private sector) would add to the understanding of cultural adaptations and should be prioritized in future research. Yet, we kept our questions general and not specific to academic settings, and most of the findings are likely applicable to cultural adaptations of technology in general. Second, we used snowball sampling as a complementary recruitment method. While snowball sampling is a widely used and practical recruitment method in qualitative research, it can lead to selection bias (eg, too homogeneous sample), primarily because participants often share common professional networks, which may hinder thematic saturation. Third, culture is a multifaceted concept. This study approached culture in the context of health and technology, which is only one of many approaches to explain and understand it. Fourth, our interviewees were predominantly health and digital health experts. Including experts with a pure technology or ICT background would have likely added a valuable perspective that might be currently missing.

Conclusions

Our work is one of the first to explore the cultural adaptation of DHIs through an academic lens. The adaptation process was described as an iterative, often unstructured, and resource-intensive process that needs careful justification and a good understanding of culture and the cultural group for which it is conducted. Based on their experiences, experts recommended that (1) the adaptation team is multiprofessional, digitally competent, and culturally sensitive (2) DHI users and (3) all other relevant stakeholders are continuously involved, and (4) that the adaptations integrate evaluations and knowledge exchange. They further emphasized that culturally adapted DHIs must be understandable, relatable, appealing, and easy to adhere to, ensuring that health technology and content reflect the target population's lived experience, sociodemographic characteristics, and digital literacy. Yet, beyond those broader recommendations, our interviews confirmed the lack of systematic, detailed approaches to culturally adapting DHIs, including how to assess whether an adaptation is needed, how to structure the adaptation process, how to choose and prioritize adaptation elements, as well as how much to adapt to ensure that adaptations are cost-effective. That uncertainty and the added complexity that technology adds to cultural adaptations were described as critical challenges. To identify general recommendations for guiding cultural adaptations of DHIs, future research should focus on thoroughly evaluating adapted DHIs and exploring systematic ways to mitigate core challenges.

Acknowledgments

VN's work was funded by the Swiss National Science Foundation (grant 202914). SJC's contribution to the manuscript was supported by NIAAA T32 AA07459. Abstract

Background: Mobile health (mHealth) interventions are increasingly used to reduce risk and promote health in real-time, real-life contexts. Engagement is critical for effectiveness of mHealth interventions but may be challenging for young people experiencing depressive symptoms.

Objective: We examined engagement with the 4-week mHealth component of a counseling-plus-mHealth intervention to reduce sexual and reproductive health (SRH) risk among young people with depression (Momentary Affect Regulation – Safer Sex Intervention [MARSSI]) to determine (1) mHealth engagement patterns over time and (2) how sociodemographic characteristics, SRH risks, and depressive symptom severity were associated with these engagement patterns.

Methods: We undertook secondary analysis of data collected from June 2021 to September 2023 in a randomized controlled trial of MARSSI versus a breast health podcast. Eligibility included age 16 - 21 years, ability to become pregnant, smartphone ownership, English fluency, past-3-month penile-vaginal sex ≥1x/week and ≥1 SRH risk, and Patient Health Questionnaire-8 item score ≥8. Intervention participants received one-on-one telehealth counseling and then used an app for 4 weeks, responding to surveys (3 prompted at quasi-random, 1 scheduled daily) about affect, effective contraception and condom use self-efficacy, sexual and pregnancy desire, and recent sex, and receiving tailored messages reinforcing the counseling. We computed mHealth engagement days (responding to ≥1 app survey) by week and overall. Latent trajectory analysis identified engagement patterns over the 4 mHealth weeks among participants with any engagement. Using regression analysis, we examined the associations of sociodemographic characteristics, SRH risks, and depressive symptom severity with mHealth engagement patterns and examined moderation by depressive symptom severity. Of the 201 intervention participants, 194 (96.5%) enrolled in the app.

Results: Among those responding to app surveys (167/194, 86.1%), the median engagement was 14 (IQR 4-23) days; 32.9% (55/167) responded on ≥20 days. Overall app engagement (median) declined from 5 (IQR 3-7) days in week 1 to 1 (IQR 0 - 5) day in week 4. On latent trajectory analysis, 4 patterns of app engagement emerged: high-throughout (48/167, 28.7%), high-then-declining (40/167, 23.9%), mid-then-declining (47/167, 28.1%), and low-throughout (33/167, 19.7%). Participants identifying gender other than female and those perceiving higher socioeconomic status were more likely to have high-throughout or high-then-declining engagement. Asian or Black non-Hispanic participants and those using low-effectiveness contraception were more likely to have no engagement. In the multivariable model, Asian (adjusted odds ratio [AOR] 0.28, 95% CI 0.10-0.81), Black non-Hispanic (AOR 0.28, 95% CI 0.12-0.66), and higher perceived socioeconomic status (AOR 1.24, 95% CI 1.05-1.48) remained significantly associated with engagement. Engagement patterns showed no differences by depressive symptom severity and no significant moderation.

Conclusions: Young people with depressive symptoms showed initial high engagement with the intervention's mHealth app to reduce adverse SRH outcomes. Methods to increase and sustain mHealth engagement and differences in engagement by sociodemographic characteristics warrant further studies to optimize the reach of mHealth interventions.

Introduction

Adolescents and young adults have high rates of unintended pregnancy and sexually transmitted infections (STIs) compared to other age groups [1,2]. Adolescents and young adults who have depressive symptoms are at particularly high risk of these adverse sexual and reproductive health (SRH) outcomes. Although depressed young women may have difficulty forming and sustaining intimate relationships and experience less interest in sexual intercourse, they may have sexual intercourse to manage their depressive symptoms, often under the influence of substances [3] and without condoms or hormonal contraception [4]. These functional encounters may lead to lower self-esteem and bad mood [4]. As a result, depressive symptoms and SRH risk may be self-reinforcing and difficult to change.

The observed associations are consistent with a functional model of sexual behavior, in which motives for sexual behavior can be understood according to motivational (approach and avoidance) and social (intrapersonal and interpersonal) dimensions [5]. Efforts to regulate affect in depression through sexual behavior may aim to enhance positive affect, reduce or cope with negative affect, or both. Individuals with depressive symptoms may also seek validation and affirmation through social interactions. Thus, sexual behavior in depression must be understood in the contexts of both individual affect regulation motives and interpersonal relationships and that these contexts and related experiences influence future motives [6].

The bidirectional, longitudinal relationship of depressive symptoms with sexual behavior and SRH risk is dynamic and can unfold on a moment-to-moment basis. For example, among adolescents and young adults who are depressed, momentary positive affect is associated with having sex [7] and momentary negative affect is associated with having sex with a non–main partner [8]. Furthermore, for adolescents and young adults with depressive symptoms, sexual intercourse events may occur on impulse, without planning [4], and greater impulsiveness is associated with incorrect condom use, if a condom is used [9]. Interrupting the cycle of poor mental health and SRH risk behavior as it develops moment-by-moment in the natural environment may reduce unplanned pregnancy and STIs for these at-risk youth.

Mobile health (mHealth) interventions are well-suited to address the interplay between poor mental health and SRH risk behaviors. Although the definition is subject to some debate [10], in general, mHealth interventions use mobile devices, including phones, tablets, wearable sensors, communication technologies, and other wireless devices, to improve health. As described in several reviews and meta-analyses, mHealth interventions have been applied to the treatment of psychiatric disorders (eg, as a way to strengthen the effects of counseling [11]), contraceptive use [12,13], STI prevention [14], and other SRH outcomes [15]. One form of an mHealth intervention, ecological momentary intervention (EMI) [16], delivers treatment in real-time, real-life contexts, which can be especially helpful for addressing momentary dynamics such as those observed between affective states, substance use, impulsiveness, and SRH risk [4,8,9,17].

To receive mHealth interventions, participants must engage with the mobile device platform, which requires carrying their device, having it powered and on, and with active interventions in which participants provide survey data, responding to queries or initiating reporting. Thus, if participants do not engage with and therefore receive an intervention, the intervention's effect cannot be assessed [18]. Furthermore, there is a presumption of a dose-response or threshold relationship, such that higher engagement is associated with improved outcomes [19] or that sufficient engagement is required to achieve the intended outcomes (ie, effective engagement) [20].

For individuals with depression, intervention engagement may be difficult to sustain owing to symptoms such as low motivation, poor organization, low energy, behavioral avoidance, negative cognition, difficulty concentrating, and impaired information processing [21-23]. Individuals with psychiatric disorders (eg, schizophrenia) [24] have demonstrated engagement with mHealth interventions focused on mental health [25-27]. However, engagement rates are highly variable and may decline over time for mHealth interventions delivered for weeks to months [24,25,28]. Additionally, individual demographic characteristics and illness severity may be associated with varying levels of engagement with an mHealth intervention [24,27]. Limited information is known about depressed persons' engagement with mHealth interventions for SRH risk [28]. To fully evaluate an mHealth intervention for adolescents and young adults with the dual challenges of depressive symptoms and SRH risk [28], we must understand engagement with the intervention and the differences in engagement by the level of depressive symptoms and other characteristics of participants from this unique population.

We developed the Momentary Affect Regulation – Safer Sex Intervention (MARSSI) to reduce the risk for unplanned pregnancy and STIs in at-risk adolescents and young adults with depressive symptoms. MARSSI is comprised of a one-on-one main counseling session, 4 weeks of EMI, and a one-on-one booster counseling session at the end of EMI. The counseling uses motivational interviewing to support behavior change and teaches skills from cognitive behavioral therapy for depression. EMI extends the effects of counseling by assessing in-the-moment SRH risk, and if risk is reported, providing personalized, tailored messages to prompt healthy behaviors and encourage cognitive behavioral skill use. We sought to determine (1) patterns of engagement with the 4-week mHealth component of MARSSI and (2) the level of depressive symptoms, SRH risks, and sociodemographic characteristics associated with the engagement patterns.

Methods

Ethical Considerations

The parent study (Catherine Henley, PhD, MPH, et al. unpublished data, October. 2024) received institutional review board approval from Sterling institutional review board (approval 8687). All participants provided informed consent.

XSL•FO
RenderX

The original institutional review board approval covered secondary analysis without additional consent.

Participants and Setting

We undertook a secondary analysis of anonymized data collected from June 2021 to September 2023 in a randomized controlled trial of MARSSI versus a breast health podcast (ClinicalTrials.gov NCT04798248). Participants were aged 16 - 21 years; biologically able to become pregnant; patients of an SRH care provider, with a visit in the past 2 years; a smartphone owner; fluent in English; not pregnant, desiring pregnancy, or within 6 months post partum; not married or engaged to be married; reporting penile-vaginal sex at least once a week, on average; endorsing at least one SRH risk in the past 3 months; and reporting elevated depressive symptoms as measured by Patient Health Questionnaire (PHQ)-8 score ≥8 [29]. SRH risks in the past 3 months included more than one sexual partner, inconsistent or no condom use, no contraception or low-effectiveness method (ie, condoms, diaphragm, withdrawal, rhythm) as primary form of contraception, penile-anal sex, sex under the influence of alcohol or other drugs, and treatment of an STI. Participants were remunerated up to US $230 in electronic gift cards for completed study activities.

To recruit participants, we partnered with 9 Planned Parenthood affiliates serving 14 US states: Planned Parenthood Great Northwest, Hawai'i, Alaska, Indiana, Kentucky (includes Washington and Idaho); Planned Parenthood of Wisconsin; Planned Parenthood Southeastern Pennsylvania; Planned Parenthood Gulf Coast (Texas and Louisiana); Planned Parenthood of the St. Louis Region and Southwest Missouri; Planned Parenthood Southwest Ohio Region; Planned Parenthood of Illinois; Planned Parenthood Mar Monte (California); and Planned Parenthood of the Pacific Southwest (California). Active recruitment methods at the Planned Parenthood affiliates included study staff sending SMS text messages and patient portal messages directly to patients through the electronic medical record system and affiliate staff mentioning the study to the patients at their appointments. Passive recruitment methods included hanging posters and distributing flyers, as well as posting information on the affiliate website and study-specific or study-affiliated social media accounts on Google, Instagram, and Facebook. Recruitment materials contained a QR code and link to a web-based self-screener for eligibility. In the trial, 405 individuals were enrolled and randomly assigned 1:1 to MARSSI (n=201) versus the podcast (n=204). The randomization scheme used blocking by study coordinator or intervention counselor and by state to account for the potential differences in the availability, quality, and access to reproductive health care services across states. The study coordinator or intervention counselor staff (n=6) could enroll and, per assigned study condition, deliver the intervention counseling to eligible individuals from any US state. Data from participants assigned to the intervention were included in the analyses reported herein.

Intervention

Participants assigned to MARSSI met with a study coordinator or an intervention counselor (master's level) for a one-on-one telehealth counseling session in which they chose the SRH risk behavior that they wished to change, developed a change plan, and discussed other SRH risks in brief [28]. Subsequently, for the mHealth component, participants used a smartphone app (MetricWire) for 4 weeks to respond to surveys (3 prompted at quasi-random times, 1 scheduled each day) about their affective states, effective contraception self-efficacy, condom use self-efficacy, desire to have sex, desire to be pregnant, and recent sexual intercourse, and then receive messages based on their responses. After the initial development, the intervention materials were revised to enhance gender inclusivity by limiting the use of gendered pronouns and including the counselor and the participant sharing their preferences for name and pronouns at the outset of the main counseling session.

Measures

We defined mHealth app engagement as responding to at least 1 survey (momentary or daily) in a day. Because MARSSI emphasizes autonomy over health behavior decisions, we did not expect or require responding to every app survey prompt. Thus, we did not consider response rate as an accurate indicator of app engagement [24,28]. The eligibility survey included PHQ-8, a self-reported measure of depressive symptoms comprising 8 of the 9 Likert-type items (each scored 0 - 3) in the well-validated PHQ-9 [30]. The PHQ-8 excludes the question on thoughts of suicide and therefore is recommended in research studies in which further evaluation (ie, with a clinical interview) may not be possible. The score range for PHQ-8 is 0 - 24, and the cutoffs for diagnosis of a depressive disorder and the level of symptom severity are the same as those used for PHQ-9 [30]. Consistent with scoring interpretation guidelines [29], we categorized PHQ-8 scores as mild (8-9), moderate (10-14), and moderately severe or severe (15-24) [15-23,31]. Each SRH risk was assessed on the eligibility survey with a single yes-no item. The baseline survey included age (years), race, ethnicity (select all that apply: American Indian or Alaska Native, Asian, Black or African American, Hispanic or Latino/a, Native Hawaiian or other Pacific Islander, White, some other race or ethnicity), gender identity (female, male, transgender female, transgender male, nonbinary or genderqueer, unsure or questioning, I do not identify as any of these), mother's highest education (did not finish high school, received a high school diploma or general equivalency diploma, completed some college, finished college, finished graduate school, law school, or medical school, don't know), and self-perceived socioeconomic status (SES) relative to other people in the United States from 10 (most well off) to 1 (least well off) [32].

Statistical Analyses

All analyses were performed in SAS (version 9.4; SAS Institute) using an α level of .05. We report mean (SD) or median (IQR) for continuous variables and frequency (%) for categorical variables. We examined engagement rates by week and overall. We used group-based latent trajectory modeling to cluster participants by their level of engagement with the mHealth app over 4 weeks [33]. These models were implemented using Proc Traj (SAS Institute) among the participants who ever engaged with the app to identify and group participants into distinct patterns of engagement over the study period. The best-fitting

XSL•FO
RenderX

model with respect to the number of engagement groups and polynomial order was selected using the model with the lowest Akaike Information Criterion. Participants who never engaged with the app during the study period formed a "no engagement" category. The identified engagement trajectory patterns comprised a trajectory group variable with categories that were ordered by the initial level of engagement.

We conducted bivariate analyses to examine the associations of sociodemographic characteristics, SRH risks, and severity of depressive symptoms with the identified patterns of mHealth app engagement by using one-way analysis of variance for continuous variables and chi-square tests for categorical variables. We then used multivariable ordinal logistic regression to examine the associations in an adjusted model and to compute the adjusted odds ratios (AORs) and 95% CIs for all predictor variables (AOR>1 indicates greater odds of being in a higher engagement trajectory, AOR<1 indicates lower odds of being in a higher engagement trajectory and thus greater odds of a lower engagement trajectory). In addition, we explored the potential for the effect modification of depressive symptom severity with sociodemographic characteristics and SRH risks by testing the interaction terms in a multivariable regression model.

Results

Baseline Characteristics of the Participants

Of the 201 intervention participants, 194 (96.5%) enrolled in the app and were included in the analyses herein. Participant characteristics at baseline are shown in Table 1.

[b]Used condoms, diaphragm, cervical cap, spermicide, sponge, fertility awareness, or withdrawal as the primary form of contraception.

[c]STI: sexually transmitted infection.

[d]PHQ-8: Patient Health Questionnaire-8 items.

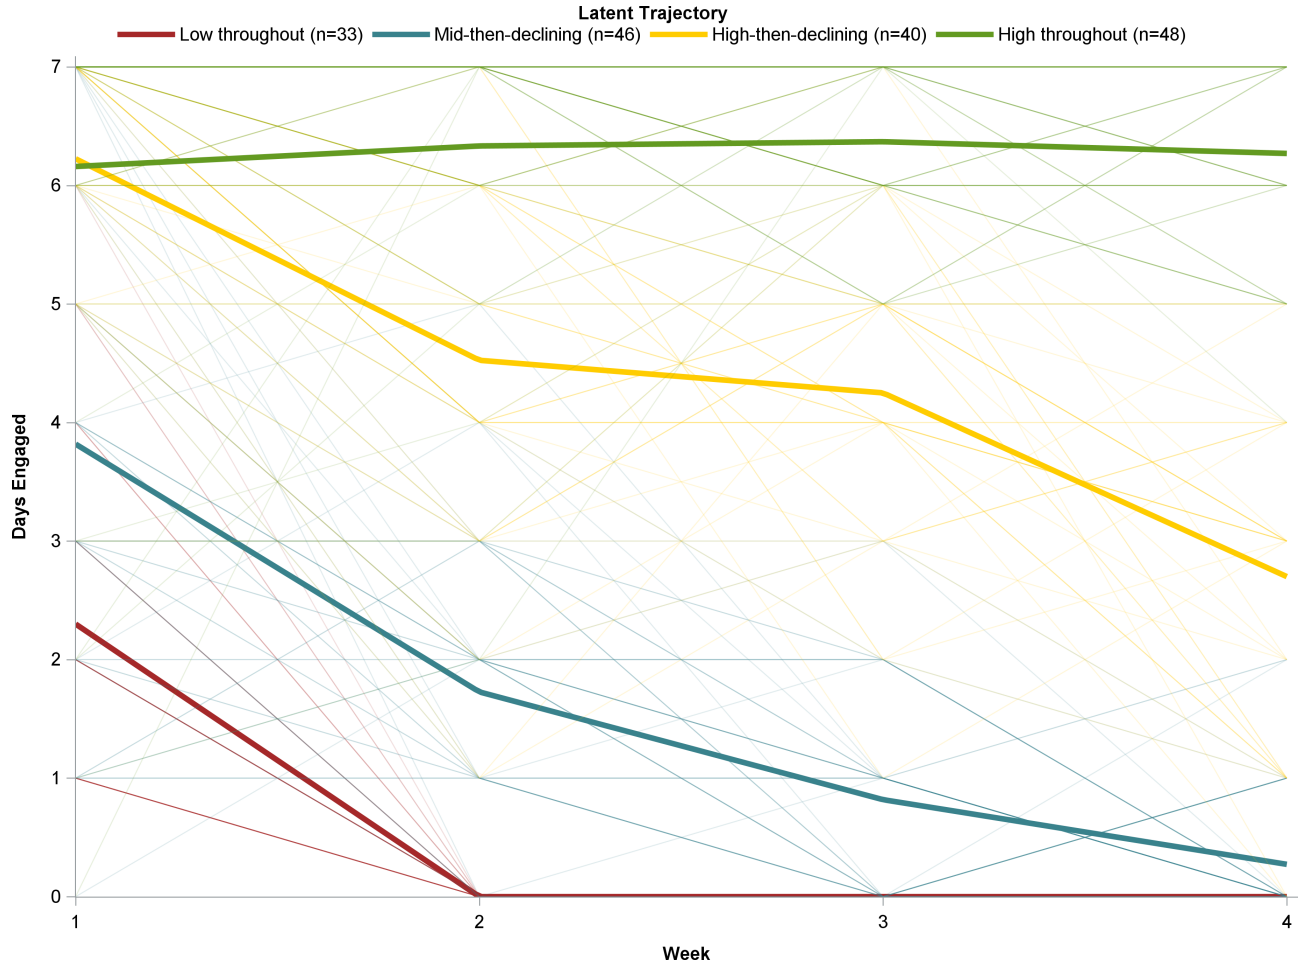
App Engagement

Of the 194 participants, 167 (86.1%) responded to at least one app survey (ie, had at least one day of engagement with the app) and 27 (13.9%) did not respond to any survey during the 4-week study period (no engagement). Among participants who ever engaged with the app, median engagement was 14 (IQR 4 - 23) days out of 28 days; 32.9% (55/167) responded on ≥20 days. The overall median engagement among app users declined from 5 days in week 1 to one day in week 4.

The latent trajectory analysis of the app users revealed 4 patterns of any engagement across the 4 weeks: high-throughout (55/167, 32.9% of participants with any engagement), high-then-declining (40/167, 23.9%), mid-then-declining (47/167, 28.1%), and low-throughout (33/167, 19.7%) (Figure 1). Participants in the high-throughout trajectory tended to use the app on 6 or 7 days every week for all 4 weeks. The high-then-declining group also used the app nearly every day in week 1 but declined in use each week thereafter to around 3 days in week 4. Participants in the mid-then-declining group began use on about half the days in week 1 and then declined over the weeks to use on 0 or 1 day in week 4. In the low-throughout group, participants engaged with the app only in week 1 and then discontinued use.

XSL•FO
RenderX

Figure 1. Latent trajectories for days of app engagement across 4 weeks among participants who had any app use in the Momentary Affect Regulation – Safer Sex Intervention.



Associations of Sociodemographic Characteristics, Sexual Risk, and Depressive Symptom Severity With App Engagement

In the bivariate analysis (Table 1), there were statistically significant differences in the level of engagement by gender identity (*P*=.04), race and ethnicity (*P*=.006), and report of low-effectiveness contraception as the primary method in last 3 months (*P*=.009). Participants identifying gender other than female were more likely to have high-throughout engagement. Those in the high-then-declining engagement group tended to perceive a higher SES score than other groups. Asian and Black or African American, non-Hispanic participants, and those using low-effectiveness contraception were more likely to have no engagement. There were no differences in the engagement patterns by depressive symptom severity.

In the multivariable model (Figure 2), race and ethnicity remained significantly associated with lower engagement with participants identifying as Asian (AOR=0.28; 95% CI: 0.10, 0.81) or Black or African American, non-Hispanic (AOR=0.28; 95% CI: 0.12, 0.66) less likely to have higher engagement compared to those identifying as White, non-Hispanic. Higher perceived SES was associated with higher engagement (AOR 1.24, 95% CI 1.05-1.48). Gender identity and use of low-effectiveness contraception were no longer statistically significant after adjustment for other covariates (gender identity: AOR 1.70, 95% CI 0.77-3.76; low-effectiveness contraception: AOR 0.98, 95% CI 0.58-1.65). The severity of the depressive symptoms was not associated with the engagement pattern and did not moderate associations between the sociodemographic characteristics and the level of engagement.

Discussion

Main Findings

This study investigates the patterns of mHealth engagement among adolescents and young adults with depressive symptoms assigned to a counseling-plus-mHealth intervention to reduce their risk for unintended pregnancy and STIs. Despite all adolescents and young adults in the study having at least mild depressive symptoms, most participants engaged with the 4-week mHealth component at least once, one-half of the participants engaged on at least 50% of the days, and one-third of the participants engaged on more than 70% of the days. Importantly, for MARSSI, the severity of the depressive symptoms did not appear to influence engagement. Women with depression may benefit from risk reduction interventions to a degree similar to women without depression [34,35]. Additionally, interventions may be more effective in reducing the risk for young women with depression if they address factors related to emotional distress [36-38]. The results of our study add evidence that mHealth interventions to reduce SRH risk that include strategies to manage psychiatric symptoms engage participants, and thus, the effectiveness of these types of interventions can be evaluated across the full range of depressive symptoms.

Across all participants with any mHealth engagement, engagement declined substantially over 4 weeks, as seen with engagement in other longitudinal studies of mHealth interventions [24,39]. However, using latent trajectory analysis, we identified 4 distinct patterns of engagement among those with any use of the mHealth app, demonstrating variability in use over time that was not evident in the overall analysis. More than one-fourth of the participants with any app engagement sustained their engagement for all 4 weeks, and another nearly one-fourth had high initial engagement that declined but remained moderate (on about half of days) through week 4 of EMI; in total, these participants represented nearly one-half of all the participants who enrolled in the app, including those who did not engage at all. Thus, overall declining engagement with an mHealth app may still be associated with continued intervention exposure for a substantial proportion of participants. Furthermore, declining engagement may be a desirable or an undesirable effect in a multiweek mHealth intervention [40]. For example, participants may have decreased app use as a result of habituation or accumulated burden—an undesirable effect of repeated app use. However, declining engagement may have been a function of perceived or actual intervention effect, a desirable consequence of app exposure; in other words, if a participant experiences improvement, that person may determine that the app is not needed as much or at all and elect to engage with it less or discontinue use altogether. Future research will need to determine the thresholds for intervention effectiveness and the reasons for app disengagement. mHealth studies should take an expansive approach to evaluating app engagement, including both querying participants regarding their reasons for

XSL•FO
RenderX

app use or nonuse and examining participant characteristics for associations with engagement.

In this study, we found differences in engagement over time by sociodemographic characteristics. First, participants identifying as Asian or as Black or African American, non-Hispanic, compared to those identifying as non-Hispanic White tended to have lower engagement trajectories. Other studies of mHealth interventions for behavior change [41] and in individuals with psychiatric disorders have found lower app engagement among participants from minoritized racial and ethnic groups, compared to White participants [24,27,42]. Smartphone usage patterns and dependency for online access differ among racial and ethnic groups [43,44]. For example, compared to White teens, Black teens report higher rates of using most common social media platforms and of being on social media almost constantly [43], and Black and Asian adults report higher rates of smartphone dependency compared to White adults [44]. Participants who identified as Asian or as Black may have been lesser engaged with the study app than White participants because they were more likely to have been using their smartphones for other purposes such as accessing social media sites. However, individuals from minoritized racial and ethnic groups have also demonstrated lower engagement with in-person interventions [24,42], suggesting that there may be alternative or additional explanations for the observed differences in engagement, such as race as proxy for social determinants of health or racism [45].

Second, we found that intervention participants with higher perceived SES tended to have higher engagement trajectories. Financial resources may also influence engagement with mHealth interventions. Although nearly all adolescents and young adults in the United States have access to or own a smartphone [46], there may be differences in smartphone usage related to SES. Adults with lower household incomes and those with lower levels of formal education are more likely than their peers to be dependent on a smartphone for online access [44] and thus may have less time free from other smartphone activities to attend to the intervention app. As with the associations of engagement with race and ethnicity, other factors may explain the positive correlation between engagement and SES, such as social context, time use, or mobile phone data plan. It will be important to understand and mitigate disparities in app engagement by sociodemographic characteristics to fully evaluate the effectiveness of mHealth interventions across racial, ethnic, and economic groups.

Limitations

Our findings contribute to the limited literature on mHealth interventions for adolescents and young adults with SRH risk that address emotional distress or depressive symptoms [47], with some caveats. In recruiting participants from across the United States and using both active and passive recruitment methods, this study yields a sample diverse in gender, race, ethnicity, and perceived SES. This diversity permitted analyses into differences in mHealth engagement for groups at particularly high risk, yet underrepresented in mHealth research [48]. However, because there were several distinct engagement patterns, a larger sample was needed to find small differences in engagement by sociodemographic factors that may be important for assessing and improving intervention effectiveness (eg, characteristics of participants who sustained high engagement vs those whose engagement was initially high but then declined). Additionally, engagement was specific to the MARSSI mHealth component, and the patterns and associations may not be generalizable to other interventions. Although MARSSI development employed a human-centered design [28,49], further tailoring of the intervention to address the unique needs of adolescent and young adult participants from minoritized and underresourced groups, rooted in their individual and cultural contexts, may increase their mHealth engagement [50].

Conclusions

In a counseling-plus-mHealth intervention to reduce SRH risk, young people with depressive symptoms demonstrated varied patterns of engagement over 4 weeks of mobile app use. It will be important to establish what level of engagement with the intervention is required to achieve positive outcomes (ie, constitutes effective engagement) [20]. Patterns of mHealth engagement did not differ by level of depressive symptoms, suggesting that mHealth interventions for SRH risk may be applied in those with and without depressive symptoms. mHealth engagement patterns did differ by racial group and perceived SES. Future research is needed to understand and address disparities in engagement with mHealth interventions as a necessary step toward improving evaluations of effectiveness and expanding reach for this rapidly growing method of intervention delivery [20].

Acknowledgments

This research was supported by grant 5TP2AH000076 (author LAS, Principal Investigator) from the Department of Health and Human Services Office of Population Affairs as part of the Teen Pregnancy Prevention Program. Contents are solely the responsibility of Boston Children's Hospital and do not necessarily represent the official views of the Department of Health and Human Services or the Office of Population Affairs. The Policy and Research Group, which conducted the independent evaluation of the intervention, provided the data analyzed herein.

Abstract

Background: Health apps are increasingly being used to promote health, manage diseases, and deliver health care services. Still, there is scarce objective information regarding their quality beyond the required Conformité Européenne mark for medical apps, leading to potential risks for users. To address these challenges, several authorities have developed health app assessment frameworks. In 2017, the TIC Salut Social Foundation (FTSS) in Catalonia developed its own health app assessment framework, which has been in use since that year. The publication of CEN ISO/TS 82304‐2 (abbreviated as 82304‐2)—a Technical Specification for assessing health apps—and the cocreation of the Label2Enable 82304‐2 handbook for certified assessment organizations provide a unique opportunity to harmonize app assessments across the European Union.

Objective: This study aimed to perform a comparative analysis of the FTSS assessment framework with 82304‐2 to explore the integration of 82304‐2 in Catalonia. Our broader aim was to provide this methodology for health authorities elsewhere to consider integrating 82304‐2 or other evaluation frameworks.

Methods: For the comparative analysis, a mixed methods approach was used, combining a qualitative case study with a quantitative analysis of the 2 frameworks. The qualitative evaluation covered rationale for assessment, framework characteristics, governance, workflows, quality aspects, and quality requirements. For the quantitative analysis, all FTSS and 82304‐2 requirements were translated into concepts and subconcepts. A scoring system identified matches of the frameworks with these subconcepts, with scores ranging from 0 (no match) to 0.5 (partial match) and 1 (full match). Integration was evaluated considering several scenarios, including adopting the Label2Enable 82304‐2 handbook, adopting the 82304‐2 requirements, adapting the 82304‐2 requirements to local needs, and maintaining the current FTSS framework.

Results: The main difference between the frameworks was the app usage–based assessment (FTSS) versus evidence- and app usage–based assessment (82304‐2). All 120 FTSS requirements and 74 quality aspect–related 82304‐2 requirements were translated into 78 concepts and 97 subconcepts. Overall, 48% (47/97) of the subconcepts were found in both frameworks, 39% (37.5/97) were specific to 82304‐2, and 13% (12.5/97) were specific to FTSS. All 82304‐2-specific subconcepts and thus all 82304‐2 requirements were found to be relevant to FTSS. FTSS decided to integrate (adopt and adapt) all 74 82304‐2 requirements. In total, 5 FTSS-specific requirements were included in the Label2Enable 82304‐2 handbook, while another 4 rigor-enhancing requirements, 1 scope-expanding requirement, and 1 context-specific requirement would be assessed on top.

Conclusions: The comprehensive comparative analysis of the FTSS framework and 82304‐2 enabled FTSS decision-making to integrate all 82304‐2 quality requirements and adopt the Label2Enable 82304‐2 handbook in the future. The many new and all relevant 82304‐2 concepts, the rigor of the handbook, and the few remaining FTSS-specific requirements are expected to be indicative of 82304‐2's potential to make harmonized, robust health app assessments common in Catalonia and elsewhere. FTSS encourages other authorities to perform a similar evaluation.

Introduction

Background

Health apps refer to apps designed for managing, maintaining, or improving the health and well-being of individual persons or the delivery of care, and thus include both medical and wellness apps [1,2]. A great number of health apps are already being used by millions of people, and several reports have pointed out the potential of these apps and digital technologies to deliver the right information to the right people at the right time. Health apps can enhance the safety, effectiveness, and efficiency of care by promoting health, contributing to the prevention and treatment of diseases, facilitating patients' equal access to personalized health care, and engaging patients in their own care. They can also respond to unmet patient needs, enable better coordination of care, exploit the possibilities of remote health promotion and remote care, and strengthen the resilience and sustainability of health systems [3-5]. However, not all health apps provide sufficient evidence to support their claims, putting users at risk and calling into question their quality [6]. This creates a need for robust evaluation and regulatory oversight [3,4].

The European Union (EU) Medical Device Regulation (MDR) mandates a conformity assessment and related Conformité Européenne (CE) mark for all medical devices, including software, and is therefore applicable to medical apps [7-9]. However, while the MDR ensures patient safety, it produces merely a CE mark, not a quality report. Additionally, Notified Bodies are only involved in the evaluation of class IIa, IIb, and III medical devices; class I medical devices are not subject to third-party assessment. Wellness apps, on the other hand, fall outside the scope of the MDR, and digital marketplaces do not require robust evaluations [6]. As a result, health apps available on the market largely lack essential quality information apart from the user star ratings in app stores, which are known to be a poor indicator of quality [10]. To address this situation, several countries and regions in Europe and worldwide have developed assessment frameworks for health apps [11]. These frameworks assess characteristics beyond the MDR, such as data privacy, and provide more assessment information than a CE mark to support decision-making. The TIC Salut Social Foundation (FTSS, Catalan abbreviation), within the Ministry of Health of Catalonia (Spain), was in 2017 one of the first European health authorities to develop such an assessment framework [12,13]. With the emergence of more frameworks, a lack of cross-country harmonization has been introduced, leading to a significant duplication of app assessment efforts for manufacturers and health care systems, causing confusion among app users [2]. In addition, despite the widespread interest in the use of health apps across Europe, even authorities with relatively well-established frameworks encounter challenges with efficient implementation [11].

The World Health Organization (WHO) has called on health authorities and researchers to establish a common methodology for evaluating health apps, highlighting the need for these evaluations to become a standard practice rather than an exception [3]. Founded upon the premise that international harmonization could highly benefit the integration of apps in health care systems [2], the European Commission commissioned the European Committee for Standardization (CEN) to develop a Technical Specification (TS) for quality and reliability of health and wellness apps, which was achieved in collaboration with the International Organization for Standardization (ISO). CEN ISO/TS 82304‐2 "Health software—Part 2: Health and wellness apps—Quality and Reliability" (henceforth referred to as 82304‐2 or the TS) was published in 2021 [1,2,14]. As a next step, the EU-funded Label2Enable project (2022‐2024) has been dedicated to facilitating the adoption of this TS as the common assessment framework within the EU and potentially beyond. The project has iteratively cocreated the Label2Enable handbook for app assessment with 82304‐2 and the Label2Enable certification scheme [15].

Objective

The objective of this study was to generate a systematic comparative analysis of the FTSS assessment framework for health apps with the 82304‐2 framework, to identify all new and relevant concepts distinct to 82304‐2 and all Catalonia-specific concepts addressed by the FTSS framework, and to adequately consider and allow proper integration of 82304‐2 in Catalonia. Our broader aim was to provide this methodology to health authorities in other regions and countries to make informed decisions about the adoption and integration of 82304‐2 or other evaluation frameworks.

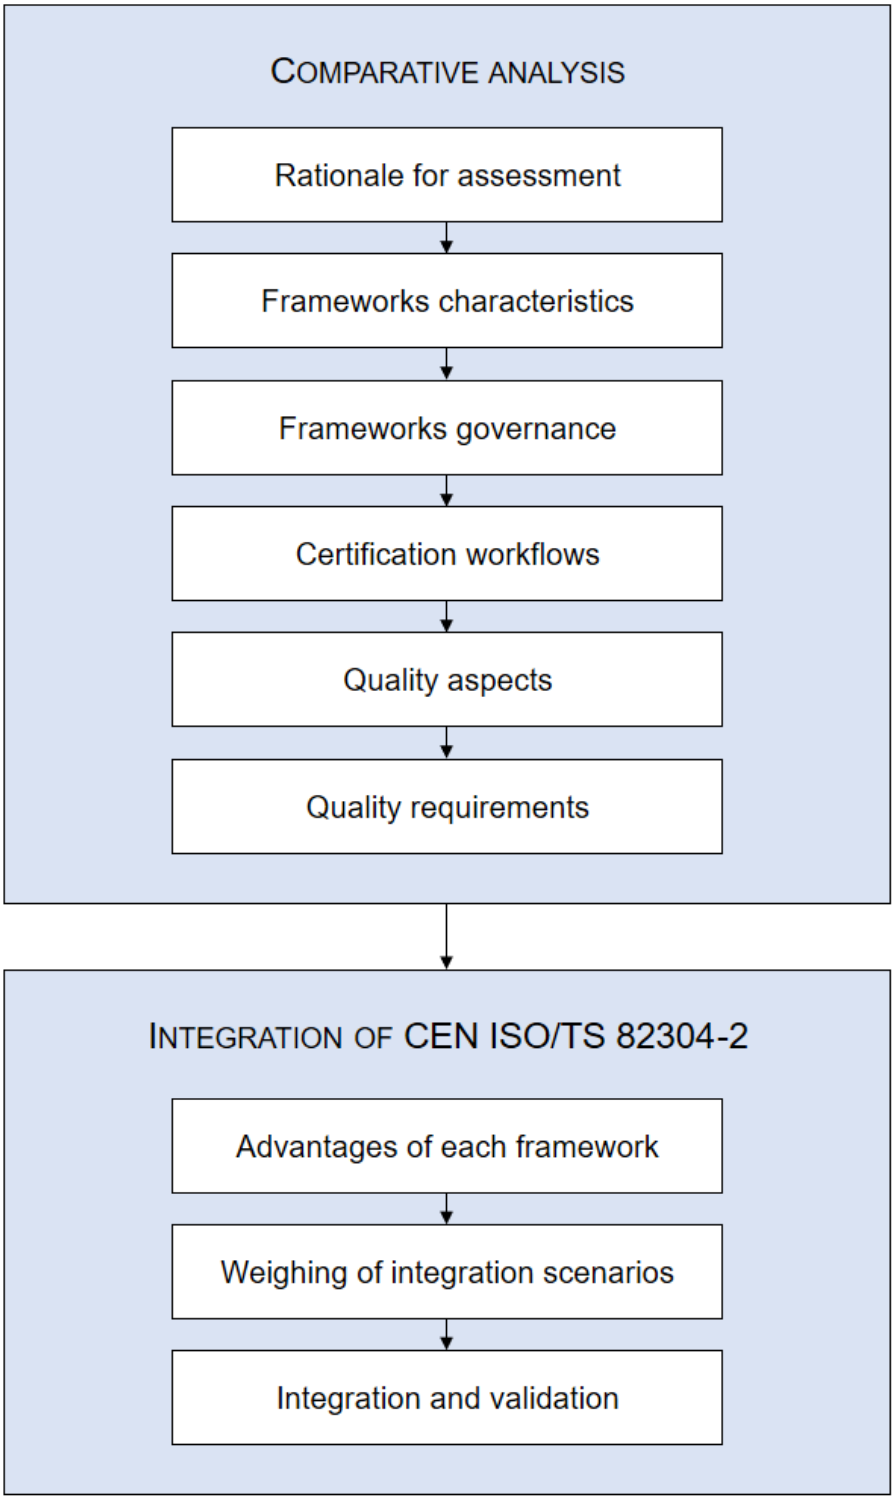
Methods

Study Design

The project was carried out in 2 parts, as depicted in Figure 1. The first part, a comprehensive comparative analysis of both assessment frameworks, is divided into 6 sections. This part aimed to identify the characteristic traits and differences of each assessment framework. The second part is divided into 3 sections and involves considering the integration of 82304‐2 in Catalonia, weighing its advantages and disadvantages, and carrying out the decision made.

XSL•FO
RenderX

Figure 1. Overview of the methodology used in this study.



Comparative Analysis

The comparative analysis was conducted using a mixed methods approach, comprising a qualitative case study, given its capacity to capture complexity, and a quantitative analysis. This methodology [16] was adapted from a comparative analysis of assessment frameworks for sustainability [17]. The analysis addressed qualitatively and descriptively the (1) rationale for assessment, (2) assessment framework characteristics, (3) assessment framework governance, (4) certification workflows and techniques used, (5) quality aspects and subaspects of each framework, and (6) quality requirements (or criteria).

To enable a quantitative analysis of the FTSS and 82304‐2 requirements shared across the 2 assessment frameworks (6), first, all concepts and subconcepts assessed in each of the 82304‐2 and FTSS requirements were identified by 2 researchers (BLC and CPB). The concepts and subconcepts were organized within the 82304‐2 subaspects (“Health

XSL•FO
RenderX

requirements," "Health risks," "Ethics," "Health benefit," "Societal benefit," "Accessibility," "Usability," "Privacy," "Security," "Technical robustness," and "Interoperability"). In cases where multiple requirements addressed the same overarching concept, distinctions were made to recognize when they assessed different subconcepts. For the case of FTSS requirements, concepts were extracted both from the FTSS quality requirements and from the FTSS assessment submission form. In some instances, individual requirements were broken down into 2 distinct subconcepts to account for a proper comparison. Similarly, multiple requirements were grouped under the same concept and subconcept when applicable.

To compare the concepts and subconcepts of both frameworks, first, the obtained 82304‐2 subconcepts were searched within the FTSS requirements. The process was repeated in the opposite direction for FTSS subconcepts in 82304‐2 requirements. When finding matches, the original requirements of 82304‐2 and FTSS were compared. In total, 3 outcomes were possible: 0="no match," 0.5="partial match," and 1="full match," considering aspects such as the intended assessment goal, the level of detail required, and any differences in scope. Further detail as to the degree and type of partial match was deemed unnecessary for this paper, as the distinction between "no match" and "partial match" was primarily used to determine which FTSS requirements to discuss with the lead expert of 82304‐2 (PH) to ensure content was not accidentally overlooked and subconcepts were adequately identified as "partial match" or "no match." Consensus on this identification was reached for all concepts and subconcepts.

Then, overall match scores were computed. The sum of all full matching subconcepts and partial matching subconcepts*0.5 was labeled "Both" (meaning that both frameworks assess this subconcept), the sum of all not matching subconcepts and partial matching subconcepts*0.5 applicable to 82304‐2 as "82304‐2 only," and the sum of all not matching subconcepts and partial matching subconcepts*0.5 applicable to FTSS as "FTSS only." Overall match scores were calculated as the sum of all full matching subconcepts and partial matching subconcepts*0.5 divided by the total number of subconcepts. The values were then converted to a percentage and plotted with R.

Integration of CEN ISO/TS 82304-2

The second part of our study consisted of an analysis of the results of the comparative analysis to decide on the integration of 82304‐2 into the FTSS assessment framework. The analysis was carried out by 2 researchers (BLC and CPB). Integration would imply using the concepts and subconcepts identified in 82304‐2 for the assessment of health apps' quality in Catalonia.

First, the advantages and disadvantages of each assessment framework and their certification workflow were identified and discussed. Next, the integration scenarios were considered—whether (1) to adopt the Label2Enable 82304‐2 certification scheme and related handbook adding only Catalonia-specific requirements, (2) to adopt 82304‐2 requirements into the FTSS framework (using the phrasing of 82304‐2), (3) to adapt 82304‐2 requirements according to FTSS needs, or (4) to maintain the current FTSS assessment framework in Catalonia.

Ethical Considerations

Approval from an ethics committee was not required under Catalan and Spanish regulations, as the study did not involve human participants, personal health data, or clinical interventions. According to Law 14/2007 on Biomedical Research (Ley 14/2007 de Investigación Biomédica) and the guidelines of the Research Ethics Committee of Catalonia (Comitè d'Ètica de la Investigació amb Medicaments de Catalunya, CEIm), studies based solely on document analysis and framework comparison do not require ethical approval. Additionally, no identifiable personal or patient data were processed.

Results

Comparative Analysis

Overview

Key findings from the comparative analysis included a significant alignment between the FTSS assessment framework and 82304‐2, with quite similar rationales for assessment, framework governance, and certification workflows. The main difference between the frameworks was the app usage–based assessment (FTSS) versus evidence- and app usage–based assessment (82304‐2). Also, the 82304‐2 framework provided many concepts new to FTSS, which were all considered relevant.

Rationale for Assessment

In Catalonia, at the beginning of 2017, the Government requested the establishment of the FTSS assessment framework to ensure the quality of health apps used within the Catalan health care system and to promote the use of these health apps [18]. The development of 82304‐2 was commissioned by the European Commission to tackle the scattered assessment landscape with its many different criteria that struggle to scale, duplicate work, produce contradicting results, create challenges for manufacturers, and generally ignore international standards applicable to health apps [1,2].

Both the FTSS and 82304‐2 rationale for assessment included the large scale (hundreds of thousands of health and wellness apps, millions of downloads), concerns about the risks (many apps collect sensitive personal information and provide health advice that may not be supported by any evidence; app stores have limited evaluations; only some apps fall under the MDR), and opportunities missed (apps that are proven effective in addressing, for example, unhealthy lifestyles, chronic diseases, access to and affordability of health and care are not necessarily adopted at scale and reimbursed).

Framework Characteristics

Table 1 summarizes and compares the main characteristics of each assessment framework [1,2,12,15,18-22]. More detailed information can be found in Multimedia Appendix 1.

XSL•FO
RenderX

Table . Comparison of the main characteristics of the TIC Salut Social Foundation (FTSS) assessment framework and CEN ISO 82304‐2 Technical Specification (TS or 82304‐2).

	FTSS assessment framework	CEN ISO/TS 82304‐2
Year of publication	2017	2021
Scope	Catalan health care system	International (initiative Europe)
Scientific evidence	The FTSS framework was based on clinical guidelines and research papers (with input of relevant stakeholders in Catalonia).	The 82304‐2 framework was based on a Delphi study with 83 experts from 8 stakeholder groups and 6 continents. The Label2Enable 82304‐2 handbook "pass/fails," and subquestions are informed by international scientific studies on health app quality and risks. The Label2Enable project included many studies to assess and fine=tune compatibility of 82304‐2 related products with mostly European multi-stakeholder needs.
Consensus	Relevant stakeholders in Catalonia	Key stakeholders, mostly European
Product information	Obtained from the FTSS assessment submission form	1 aspect: product information
Quality aspects	4 quality aspects: • Clinical contents and functionality • Usability, accessibility, and design • Security and privacy of data • Technological robustness	4 quality aspects: • Healthy and safe • Easy to use • Secure data • Robust build
Quality requirements	120 quality requirements	74 quality requirements within the 4 quality aspects (81 requirements with the additional 7 requirements in "Product information")
Score-impacting requirements	Maximum 120	Maximum 67
Structure of each requirement	Affirmative sentence with: • Description • Levels of obligatoriness	Question with: • Condition • Purpose • Response options • Evidence • Notes
Assessed apps	20 for testing, 55 for assessment, 23 as smoke test	35 for testing (11 in development of 82304‐2, 24 in development of the Label2Enable 82304‐2 handbook)
Certified apps	14 out of 55 assessed	0 (given testing phase)
Results communication	Certification seal + internal report	Quality label + quality report

Framework Governance

Both FTSS and Label2Enable have a stakeholders and experts organization to help approve, maintain, and improve their framework. Both FTSS and Label2Enable have defined a methodology of maintenance, with many steps overlapping (see Figure 2 for FTSS and Figure 3 for Label2Enable). Table 2 outlines and compares these maintenance methodologies. A broader explanation of each governance process can be found in Multimedia Appendix 2.

XSL•FO
RenderX

Table . Comparison of the main traits of the maintenance process of the TIC Salut Social Foundation (FTSS) assessment framework and the CEN ISO/TS 82304 - 2 (82304 - 2) Label2Enable handbook, outlined in Figures 2 and 3 (and referenced in this table).

	FTSS assessment framework	CEN ISO/TS 82304 - 2: Label2Enable handbook
Maintenance cycle	Maintained every 2-3 years	Intent to maintain annually and more frequently if needed
Methodology (steps 1 and 2 of Figures 2 and 3)	Experts to consult recruited per quality aspect	Experts to consult recruited for each quality requirement
Experts (step 2 of Figures 2 and 3)	Societies of health professionals [23], technology and data protection experts, quality assessors	Subject matter experts and key stakeholders
Rationale validation (step 3 of Figures 2 and 3)	Legislation, stakeholder needs, and common practice	EU level legislation, stakeholder needs, common practice, standardization, and scientific research findings
Assessment method (step 4 of Figures 2 and 3)	Decided for each requirement. Can include expert and trusted existing assessments	Evolves the assessment method and efficiency from expert to manual, where applicable, using automated and trusted existing assessments
Obligatoriness definition (step 5 of Figure 2)	Establishes which requirements are mandatory to obtain the certificate, which can be reviewed over time	Establishes which requirements are mandatory to qualify for the quality label, which can be reviewed over time
Assessors training (step 5 of Figure 3)	Not contemplated by FTSS as assessors have previous knowledge and experience	Considers the needed skills of the assessor and its training based on the assessment methods
Evidence definition (step 6 of Figure 3)	No	Defines the specific evidence needed to pass or fail for each requirement
Impact (step 9 of Figure 3)	Not evaluated by FTSS per se, but the FTSS framework was built by considering its impact	Explores the "compatibility" with what key stakeholders and authorities consider useful (and proportionate)

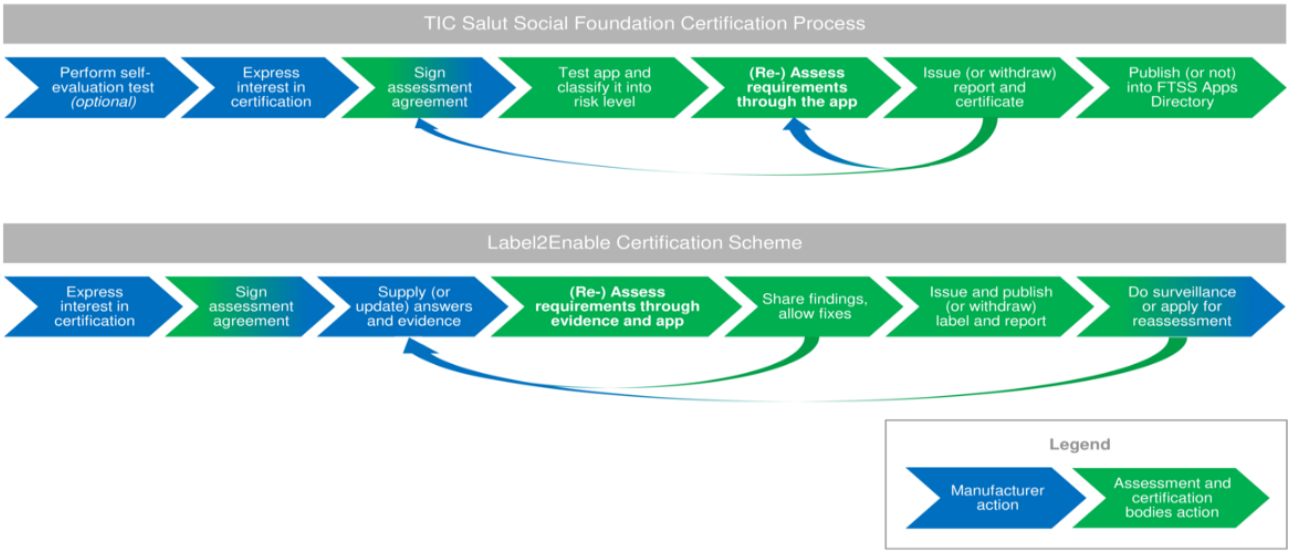
Certification Workflows

The certification workflows of FTSS [21] and 82304‐2 (as defined by Label2Enable) are quite comparable (Figure 4). The main difference between the two is that the FTSS assessment is mostly app usage–based, while the Label2Enable 82304‐2 assessment is evidence- and app usage–based. In FTSS, assessors use the app and analyze its content and functionalities to decide on the pass or fail of each requirement. Following the Label2Enable 82304‐2 handbook, the manufacturer must supply evidence for each quality requirement that they claim to meet. Subsequently, a conformity assessment body assesses the evidence to determine the pass or fail, also checking the app. Other differences are that FTSS includes an optional self-evaluation test [24] and publishes certified apps in the FTSS directory. Label2Enable intends to provide a verification service of the label it supplies and proposes to generate a directory. For more detail about the certification workflows, see Multimedia Appendix 3.

Figure 4. Overview of the certification workflows of TIC Salut Social Foundation (FTSS) (above) and the Label2Enable certification scheme (below).

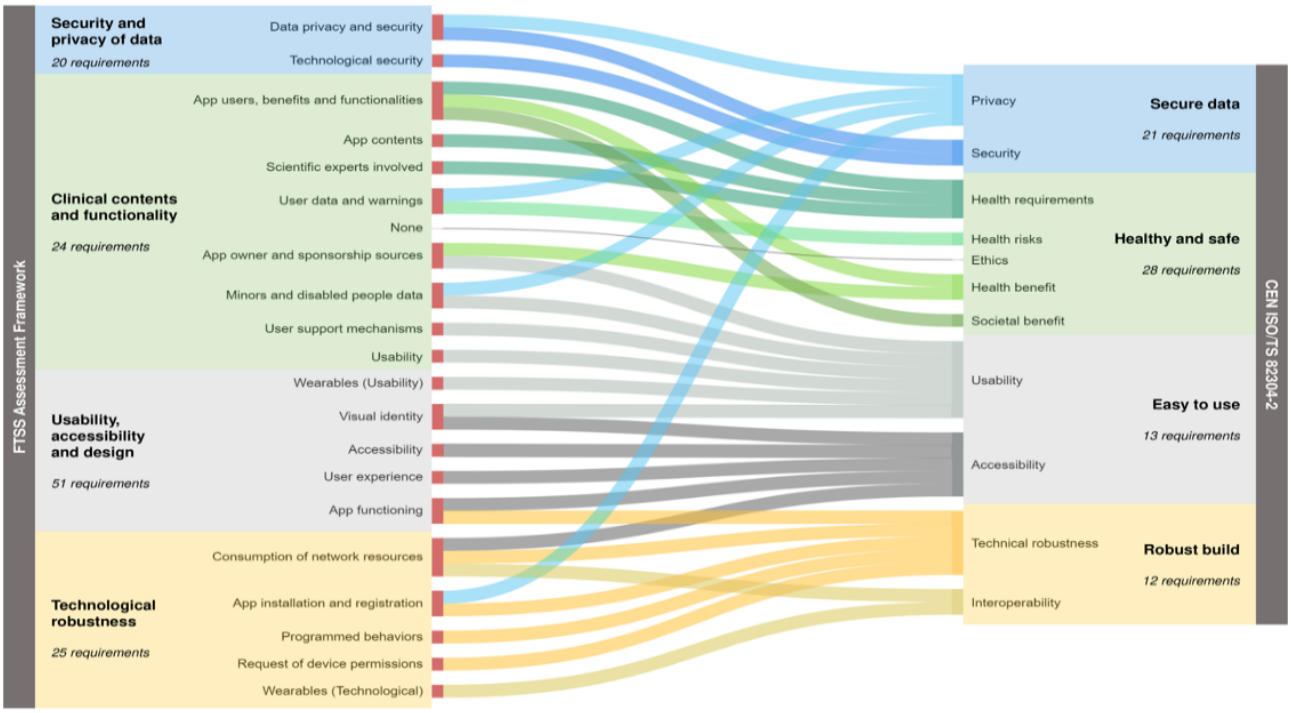


Quality Aspects

The FTSS and the 82304‐2 assessment frameworks both contain 4 overarching quality aspects [2,20]. Based on the semantics of each aspect and the concepts and subconcepts assessed in each, a match between the aspects of the 2 frameworks was observed (Figure 5). On a more detailed level, differences in distribution applied, which highlighted a need to consider assessment frameworks in its entirety in a comparative analysis, instead of merely considering semantically similar subsections. The organization of 82304‐2 seems a bit more logical; FTSS has some scattered requirements when compared to 82304‐2. For example, the quality aspect "Clinical contents and functionality" of FTSS is broader than "Healthy and safe" of 82304‐2, with many of FTSS' subaspects connecting to 82304‐2's "Easy to use" and some to "Secure data." "Technological robustness" is also broader than "Robust build." The concepts gathered in 82304‐2 subaspect "Privacy" are distributed among 4 FTSS subaspects, from 3 different quality aspects. All in all, concepts assessed are fairly common in both frameworks, but wording used for aspects and subaspects within FTSS and 82304‐2 tends to differ, with some exceptions, such as "Usability" and "Accessibility."

XSL•FO
RenderX

Figure 5. Matches found between the quality aspects and subaspects of the TIC Salut Social Foundation (FTSS) and the CEN ISO/TS 82304 - 2 (82304 - 2) assessment frameworks. The 4 quality aspects of FTSS (eg, "Security and privacy of data") are displayed in bold on the left, and the 4 quality aspects of 82304 - 2 (eg, "Secure data") in bold on the right. The colored boxes also contain the number of quality requirements within the quality aspect and the subaspects in which these requirements are clustered. The similar background colors (blue, green, grey, and yellow) indicate a match of the quality aspects between the 2 frameworks. The lines in the middle connect the concepts within the FTSS and 82304 - 2 quality requirements that were similar. The color coding of the connecting lines differs per 82304 - 2 subaspect it originates from and is merely used to support easy recognition of the distribution of the 82304 - 2 concepts across FTSS subaspects. Note that this is a qualitative analysis; thus, the thickness of the connection lines is not numerically representative.



Quality Requirements

To enable a comparison of all the 82304 - 2 and FTSS quality requirements, in total, 78 different concepts and 97 subconcepts were extracted from all 74 quality requirements of the 82304 - 2 framework and all 120 quality requirements of the FTSS framework combined. Overall, 48% (47/97) of the subconcepts of both frameworks were a partial or full match, 39% (37.5/97) were 82304 - 2-specific ("82304 - 2 only") and 13% (12.5/97) FTSS-specific ("FTSS only"). The subaspect "Accessibility" had the highest match, with 94% (7.5/8) of subconcepts assessed in both frameworks, and FTSS addressing another 6% (0.5/8) (see Figure 6). Other subaspects such as "Health requirements," "Health risks," "Health benefit," and "Usability" had at least 50% of subconcepts covered by both frameworks. The 82304 - 2 requirements were found to cover most of the FTSS requirements, ranging from subaspects such as "Health benefit" and "Societal benefit" missing no concepts (0%) to "Technical robustness" missing a maximum of 38% (5/13). The most relevant "82304 - 2 only" subaspect was "Ethics," which is not assessed by FTSS. For other subaspects ("Societal benefit," "Security," and "Interoperability"), 82304 - 2 covered at least 50% of the subconcepts.

For more detail, Table 3 provides the match scores obtained for each concept assessed in the frameworks. Note that this comparison has been performed with the original 82304 - 2 rather than with the more detailed Label2Enable 82304 - 2 handbook for certified app assessment organizations, which provides standardized subquestions to assess the 82304 - 2 quality requirements and thus may add more subconcepts.

XSL•FO
RenderX

Figure 6. Percentage match of subconcepts between the CEN ISO/TS 82304‐2 (82304‐2) and TIC Salut Social Foundation (FTSS) assessment framework clustered according to the 82304‐2 subaspects. Colored boxes framing the subaspects indicate the 82304-2 aspect to which they originally belong to: “Healthy and safe” (green), “Easy to use” (gray), “Secure data” (blue), and “Robust build” (yellow).

Concepts extracted within each subaspect	Subconcepts extracted (n)	Concepts match (sum of subconcepts match scores)		
		Both	82304 - 2 only	FTSS only
Export of app data	1	0	1	0

[a]Concepts and subconcepts of each requirement in each assessment framework have been extracted and organized according to 82304 - 2 subaspects but include both 82304 - 2 and FTSS requirements.

[b]This subconcept is not score-impacting in 82304 - 2.

[c]This subconcept is not score-impacting in the FTSS framework.

[d]This "FTSS only" subconcept is now included in the subquestions of the Label2Enable 82304 - 2 handbook.

[e]This "FTSS only" subconcept is now partially included in the subquestions of the Label2Enable 82304 - 2 handbook. This means that the subconcept is included, but with a lower level of detail. For example, the Label2Enable 82304 - 2 handbook checks whether measures to avoid misuse are in place, but not all measures that FTSS assesses have been included. In most cases, the Label2Enable consortium considered this level of detail not relevant.

[f]This "FTSS only" subconcept is context-specific for Catalonia or Spain. It is not for 82304 - 2 uptake.

[g]This "FTSS only" subconcept is scope-expanding, that is, it goes beyond the definition of a health app assessment framework, at least for 82304 - 2. Currently, it is not for 82304 - 2 uptake.

[h]API: application programming interface.

Both for the "82304 - 2 only" and the "FTSS only" subconcepts, it is important to consider that these subconcepts may not be relevant or may be of lesser importance in the other assessment framework. Of the initial 13% (12.5/97) "FTSS only" subconcepts, 7% (7/97) were in the meantime included in the subquestions of the Label2Enable 82304 - 2 handbook as considered relevant, 1% (1/97) was scope-expanding and thus was not for 82304 - 2 uptake, and 1% (0.5/97) was related to specific Catalan and Spanish regulations, also not for 82304 - 2 uptake. The remaining 4% (4/97) "FTSS only" subconcepts were specific to app usage–based assessment of the technical robustness of the app, labeled as rigor-enhancing subconcepts, and not included in the Label2Enable 82304 - 2 handbook, as the evidence-based assessment was considered sufficient.

Integration of CEN ISO/TS 82304-2

Advantages of Each Framework

In general, both assessment frameworks were found to be quite similar. The international applicability, foundation in standardization, scientific evidence, concepts covered, and maintenance of 82304 - 2 and Label2Enable make the framework distinctive in rigor and capable of enabling harmonization and preventing a duplication of efforts. In addition, the 82304 - 2 health app quality label and report, the more detailed version of the 82304 - 2 health app quality label that was cocreated with health care professionals to support decision-making on a health app, are expected to be useful for potential users, health professionals, and health systems to increase the willingness to use health apps. It is remarkable of FTSS; nevertheless, that the assessment of their framework is supported by societies of health professionals collaborating in the Functional Experts Committee, and that they have more years of experience in their assessment. On the other hand, Label2Enable tested with medical societies the usefulness of the health app quality report in providing guidance on health apps. An article with the European Society of Cardiology established that 82304 - 2 covered all specified requirements for apps in the 4 intended uses and 3 health issues investigated [25].

Regarding the assessment itself, combining evidence- and app usage–based assessment, as defined in the Label2Enable 82304 - 2 handbook, was considered by the researchers to provide the most advantages in rigor. The objectivity and consistency of the assessment are higher in Label2Enable due to the specific terminologies (eg, 'intended use,' 'intended user'), and the clarity for each quality requirement of what is needed to pass, although it is valuable of FTSS that their framework calculates the risk level of the app to determine the number of mandatory requirements. CEN ISO/TS 82304 - 2 has a similar approach, with at most 67 score-impacting requirements, depending on, among other intended uses, whether an app includes health information, processes personal data, and is interoperable. On a global level, 4 requirements are mandatory to qualify for an 82304 - 2 label; on an EU level; more requirements are mandatory based on an alignment with EU-level legislation and values. Additionally, FTSS has a self-evaluation (readiness) test for manufacturers, which was recommended to be implemented similarly for 82304 - 2.

Considering the quality requirements themselves, the most important dimension to decide on integration, 82304 - 2 covered 87% (84.5/97) of the subconcepts of both frameworks (47/97 (48%) "Both" plus 37.5/97 (39%) "82304 - 2 only"). By having added 7 "FTSS only" subconcepts to the subquestions, the current Label2Enable 82304 - 2 handbook contains 100% of the EU-relevant requirements of 82304 - 2 and FTSS assessment frameworks. The remaining 5.5 FTSS subconcepts (1 scope-expanding, 0.5 context-specific, and 4 rigor-enhancing) are specific to the FTSS assessment framework and can be assessed separately on top in Catalonia. Overall, 82304 - 2 and the Label2Enable certification scheme provide many advantages; in short, a broader, more objective, pan-European, evidence-based assessment framework that was considered to provide an enhanced value.

Weighing of Integration Scenarios

Given the advantages that 82304 - 2 proved to provide, scenario (4) was disregarded, making the remaining viable integration scenarios (1) to adopt the Label2Enable 82304 - 2 certification scheme and related handbook, adding Catalonia-specific additional requirements on top, (2) to adopt the 82304 - 2

XSL•FO
RenderX

requirements into the FTSS framework (using the phrasing of 82304 - 2), or (3) to adapt 82304 - 2 requirements according to our needs.

The Label2Enable consortium proposes an EU-level assessment via the Label2Enable certification scheme and 82304 - 2 handbook, with each country (or region) then assessing only the requirements specific to the country (or region), being context-specific, scope-expanding, and rigor-enhancing requirements. For Catalonia and manufacturers involved, cross-country recognition would simplify and accelerate the certification process. Thus, FTSS sees value in directly using the Label2Enable certification scheme (scenario 1) once it is operational and 82304 - 2 health app quality labels and reports are issued.

However, as the Label2Enable certification scheme is not yet operational, and the Government of Catalonia needs to carry on with app assessments and is interested in already improving its framework, we decided to start by implementing 82304 - 2 ourselves and adapting some requirements according to our needs (mix of scenarios 2 and 3). This allowed the Label2Enable certification scheme to follow its process of implementation in Europe while updating the FTSS framework.

Integration and Validation

All 81 82304 - 2 requirements were incorporated in the new FTSS framework, using different integration mechanisms based on the match scores. For unmatched 82304 - 2 concepts and subconcepts, the 82304 - 2 requirements were adopted as is. For full matches, FTSS-related subtleties were added to the 82304 - 2 requirements. Of the partially matched FTSS subconcepts, 8 could be added to existing 82304 - 2 requirements. Next, the remaining 3 partially matched FTSS subconcepts, the 7 unmatched "FTSS only" subconcepts, and 1 new concept originating from a consultation of the newest regional guidelines [26] and Catalan subject matter experts, as per the methodology outlined in Figure 2, were phrased as a question to create 11 new quality requirements for the new FTSS framework. The entire set of requirements was translated to Catalan using plain language.

Subsequently, 5 of these 11 new requirements were included in the Label2Enable 82304 - 2 handbook. The 6 remaining FTSS-specific requirements included 1 scope-expanding requirement (wearables), 4 rigor-enhancing requirements (additional app usage–based assessment), and 1 context-specific requirement (ensuring that apps developed within the Ministry of Health of Catalonia contain the required visual identity).

FTSS has already developed a new web-based form for submitting the necessary information and evidence for assessment. Assessment results will be tested in the following months, and the intent is to present the results with a quality label very similar to that of 82304 - 2. Once the Label2Enable 82304 - 2 handbook is operational and 82304 - 2 quality labels and reports are issued, scenario 1 will become feasible. Then, the new Catalan assessment framework would consist of the 82304 - 2 label and report with 81 requirements and its added Label2Enable 82304 - 2 handbook subquestions, plus 6 additional requirements assessed by FTSS. That would mean the 82304 - 2 label covers 93% (81/87) of the Catalan assessment, with FTSS having to assess only 7% (6/87).

Discussion

Principal Findings

We successfully achieved our objective of generating a systematic and comprehensive comparative analysis of the FTSS assessment framework for health apps with the 82304 - 2 framework. We identified 78 concepts and 97 subconcepts; 37.5 of these were new or partially new subconcepts from 82304 - 2, all relevant to Catalonia, and 12.5 were FTSS-specific. All 81 82304 - 2 requirements were incorporated in the new FTSS framework. FTSS subtleties and partially matched subconcepts were added to the existing 82304 - 2 requirements where suitable. The remaining FTSS-specific concepts and subconcepts were rephrased as questions to create 11 additional quality requirements. Of these 11 requirements, 5 were integrated in the Label2Enable 82304 - 2 handbook. Once the Label2Enable 82304 - 2 handbook is operational and can be adopted, the remaining 6 requirements will be assessed on top of the existing 81 82304 - 2 requirements. Of these 6, 1 requirement is scope-expanding, 4 are rigor-enhancing, and 1 is context-specific.

The methodology used enabled us to adequately consider and achieve proper integration of 82304 - 2 in Catalonia. We believe that this comparative methodology can serve as a useful model for health authorities in other regions and countries considering or seeking to integrate 82304 - 2 into their own assessment framework and adopt the Label2Enable 82304 - 2 handbook. In such cases, we expect that the comparison of the quality requirements is key. In our case, extracting the concepts and subconcepts from the FTSS and 82304 - 2 quality requirements highly increased the reliability of the percentage matches obtained. The percentages obtained for each subaspect, the relevance of all "82304 - 2 only" concepts to Catalonia, as well as the low percentage of Catalonia-specific requirements to be assessed on top, were particularly useful for decision-making and necessary for actual 82304 - 2 integration.

The Results From a Theoretical Perspective

Rogers' diffusion of innovation theory [27] was foundational in the Label2Enable project and is of value given our broader aim to provide this methodology for health authorities elsewhere to consider integrating 82304 - 2 or other evaluation frameworks. Rogers' theory acknowledges 5 attributes that influence rate of adoption of an innovation. In this case, 82304 - 2 can be considered an innovation. The first and main attribute, according to Rogers, and in our experience, is relative advantage, the degree to which 82304 - 2 is perceived as better than the current FTSS framework. Overall, 82304 - 2 has been observed to provide a positive relative advantage in comparison with the current FTSS framework. First, 82304 - 2 entails a more structured, better maintained, standards- and evidence-based framework, with additional value-adding concepts and subconcepts to assess the quality of a health app compared to the FTSS framework. Second, 82304 - 2 is an international standardization effort, and the Label2Enable 82304 - 2 handbook adopts a pan-European perspective, making

XSL•FO
RenderX

it a more robust and scalable solution for app assessment across borders. This broader scope allows for the harmonization of assessment requirements, which is especially beneficial given the current lack of cross-country standardization and efficiency and scalability challenges in health app assessments. This advantage cannot be reached with a regional framework. Thirdly, the Label2Enable 82304 - 2 handbook's evidence-based assessment approach on top of app usage–based assessment with clearly defined terminologies and definitions of what is needed to pass was evaluated favorably by FTSS. For this reason, the Label2Enable 82304 - 2 handbook will be adopted, and all 82304 - 2 requirements were incorporated in the new FTSS framework. FTSS subconcepts not covered by 82304 - 2 were maintained as additional requirements, as suggested by Frey et al [28] and already operationalized by the Australian eHealth Agency's framework [29].

Rogers' second attribute is compatibility, the degree to which integration of 82304 - 2 is perceived as consistent with the existing known values, experiences, and needs of Catalonia. Beyond our decisions detailed in the previous paragraphs, we propose multistakeholder feedback to assess compatibility and specify expected benefits, challenges, and the practical implications of integration from a multistakeholder perspective, enhancing existing knowledge on the compatibility of 82304 - 2 from a health authority perspective [30]. In June 2023, FTSS invited the members of the Functional Experts Committee, formed by different societies of health professionals, to discuss the value of 82304 - 2. Careers of its 8 members can be found on the FTSS website [23]. They concluded that this certification could become greatly useful if it became mandatory for all health apps in the European market, and especially if it appeared in the apps marketplaces. This way, the quality of all published health apps would be ensured, and patients, professionals, and health care systems would use and recommend health apps with more confidence and reliability. Additionally, in a later meeting, they valued the Label2Enable health app quality report as a powerful tool to obtain relevant quality information about health apps and thus allow them to prescribe these apps. In the Label2Enable project, the manufacturer perspective was obtained through a discrete choice experiment with 41 manufacturers and a pilot study with 24 manufacturers. The first study showed that manufacturer willingness to pay for app assessment was primarily associated with the potential for integration of the health app into clinical guidelines and reimbursement or procurement [31]. In the second study, after having participated in a pilot 82304 - 2 assessment, 87.5% (21/24) of the manufacturers responded positively to willingness to "do it again" [32]. The Catalan health care system currently considers making this new assessment free of charge for apps of interest.

Rogers' third attribute is complexity, the degree to which 82304 - 2 integration is perceived as relatively difficult to understand and use. Once the Label2Enable 82304 - 2 handbook is operational and 82304 - 2 quality labels and reports are issued, the new Catalan assessment framework would consist of the 82304 - 2 quality label and report plus only 6 additional requirements assessed by FTSS (7%, 6/87). A further expansion of the 82304 - 2 scope, as currently advocated for the upcoming 82304 - 2 revision, would likely eliminate the need for assessing the scope-expanding requirement by FTSS, further reducing the Catalonia-specific workload to 6% (5/87). Uptake of 82304 - 2 thus avoids considerable duplication of assessment efforts with similar requirements. Currently, however, as the Label2Enable 82304 - 2 handbook was not yet available, we used an extensive analysis of 82304 - 2 to consider and achieve proper integration. To operationalize the new framework, training of the assessors will be required. Although it is expected that this integration may carry more workload for assessors, at least in the beginning, the time investment was considered acceptable in view of the enhanced value of the new framework and quality of certified apps that combined promote health app use. To end with, it will be necessary to properly decide how the quality labels are used; for instance, which scores are considered sufficient for apps to be used within the Catalan health care system.

The final 2 of Rogers' attributes, trialability, the extent to which 82304 - 2 can be tested before its integration, and observability, the level to which 82304 - 2 integration provides tangible results, were considered of lesser importance at this stage. Taking into account that Label2Enable has already performed tests with 24 apps with the handbook [32], trials were considered mostly covered. However, also considering the handbook evolved after testing with 24 apps, Catalonia will test the resulting assessment framework with a minimum of 6 apps (hospital and private apps) by mid-2025. This test will include an analysis of the time investment for both manufacturers and assessors and the elapsed time between the assessment request and the availability of the assessment results. Finally, regarding observability, we especially perceive great potential of 82304 - 2 in increasing the trust in and willingness to use health apps among all stakeholders, supported by recent [25,30] and upcoming 82304 - 2-related publications. Once certificates are issued, it will be possible to observe the actual increase in the degree of trust and—gradually—use. For now, with the new 82304 - 2 integrated assessment framework in Catalonia in place, entities within the Ministry of Health of Catalonia have gained more trust in the assessment framework. They are offering guidelines on health app development [26,33] to all health care providers (primary care and specialized care) within the Catalan health care system, developed by FTSS in parallel with the new assessment framework. They are also using the new assessment framework to ensure the quality of all apps integrated within the electronic health record patient portal (La Meva Salut).

Future Developments

This study was one of many studies within Label2Enable; some have already been published [25,30-32,34], and others are expected to be published later in 2025. Most of these studies aimed at assessing the needs of a specific stakeholder group, the compatibility of 82304 - 2 with these needs, and how to further increase related outcomes. In total, 4 multistakeholder backcasting workshops were used to arrive at a multistakeholder road map toward the preferred future of digital health and care and the role of digital health quality labeling in it [35]. Part of this road map is a demonstrator phase in which the first 50 - 100 health app quality labels and related, more detailed reports can

XSL•FO
RenderX

be issued. In this effort, the inter-rater reliability, efficiency, clarity, and scalability of the Label2Enable 82304‐2 handbook for certified app assessment organizations and the multistakeholder usefulness of the 82304‐2 health app quality report, both cocreated in the Label2Enable project, can be tested at a larger scale and further fine-tuned. Multistakeholder effectiveness is expected to further support decision-making by authorities and other stakeholders on adopting 82304‐2.

Practical Recommendations

Following findings from this study, the Label2Enable project, and the WHO [3,35,36], we made recommendations for other authorities and stakeholders who seek to capture the value of digital health products (Textbox 1).

Textbox 1. Recommendations to other health authorities and stakeholders who seek to capture the value of digital health products.

1. Build your digital health policy based on international policies and applicable regulations, and an understanding of how digital health products can support the aims and address the challenges of your health care system or context.
2. Assign and equip an entity for regulation, oversight, and implementation of health apps or the larger scope of digital health products. Avoid, if possible, scattering responsibilities across authorities.
3. Determine your common assessment framework, assessment organization, and assessment process instead of starting from scratch. Identify with local stakeholders and experts the potential need for additional context-specific, scope-expanding, and rigor-enhancing requirements. Consider using 82304‐2 and the Label2Enable 82304‐2 handbook, and, if you have a framework in place, consider following the methodologies used in this study to evaluate and integrate 82304‐2. If more semantic rigor is preferred for analyzing concept matches, semantic knowledge tools can be considered. Consider also comparing other traits of the frameworks if applicable.
4. Engage with stakeholders, ranging from related authorities, health care providers, health professionals, and patients to digital health manufacturers, to assess their needs in integrating health apps. For instance, manufacturers' needs in meeting the assessment requirements; related authorities' needs in meeting health care system goals; health care providers', professionals', and patients' needs in selecting, integrating, and using apps and the related data; and enabling, capturing, and measuring the value of apps and their data for the individuals, health care system, and society at large.
5. Facilitate the use of quality health apps with transformation and support. For example, by integrating them into health care pathways and developing guidelines. Measure progress in integrating health apps, multistakeholder value added, and what is required to enhance that value.

Conclusions

The methodology presented has allowed a systematic, comprehensive comparative analysis of Catalonia's FTSS health app assessment framework and 82304‐2. The results informed the FTSS decision to integrate the 82304‐2 quality requirements to achieve a more comprehensive, evidence-based, standardized approach to health app assessment, and adopt the Label2Enable 82304‐2 handbook in the future. CEN ISO/TS 82304‐2 included many subconcepts new to FTSS, which were all considered relevant for Catalonia. The Label2Enable 82304‐2 handbook was found to be value-adding in rigor and consistency, and the remaining FTSS-specific requirements were few. These findings are expected to be indicative of the potential of 82304‐2 to contribute to solving the heterogeneous and complex landscape of assessment frameworks for health apps, making robust health app assessments common. FTSS highly encourages other authorities to undertake a similar evaluation or to wait until the Label2Enable 82304‐2 handbook is operational to adopt it in full.

Acknowledgments

This study was initiated and led by the TIC Salut Social Foundation (FTSS), within the Ministry of Health of Catalonia, and later integrated and conducted as part of the Label2Enable project and funded by the European Union (Project: 101057522—Label2Enable—HORIZON-HLTH-2021-IND-07). Views and opinions expressed are, however, those of the authors only and do not necessarily reflect those of the European Union or European Health and Digital Executive Agency. Neither the European Union nor the granting authority can be held responsible for them. Publication costs and part of the development costs were covered by FTSS. Although FTSS was part of the Label2Enable consortium, the actions, findings, and conclusions presented in this study have not been instructed by Label2Enable. This study has been conducted following the willingness and needs identified by the Ministry of Health of Catalonia, based on their existing knowledge on health apps assessment.

Data Availability

Most of the data used in this study are publicly available and can be accessed or purchased online via the links provided in the references. Additional data regarding the methodology and results may be made available upon reasonable request to the corresponding author.

Abstract

Background: Military veterans may be at increased risk of posttraumatic stress disorder (PTSD) compared to the general population. PTSD is often comorbid with harmful and problematic patterns of gambling. Behavioral therapies such as acceptance and commitment therapy have shown promise in treating these co-occurring disorders, especially if combined with mobile health (mHealth) interventions to circumvent known help-seeking barriers faced by veterans. However, to date, recruitment for mHealth interventions has been challenging and may impact intervention feasibility.

Objective: In this paper, our objectives were to describe the strategies used to recruit UK military veterans with PTSD or experience of harmful gambling to a pilot study of a smartphone-based digital intervention, ACT Vet.

Methods: We used several recruitment strategies, such as direct mailing, paid study advertising on social media (Facebook) and an online research platform (Prolific), study-specific website management, in-person event hosting with veterans' charities, snowball sampling, and incentives for completion.

Results: Results showed that, over 27 days, recruitment through Facebook accounted for 21 eligible veterans (n=7, 33% through unpaid advertising and n=14, 67% through paid advertising), whereas Prolific accounted for 50 veterans. Additional strategies recruited 8 eligible veterans. In total, 79 eligible military veterans were recruited for ACT Vet, with 24 (30%) completing the final steps of the study.

Conclusions: Difficulties such as low advertisement conversion rate and participant and data attrition arose throughout this study. Our findings illustrate the relative effectiveness of social media– and online platform–based initiatives in recruiting veterans with PTSD or harmful gambling. Future research should consider establishing an online presence for effective digital intervention recruitment with diverse branding to attract representative samples of veterans for mHealth research.

Introduction

Military veterans may face barriers when accessing help and support for difficulties related to mental health up to 11 years after service [1-3]. Among veterans, posttraumatic stress disorder (PTSD) is often prevalent alongside challenges related to anxiety, alcohol misuse, and depression that contribute to poorer well-being [4,5]. Moreover, veterans are also more likely to engage in and experience avoidance behaviors, including harmful gambling behaviors motivated by escape or avoidance of distress [6-9]. Recently, Dighton et al [9] highlighted that veterans may engage in gambling as a coping mechanism for distressing PTSD symptoms. They argue that increased gambling behaviors may lead to harmful gambling (gambling disorder), defined as problematic gambling behaviors that cause ongoing distress [10], and are likely to have an impact on the individual and the wider health and well-being systems that aim to provide support [11]. Therefore, there is an urgent need for

XSL•FO
RenderX

improved access to efficacious treatment or interventions that may help manage comorbid mental health challenges such as PTSD and harmful gambling.

Promising therapeutic interventions for military veterans experiencing PTSD and comorbid harmful gambling include third-wave, mindfulness approaches such as acceptance and commitment therapy (ACT) [12-15]. ACT involves 6 core principles, defined as being present in the moment, identifying important values, committing to action, the self as context, cognitive defusion, and acceptance [16]. These principles focus on building psychological flexibility, the capacity to adapt and manage distress in accordance with valued goals [16,17]. There is also growing evidence of the feasibility and acceptability of mobile health (mHealth) interventions for PTSD, depression, alcohol misuse, and mental health [18-20]. Such apps embed forms of therapeutic support (eg, ACT) using smartphones, which allows for quick access to independent support supplemented by regular notifications, which may help with therapy engagement [21]. A meta-analysis by Linardon [22] revealed that smartphone-based apps could be effective in building acceptance and mindfulness skills (key elements of ACT). In addition, Farzandipour et al [18] suggested that apps may reduce self-reported PTSD symptoms. However, while Hawker et al [23] suggested that gambling-related apps could be accepted as an intervention, there is a lack of evidence-based treatment testing for many apps that are currently available [24,25]. Thus, evidence-based ACT mHealth apps may provide timely and easy-to-access help for military veterans with comorbid gambling-related harms and mental health difficulties.

When designing and evaluating interventions, feasibility trials, including those involving treatment for gambling in military veterans and nonveterans using mental health mHealth apps, tend to experience recruitment challenges and show high rates of attrition [26-28]. Combined recruitment strategies such as advertising on social media, emailing, printing flyers, offering incentives, and collaborating with relevant organizations are recommended when recruiting and retaining participants in evaluations of mHealth interventions [28-30]. In-person strategies should not be excluded where possible. For example, in-person strategies such as attending local events could provide participants with needed human interaction [28], acting as a guide to the mHealth intervention [29,30] and mitigating any concerns. However, advertising using social media platforms such as Facebook may be particularly useful in reaching individuals considered “hard to reach,” such as veterans [30-32]. Previous studies have shown that, while high rates of attrition still occur, recruitment for mHealth interventions using paid social media advertising may be more cost-effective and can target “hard-to-reach” populations effectively [32-34]. Thus, social media could help counter recruitment challenges faced during feasibility trials.

In addition, Pickering and Blaszczynski [35] have raised concerns regarding the quality of data and increased risk of bias from gambling research using online crowdsourcing platforms such as Amazon Mechanical Turk [36], Qualtrics [37], and Prolific [38]. However, Russell et al [39] argue that they can be effective in recruiting specific hard-to-reach groups given that stringent data quality checks are conducted to reduce potential biases [39]. These checks could include eligibility screening and validation of data quality such as military service numbers, which are identifiers unique to military populations. Prolific can provide high-quality data while being a cost-effective recruitment strategy [40,41]. Therefore, the combination of online crowdsourcing, social media advertising, and traditional recruitment (face-to-face meetings, emails, and flyers) may be effective for recruiting hard-to-reach and vulnerable populations such as military veterans in the United Kingdom with comorbid diagnoses of PTSD and harmful gambling (gambling disorder). However, to date, little is known about the relative effectiveness of these recruitment strategies.

In this study, we sought to compare these recruitment and retention methods for a pilot study designed to evaluate a 10-week app-based ACT intervention for UK military veterans experiencing PTSD and harmful gambling. Veterans were screened for PTSD severity using the PTSD Checklist for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) [42], with scores of 20 or above conferring study eligibility. Veterans experiencing harmful gambling were screened using the Problem Gambling Severity Index [43], with scores of 1 or above conferring eligibility, indicating some form of harmful gambling. Drawing on the work of Williamson et al [32] conducted on UK military veterans and alcohol use, the aim of this paper is to define and reflect on the recruitment strategies and make recommendations for future studies recruiting and retaining military veterans with co-occurring PTSD and harmful gambling.

Methods

Ethical Considerations

The recruitment strategies used in this study formed part of a larger study approved by the Swansea University School of Psychology Research Ethics Committee (1-2023-6798-6614). All participants provided written informed consent to take part. The data obtained were fully anonymized by the research team, and all participants were compensated with either Prolific funds or online shopping vouchers on completion of the larger study.

ACT Vet

We developed the ACT Vet app using a co-design approach with veterans with lived experience of harmful gambling or PTSD and then adopted the Ionic Capacitor framework to achieve a research-viable product standard. ACT Vet is a self-guided app addressing the core components of ACT through seven modules: (1) an introduction that provides an overview of ACT Vet and ACT as a therapeutic practice, (2) Exploring thoughts around coping (cognitive defusion), (3) Control as the problem (acceptance), (4) Contact with the present (present moment awareness), (5) The self as the observer (self as context), (6) Living by your values (values), and (7) Committing to action (committed action). The modules took approximately 15 minutes to complete, with a mandatory break period of 5 days taking place between completed and new modules. The ACT-specific module content took approximately 4 weeks to complete, and participants were encouraged to use the app for the remainder of the 10-week study.

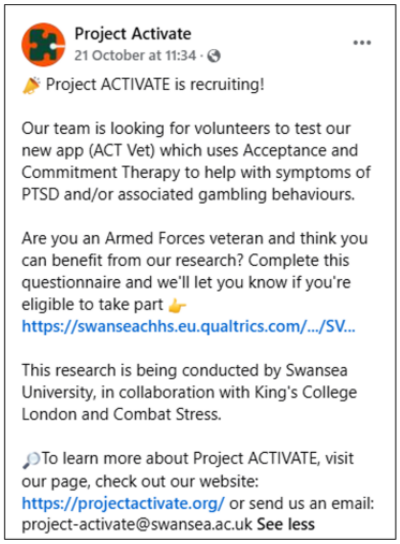
XSL•FO
RenderX

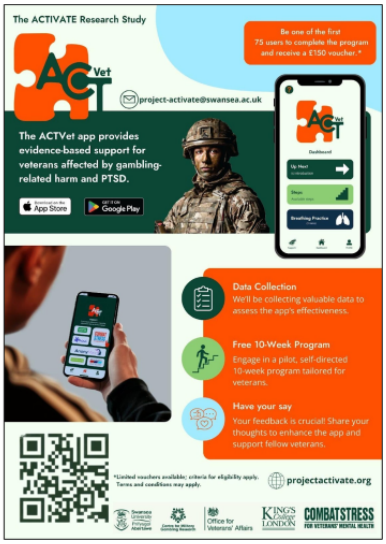
Online Recruitment

The primary recruitment and retention strategies included online engagement, providing study details and links across social media sites: Facebook, X (formerly known as Twitter), and Instagram. Individual project pages across each site (Facebook, X, and Instagram) were created (in May 2024) with the purpose of information sharing using blog-type posts and project recruitment (Figure 1, left panel). Paid Facebook advertisements were used as they have been considered a useful tool in similar veteran-specific app-based recruitment efforts [32]. These advertisements were run for a total of 27 days. The textual keywords that the target audience needed to have on their profiles to be included are as follows: Armed Forces Day (United Kingdom), veterans' benefits (military) or army men, school or university, British Army and employers, Royal Air Force Regiment, Royal Marines, veteran, His Majesty's Armed Forces, and Royal Navy or British Army. Figure 1, middle panel shows the imagery and copy used for the advertisement.

Additionally, Prolific, which is an online recruitment platform where researchers advertise studies among a large pool of vetted participants, was used to screen potential participants who were UK military veterans aged ≥18 years. A dedicated project-specific website was also launched that housed information and links related to participating in the study.

Figure 1. Screenshots from the ACT Vet app: (left panel) Facebook project page, (middle panel) paid advertisement, and (right panel) flyer for ACT Vet.





Other Recruitment Strategies

Email addresses were collected from organization websites, and study details were sent. The research team carried out face-to-face meetings and visits with organizations such as the Forces in Mind Trust, National Health Service West Midlands Gambling Harms Clinic, the Royal British Legion, Combat Stress, Help for Heroes, Beacon Counselling Trust, GamFam, and GamCare. Physical and digital flyers (Figure 1, right panel) were created and circulated among organizations. Members of the research team also had personal contacts they used, including details of veterans who had previously agreed to participate in the study. Any veteran who agreed to take part was asked to encourage others who may have benefited from participating (snowball sampling).

The information regarding the recruitment source for each participant was documented and assigned a unique identifier, allowing the research team to track where participants had viewed and accessed the prescreening questionnaire (eg, Facebook, Prolific, or website). If eligible, previous military service numbers were also confirmed for the identification of spam or bots to ensure the integrity of the data. Unless provided by the recruitment platform, demographic information was collected at the baseline time point. Finally, it was advertised that, on completion of the 10-week program, each participant would be offered a high street voucher of £150 (US $189.77) for their time.

Measures and Analysis

Our primary outcome measures included advertisement duration in days, cost in GBP (and the USD equivalent), online market reach or armed forces audience criteria, online post link clicks, and online post shares and reactions. Please note that online market reach differs depending on when digital marketing campaigns are conducted because of the underlying Facebook or Meta analytics. Means and SDs were reported for the continuous variable (respondents' ages), and percentages and frequencies were reported for categorical variables.

Results

Online Recruitment

Facebook

From the dedicated Facebook page, posts were circulated in veteran and gambling-related groups. Paid advertisements were also circulated separately for a total of 27 days to reach veterans or those with connections to veterans aged 18 to 65 years in the United Kingdom. Facebook campaign key performance indicators provide the performance and cost breakdown of each advertisement campaign and are shown in Table 1.

XSL•FO
RenderX

Table . Key performance indicators (KPIs) for ACT Vet paid Facebook advertising.

KPI	Paid advertisement campaign number		
	1	2	3
Advertisement duration (days)	3	14	10
Cost, £ (US $)	5.00 (6.33)	100.00 (126.51)	177.70 (224.81)
Total reach (number of people)	1132	14,682	117,085
Number of link clicks	61	506	854
Cost per click, £ (US $)	0.08 (0.10)	0.20 (0.25)	0.21 (0.27)
Number of post shares	2	14	1
Number of post reactions	1	12	2

The first paid campaign was run as a test for 3 days and reached 1132 people (n=112, 9.89% female; n=1020, 90.1% male), of whom 340 (30.03%) were aged between 35 and 44 years, with 1114 (98.41%) viewing it on mobile devices. The second advertisement campaign reached a total of 14,682 people (n=3656, 24.9% female; n=11,026, 75.1% male), of whom 4405 (30%) were aged between 55 and 64 years, with 12,263 (83.52%) viewing it on mobile devices. The third advertisement campaign reached a total of 117,085 people (n=70,836, 60.5% female; n=46,249, 39.5% male); 35,126 (30%) were aged ≥65 years, with 67,326 (57.5%) being reached using the audience network (third-party apps such as Instagram or mobile games).

Facebook accounted for 7 participants who were eligible and consented through organic (without paid advertising) page or post interactions, with an additional 14 who were eligible and consented through paid advertising, which cost £20.19 (US $25.55) per consenting individual. Recruitment outcomes from paid Facebook advertising are shown in Table 2. In total, Facebook accounted for 21 eligible participants. Unless provided by the recruitment platform, demographic information was only collected at the baseline time point.

Table . Total recruitment outcomes across paid Facebook advertising and Prolific.

	Paid Facebook advertising	Prolific
Total cost, £ (US $)	282.70 (357.65)	157.50 (199.25)
Number of clicks or submissions	1421	71
Cost per click or submission, £ (US $)	0.49 (0.62)	0.75 (0.95)
Number of eligible consenting individuals	14	50

X (Formerly Known as Twitter)

Additionally, a dedicated X page was created and amassed 170 followers. The page consisted of 32 posts related to recruitment advertising and blog-type posts showing the research team's activities. The highest engagement was with a blog-type post with 419 views, followed by a recruitment advertisement with 328 views. No participants were directly recruited.

Instagram

An Instagram page was also created, which resulted in 16 followers. The page consisted of 4 posts designed to raise awareness of the project and recruit participants. The highest engagement was through 6 likes on a post circulating project awareness. No participants were directly recruited.

Prolific

The study also used Prolific. The built-in screening criteria of "UK military veteran" and "aged ≥18 years" were applied, yielding a total of 287 eligible participants who had been active in the previous 90 days on Prolific. The study recruitment target was set at 150 participants. Sensitive content warnings were given as the study involved topics related to mental health. Participants were paid £0.75 (US $0.95), the equivalent to £9.00 (US $11.39) per hour, for the 5 minutes it took to complete the prescreening questionnaire. The total cost (including fees and value-added tax) for the screening was £157.50 (US $199.25). From this screening, 71 submissions were made (n=63, 89% male; n=8, 11% female), with a mean age of 45 (SD 13.24) years. Of these 71 participants, 50 (70%) met the eligibility criteria and consented to be sent app codes, which cost, on average, £3.15 (US $3.99) per consented individual. Table 2 shows the total recruitment outcomes from Prolific. Recruitment ceased without meeting the target of 150 participants due to time constraints.

Website

The project-specific website (including domain hosting) was used as a platform for project dissemination and recruitment and was launched on January 8, 2024, and continued to function until the project end. Four eligible participants completed the prescreening.

Email

After collecting email addresses from organization websites, nearly 200 emails were sent. One eligible participant was recruited and consented to be sent app codes.

XSL•FO
RenderX

Face to Face

Throughout recruitment, a total of 15 veteran, charity, or clinical meetings (in person and online) related to military veterans or gambling across the United Kingdom were conducted. Contact with organizations was vital to raise awareness of the study and interact with the veteran community. One eligible participant consented to be sent app codes directly from a face-to-face meeting, whereas another participant consented to be sent app codes via word of mouth after a meeting.

Unknown

One participant accessed the prescreening questionnaire directly, and the recruitment strategy could not be identified.

Study Attrition and Sample Characteristics

Figure 2 shows the attrition from initial screening to week 10, and the completed time points are split by recruitment source. A total of 35 participants (n=31, 89% male; n=3, 9% female; and n=1, 3% undisclosed) completed in-app baseline time points, and 1 (3%) participant formally withdrew from the study. The mean age was 44.77 (SD 10.89) years, and all participants (35/35, 100%) were of White British ethnicity, with 49% (n=38) having a diagnosis of PTSD and none having a *DSM-5* diagnosis of gambling disorder. A total of 24 participants (n=21, 88% male; n=2, 8% female; and n=1, 4% undisclosed) with a mean age of 45.29 (SD 10.70) years finished the week 10 time points and had a mean PTSD Checklist for the DSM-5 score of 40.92 (SD 20.12) and mean Problem Gambling Severity Index score of 5.47 (SD 3.59), indicating moderate risk of problem gambling. According to responses to the mHealth App Usability Questionnaire, participants provided high ratings of usability (mean 6.09, SD 0.76; range 4.18-7.00), indicating that the app was liked by veterans.

Discussion

Principal Findings

This paper outlines recruitment and retention strategies used for ACT Vet, a smartphone digital intervention for UK military veterans with PTSD and harmful gambling. Overall, Facebook (both unpaid and paid advertising) and Prolific were the most effective strategies for recruiting eligible participants. The combined alternative recruitment methods (hub visits, meetings, emails, and website) allowed for building interdisciplinary networks among researchers, service users, and practitioners but resulted in few participants. Challenges throughout recruitment remained and included low conversion rates from social media advertising, spam or bots, ineligible participants, participant attrition, and missing questionnaire time points. However, app usability ratings were high, and the app was well received.

Social media was effective in recruiting eligible participants, aligning with previous findings [30,32-34]. In this study, although we only ran brief advertisement campaigns, Facebook outperformed traditional strategies in the recruitment of eligible veterans. However, there was a noteworthy difference in link clicks through to eligible consent using paid Facebook advertising. Most of those who showed initial interest by clicking the advertisement link (n=1421) did not proceed through to eligible consent (n=1407, 99.01%). Even so, as evidenced by these results and highlighted by Aily et al [33], a low conversion rate from Facebook paid advertising can still contribute to a cost-effective recruitment strategy.

Prolific was also effective in recruiting and retaining eligible military veterans. Most of those who completed final questionnaire time points were recruited via Prolific (n=19, 79%) and helped the study access secondary categories of groups that may be hard to reach [39]. Prolific was also the most cost-effective compared to all other strategies. This is in line with previous work that argues that Prolific can be cost-effective and reliable for high-quality data [40,41]. Hence, our study shows that the combination of Facebook and Prolific is important in recruiting for clinical research, particularly military veterans with co-occurring PTSD and harmful gambling.

Challenges

Notwithstanding the aforementioned advantages to the approaches used, we did encounter some recruitment and retention challenges. Few veterans were recruited through strategies such as face-to-face meetings, emails, or visits to organizations. Veterans can take up to 11 years to access support services and may face significant barriers and stigmatization when accessing treatment [1,3], which may have contributed to the limited interaction observed in this study. However, due to the anonymous nature of this study, it was difficult to measure whether more veterans who later accessed the online information were recruited because of our in-person visits. For this reason, it is advisable that future digital or online interventions maintain a physical presence among service users, charities, and hubs to build in-person networks and raise further awareness. Moreover, future recruitment initiatives should consider ensuring that long-term strategies and resources are dedicated to developing engaging content and other in-person activities with veterans.

In addition, the reliance on social media resulted in many spam responses and unreliable data, which may have contributed to the large attrition rate. Even among eligible participants, close to half (n=39, 49%) did not respond after requesting and being sent individualized app codes and did not go on to complete baseline measurements. These participants could not be contacted and, therefore, were considered to have withdrawn. Similar instances of attrition have been noted in UK-based military veteran digital interventions that have used social media for recruitment [19,20] and are considered a key challenge in clinical mHealth research. As recommended by Parkes et al [20], future work using social media for recruitment should also ensure that additional strategies and resources are made available to counteract any attrition from social media recruitment.

Data attrition inevitably resulted when participants did not complete required questionnaires when requested. This led to variation between program time and data points. In this study, there was an overall decrease in completion of all measures from baseline to each time point, yet the final week, week 10, had more completions than interim weeks such as weeks 4 and 6. One reason for this could be that participants stopped using ACT Vet after all steps had been completed within the app by the week 4 time point. While push notifications and email reminders were sent, this study still experienced a decrease in completed measures during those weeks. The opportunity to provide week 10 data was provided using an email link after a lengthy period despite also being the final time point, which may have resulted in an increased response rate. Thus, if the program length extends past the intervention length (ie, in study designs with extended follow-up), attrition is likely to occur without targeted initiatives to increase engagement.

A final retention challenge may have inadvertently stemmed from offering remuneration in a single large amount at the end of the study. That is, attrition may have been reduced had we adopted a progressive or escalating schedule of payments similar to those used in research on incentivized treatment attendance or adherence to interventions for related addictive behaviors [44]. This possibility warrants consideration in future mHealth intervention research.

Limitations

There were some limitations to the recruitment and retention methods we used. First, participants recruited through Prolific were self-selected, which may increase the likelihood of bias and decrease the likelihood of obtaining a representative sample [35]. Despite this, data integrity measures were implemented throughout, such as requiring service numbers as evidence of veteran status and validating data quality. Second, as found in similar recruitment efforts, the use of online media platforms may have excluded veterans without social media or with limited experience using technology [32]. However, this study implemented mitigating strategies to reduce these issues [30]. Third, the range of colors, imagery, and designs used for the project-specific branding may have resembled army branding (ie, army green and camouflage patterns). There is a possibility that this branding impacted recruitment of veterans from other

XSL•FO
RenderX

services such as the Royal Navy and the Royal Air Force, both of which have unique colors and branding. Finally, 89% (n=31) of all eligible recruited participants were male, which resulted in an underrepresentation of female veterans. Although female representation in the regular UK armed forces increased by 11.7% in 2024 [45], the veteran criteria for ACT Vet likely resulted in a sample that reflected representation in the UK armed forces, as previously noted by Williamson et al [32]. Furthermore, men are considered at high risk of harmful gambling [46], which may have contributed to the sex variance observed.

Conclusions

In conclusion, our findings showed the effectiveness of social media and online platforms compared to additional recruitment strategies in line with previous findings and recommendations for mHealth recruitment [30,33,34], particularly for military veterans [32]. Furthermore, these findings can be extended to populations with comorbid conditions, such as veterans with both PTSD and harmful gambling. In this paper, we offer some key recommendations for future recruitment efforts. First, face-to-face meetings and visits should be organized as early as possible to strengthen interdisciplinary relationships and networks, but they should not be solely relied upon for recruitment. Second, a strong online presence should be built across various platforms, and unpaid and paid strategies should be used. This will assist in project awareness and recruitment from populations that may be hard to reach, such as those with PTSD and harmful gambling. Finally, increased efforts should be made to diversify branding and advertising. For military veteran research, this should reflect all 3 UK regular armed forces services (Army, Royal Navy, and Royal Air Force), which, in turn, may also lead to an increase in participation from female veterans with comorbid disorders. It is hoped that these findings inform future recruitment initiatives in veteran and gambling research and mHealth research more broadly.

Acknowledgments

The authors are grateful to the national veterans' service charities and Dr Catherine Hitch for their input.

Funding

This study was funded by an award made from the Office for Veterans' Affairs (Veterans' Health Innovation Fund) in 2023 to SD, DL, and DM as part of an independent research initiative by the then UK government. The views, findings, and conclusions expressed herein are those of the authors and do not reflect the policies or positions of the UK government.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to the sensitive nature of the data but are available from the corresponding author on reasonable request.

Abstract

Background: The expansion of mobile health app or apps has created a growing need for structured and predictive tools to evaluate app quality before deployment. The Mobile App Rating Scale (MARS) offers a standardized, expert-driven assessment across 4 key dimensions—engagement, functionality, aesthetics, and information—but its use in forecasting user satisfaction through predictive modeling remains limited.

Objective: This study aimed to investigate how k-means clustering, combined with machine learning models, can predict user ratings for physical activity apps based on MARS dimensions, with the goal of forecasting ratings before production and uncovering insights into user satisfaction drivers.

Methods: We analyzed a dataset of 155 MARS-rated physical activity apps with user ratings. The dataset was split into training (n=111) and testing (n=44) subsets. K means clustering was applied to the training data, identifying 2 clusters. Exploratory data analysis included box plots, summary statistics, and component+residual plots to visualize linearity and distribution patterns across MARS dimensions. Correlation analysis was performed to quantify relationships between each MARS dimension and user ratings. In total, 5 machine learning models—generalized additive models, k-nearest neighbors, random forest, extreme gradient boosting, and support vector regression—were trained with and without clustering. Models were hypertuned and trained separately on each cluster, and the best-performing model for each cluster was selected. These predictions were combined to compute final performance metrics for the test set. Performance was evaluated using correct prediction percentage (0.5 range), mean absolute error, and R^2. Validation was performed on 2 additional datasets: mindfulness (n=85) and older adults (n=55) apps.

Results: Exploratory data analysis revealed that apps in cluster 1 were feature-rich and scored higher across all MARS dimensions, reflecting comprehensive and engagement-oriented designs. In contrast, cluster 2 comprised simpler, utilitarian apps focused on basic functionality. Component+residual plots showed nonlinear relationships, which became more interpretable within clusters. Correlation analysis indicated stronger associations between user ratings and engagement and functionality, but weaker or negative correlations with aesthetics and information, particularly in cluster 2. In the unclustered dataset, k nearest neighbors achieved 79.55% accuracy, mean absolute error=0.26, and R^2=0.06. The combined support vector regression (cluster 1)+k-nearest neighbors (cluster 2) model achieved the highest performance: 88.64% accuracy, mean absolute error=0.27, and R^2=0.04. Clustering improved prediction accuracy and enhanced alignment between predicted and actual user ratings. Models also generalized well to the external datasets.

Conclusions: The combined clustering and modeling approach enhances prediction accuracy and reveals how user satisfaction drivers vary across app types. By transforming MARS from a descriptive tool into a predictive framework, this study offers a scalable, transparent method for forecasting user ratings during app development—particularly useful in early-stage or low-data settings.

Introduction

The Mobile App Rating Scale (MARS) is a tool designed to assess the quality of mobile health apps [1]. It was developed to meet the increasing demand for a standardized and reliable method for app evaluation. This 23-item, 5-point rating system evaluates aspects such as user engagement (engagement), feature performance (functionality), visual design (aesthetics), content accuracy (information), and overall satisfaction, providing a holistic assessment to identify high-quality apps [2].

Although MARS has been widely used to quantify app quality across various categories [3-11], no study has yet explored its potential to predict app user ratings—a key indicator of an app's popularity and perceived value. User ratings are meaningful because they reflect the aggregated experiences of the user base and often influence app visibility, downloads, and credibility in app store ecosystems. Exploring how MARS scores relate to these ratings could offer insights into the underlying drivers of user satisfaction and support more informed design and evaluation decisions.

This work builds upon our previous research in which we applied k-means clustering to MARS-rated drug-drug interaction apps [12]. That study revealed that the correlation between MARS dimensions and user ratings varied significantly across app clusters. In some groups, functionality was most strongly associated with user ratings, while in others, dimensions like engagement or information played a larger role. These findings highlighted that relationships between expert scores and user feedback are not uniform but highly context-dependent. Clustering enabled the identification of feature-based subgroups aligned with distinct satisfaction profiles—reinforcing the value of segmentation when interpreting MARS-based evaluations.

Complementary work by Aziz et al [13] and Mertens et al [14] also demonstrated the value of clustering in understanding user behavior and engagement in mobile interventions. Aziz et al identified behavioral archetypes based on app usage and personality traits, while Mertens et al showed that user impact varies depending on engagement profiles over time. Although these studies focus on clustering users rather than apps, they reinforce a common insight: segmentation enhances our understanding of satisfaction drivers.

Alternatively, other researchers have pursued bottom-up strategies for quality assessment that rely on postlaunch user data. For example, Haoues et al [15] used machine learning and natural language processing on user reviews within the International Organization for Standardization or International Electrotechnical Commission 25010 framework to assess app quality. While these methods can capture sentiment and usability themes, they require large volumes of user feedback—often unavailable in early-stage development.

Building on these findings, our study combines unsupervised clustering and supervised machine learning to predict app store user ratings based on expert-evaluated app quality dimensions. By segmenting apps into meaningful groups and training cluster-specific models, we aimed to improve prediction accuracy and uncover which MARS dimensions matter most in each context. This top-down approach enables forecasting of user satisfaction before release, making it particularly valuable in low-data settings. Ultimately, it offers developers a proactive, scalable framework to anticipate user expectations and optimize app design before launch.

Methods

Reporting Standards

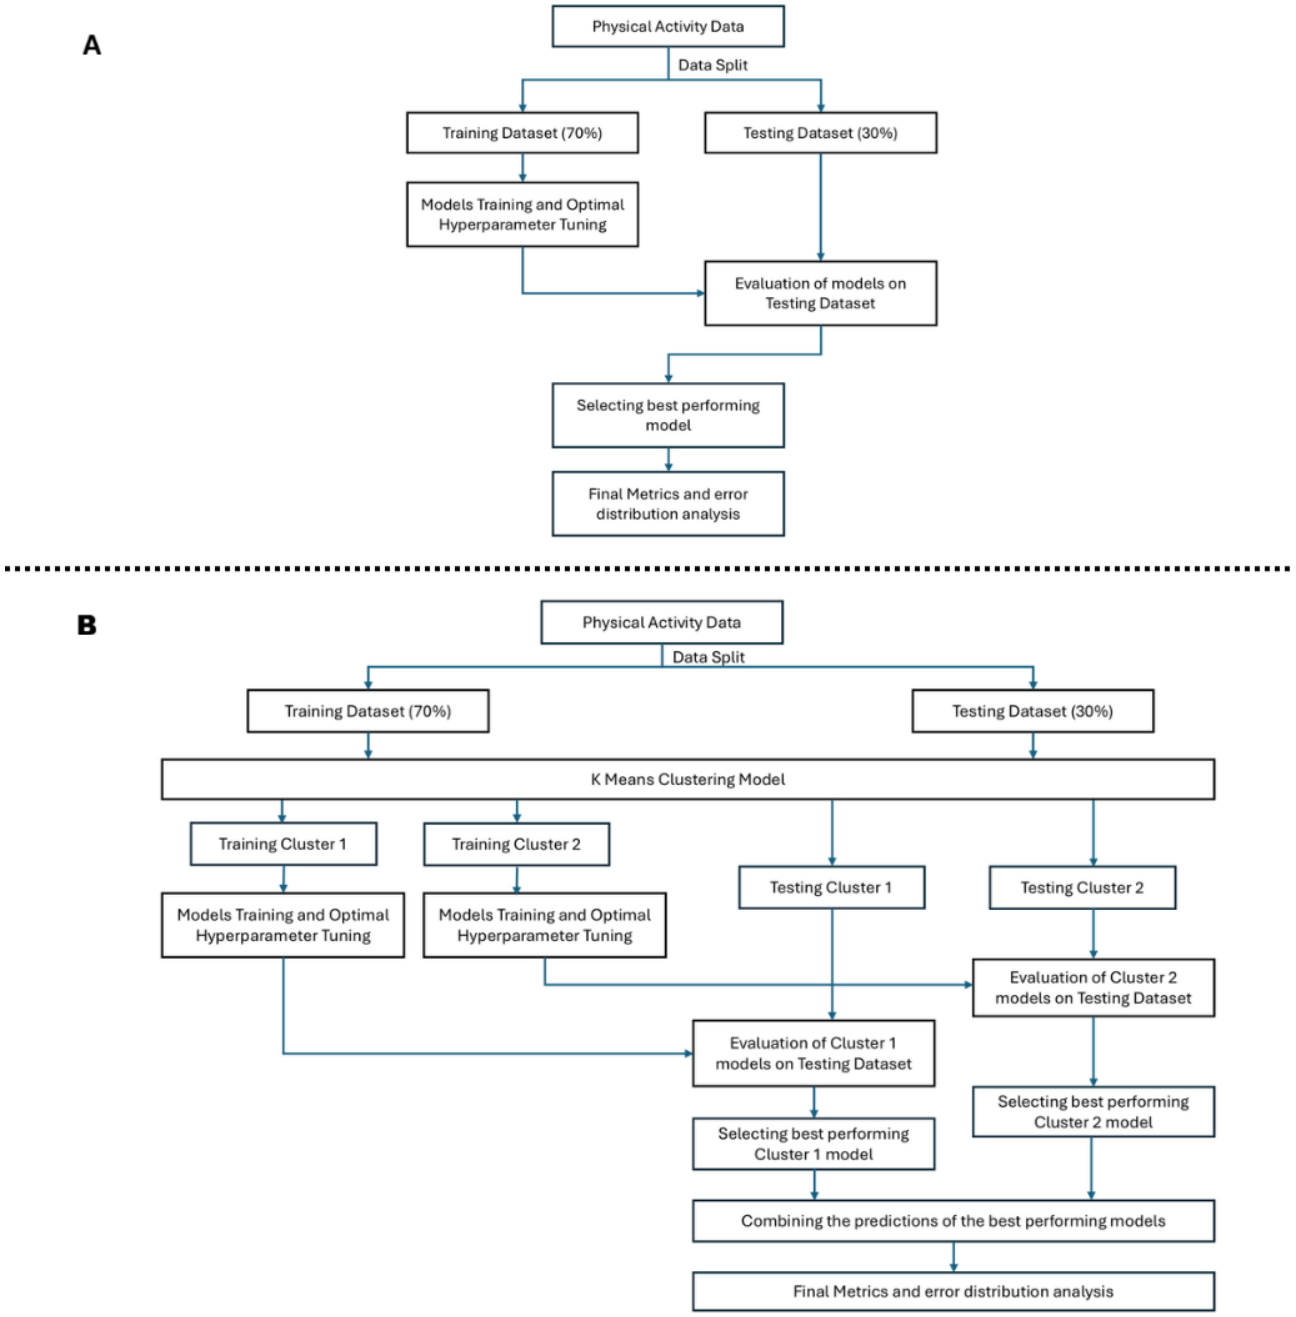
This study adheres to the Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis (TRIPOD) [16] guidelines to ensure comprehensive and transparent reporting of prediction model development and evaluation.

Data Source and Eligibility Criteria

This study uses physical activity app data originally compiled by Paganini et al [3] and made accessible by Terhorst et al [17]. The dataset included item-level MARS scores previously evaluated and published by the original authors as part of their systematic app evaluation studies, with complete assessments by trained experts. No new MARS evaluations were conducted. Since the objective of this study was to examine the predictive utility of MARS scores in relation to user ratings, we worked directly with the original reported scores to maintain analytical neutrality and avoid introducing evaluator bias. Of the 312 apps in the dataset, 155 had complete MARS evaluations and corresponding user ratings and were included in the analysis. Apps with missing data for any dimension or user rating were excluded using a complete-case approach, with no imputation performed. Figure 1 illustrates the overall workflow of the study, with Figure 1A depicting the modeling process without clustering and Figure 1B showing the process incorporating clustering.

XSL•FO
RenderX

Figure 1. Workflow for predictive modeling (1A) without clustering (1B) with K-means clustering.



Outcome and Predictor Variables

The outcome variable was the average user rating on a scale from 1 to 5. Predictor variables included the 4 MARS dimensions: engagement, functionality, aesthetics, and information. No transformations or standardization were applied to the predictor variables.

Exploratory Data Analysis

The dataset was first divided into training (111/155, 70%) and testing (44/155, 30%) sets. The training dataset was used for exploratory data analysis (EDA) and training the k-means and prediction models, while the testing dataset was held out for final model evaluation. During the EDA phase, we examined the relationships between user ratings and the 4 MARS dimensions. We visualized distribution patterns using box plots, which provided insights into the central tendencies and variability across the dimensions. In addition, we created a summary table to present descriptive statistics for each dimension, including the mean, median, 25th and 75th percentiles, range, minimum, and maximum values [12,18]. We then generated component+residual plots for each MARS dimension to better understand the data patterns and guide the selection of appropriate modeling techniques [19]. In these plots, the blue line represents the fitted values showing the main trend between the predictor and user ratings, while the pink line provides a smoother fit, highlighting any deviations or nonlinear relationships. Finally, we conducted a correlation analysis to quantify the strength and direction of associations between each MARS dimension and user ratings, highlighting dimensions with the most significant impact on user satisfaction [12].

XSL•FO
RenderX

Model Development and Hyperparameter Tuning

We applied 5 machine learning models: generalized additive models (GAM), k-nearest neighbors (KNN), random forest (RF), extreme gradient boosting (XGBoost), and support vector regression (SVR). Each model was selected for its unique approach to capturing different data patterns: GAM for handling potential nonlinear relationships [20], KNN for proximity-based prediction by averaging ratings of similar apps [21], RF as an ensemble approach combining multiple decision trees to improve accuracy [22], XGBoost for its boosting techniques that enhance prediction accuracy [23], and SVR for determining the optimal hyperplane to separate groups effectively [24].

Hyperparameter tuning for each of the 5 models was conducted using 5-fold cross-validation on the training dataset [25], optimizing the models for the best predictive performance. For GAM, tuning involved adjusting the number of knots in the smoothing splines to capture different levels of nonlinearity [26]. For KNN, a range of k values was evaluated to find the optimal number of neighbors [27]. For RF, the number of randomly selected features at each split was tuned to balance model depth and generalization [23]. For XGBoost, the number of boosting rounds, learning rate, and tree depth were optimized [23]. SVR tuning involved testing different combinations of cost and gamma parameters to optimize the margin of tolerance and the influence of individual data points [24]. The best hyperparameters were selected based on achieving the highest percentage of correct predictions (within a 0.5 range), the lowest mean absolute error (MAE), and the highest R^2 values [28]. After identifying the optimal hyperparameters, the models were evaluated on the testing dataset using the same metrics. All analyses were conducted using the latest version of RStudio.

Clustering Analysis

To further refine the predictive modeling, we incorporated k-means clustering as a preprocessing step, grouping the apps into clusters based on their MARS scores. This approach aimed to capture more nuanced relationships between app characteristics and user ratings [12]. The optimal number of clusters was determined using an elbow plot, which identifies the point where the within-cluster sum of squares (WCSS) shows a diminishing return with increasing clusters [12,29]. Although widely used, this method involves a degree of subjectivity, as identifying the inflection point in the curve relies on visual interpretation.

Cluster-Specific Modeling

To characterize the clusters identified through k-means, we performed a second round of EDA, mirroring the initial steps conducted on the entire training dataset. Following the EDA, the machine learning models were applied separately to each cluster, with hyperparameter tuning conducted individually for each cluster to ensure optimal model performance. This cluster-specific approach aimed to better capture the unique relationships between MARS scores and user ratings within each group.

The testing dataset was segmented using the trained k-means clustering model to allocate each data point to the appropriate cluster. Each cluster-specific model was then tested on its respective cluster within the testing dataset, using the same evaluation metrics as before.

Combined Prediction and Performance Evaluation

To assess the overall effectiveness of the clustering-based approach, predictions from the best-performing models were consolidated to compute the overall metrics for the entire testing dataset. The best model for each cluster was selected based on the highest correct prediction percentage, the lowest MAE, and the highest R^2 value. Predictions from each cluster's best model were combined to calculate the final overall metrics for the entire testing dataset. This enabled the direct comparison of outcomes of the model's performance with and without the clustering step.

Scatter plots of actual versus predicted user ratings, with a 0.5 tolerance band, were used to visually assess alignment across the test set for both unclustered and clustered models. The diagonal line in each plot indicates where predicted ratings equal actual ratings. We also analyzed the distribution of prediction accuracy across error ranges, which provided deeper insights into how many apps were accurately predicted within each range. These distributions were visualized using bar plots.

Model Generalizability Across App Categories

To validate our model's generalizability, we applied the same clustering and modeling approach to 2 additional datasets: mindfulness [4] and older adults [6] apps. The process of evaluation remained the same, with clustering, hyperparameter tuning, and model evaluation performed as previously described.

Ethical Considerations

This study did not involve human participants, patient data, or identifiable information. The analysis was limited to publicly available mobile applications and datasets. Institutional review board approval was not required, and informed consent was not applicable.

Results

K Means Clustering

The knee plot, shown in Figure 2, illustrates the relationship between the number of clusters and the WCSS. As the number of clusters increases, the WCSS decreases, indicating that data points are more tightly grouped within each cluster [12]. However, beyond 2 clusters, the rate of decrease in WCSS slows significantly, marking an "elbow" point. This suggests that adding more clusters beyond 2 provides diminishing returns in compactness. Thus, selecting 2 clusters was deemed optimal, as it balances the trade-off between data cohesion within clusters and the simplicity of the model structure.

EDA

Data Distribution

The EDA began by examining the distributions of the 4 MARS dimensions and user ratings without applying clustering. The box plots (Figure 3) for the "Without Clustering" group showed centralized distributions across all dimensions, with some variability, particularly in engagement (range=3.80) and aesthetics (range=4.00). These findings provided a baseline understanding of the training dataset's characteristics.

Application of k-means clustering resulted in 2 clusters: cluster 1 with 62 apps (55.9%) and cluster 2 with 49 apps (44.1%). The trained clustering model was then used to assign the testing apps to clusters, resulting in 21 apps in cluster 1 and 23 in cluster 2. Although the distribution is slightly imbalanced, both clusters retained sufficient size in both the training and testing sets to support reliable model training and evaluation. We then re-evaluated the distributions for each dimension and user rating within each cluster, as shown in the box plots (Figure 3) and summary statistics table (Table 1). Cluster 1 consistently exhibited higher medians across all dimensions—engagement (3.80), functionality (4.38), aesthetics (4.00), and information (3.42)—compared to cluster 2, which had corresponding medians of 2.40, 3.62, 3.00, and 2.75, respectively. These results suggest that cluster 1 apps, based on MARS evaluations, demonstrate stronger quality features than cluster 2, which includes lower-rated apps. The "Without Clustering" analysis produced average scores that fell between the 2 clusters.

Training data sample size (Cluster 1), (n=62)			
Engagement	3.84 (0.55)	3.80 (3.50-4.30)	2.10 (2.90-5.00)
Functionality	4.42 (0.43)	4.38 (4.15-4.75)	1.75 (3.25-5.00)
Aesthetics	4.05 (0.51)	4.00 (3.71-4.33)	2.00 (3.00-5.00)
Information	3.32 (0.47)	3.42 (3.13-3.60)	2.15 (2.25-4.40)
User ratings	4.56 (0.27)	4.50 (4.50-4.70)	1.10 (3.90-5.00)
Training data sample size (Cluster 2), (n=49)			
Engagement	2.46 (0.61)	2.40 (2.10-3.00)	2.40 (1.20-3.60)
Functionality	3.62 (0.62)	3.62 (3.12-4.12)	2.62 (1.88-4.50)
Aesthetics	2.80 (0.67)	3.00 (2.50-3.33)	3.17 (1.00-4.17)
Information	2.62 (0.55)	2.75 (2.38-3.00)	2.25 (1.17-3.42)
User ratings	4.32 (0.44)	4.50 (4.10-4.50)	2.50 (2.50-5.00)

Component+Residual Plots

From the component+residual plots of the unclustered analysis (Figure 4A), residuals appear widely dispersed (–2.0 to +1.0) across all dimensions, with only subtle trends. Engagement (1.20 to 5.00) shows a slight positive relationship with user ratings, while functionality (1.88 to 5.00) displays an initial upward trend in residuals up to around 4.0, then plateaus—suggesting diminishing returns at higher scores. In contrast, aesthetics (1.00 to 5.00) and information (1.17 to 4.40) show a negative trend, indicating inverse associations with user ratings. These generalized, nonlinear patterns reflect the broad variability of app characteristics in the training dataset, especially for aesthetics (range=4.00) and engagement (range=3.80).

In Cluster 1 (Figure 4B), residuals were more consistent and compact across all dimensions (–0.6 to +0.4), reflecting the group's overall uniformity. Engagement (2.90 to 5.00) showed an initial upward trend that plateaued beyond approximately 4.3, while functionality (3.25 to 5.00) also rose early before flattening after 4.5—indicating nonlinear associations with user ratings. Aesthetics (3.00 to 5.00) displayed a complex curve, dipping, then rising, then falling again. Information (2.25 to 4.40) followed a similar nonlinear pattern, declining first, then increasing, and eventually leveling off around 3.5 - 4.0. These results suggest that although cluster 1 is more cohesive, relationships between MARS dimensions and user ratings remain complex.

In cluster 2 (Figure 4C), residuals showed greater variability with values ranging from approximately –1.5 to +0.5. Engagement (1.20 to 3.60) showed a downward trend, between 2.0 and 3.2, indicating a weak negative association with user ratings. Functionality (1.88 to 4.50) and aesthetics (1.00 to 4.17) exhibited slight upward trends, between 2.5 - 4.0 and 2.0 - 3.5, respectively, indicating modest positive associations. Information (1.17 to 3.42) showed a nonlinear pattern—increasing initially up to 2.6, then declining beyond 2.8—suggesting that high Information scores may correspond to lower user ratings. These findings highlight greater heterogeneity and less stable patterns in cluster 2, reinforcing the need for distinct modeling approaches between clusters.

In summary, the unclustered data shows weak and scattered associations. Cluster 1 reveals cohesive but complex nonlinear patterns across all dimensions. Cluster 2 shows more variability, with modest positive trends in functionality and aesthetics.

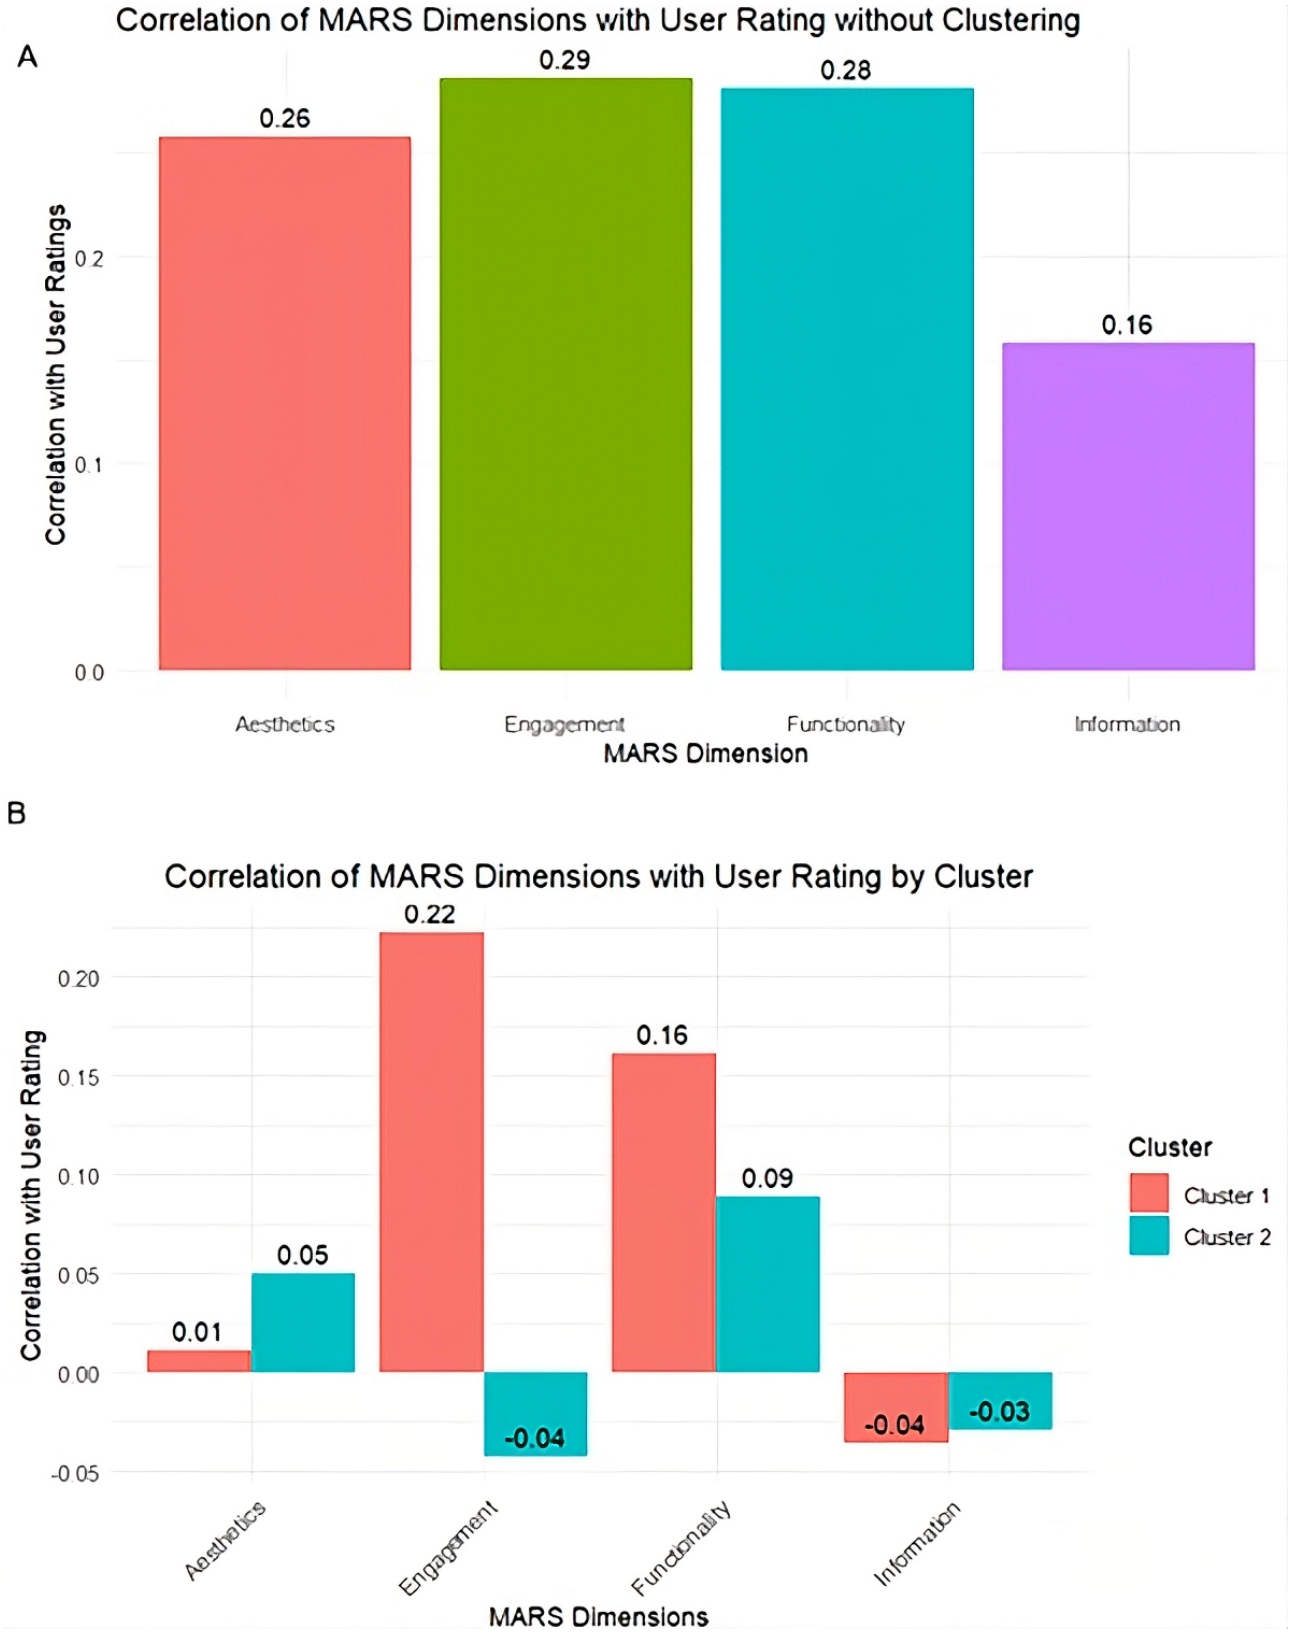
Correlation Analysis

Correlation analysis between MARS dimensions and user ratings (Figure 5) revealed different patterns when comparing the unclustered dataset to the segmented clusters. In the unclustered analysis (Figure 5A), engagement and functionality show positive correlations with user ratings, at 0.29 and 0.28, respectively, indicating a moderate association. Aesthetics follows with a correlation of 0.26, while information has the lowest correlation with user ratings at 0.16. These findings suggest that, across the entire dataset, engagement and functionality are the primary drivers of user satisfaction.

Figure 5. Correlation of MARS dimensions with user rating (5A) without clustering (5B) with clusters. MARS: Mobile App Rating Scale.



XSL•FO
RenderX

Within the clusters (Figure 5B), correlations appear less pronounced. In cluster 1, engagement has the highest correlation (0.22), followed by functionality (0.16). Aesthetics and information show minimal or no correlation, at 0.01 and -0.04, respectively. This indicates that while engagement and functionality remain relevant in cluster 1, their influence is weaker compared to the unclustered data.

In cluster 2, correlations are uniformly weak. Engagement (–0.04) and information (–0.03) show negative correlations, while aesthetics (0.05) and functionality (0.09) exhibit weak positive associations. These findings suggest that in cluster 2, no single MARS dimension strongly influences user ratings, pointing to a user base whose satisfaction may depend on factors outside the scope of MARS, or potential misalignment between expert evaluations and user perceptions.

Predictions

Table 2 presents the final hyperparameter settings selected for each model and cluster. Table 3 summarizes the predictive performance of the models across the testing dataset and within each cluster.

Without clustering, KNN and SVR achieved the highest correct prediction percentage at 79.55%, both maintaining relatively low MAEs (0.26 and 0.29, respectively). GAM also performed reasonably well with 77.27% accuracy and the lowest MAE (0.25). RF and XGB showed weaker performance, with lower correct prediction percentages (72.72%) and negative R^2 values (−0.19), indicating poor model fit for these models. KNN was selected as the best-performing model without clustering due to its lower MAE of 0.26 and higher *R*-square of 0.06, compared to SVR's MAE of 0.29 and *R*-square of −0.13.

Table . Tuned hyperparameters by model type and cluster.

Cluster 2, (n=17)			
GAM	88.24	0.29	−0.05
KNN	88.24	0.28	0.03
RF	82.35	0.34	−0.45
XGB	64.71	0.43	−1.26
SVR	88.24	0.28	−0.04
Combined cluster model, (n=44) SVR+KNN	88.64	0.27	0.04

[a]MAE: mean absolute error.

[b]GAM: generalized additive models.

[c]KNN: K-nearest neighbors

[d]RF: random forest.

[e]XGB: extreme gradient boosting.

[f]SVR: support vector regression.

In Cluster 1, SVR delivered the highest accuracy, achieving an 88.89% correct prediction rate and an MAE of 0.27. This model was closely followed by GAM and KNN, both achieving 85.19% accuracy, with GAM having a slightly lower MAE (0.24). For RF and XGB, the performance dropped, with RF showing a correct prediction percentage of 81.48% and XGB at 77.78%. The R^2 values indicate a better model fit within this cluster, especially for GAM and KNN, which displayed positive R^2 values, while RF and XGB struggled, showing low or negative values. SVR was selected as the best-performing model for cluster 1.

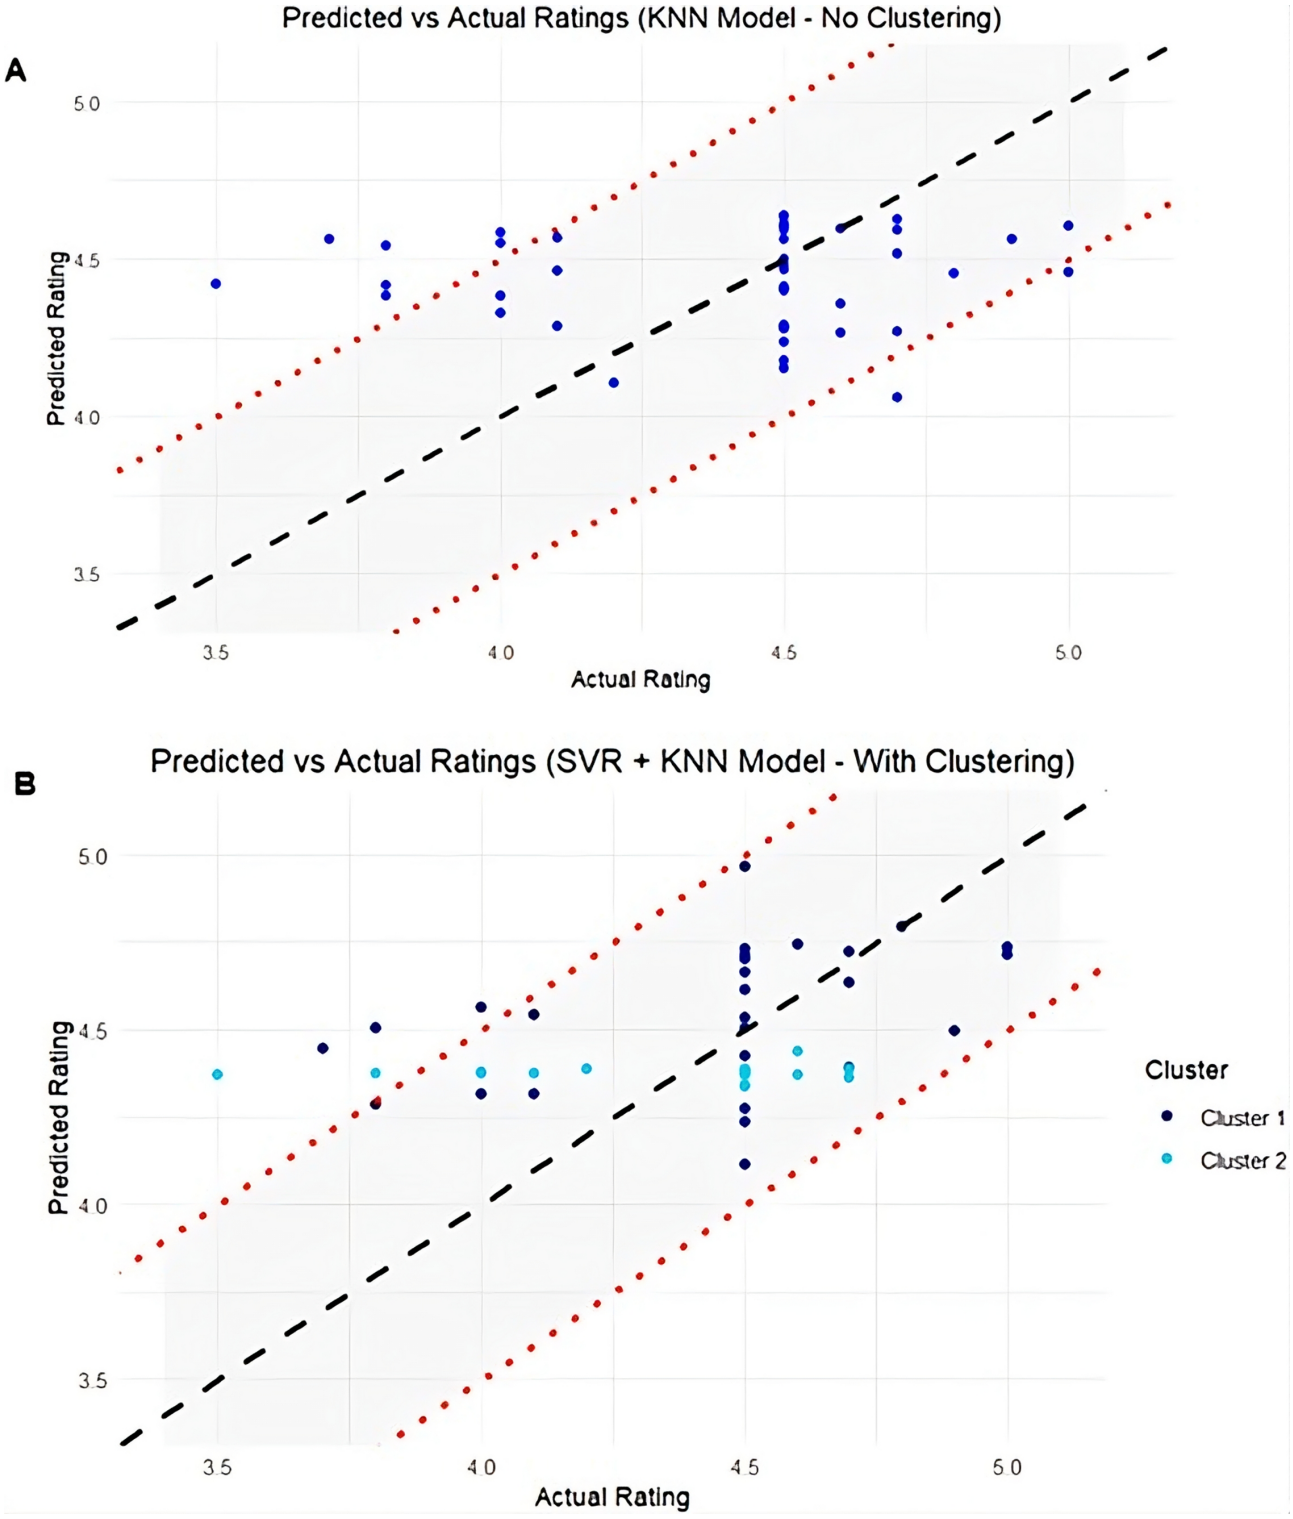
In cluster 2, SVR, KNN, and GAM achieved the same prediction accuracy, each at 88.24%. RF and XGB showed notable drops in performance, with XGB achieving the lowest accuracy (64.71%) and a high negative R^2 (−1.26), indicating poor fit and low predictive reliability within this cluster. KNN was selected as the best-performing model due to its lower MAE (0.28) and a positive R^2 (0.03), compared to GAM's MAE of 0.29 and R^2 of −0.05, and SVR's MAE of 0.28 and R^2 of −0.04.

The best-performing models from each cluster—SVR from cluster 1 and KNN from cluster 2—were selected, and their predictions were combined to compute the final metrics for the entire testing dataset. This combined approach achieved an improved overall correct prediction percentage of 88.64% outperforming the best unclustered data model, KNN, which achieved 79.55% accuracy.

To evaluate prediction alignment, we plotted actual versus predicted user ratings across the full test set for both the unclustered and clustered approaches (Figure 6). The unclustered KNN model (Figure 6A) exhibited wider deviations, particularly for lower and higher actual ratings. Two apps were underpredicted, and seven were overpredicted. In contrast, the cluster-based SVR+KNN model (Figure 6B) showed closer alignment with the actual values, with a greater number of predictions falling within the 0.5 tolerance band. Five apps were overpredicted, with 3 belonging to cluster 1 and 2 to cluster 2. This indicates improved accuracy and consistency following the clustering step.

XSL•FO
RenderX

Figure 6. Comparison of actual versus predicted user ratings (6A) KNN model predictions without clustering (6B) Combined SVR and KNN model predictions following clustering. KNN: k-nearest neighbors; SVR: support vector regression.



The error distribution plots (Figure 7) show the extent of prediction deviations across models. In the unclustered KNN model (Figure 7A), 2 apps had errors between −1 to −0.5, 35 were within the −0.5 to 0.5 range, and 7 had errors between 0.5 to 1. In comparison, the clustered SVR+KNN model (Figure 7B) showed improved precision, with 39 apps within the −0.5 to 0.5 range and only 5 apps falling in the 0.5 to 1 range.

Further to assess generalizability, the clustering-based modeling framework was validated on 2 external datasets: mindfulness apps (n=85) and older adult apps (n=55). In both cases, clustering either matched or outperformed the best-performing unclustered models. For the mindfulness dataset, the combined SVR+XGB cluster model achieved the highest overall accuracy (66.67%), a lower MAE (0.46), and a positive R^2 (0.07)—improving upon the best unclustered model (SVR), which had a negative R^2 (–0.06). Notably, cluster 2 models outperformed cluster 1, with XGB achieving an R^2 of 0.40, indicating that meaningful patterns emerged when segmenting

XSL•FO
RenderX

the apps. For the Elderly dataset, the combined KNN-based cluster model produced the best results, with 73.34% accuracy, an MAE of 0.48, and a positive R^2 (0.12)—surpassing the unclustered RF model, which had an R^2 of –0.08. Full results of both datasets are detailed in the Multimedia Appendix 1.

Discussion

Principal Findings

This study evaluated whether MARS scores could be used to predict user ratings through a clustering-based machine learning approach. The combined SVR+KNN model outperformed unclustered models, with higher accuracy and lower error. Clustering revealed distinct satisfaction patterns across app types and improved prediction alignment. These findings suggest that expert-driven MARS evaluations, when paired with data-driven modeling, can effectively forecast user satisfaction and ratings before app release.

In the unclustered dataset, MARS scores tended to average out, potentially obscuring the influence of specific features. Clustering enabled a deeper examination by isolating distinct subgroups, revealing more nuanced relationships between app characteristics and satisfaction—reflecting the diverse feature priorities among physical activity app users.

Cluster 1, characterized by higher mean scores across all MARS dimensions, appears to represent apps that align closely with user expectations by delivering a balanced, comprehensive experience. Users in this cluster may value features such as personalized workout recommendations, progress tracking, interactive challenges, or goal-setting tools [30-33]. These attributes contribute to a well-rounded app experience, where multiple dimensions—such as engagement through interactive features and functionality through reliable tracking—enhance overall satisfaction as reflected in the correlation analysis (Figure 5) with user ratings.

Conversely, cluster 2 exhibited lower scores across all MARS dimensions, likely representing simpler, function-focused apps. Residual plots (Figure 4C) showed negative patterns for engagement and information and modest positive trends for functionality and aesthetics—indicating that only certain dimensions influenced user ratings. Correlation analysis (Figure 5B) further supported this, revealing weak or negative associations for most dimensions, with functionality showing the strongest correlation. These patterns suggest that users in this segment prioritize basic features such as step counting, activity logging, or workout timers, with less emphasis on visual design or interactive elements [30-33].

Notably, the median user rating for the unclustered dataset, as well as for both clusters, remained consistent at 4.5 (Table 1), indicating a shared baseline of high satisfaction across groups, despite the lower MARS dimension scores observed in cluster 2. This indicates that functional adequacy alone may drive satisfaction for utilitarian apps, even when MARS scores are lower. This observation aligns with previous research showing that user expectations vary by app context. For example, Portenhauser et al [6] found that older adults prioritize simplicity, while Mani et al [4] noted that mindfulness app users emphasize content credibility. These findings also resonate with our earlier work on drug-drug interaction apps [12], which showed that the relationship between MARS dimensions and user satisfaction varied across clusters. Collectively, these results reinforce that no single MARS dimension universally predicts user satisfaction; instead, the relevance of each dimension depends on the app's functional scope and the expectations of its target audience.

From the correlation analysis, we observe that only certain MARS dimensions—particularly engagement and functionality—consistently correlate with user ratings, though the strength of these associations varies by cluster. This raises the broader question of how well expert evaluations align with real-world user perceptions [34,35]. While MARS is designed to objectively assess app quality, our findings suggest that its dimensions do not contribute equally to user satisfaction. For example, in cluster 2, all dimensions show weak or negligible correlations, offering little explanatory value regarding what drives user satisfaction in this group. This underscores the importance of context-aware evaluations—an insight that only became apparent after clustering revealed how user expectations vary across app groups.

In predictive modeling, KNN emerged as the top performer in the unclustered dataset, achieving an accuracy of 79.55%, with a relatively low MAE of 0.26 and an R^2 of 0.06. The low MAE suggests that KNN's predictions were generally close to actual user ratings, but the modest R^2 reflects limited explanatory power.

The prediction outcomes improved when clustering was applied, as models could be tailored to more similar groups of apps. In Cluster 1, SVR achieved the highest accuracy at 88.89%, with an MAE of 0.27 and a modest R^2 of 0.05, while KNN and GAM also showed improved performance with R^2 values above 0.10. This suggests that in apps with higher MARS scores, expert-assessed quality tends to align more closely with what users value—which is reflected in the improved R^2 values.

In contrast, Cluster 2 posed greater challenges. Although KNN and SVR both achieved high accuracy (88.24%), R^2 values for most models remained low or negative—notably −1.26 for XGB and –0.45 for RF. Even the best-performing models in this cluster, like KNN, achieved only a 0.03 R^2, indicating that while predictions were accurate in terms of MAE, they explained very little of the variance in user ratings. This suggests that user satisfaction in these simpler apps may stem from minimal but sufficient functionality rather than broader quality dimensions emphasized by MARS. The weak positive correlation for functionality further supports this interpretation, highlighting a possible disconnect between expert-assessed quality and user-perceived value in utility-focused apps.

The combined approach—using SVR for cluster 1 and KNN for cluster 2—achieved the highest overall accuracy at 88.64%, with a consistent MAE of 0.27 and R^2 of 0.04. While this confirms the value of clustering, the modest R^2 values across both settings underscore that MARS alone cannot fully explain user ratings. User satisfaction may be influenced by external factors such as marketing, demographics, or social dynamics—elements not captured by MARS. This highlights the need for future studies to incorporate contextual and user-centered variables (eg, downloads and review sentiment) to improve generalizability.

XSL•FO
RenderX

Further, an interesting observation emerged that even though the correlations between individual MARS dimensions and user ratings were weaker within clusters, the prediction accuracy improved. This highlights a limitation of traditional correlation analysis, which only captures simple, one-to-one relationships. In contrast, machine learning models can identify more complex patterns by analyzing multiple variables together, especially after clustering separates apps into more similar groups. This explains why weak correlations can still lead to strong predictions—an effect also noted in previous research that supports using model-based approaches over basic correlation in complex data contexts [36,37].

The comparison of actual versus predicted ratings shows that the unclustered KNN model (Figure 6A) exhibited underfitting, particularly at the extremes—likely a result of averaging across diverse app types. In contrast, the clustered SVR+KNN model (Figure 6B) demonstrated closer alignment with actual ratings and fewer large deviations. This improvement can be attributed to clustering, which grouped similar apps together, enabling the models to learn clearer and more relevant patterns. The error distribution plots (Figure 7) further support this, showing a reduction in the number and extent of prediction errors. Importantly, the overpredicted apps in the SVR+KNN model were distributed across both clusters—3 from cluster 1 and 3 from cluster 2—indicating that residual errors were not driven by any single subgroup but instead reflect natural prediction variability.

The evaluation of our framework on 2 external datasets—mindfulness and older adults—further supports the model's generalizability. As reported in the Results, clustering-based models consistently outperformed or matched the best unclustered models across both domains.

Taken together, our findings highlight the value of integrating structured expert evaluations with unsupervised clustering and machine learning to forecast user satisfaction in mobile health apps. By transforming MARS scores into actionable predictors, this framework enables early-stage evaluation of app quality, especially in the absence of large-scale user feedback. The improved predictive performance of cluster-specific models—validated across both physical activity and external domains—demonstrates that user satisfaction is best understood as context-specific, shaped by both app features and audience expectations. As the mobile health ecosystem continues to expand, such scalable and interpretable modeling approaches can play a pivotal role in guiding user-centered app design, regulatory review, and quality benchmarking before release. For real-world implementation, developers can first assign MARS scores to a representative set of apps within their domain to build context-specific clusters. They can then score their own app using the MARS framework and input these scores into our modeling pipeline to forecast its projected user rating. In future work, we aim to develop a standardized, user-friendly tool that will allow developers and evaluators to input MARS scores and receive predicted user satisfaction outcomes, streamlining early-stage decision-making.

Conclusion

This study demonstrates the effectiveness of combining unsupervised k-means clustering with supervised machine learning models to predict user ratings based on MARS dimensions in physical activity apps. The clustering approach revealed distinct user segments—cluster 1 users preferred feature-rich, engaging apps, while cluster 2 users gravitated toward simpler, utility-focused tools. By tailoring models to these groups, our combined approach (SVR for cluster 1 and KNN for cluster 2) outperformed the best unclustered model (KNN) in accuracy and reliability, offering more context-aware and consistent predictions.

This framework enables developers to forecast user satisfaction before app release using MARS-based expert evaluations. By identifying their app's alignment with specific user clusters, teams can make informed design choices, benchmark against competitors, and tailor strategies—even in low-data environments.

While prior applications of MARS have largely been descriptive, this study presents a predictive framework that transforms expert scores into actionable, prelaunch indicators of user satisfaction. Unlike postmarket sentiment analysis, our method supports proactive, data-informed decision-making that bridges the gap between expert evaluation and real-world user expectations.

By demonstrating improved predictive performance across clusters and validating the approach on external datasets, this work lays the foundation for a new generation of app evaluation tools that are not only interpretable and resource-efficient but also predictive. Future research should build on this by incorporating richer behavioral signals and contextual app metadata to further improve personalization and model precision.

Limitations

This study has several limitations. First, MARS scores offer a static, expert-driven evaluation and may not capture changes in app quality over time. Second, user satisfaction is shaped by contextual and behavioral factors that are not included in the MARS framework. Third, the sample size may limit the robustness of clustering and reduce generalizability across broader app ecosystems. Fourth, the accuracy of predictions is contingent on high-quality and consistent MARS scoring, as variability in rating practices could undermine model performance. Fifth, there is a risk of overfitting, particularly within cluster-specific models trained on relatively small subsets. Although hyperparameter tuning and cross-validation were used to minimize this, models such as RF and XGB may still capture spurious patterns specific to the training data. Finally, while the models were hypertuned using cross-validation, tuning choices are often context-dependent, and future applications may require re-optimization to fit specific app categories or user groups.

Future Scope of Work

Future work will be to quantify how well expert-driven MARS evaluations align with real-world user ratings, especially across diverse user segments. Incorporating additional contextual

XSL•FO
RenderX

data—such as user demographics, review sentiment, or app usage patterns—may help explain residual variance and improve model generalizability beyond MARS dimensions alone. To support practical adoption, we also plan to develop a standardized, user-friendly tool that enables developers to input MARS scores and apply our modeling framework to forecast projected user ratings, thereby streamlining early-stage decision-making.

Acknowledgments

This research received no external funding. No generative artificial intelligence or large language models were used in the writing, editing, or analysis of this manuscript.

Data Availability Mobile App Rating Scale

The study uses previously published Mobile App Rating Scale (MARS) data made available by Terhorst et al [3]. The data analysis and model development code are available from the corresponding author upon request.

Authors' Contributions

AB and JFFA jointly contributed to the conceptualization and methodology of the study. AB conducted the formal analysis, data processing, and model development and prepared the original draft of the manuscript. Both authors contributed to the review and editing of the manuscript. JFFA provided overall supervision and guidance throughout the project.

Abstract

Background: The health impact of summer heat on older adults is a growing public concern, yet the physiological responses, particularly changes in resting heart rate (RHR), and the role of personal heat adaptation behaviors remain underexplored. Wearable devices offer an opportunity to objectively monitor physiological responses and evaluate the effectiveness of adaptation strategies in real-world settings.

Objective: This study aimed to quantify the short-term association between summer temperatures and RHR in older adults and to examine how individual heat adaptation behaviors modify this relationship, with additional consideration of personal characteristics such as age, sex, BMI, and chronic disease status.

Methods: We conducted a panel study among 83 community-dwelling older adults (≥65 y) in Taipei City during the summer of 2021 (May to September). Participants wore Garmin smartwatches to continuously monitor heart rate. Daily RHR was defined as the lowest 30-minute average heart rate. In September, heat adaptation behaviors were assessed via structured telephone interviews. Ambient temperature and relative humidity were obtained from a nearby monitoring station. Linear mixed-effect models were used to estimate temperature-RHR associations, and interaction terms were included to examine behavioral modifications. Subgroup analyses were conducted to explore effect modification by individual characteristics such as age, sex, BMI, and chronic disease status.

Results: Each 1 °C increase in daily mean temperature over lag days 0 - 1 was associated with a 0.11 (95% CI 0.07-0.15; *P*<.001) beats/min increase in RHR. After mutual adjustment for behaviors, several heat adaptation strategies showed significant protective effects, including reducing physical activity (β=−.15, *P*=.001), drinking cold beverages (β=−.24, *P*<.001), increasing naps or sleep duration (β=−.28, *P*=.003), drinking additional water ≥500 mL (β=−.10, *P*=.02), using air conditioner (AC) before (β=−.15, *P*=.002) and during sleep (β=−.13, *P*=.007), and using electric fans during sleep (β=−.12, *P*=.01). Subgroup analyses revealed stronger effects for certain behaviors in vulnerable populations: reduced physical activity was particularly beneficial for those with higher BMI; AC use and cold beverage intake were more effective in people with diabetes; increased naps yielded the largest benefits in individuals with hypertension; and the use of AC or fans during sleep was especially protective for older adults and females.

Conclusions: Summer heat is associated with elevated RHR in older adults, but this effect can be mitigated through targeted heat adaptation behaviors. Smartwatch monitoring provides a feasible and informative approach for capturing physiological changes, supporting the development of personalized heat-health recommendations for aging populations in a warming climate.

Introduction

Many epidemiological studies have demonstrated the impact of extreme ambient heat exposure on all-cause and cardiovascular mortality [1-3]. The specific causes of cardiovascular mortality and morbidity include heart failure, stroke, ischemic heart disease, hypertensive heart disease, arrhythmias, and cardiac arrest [4,5]. In the context of global warming, the risk of heat-related cardiovascular mortality is increasing [6,7]. Older adult individuals are more susceptible to heat-related deaths [5], likely due to impaired cardiopulmonary reserve and thermoregulatory capability, as well as relative socioeconomic disadvantages [8,9].

On an individual level, identifying personal risk factors and implementing appropriate adaptive behaviors may help mitigate heat-related risks [8]. However, existing studies on the effectiveness of heat adaptation behaviors have notable limitations, including their reliance on self-reported symptoms, cross-sectional designs that limit causal inference, and inconsistent findings regarding the effectiveness of specific adaptation measures. For example, a study in Guangdong, China, demonstrated an association between drinking more water and wearing light clothing with a reduced risk of heatstroke [10]. In contrast, other studies have shown that the implementation of heat adaptation behaviors is linked to an elevated risk of heat-related illness or symptoms [11-14]. These inconsistencies highlight the need for more robust, longitudinal studies.

Most current studies depend on self-reported symptoms and behaviors, introducing potential reporting bias and reverse causality issues where individuals experiencing symptoms may be more likely to adopt adaptation behaviors. Our previous research has addressed some of these limitations by using effect modification analysis to demonstrate the benefits of heat adaptation behaviors in reducing heat-related symptoms associated with obesity [14]. Given that symptom reporting is inherently subjective, using objective physiological indicators remains critical to comprehensively assess the health impacts of heat exposure and validate the benefits of heat adaptation behaviors.

Heart rate plays a central role in thermoregulatory response and is affected by autonomic nerve and neurohormone regulations [15]. Resting heart rate (RHR) has been known as a significant predictor of mortality and morbidity [15]. According to a meta-analysis of 87 prospective studies, an increase of 10 beats per minute in baseline RHR is linked to a 15% rise in cardiovascular mortality and a 17% rise in all-cause mortality [16]. This suggests that even a single beat per minute increase in RHR is not clinically negligible.

However, RHR measurements can vary significantly under different conditions (eg, higher during the daytime than at nighttime and higher in a hospital setting than at home), which limits its clinical application and interpersonal comparison [17]. This challenge has been addressed by the increasing prevalence of wearable devices. Wearable devices using photoplethysmography sensors to measure heart rate usually provide good precision, especially in resting conditions [18-20]. Nevertheless, these devices present several limitations in real-world applications, including motion artifacts during physical activity, reduced signal accuracy in individuals with darker skin pigmentation or tattoos, variability caused by inconsistent wrist positioning and contact pressure, interference from ambient light and low temperatures, as well as interdevice variability in measurement precision [21-23]. Despite these limitations, wearable technology continues to serve as a valuable tool for objective, long-term ambulatory heart rate monitoring in nonclinical settings.

The objectives of this study are twofold—first, to investigate the impact of summer temperatures on the RHR of older adult individuals using wearable devices and time-series data analysis; and second, to evaluate the benefits of personal heat adaptation behaviors by examining the effect modification of heart rate. By integrating physiological data from wearable technology with behavioral adaptation patterns, this research aims to provide evidence-based recommendations for personal heat adaptation strategies. The findings can inform public health interventions targeting heat-vulnerable populations, particularly older adults, and support the development of personalized guidance to reduce heat-related cardiovascular risks in aging societies under climate change.

Methods

Study Design and Participants

This investigation was devised as a prospective, longitudinal cohort study aimed at examining the older adult population residing in the Taipei Basin, a region in northern Taiwan characterized by a humid subtropical climate (Köppen climate classification: Cfa). Between 1987 and 2009, Taipei City noted an average temperature increase of 1.57 °C per century, surpassing the global average warming rate of 0.6 °C per century, as indicated in the National Oceanic and Atmospheric Administration's 2023 Annual Climate Report [24,25]. The Taipei Basin, which includes the densely populated cities of Taipei and New Taipei, is marked by a significant urban heat island effect due to its extensive urbanization. The Surface Urban Heat Island Index in Taipei during the summer reaches as high as 9 °C during the day and 3 °C at night, the highest among all cities in Taiwan [26].

Participants were recruited from an established older adult cohort, originally assembled between 2016 and 2018, to investigate the health impacts of air pollution [27]. The initial cohort was recruited from hospitals across 5 regions in Taiwan, where older adults attended government-funded health examinations. For this study, further enrollment took place between May and November 2020 [28]. Eligible participants were selected from the original cohort based on the following criteria: residence in the Taipei Basin, ownership of a smartphone compatible with the Garmin app, and the ability and willingness to wear a smartwatch consistently. Individuals with severe language, cognitive, or communication impairments were excluded. While leveraging an existing cohort provided a robust foundation, the requirement for smartphone ownership and wearable device usage may have introduced selection bias toward participants with higher socioeconomic status or greater technological proficiency, potentially limiting generalizability.

XSL•FO
RenderX

However, the sample reflects a growing segment of older adults who are increasingly adopting mobile health technologies. Of the 97 cohort members eligible for this study, 14 were lost to follow-up due to refusal to continuously wear the device, resulting in 83 participants who provided sufficient wearable data for analysis. The study size was determined by the number of eligible and consenting participants; no formal sample size calculation was performed due to the exploratory panel design, which used repeated daily measurements to enhance statistical power. From September to October 2021, the participants were interviewed via telephone to gather information on their personal background, health condition, and behaviors related to heat adaptation. To explore the impact of summer temperatures on heart rate, the study extracted heart rate data from May to September 2021 for statistical analysis.

Ethical Considerations

The study was conducted in accordance with the principles outlined in the Declaration of Helsinki and received approval from the Institutional Review Board of National Taiwan University Hospital (IRB 202003049RINB). All participants were recruited voluntarily and provided written informed consent before their participation. They were informed of their right to withdraw from the study at any time without consequence. No financial compensation was provided for participation. All collected data were deidentified before analysis to ensure participant privacy and confidentiality.

Questionnaire Assessment

A structured questionnaire was developed to gather data on various aspects, including personal habits (such as cigarette smoking and alcohol consumption), comorbidities (like diagnosed diabetes mellitus, hypertension, and heart diseases), educational levels, and adaptation strategies for dealing with heat and its related symptoms. Telephone interviews were conducted by an experienced interviewer who had previously administered face-to-face interviews with the participating older adult individuals using the same questionnaire [14]. A specific question, “What was the method from the following list that you used to adapt to heat during the extremely hot days in the past year?” was used to identify 15 adaptation behaviors.

For behaviors involving the use of air conditioners (ACs) or electric fans, participants were asked to report whether they used these devices during specific time periods of the day (morning, noon, afternoon, before sleep, and during sleep) and to indicate usage if it typically totaled more than 1 hour within each period, including intermittent use.

As the data relied on self-reported behaviors, particularly over a 2‐4 month recall period, responses may have been subject to recall bias. Evidence from recall error studies indicates that a 90-day recall period yields the lowest bias, compared with the tendency for overreporting with shorter recall periods (eg, 30 d) and underreporting with longer periods (eg, 365 d) [29]. To help mitigate this, interviews were conducted by a familiar interviewer using a standardized protocol to improve consistency and participant comfort. In future studies, the incorporation of real-time behavior logging through mobile apps may further improve data accuracy and reduce recall-related limitations.

RHR Measurement

Study participants were directed to wear a Garmin Vivosmart 4 smartwatch (Garmin International Inc) on their preferred wrist for continuous monitoring of their heart rate. At the initiation of the wearable device setup, participants’ height and weight were measured. The device uses photoplethysmography sensors, which detect changes in blood volume by measuring variations in light absorption through the skin. The heart rate data were uploaded to the Garmin Connect platform via a smartphone-internet connection and then retrieved from the National Taiwan University Medical Genie Platform [30], integrated via the Garmin Health application programming interface. Participants were instructed to wear the smartwatch consistently throughout the day and night, ensuring a minimum daily usage of 8 hours, with the daily RHR determined from the lowest 30-minute average within a 24-hour span [31].

In older adult individuals, the Garmin Vivosmart series has shown good accuracy for RHR monitoring, with a concordance correlation coefficient of 0.93 compared with electrocardiogram measurements from the Polar H7 chest-strapped heart rate monitor [32]. However, despite its strengths, photoplethysmography-based heart rate monitoring may be affected by age-related skin changes—such as wrinkles, roughness, pigmentation, dilated blood vessels, and reduced skin tone—which may alter light absorption and degrade signal quality [33,34]. In addition, vascular aging and increased arterial stiffness in older adults may influence pulse waveforms and reduce measurement precision [35]. These limitations should be considered when interpreting heart rate data in older populations.

Exposure Assessment

In this study, the hourly values of air temperature and relative humidity were obtained from the Environmental Protection Agency air pollution monitoring stations located closest to the participants’ residences. The monitoring stations, positioned 13 to 15 meters above ground level, used Metone 083R instruments to measure temperature and humidity with accuracies of 0.1 °C and ±1% at 23 °C, respectively. The distance between each participant’s residence and the nearest monitoring station ranged from 0.23 to 4.29 kilometers, with a mean distance of 1.74 kilometers. For analysis, air temperature and relative humidity measurements were averaged on a daily basis. The heat index was calculated using these daily average values based on the algorithm released by the US National Weather Service in 2011 [36], with the detailed algorithm and equation provided in Method S1 in Multimedia Appendix 1.

Statistical Analysis

A linear mixed-effect (LME) model was used to evaluate the association between personal characteristics, meteorological conditions, and RHR, incorporating random intercepts for individual participants to account for repeated measurements within participants. For the assessment of the impact of temperature and humidity on RHR, the LME model included adjustments for age (continuous variable), sex (male or female), hypertension (yes or no), diabetes (yes or no), heart diseases (yes or no), and educational attainment (<13 or ≥13 y). Days

XSL•FO
RenderX

with missing RHR data (11,016/12,699, 13.3%) due to nonwear were excluded from the analysis.

To assess the modifying effects of personal characteristics and adaptive behaviors, subgroup analysis was performed based on age (≤ or > median), sex (female or male), hypertension (no or yes), diabetes (no or yes), heart disease (no or yes), BMI (≤ or > median), educational attainment (<13 or ≥13 y), and each adaptive behavior (no or yes). The *P* value for the interaction term in the LME model was used to evaluate the statistical significance of effect modification.

To better evaluate the independent impact of each adaptive behavior on heart rate response to heat, we performed 2 mutually adjusted models for various heat adaptation behaviors. In the first model, AC and electric fan use across different time periods were mutually adjusted to identify which specific usage patterns had significant modifying effects. In the second model, the significant AC and electric fan usage behaviors identified in the first model were further adjusted alongside other adaptive behaviors that had shown significant modifying effects when tested individually.

Furthermore, a 3-way interaction term was applied in the LME model to examine whether the modifying effect of heat adaptation behaviors depends on personal characteristics.

To assess the robustness of the association between ambient temperature and RHR, we conducted a series of sensitivity analyses using progressively adjusted models. Model 1 was unadjusted (crude); model 2 adjusted for age, sex, and BMI; model 3 additionally included hypertension, diabetes, and heart disease; and model 4 (the final fully adjusted model) further accounted for educational attainment. All models were estimated using LME models with random intercepts for individuals. In addition, the aforementioned subgroup analyses were used to examine whether specific demographic or clinical subgroups exhibited differential RHR responses to heat exposure, further supporting the consistency and robustness of the observed associations. All analyses were executed using JMP 17 (JMP Statistical Discovery LLC), with all statistical tests being 2-sided and a *P* value of <.05 deemed statistically significant.

Results

Participant Characteristics

In this study, 83 older adult participants wore wearable devices throughout the warm season from May to October 2021, averaging 132.7 days of use and providing 11,016 RHR measurements. Details on their demographics, duration of device use, and heat adaptation methods are outlined in Table 1. The participants, with an average age of 73.7 (SD 3.6) years, had chronic disease rates of 15% (12/83) for diabetes, 42% (35/83) for hypertension, and 15% (12/83) for heart disease. These rates are slightly lower than previously reported national estimates among Taiwanese older adults, where the prevalence of hypertension and diabetes has been found to range from 48% to 60% and 20% to 24%, respectively [37,38]. This may suggest that our sample represents a relatively healthier segment of the older adult population, possibly because participants were initially recruited from individuals who attended older adult health check-up programs, reflecting greater health awareness and engagement.

They reported an average of 8.4 different heat adaptation behaviors, with the most prevalent including wearing light clothes (79/83, 95%), using AC (78/83, 94%) and electric fans (77/83, 93%), and using shade strategies such as umbrellas or hats (67/83, 81%), and staying indoors (60/83, 72%). Drinking more water (58/83, 70%) and increasing bathing or showering frequency (50/83, 60%), along with opening windows (49/83), were also common practices.

Device Adherence and Missing Data

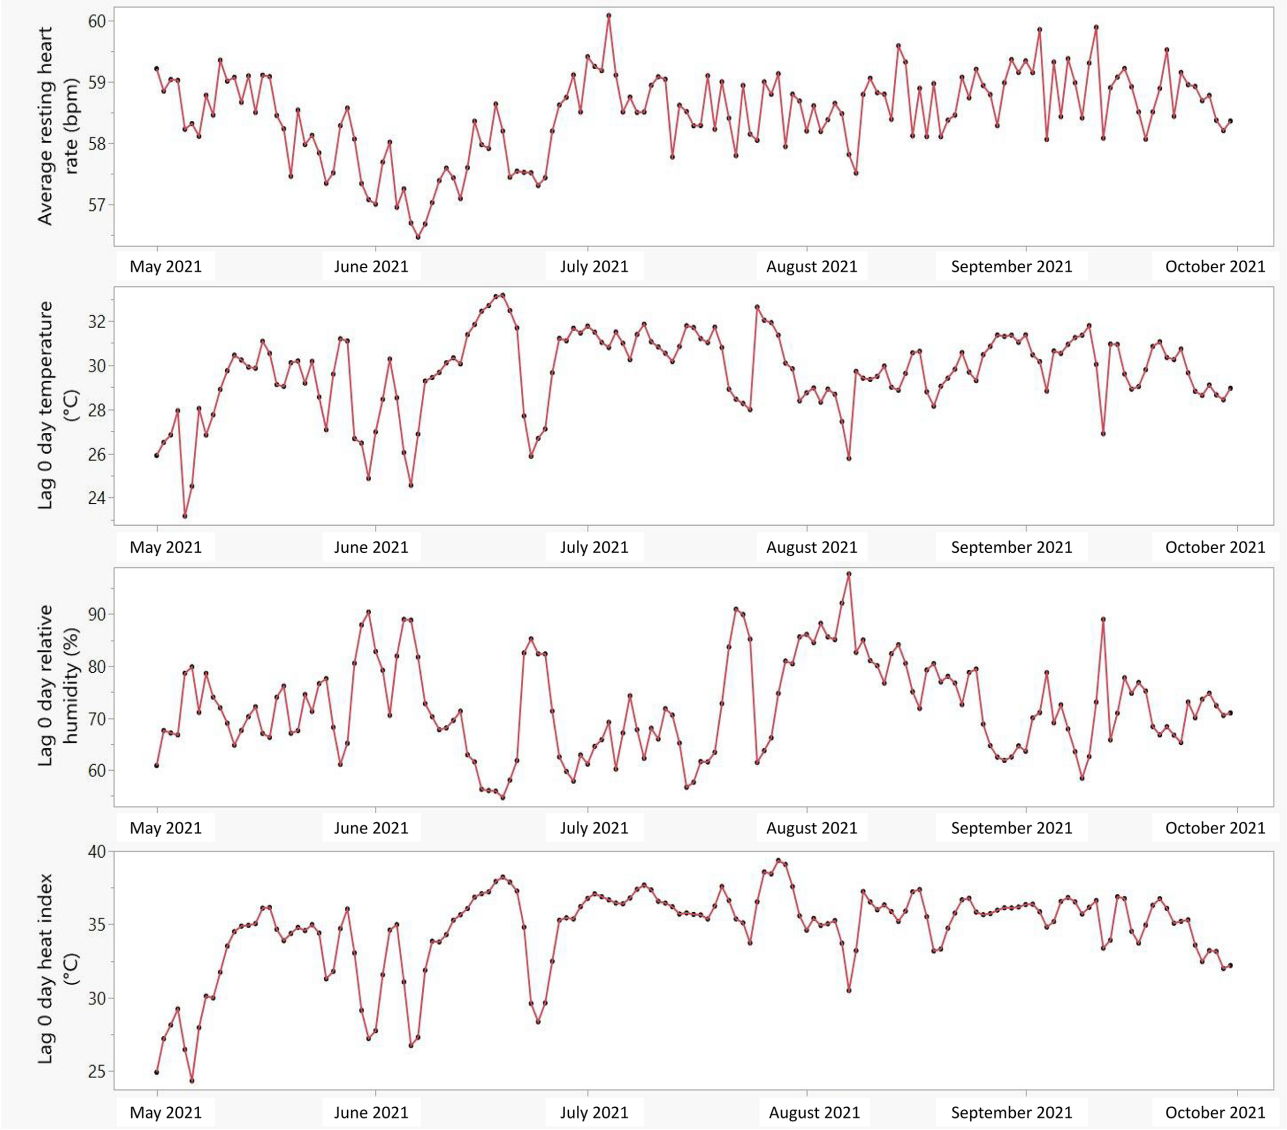
The number of participants providing RHR values each day is illustrated in Figure S1 in Multimedia Appendix 1. A gradual decline in device wear over the study period (from 83 to 63 participants) suggests potential adherence fatigue or reduced engagement. Missing RHR data were primarily due to smartwatch nonwear, which occurred more frequently on hotter days, likely due to discomfort or device removal during heat exposure (Figure S2 in Multimedia Appendix 1). Missingness was not associated with age (Figure S3 in Multimedia Appendix 1), but this pattern may have resulted in a mildly underrepresentation of high-temperature days.

Environmental Conditions

The distribution of temperature and humidity during the study period is summarized in Multimedia Appendix 2 and illustrated in Figure 1. The average temperature was 29.6 °C (SD 1.9 °C), with a mean humidity of 72.1% (SD 9.3%), and the heat index averaged 34.2 °C (SD 3.1 °C). Temperature and humidity were strongly inversely correlated (Spearman $\rho=-0.82$, $P<.001$), while temperature and heat index were positively correlated ($\rho=0.84$, $P<.001$).

XSL•FO
RenderX

Figure 1. Daily resting heart rate, temperature, humidity, and heat index during the study period.



Associations Between Individual Characteristics and RHR

Multimedia Appendix 3 outlines the results from univariate regression analyses linking individual traits with RHR. Diabetes was associated with a higher RHR, with a regression coefficient of 3.95 (95% CI 0.29 - 7.60; *P*=.04), while hypertension and heart diseases did not show significant effects. No significant correlations were found with age, sex, BMI, or education level. The morning use of electric fans initially correlated with higher heart rates (coefficient=2.76, 95% CI 0.14 - 5.37; *P*=.04), but this association became nonsignificant after adjusting for personal characteristics (data not shown). Other heat adaptation behaviors did not significantly affect RHR.

Associations Between Temperature and RHR

Table 2 shows that temperature and the heat index positively correlate with RHR on the same and following day, with effects diminishing and turning negative by Lag 4 and 5. Humidity negatively correlates with RHR initially, with significance lasting through Lag 2, but becomes nonsignificant thereafter. For example, each 1.9 °C increase in ambient temperature (1 SD) was associated with a 0.19 (95% CI 0.12-0.26; *P*<.001) beats per minute increase in RHR on Lag 0 . Model fit statistics favored ambient temperature over heat index as the exposure metric: both Corrected Akaike Information Criterion and Bayesian Information Criterion were consistently smaller for temperature-based models, supporting its use as the primary indicator of heat exposure in this study.

XSL•FO
RenderX

Table . Association between temperature and humidity and resting heart rate in various lag days. Coefficients were estimated for an SD increase in temperature (1.9 ˚C), relative humidity (9.3%), and heat index (3.1 ˚C) by mixed effect models with random intercept for individuals and with adjustments for age, sex, BMI, hypertension, diabetes, heart diseases, and education attainment.

Condition and lag day	Coefficient (95% CI)	*P* value

Sensitivity Analyses

Sensitivity analyses using progressively adjusted models (Table S1 in Multimedia Appendix 1) demonstrated that the association between ambient temperature and RHR was consistent across all models, from the unadjusted model to the fully adjusted model, including age, sex, BMI, comorbidities, and educational attainment. This indicates that the observed associations are robust and not substantially influenced by confounding from the included covariates.

Effect Modification by Personal Characteristics and Heat Adaptation Behaviors

Subgroup analyses demonstrated that the association between ambient temperature and RHR varied significantly by personal characteristics and heat adaptation behaviors (Table 3). Sex modified the response, with males showing a greater RHR increase per 1 °C rise in temperature (coefficient=0.20, 95% CI 0.14 - 0.27) than females (coefficient=0.06, 95% CI 0.003 - 0.11; for interaction *P*<.001). A similar pattern was seen for BMI, where those above the median had stronger responses than those below (0.13 vs 0.10; for interaction *P*=.02). Participants without diabetes had a significant RHR increase (0.14 beats per minute [bpm]), while those with diabetes showed no clear change (–0.09 bpm; for interaction *P*<.001). Lower education levels were also associated with stronger RHR responses.

Several adaptation behaviors were linked to reduced RHR increases. Using AC (0.07 vs 0.19 bpm; *P*=.01), electric fans during sleep (0.08 vs 0.20 bpm; for interaction *P*=.008), and drinking extra water (0.05 vs 0.24 bpm; for interaction *P*<.001) were protective. Other beneficial behaviors included drinking cold beverages (−0.09 vs 0.16 bpm; for interaction *P*<.001), eating more fruit (0.05 vs 0.16 bpm; for interaction *P*=.01), and increasing sleep or nap time (−0.12 vs 0.13 bpm; for interaction *P*=.005). In contrast, opening windows was associated with greater RHR increases (0.19 bpm; *P*<.001). Notably, participants engaging in 8 or more adaptation behaviors had significantly lower RHR responses compared with those with fewer behaviors (0.06 vs 0.21 bpm; for interaction *P*<.001), suggesting a cumulative protective effect. These results highlight the modifying roles of individual health factors and behavioral adaptations in shaping physiological responses to heat.

Multivariate Models of Heat Adaptation Behaviors

To assess the independent effects of specific heat adaptation behaviors, we conducted 2 mutually adjusted models evaluating their interaction with temperature on RHR (Table 4). Model m1 examined the effect of AC and electric fan use across different times of day. Among these, using AC before sleep (coefficient=−0.19, 95% CI –0.29 to −0.08; *P*<.001) and during sleep (coefficient=−0.15, 95% CI −0.24 to −0.05; *P*=.002) were significantly associated with attenuated RHR responses to temperature. Electric fan use during sleep also demonstrated a protective effect (coefficient=−0.19, 95% CI −0.31 to −0.07; *P*=.002). Fan use during other time periods and daytime AC use did not show statistically significant effects.

Use electric fans in the afternoon	0.19 (−0.06 to 0.45)	.14
Use electric fans before sleep	−0.16 (−0.4 to 0.08)	.19
Use electric fans during sleep	−0.19 (−0.31 to −0.07)	.002
Model m2: mutual adjustment for significant adaptation behaviors		
Open window	0.05 (−0.06 to 0.15)	.39
Reduce physical activity	−0.15 (−0.23 to −0.06)	.001
Drink cold water or beverage	−0.24 (−0.35 to −0.13)	<.001
Increase naps or sleep	−0.28 (−0.46 to −0.1)	.003
Drink more water (extra ≥500 mL)	−0.10 (−0.19 to −0.01)	.02
Eat more fruit	−0.06 (−0.15 to 0.02)	.13
Use AC before sleep	−0.15 (−0.24 to −0.05)	.002
Use AC during sleep	−0.13 (−0.22 to −0.03)	.007
Use electric fans during sleep	−0.12 (−0.22 to −0.03)	.01

[a]AC: air conditioner.

Model m2 included multiple significant behaviors from previous subgroup analyses, allowing for mutual adjustment. The most protective effects were observed for increasing nap or sleep time (−0.28, 95% CI −0.46 to −0.10; *P*=.003), and drinking cold beverages (−0.24, 95% CI −0.35 to −0.13; *P*<.001). Other behaviors with significant effects included reducing physical activity (−0.15, 95% CI −0.23 to −0.06; *P*=.001), drinking extra water (−0.10, 95% CI −0.19 to −0.01; *P*=.02), and continued support for AC use before or during sleep and fan use during sleep.

In contrast, opening windows and eating more fruit did not significantly modify RHR response to temperature after adjustment for other behaviors. These findings highlight that certain behaviors, particularly those that directly cool the body or reduce exertion, have independent and additive effects in mitigating physiological stress during heat exposure.

Effect Modification of Heat Adaptation Behaviors by Participant Characteristics

Subgroup analyses revealed that the effectiveness of heat adaptation behaviors in mitigating RHR response to temperature varied significantly across individual characteristics (Table 5). Opening windows was associated with a greater increase in RHR among individuals with higher BMI compared with those with lower BMI (0.30 vs 0.10 bpm, for interaction *P*=.02), suggesting that this behavior may expose more heat-vulnerable individuals to excessive ambient temperatures.

Reducing physical activity was more protective in participants with heart disease (−0.33 vs −0.08 bpm, for interaction *P*=.03) and those with higher BMI (−0.28 vs 0.03 bpm, for interaction *P*<.001), indicating that limiting exertion may be particularly beneficial for those with cardiometabolic risks. Similarly, drinking cold beverages led to a stronger reduction in RHR among older adults (−0.41 vs −0.14 bpm, for interaction *P*=.02), males (−0.39 vs −0.16 bpm, for interaction *P*=.048), and individuals with diabetes (−0.46 vs −0.12 bpm, for interaction *P*=.007).

[a]The *P* value for the interaction refers to the effects of the 3-way interaction between personal characteristics, adaptation behaviors, and temperature on resting heart rate.

[b]Not applicable.

[c]HTN: hypertension.

[d]DM: diabetes mellitus.

XSL•FO
RenderX

Increasing nap or sleep time showed sex-specific and disease-related differences in effect. The behavior led to greater RHR reductions in females than males (−0.43 vs 0.03 bpm, for interaction *P*=.01), in participants with hypertension versus without hypertension (−1.06 vs −0.05 bpm, for interaction *P*<.001), and in those without heart disease compared with those with heart disease (−0.37 vs 0.07 bpm, for interaction *P*=.03). Drinking additional water (≥500 mL) was also more effective in participants with lower BMI (−0.31 vs −0.03 bpm, for interaction *P*=.002) and those without heart disease (−0.23 vs 0.10 bpm, for interaction *P*=.007).

Fruit consumption showed opposing effects between people with diabetes and without diabetes: while it was associated with a decrease in RHR among people without diabetes (−0.17 bpm), it was paradoxically linked to an increase among people with diabetes (0.26 bpm, for interaction *P*<.001). This finding suggests potential metabolic differences in behavioral responses.

The use of AC also showed heterogeneity. AC use before sleep was more protective among people with diabetes (–0.47 vs –0.13 bpm, *P*=.009), while AC use during sleep had a stronger effect in females than males (–0.22 vs 0.07 bpm, *P*=.001). Similarly, the use of electric fans during sleep was associated with a greater reduction in RHR among older adults (–0.30 vs 0.09 bpm, *P*<.001), females (–0.23 vs 0.06 bpm, *P*=.002), participants without hypertension (–0.25 vs 0.03 bpm, *P*=.002), and those with lower BMI (–0.25 vs 0.04 bpm, *P*=.002).

These results underscore that not all adaptation behaviors are equally effective across individuals. Tailoring behavioral recommendations based on age, sex, BMI, and chronic disease status may enhance the protective effects of personal strategies during heat exposure.

Discussion

Principal Findings and Personalized Heat Adaptation

The results of this longitudinal study highlight the significant influence of summer temperatures on the RHR of older adult individuals, with clear evidence demonstrating that heat adaptation behaviors can effectively mitigate these impacts. By leveraging wearable device technology, we captured objective physiological data, revealing lag and interaction patterns in heart rate responses to varying temperatures and humidity levels. Our findings underscore the importance of adaptive behaviors such as using AC, using electric fans during sleep, increasing water intake, reducing physical activity, increasing rest time, and drinking cold water, all of which were shown to have a protective effect on RHR. Notably, these adaptive strategies appeared to be more beneficial for certain subgroups: reducing physical activity for individuals with higher BMI, using electric fans during sleep and drinking cold water for the older age group, increasing rest time for participants with hypertension, and drinking cold water and using AC before sleep for participants with diabetes. However, eating more fruit may not be an ideal heat adaptation behavior for patients with diabetes. These results emphasize the need for personalized heat adaptation recommendations.

Comparison With Previous Research and Mechanistic Insights

The observed RHR response to summer temperature (0.1 beats/min per 1 °C) was consistent with findings from a large cross-sectional study in China (0.133 beats/min per 1 °C) [39]. Heart rate can serve as an early indicator of heat effects, as the increase in heart rate occurs before the rise in core body temperature at the inflection point of heat response [40]. The physiological mechanism involves an increase in heart rate due to heat stimulating the sympathetic nervous system, while stroke volume is limited due to reduced venous return, as blood pools in the skin vessels to dissipate more heat [41,42]. Another follow-up study showed that temperature increases during the warm season decrease parasympathetic modulation of heart rate and modify baroreflex sensitivity in as little as 6 hours [43]. The immediate response to heat aligns with our findings of peak RHR response to heat on lag 0 - 1 days.

Interpretation of Humidity-Related Effects

In this study, humidity exhibited a negative correlation with both temperature and RHR. This phenomenon may be related to the frequent afternoon rainfall during summer in Taiwan. In addition to increasing humidity, the evaporation process during rainfall absorbs a significant amount of heat energy, leading to a decrease in air temperature [44]. Furthermore, the cloud cover before and after the rainfall blocks sunlight, reducing solar radiation reaching the ground and further lowering the temperature [45]. Solar radiation significantly influences human thermal sensation by elevating skin temperature and perceived heat load, thereby reducing self-regulated outdoor exercise intensity [46-48]. Although high humidity impairs the body's ability to dissipate heat through sweat evaporation, thereby increasing heat strain and reducing self-paced exercise performance under hot conditions [49,50], the observed negative association between humidity and RHR may reflect its collinear relationship with concurrent reductions in temperature and solar radiation exposure.

Behavioral Adaptation Versus Physiological Response

Previous research [10-13], including our own [14], has shown a significant positive correlation between personal heat adaptation behaviors and self-reported heat-related symptoms. However, in this study, no direct significant correlation was found between personal heat adaptation behaviors and RHR. This suggests that individuals adjust their behaviors in response to perceived heat-related symptoms but are unable to perceive cardiovascular impacts in advance to take preventive measures.

Through the analysis of effect modification, we can clearly demonstrate the impact of heat adaptation behaviors on heart rate response to heat. In our previous research on heat-related symptoms, significant effects were only observed when combining 2 adaptive behaviors [14]. However, for RHR, a single adaptive behavior alone has an independently significant modifying effect, demonstrating beneficial effects on physiological response.

Effectiveness of AC, Especially at Night

The benefits of AC stem from maintaining a cooler, more stable indoor environment, thereby reducing thermal stress. Studies

XSL•FO
RenderX

from various countries, including the United States [51,52], Spain [52,53], China [54], Canada [52], and Japan [52,55], have shown that AC use can lower heat-related mortality. A randomized controlled trial demonstrated that providing targeted heat health messages increased AC use and reduced the risk of self-reported heat stress among older adults [56]. Our study extends these findings by demonstrating the specific impact of AC use on an objective physiological measure—RHR—highlighting its potential role in preventing heat-related cardiovascular events. Furthermore, the stronger protective effect of AC use at night highlights the significance of nighttime heat, which aligns with previous literature showing the impact of nighttime warming on mortality, especially under the urban heat island effect [57]. For patients with diabetes, nighttime AC is even more beneficial in lowering RHR, likely due to their increased vulnerability to heat exposure caused by impaired thermoregulatory and autonomic nerve responses [58].

Protective Role and Limitations of Electric Fan Use

Electric fans enhance convective and evaporative heat loss from the skin, significantly improving thermal comfort while consuming up to 50 times less electricity than AC [59]. However, at extremely high temperatures, such as around 36 °C with 80% relative humidity or 42 °C with 50% relative humidity, electric fans can exacerbate physiological heat strain [60]. In addition, the cooling efficacy diminishes with age and in conditions that impair sweating efficiency [61]. According to biophysiological modeling, the recommended safe temperature thresholds for electric fan use are 39 °C for healthy adults aged 18 - 40 years, 38 °C for those older than 65 years, and 37 °C for older adults on anticholinergic medications [59]. During the study period, nighttime temperatures ranged between 28 °C and 32 °C (average 28 °C), which is below the recommended safe temperature thresholds for electric fan use. This may explain the observed protective effects of nighttime electric fan use for older adults.

The protective effect of electric fan use during sleep on RHR was more pronounced in senior participants and women, potentially because these groups are more susceptible to heat-related hazards and have reduced sudomotor function [5,62]. Conversely, no protective effect was observed in individuals with higher levels of obesity, likely due to subcutaneous fat reducing the surface area-to-mass ratio, limiting heat exchange with the environment [63]. Furthermore, sweat gland density is lower in areas with higher adipose content, weakening heat dissipation through sweat evaporation [64]. Similarly, individuals with hypertension did not show a protective effect of electric fan use on RHR during sleep, unlike people without hypertension. This may be attributed to heightened sympathetic nervous system activity in people with hypertension [65], leading to skin vasoconstriction and diminished water vapor evaporation from the skin [66]. In addition, certain antihypertensive medications, such as beta-blockers, calcium-channel blockers, and diuretics, reduce heart rate and cardiac contractility, while also increasing the risk of dehydration [67].

Modifying Physical Activity and Sleep During Heat Exposure

Reducing physical activity lowers the RHR response to heat exposure because physical exertion increases metabolic heat production. Combined with environmental heat, this exacerbates heat stress [8]. The protective effect of reduced physical activity is likely more pronounced in individuals with heart disease and those with a higher BMI, as the added internal heat may increase strain on their cardiovascular system. In these populations, compromised cardiac function and an already elevated cardiac workload make them more vulnerable to heat stress [68].

In addition to the protective benefit of reducing physical activity during heatwaves, increasing naps or sleep also demonstrated independent protective effects, likely due to the enhancement of autonomic balance through increased parasympathetic activity and reduced sympathetic activity associated with longer daytime naps [69] and extended nighttime sleep [70]. The stronger effect observed in females may be linked to generally lower physical fitness levels and reduced thermoregulatory capacity [71], while the heightened response in individuals with hypertension could be attributed to elevated sympathetic nerve activity [65]. The observation that individuals with heart disease experienced less benefit from increased naps or sleep compared with those without heart disease may be explained by the high prevalence of sleep-disordered breathing in patients with heart conditions [72].

Effects of Cold Water Consumption and Hydration

Our study found that drinking cold water significantly reduced the RHR response to heat, with a more pronounced effect observed in males, those with diabetes, and older adults. This aligns with previous research, including a randomized crossover study demonstrating that cold and room-temperature water increase vagal activity, leading to a greater reduction in heart rate compared with body-temperature water [73]. A systematic review further supports these findings, noting that cold beverages help attenuate core temperature and improve performance in the heat [74]. The stronger effects observed in our subgroups may be explained by physiological differences: men have been shown to experience greater core temperature increases after repeated exertion [75] and stronger parasympathetic activation during cooling tasks [76]. People with diabetes and older adults often exhibit impaired thermoregulation [8], heightened sympathetic activity, and reduced parasympathetic tone [77,78], which may amplify the benefits of cold water on RHR. Further research is necessary to clarify the mechanisms behind these effects and their broader implications for mitigating heat-related health risks.

In our mutually adjusted model, both increased water intake and cold water exhibited independent protective effects. Hydration replenished fluids, maintaining blood volume, cardiac preload, and output, thereby enhancing skin blood flow, facilitating heat dissipation, and promoting the restoration of heart rate variability [79,80]. However, participants with heart disease and higher BMI showed a blunted response to increased water consumption. In patients with heart disease, maintaining fluid balance can be challenging, and the ability to augment cardiac output is less efficient through fluid supplement,

XSL•FO
RenderX

potentially due to the limitations imposed by the Frank-Starling mechanism [81]. Similarly, increased BMI is associated with impaired left ventricular diastolic function, which reduces the effectiveness of fluid supplementation on improving cardiac function [82].

Reconsidering the Role of Window Opening

Opening windows during heatwaves was a common adaptation in our study, with 59% (49/83) of participants reporting this behavior. However, we found that opening windows increased the RHR response to heat. This finding aligns with our previous research, which showed that this behavior intensified the association between body fat and heat-related symptoms (not opening windows: odds ratio [OR] 0.91, 95% CI 0.07-11.12; opening windows: OR 1.71, 95% CI 1.06-1.29; interaction *P*=.19), suggesting a potentially harmful effect. On hot days, opening windows can increase the inflow of hot air, raising indoor temperatures more effectively than heat conducted through the building [14]. In the mutually adjusted model, the effect of window opening became nonsignificant, likely due to confounding effects from other adaptation behaviors, such as the tendency to close windows when using AC [83]. In summary, although opening windows is a commonly used adaptation during hot weather, it does not appear to reduce heat-related health risks.

Fruit Consumption and Heat Response in Patients With Diabetes

In our study, the heat adaptation behavior of consuming more fruits among patients with diabetes was found to increase the RHR response to heat. A meta-analysis of 19 randomized controlled trials has shown that, without exceeding total energy intake, increased fresh and dried fruit consumption can aid in glycemic control [84]. However, whether the observed phenomenon in our study is due to excessive intake remains uncertain. A limitation of this study is the lack of information on individual total caloric intake, as well as whether the fruits were consumed as whole fruit or fruit juice. Taiwan's summer is characterized by an abundance of high-sugar fruits such as watermelon, passion fruit, pineapple, mango, longan, and sugar apple. Given that increased fruit consumption is a common adaptation behavior (reported by 35/83, 42% of participants), further research is warranted to clarify the impact of this dietary behavior on heat-related health risks in patients.

Strengths

This study has several strengths. First, continuous measurement of RHR via a smartwatch provides an objective assessment of physiological responses to heat. Second, compared with studies focusing on subjective heat-related symptoms [14], integrating RHR with adaptation behaviors minimizes the risk of reverse causality, as individuals generally do not consciously perceive their heart rate response to heat, which might otherwise influence their behavior. Third, the use of moderation and mutually adjusted statistical analysis strategies allowed us to delineate the independent health benefits of different heat adaptation behaviors.

Limitations

Several limitations should be acknowledged. First, the relatively small sample size of 83 participants, all from the Taipei Metropolitan Area, may limit the generalizability of our findings to the broader older adult population, particularly those in different geographic regions or climates. However, our study may serve as a model for assessing the health impacts of summer heat and developing region-specific personal adaptation strategies. Second, the collection of heat adaptation behavior data through telephone interviews conducted in September introduces the potential for recall bias, as participants were asked to recall behaviors from the preceding months. This reliance on self-reported data may also lead to inaccuracies in reporting. Third, the cross-sectional nature of the adaptation behavior data prevents the assessment of changes in behaviors over time or in response to specific heat events. Fourth, smartwatch nonwear was more common on hotter days, possibly due to discomfort or device removal during heat exposure. This pattern of missingness may lead to underrepresentation of high-temperature days in the dataset and result in conservative estimates of the heat's effect on RHR. In addition, using meteorological data from monitoring stations may introduce some exposure misclassification, as it does not account for indoor conditions and outdoor activities that affect individual exposure. Wearable thermosensors could offer a future solution [18]. Nonetheless, such misclassifications are likely nondifferential and may result in an underestimation of the observed associations.

Conclusion

By integrating objective physiological monitoring with self-reported behavioral data, this study provides a novel contribution to the field of environmental health by moving beyond subjective symptom reporting to evaluate the real-time cardiovascular effects of heat and the modifying role of personal adaptation strategies. This combination enables more accurate assessments of heat stress responses and intervention effectiveness in older adult populations.

Our findings demonstrate that common heat adaptation behaviors can significantly reduce cardiovascular strain during hot weather, particularly in older adults. Based on subgroup-specific responses, several behaviors should be prioritized for health promotion: using AC (especially before and during sleep), drinking cold water or beverages, reducing physical activity during hot periods, and increasing rest or nap time. These targeted strategies may be especially effective for vulnerable subgroups, including individuals with diabetes, hypertension, higher BMI, or advanced age.

This information may guide public health education and risk communication campaigns aimed at older adult populations, particularly in regions experiencing intensified heat due to climate change. Future research using enhanced time-series tracking and wearable technologies may further refine personalized adaptation guidance and support climate-resilient health systems.

Abstract

Background: Wrist-worn photoplethysmography (PPG) sensors allow for continuous heart rate (HR) measurement without the inconveniences of wearing a chest belt. Although green light PPG technology reduces HR measurement motion artifacts, only a limited number of studies have investigated the reliability and accuracy of wearables in non–laboratory-controlled conditions with actual specific and various physical activity movements.

Objective: The purpose of this study was to (1) assess the reliability and accuracy of the PPG-based HR sensor of the Fitbit Charge 4 (FC4) in ecological conditions and (2) quantify the potential variability caused by the nature of activities.

Methods: We collected HR data from participants who performed badminton, tennis, orienteering running, running, cycling, and soccer while simultaneously wearing the FC4 and the Polar H10 chest belt (criterion sensor). Skin tone was assessed with the Fitzpatrick Skin Scale. Once data from the FC4 and criterion data were synchronized, accuracy and reliability analyses were performed, using intraclass correlation coefficients (ICCs), Lin concordance correlation coefficients (CCCs), mean absolute percentage errors (MAPEs), and Bland-Altman tests. A linear univariate model was also used to evaluate the effect of skin tone on bias. All analyses were stratified by activity and pooled activity types (racket sports and running sports).

Results: A total of 77.5 hours of HR recordings from 26 participants (age: mean 21.1, SD 5.8 years) were analyzed. The highest reliability was found for running sports, with ICCs and CCCs of 0.90 and 0.99 for running and 0.80 and 0.93 for orienteering running, respectively, whereas the ICCs and CCCs were 0.37 and 0.78, 0.42 and 0.88, 0.65 and 0.97, and 0.49 and 0.81 for badminton, tennis, cycling, and soccer, respectively. We found the highest accuracy for running (bias: 0.1 beats per minute [bpm]; MAPE 1.2%, SD 4.6%) and the lowest for badminton (bias: −16.5 bpm; MAPE 16.2%, SD 14.4%) and soccer (bias: −16.5 bpm; MAPE 17.5%, SD 20.8%). Limit of agreement (LOA) width and artifact rate followed the same trend. No effect of skin tone was observed on bias.

Conclusions: LOA width, bias, and MAPE results found for racket sports and soccer suggest a high sensitivity to motion artifacts for activities that involve "sharp" and random arm movements. In this study, we did not measure arm motion, which limits our results. However, whereas individuals might benefit from using the FC4 for casual training in aerobic sports, we cannot recommend the use of the FC4 for specific purposes requiring high reliability and accuracy, such as research purposes.

Introduction

Over the recent years, connected bracelet and watch sales have been regularly increasing [1]. These tools allow individuals to monitor various active life parameters, such as time of activity, sleep quality, step numbers, and energy expenditure, among others. Most of them are computed through algorithms that use accelerometry and heart rate (HR) data. Although these new devices are used for training by both recreational athletes and elite athletes, chest belts remain the gold standard, especially among high-level athletes, for measuring HR, as they are based on R peak detection from the QRS electrocardiogram (ECG) complex [2,3]. In opposition to chest belts, other wearables perform additional measurements (eg, accelerometry and

XSL•FO
RenderX

positioning measurements via a GPS), which, when combined with HR data and algorithm processing, provide data on other parameters, such as energy expenditure and quality of sleep. Moreover, wrist-worn devices could reduce the tolerance and acceptability issues observed with chest belts [4]. Wrist-worn devices usually estimate continuous HR through the photoplethysmography (PPG) technique, which was first used in the late 1930s [5]. PPG involves measuring light absorption through tissues of interest [6]; red and infrared lights are emitted by an LED through the skin, and a photoreceptor captures the remaining emissions after tissue absorption [7]. However, even if the concept remains similar, connected watches usually come with a green light PPG sensor for its ability to reduce motion artifacts, contrary to the red ones commonly used in the medical field for blood oxygen saturation evaluation [8,9]. The reason for this is that the deeper the light penetrates the tissue (eg, red wavelength), the more the pulse wave is affected by limb movements [10,11]. As light penetration depends on light wavelength, the shorter wavelength of green light provides less information from deeper nonpulsatile tissues [9,12]. Considering this, green light is less prone to motion artifacts during normal daily life [13-15]. In the case of HR monitoring via watches or bracelets during activities, signal accuracy and reliability may vary according to numerous factors. Among them, gear placement on skin, strap tightening (which induces skin compression), skin tone, and activity type and intensity can affect HR recording [15-21]. PPG HR sensor accuracy has been investigated during physical activity across a spectrum of intensities. However, researchers tend to measure PPG HR sensor accuracy with treadmill running or cycling ergometers in laboratory-controlled conditions [17,22-24]. To our knowledge, only a few evaluations of connected device accuracy (eg, accuracy of a smartwatch, as evaluated in this paper) were performed in ecological conditions across different physical activity types. As this type of device is meant to be used in non–laboratory-controlled conditions or free-living conditions, this study aimed to evaluate the accuracy and validity of the PPG HR data from the Fitbit Charge 4 (FC4; Fitbit LLC) across multiple physical activity types. Therefore, the objectives of this study were to (1) assess the accuracy and reliability of FC4 HR measurement in ecological conditions and (2) quantify the potential impact of activity type on accuracy.

Methods

Participants

A total of 26 healthy young adults from the Sport Sciences University of Calais, France, who were practicing physical activities on a weekly basis, volunteered and were included in this study, which was advertised on the university campus and via social networks. No inclusion or exclusion criteria were used.

A minimum HR sample size was calculated with G*Power (version 3.1.9.6) [25] by using a significance level (α) of 5%, a statistical power of $1 - \beta = 80\%$, and an effect size of 0.075 (computed from the expected HR mean and SD). The number of necessary HR samples was below 6000, representing 100 minutes of recording (sample rate=1 s^{-1}). Measurements were performed during participants' regular training sessions for soccer, badminton, orienteering running, basketball, tennis, and road biking.

Ethical Considerations

This study was approved by the National Commission for Data Protection and Liberties (CNIL-France; registration number: 2224247). All participants gave their written informed consent, with the possibility to opt out of the protocol at any point. Data collected throughout the protocol were deidentified for privacy and confidentiality reasons. Finally, although participants could not be financially compensated for their participation, which did not impact their usual routine, each of them personally received an individualized analysis of their HR data, so that they could receive information about cardiac demand during various phases of their training sessions (intensity levels, duration, and cardiac work zone) and adjust their sessions' contents if needed.

Data Collection

PPG HR signals from the FC4 were compared to those from the Polar H10 thoracic belt (Polar Electro Oy), which was used as the criterion sensor [26]. The assessment of skin tone was performed with the Fitzpatrick Skin Scale, which ranges from 1 (lightest tone) to 6 (darkest tone) [27].

Participants were asked to wear both sensors simultaneously at each session. The FC4 was placed on the wrist of the nondominant arm (ie, around 2 cm away [proximal] from the ulnar styloid process), whereas the Polar H10 thoracic belt was placed under the thorax (ie, on the xyphoid process) and paired with Polar V800 wristwatches for HR recording. Each device was placed firmly against the skin, as recommended by the manufacturer's instructions.

Data Extraction and Analysis

Data were extracted through both companies' web services (ie, the Fitbit app [28] and Polar Flow website [29] for the FC4 and Polar H10, respectively). A MATLAB script (The MathWorks Inc) was then used to synchronize the two devices' HR measurements. Record alignments were performed by using a least square method to minimize squared deviation between FC4 and Polar H10 records, and they were smoothed over a 10-second window to calibrate the sample rate from both devices, as previously described [18,30]. Data normality was verified by a Kolmogorov-Smirnov test.

FC4 artifact data were defined as values that deviated from the criterion data by 20 beats per minute (bpm). Bland-Altman tests were performed on smoothed data to assess the accuracy of FC4 HR data by participant and by activity [31]. Means (bias) and SDs of the differences between the FC4 and H10 values were used to evaluate upper and lower limits of agreement (LOAs), per the following formula: upper/lower LOA = bias ± 1.96 × SD. Mean absolute error (MAE) and mean absolute percentage error (MAPE) were calculated to quantify mean differences between FC4 and Polar H10 HR data. Two tests were performed to evaluate the reliability of the FC4: (1) 2-way random intraclass correlation coefficients (ICCs) with an absolute consistency type were calculated and interpreted according to

XSL•FO
RenderX

current guidelines (ICC<0.5: poor; 0.5<ICC<0.75: moderate; 0.75<ICC<0.90: good; ICC>0.90: excellent reliability) [32], and (2) a computation of Lin concordance correlation coefficients (CCCs) was performed, interpreted following McBride's [33] recommendations (CCC<0.90: poor; 0.90<CCC<0.95: moderate; 0.95<CCC<0.99: very good; CCC>0.99: almost perfect strength of agreement).

All statistical analyses were stratified by activity type, and a Kruskal-Wallis test was performed to compare activity bias, with activity types as independent groups. Mann-Whitney *U* tests were implemented to compare bias from 0 among activity types (independent groups). Further, a linear univariate model was used to estimate the effect of skin tone on bias while controlling the impact of activity type. Statistics were performed using IBM SPSS statistics 25 software (IBM Corp).

Results

Participants' Characteristics

A total of 26 young adults (11 women and 15 men) were included in this study. Their characteristics are compiled in Table 1. In total, 77.5 hours of practice were recorded, distributed across 55 sessions (Table 2).

Table . Participants' characteristics.

	Male (n=15), mean (SD)	Female (n=11), mean (SD)	All participants (N=26), mean (SD)
Age (y)	21.2 (7.0)	20.8 (3.7)	21.1 (5.8)
Weight (kg)	75.8 (9.6)	57.6 (8.9)	68.1 (12.9)
Height (cm)	183 (6)	166 (8)	176 (11)
BMI (kg/m^2)	22.6 (1.8)	20.9 (1.7)	21.9 (1.9)
Skin tone (Fitzpatrick Skin Scale score)	2.9 (0.6)	2.8 (0.6)	2.9 (0.6)

Table . Descriptive data of recorded sessions.

Activity		Sessions, n	Recorded time, h	Participants, n

	Soccer	−16.5	26.7; −59.6	86.3	35.5	19.2 (19.7)	17.5 (20.8)

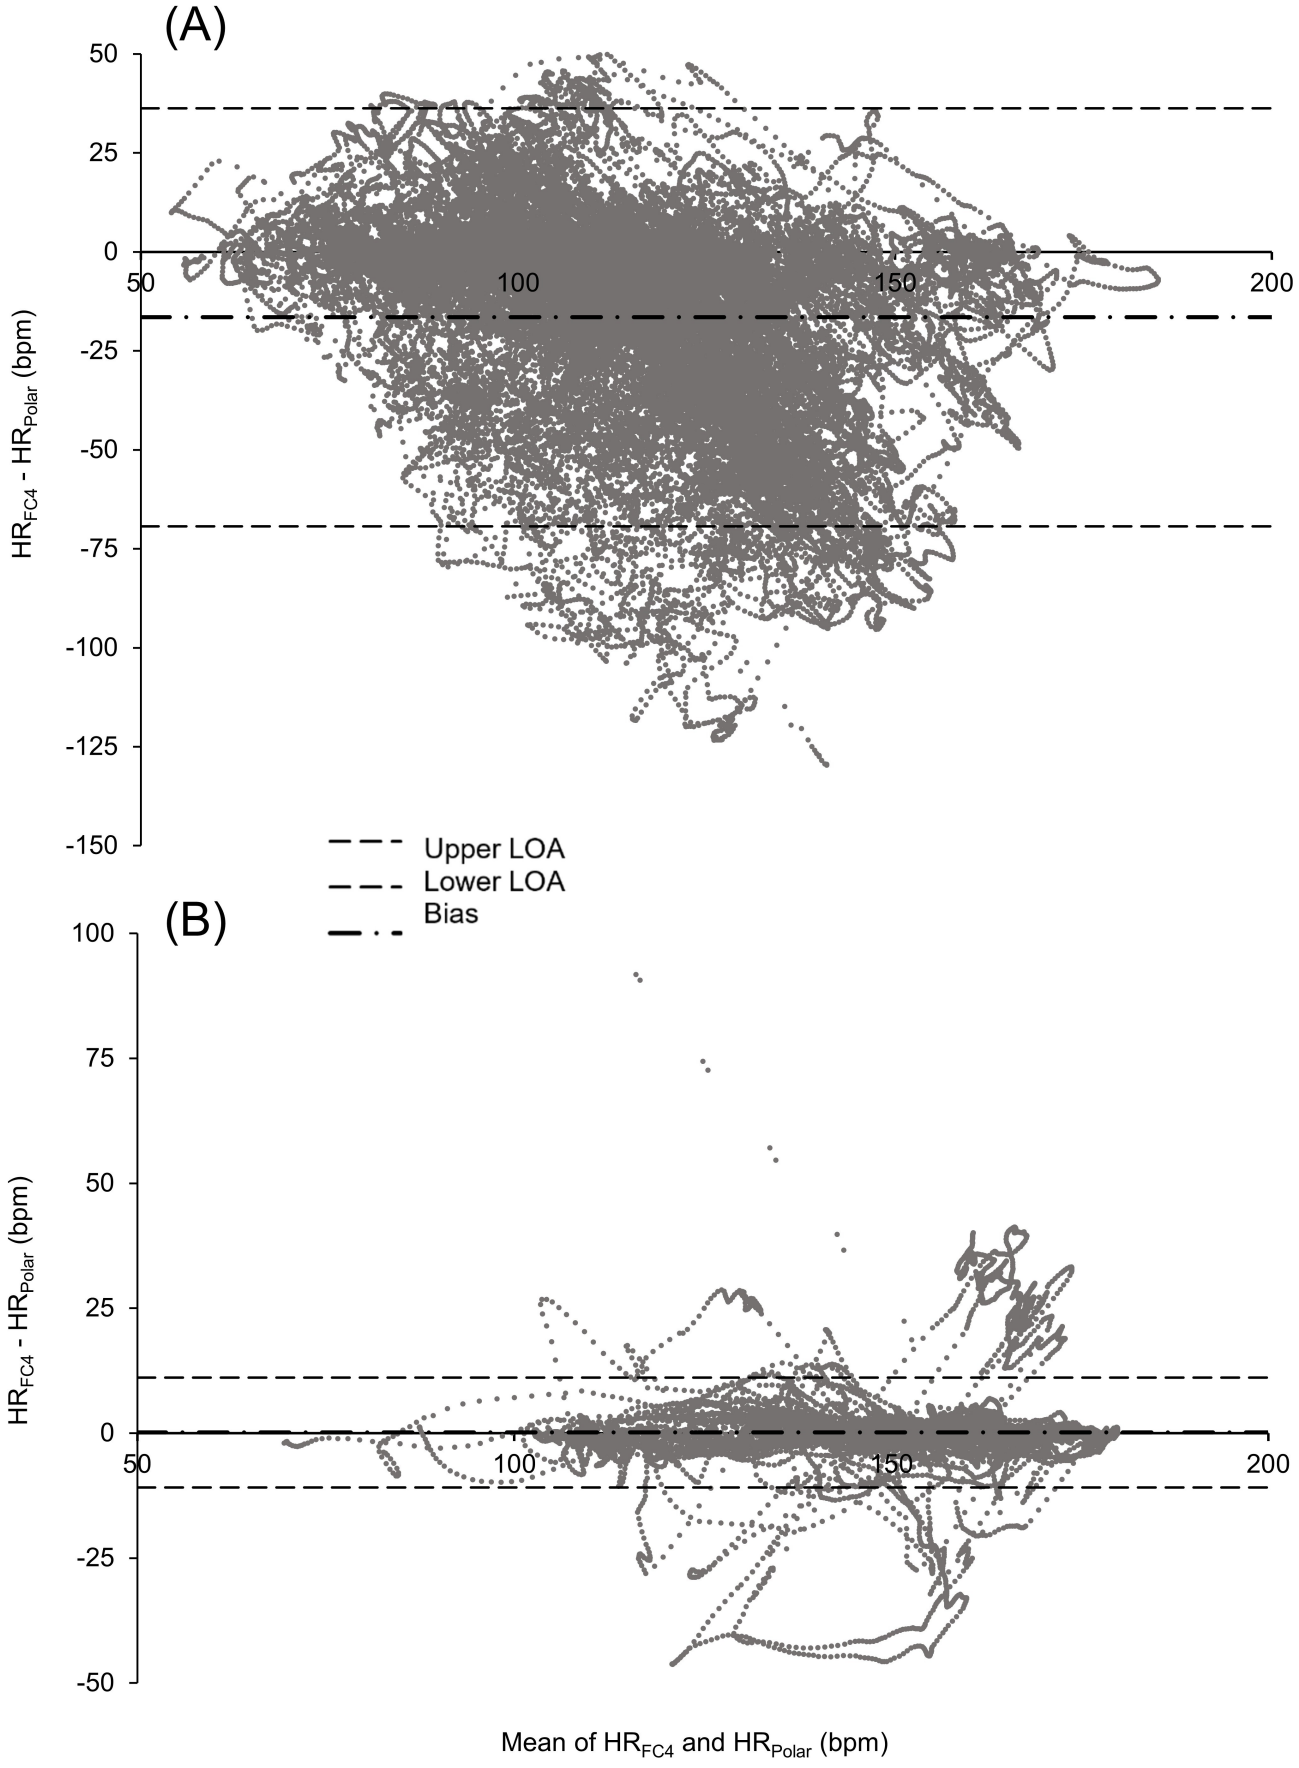
[a]bpm: beats per minute.

[b]LOA: limit of agreement.

Biases were different between each activity (P<.001), with all of them also being different from 0 (P<.001). The lowest bias values, MAEs, and MAPEs were found for running and cycling, and the highest ones were found for badminton and soccer. Furthermore, the narrowest LOA width was found for running, and the widest was found for badminton (Figure 1). We found similar results by grouping activities; the lowest bias, MAE, MAPE, and LOA width were found for running activities (running and orienteering running), and the largest ones were found for racket sports (badminton and tennis; Table 3).

XSL•FO
RenderX

Figure 1. Bland-Altman plots for (A) badminton and (B) running. Badminton exhibits the highest bias, and the bias for running is the closest to the origin. Each activity represents, respectively, 14 and 15.07 hours of recording. bpm: beats per minute; FC4: Fitbit Charge 4; HR: heart rate; LOA: limit of agreement; Polar: Polar H10.



XSL•FO
RenderX

Reliability

ICCs and CCCs are presented in Table 4. ICCs and CCCs indicated poor reliability (<0.50 and <0.90, respectively) for racket sports and soccer but excellent reliability for running overall (the total ICC and CCC for all running activities overall were >0.90 and >0.99, respectively). The largest percentages of artifact HR data were found for badminton and soccer, whereas running exhibited the lowest (Table 3). The results were similar when pooling activities; the highest rate of artifact HR data was found for racket sports, and the lowest was found for running sports (Table 3).

Table . Intraclass correlation coefficients (ICCs) and Lin concordance correlation coefficients (CCCs) by single and pooled activities.

Activity		ICC (95% CI)	CCC
Racket sports			
	Badminton	0.365 (0.517-0.154)	0.778
	Tennis	0.421 (0.320-0.421)	0.884
	Total	0.435 (0.237-0.574)	0.883
Running sports			
	Orienteering running	0.801 (0.865-0.801)	0.932
	Run	0.900 (0.898-0.900)	0.999
	Total	0.926 (0.915-0.935)	0.996
Other sports			
	Bike	0.658 (0.702-0.603)	0.971
	Soccer	0.487 (0.158-0.487)	0.809

Effect of Skin Tone

Mean Fitzpatrick Skin Scale scores are shown in Table 1. No overall interaction and no interaction in each activity were found between bias and skin tone, while being standardized by activity type.

Discussion

Main Results

In this study, we evaluated the HR accuracy and reliability of the FC4 by comparing it to the Polar H10 chest belt (criterion sensor) in non–laboratory-controlled conditions. Our results showed negative biases for most activities (except running and cycling; Table 3), the presence of artifact data, and HR underevaluation by the FC4 (Figure 2). These results are similar to earlier findings that show the tendency of PPG wrist sensors to overestimate or underestimate HR [34-36]. ICCs and CCCs were fluctuant, mainly depending on the activity type. The FC4 shows good reliability for running activities, with almost perfect and moderate CCCs and excellent and good ICCs for running and orienteering running, respectively. Additionally, running was the activity with the lowest bias, the lowest MAPE, and the smallest LOA width. On the other hand, we found lower ICCs for badminton, soccer, and cycling, which also showed higher artifact ratios. Thus, we suggest that the excessive amount of arm movement in these activities could affect HR recording, as previously shown [37]. Badminton and tennis are characterized by “sharp” movements and rotations of the nondominant arm, whereas soccer can induce some instability of the sensor due to random arm and wrist actions, which can result in watches sliding over skin and the transient loss of HR signals (Figure 2). Furthermore, although cycling shows an overall good CCC (0.971), the ICC (0.658), MAPE (8.1%, SD 11.0%), and LOA width (64.03 bpm) indicate a lack of reliability during this activity. Since cycling remains a lower limb cyclic activity, there are little to no arm movements that may affect sensor placement. However, wrist position on handlebars (eg, during road cycling) and the contractility of wrist muscle flexors and extensors could alter vascular arteriovenous system detection and lower signal quality while enhancing compression forces [6,8,16,17]. ICCs and CCCs were calculated for pooled activities—running sports (running and orienteering running) and racket sports (tennis and badminton). These activities mostly rely on the same corporal pattern, and grouping them allowed us to equilibrate the time of practice between other activities. Our data showed no differences in ICC or CCC parameters, with those for running sports and racket sports showing excellent and poor reliability, respectively (ICC: 0.926 vs 0.435; CCC: 0.996 vs 0.883; Table 4).

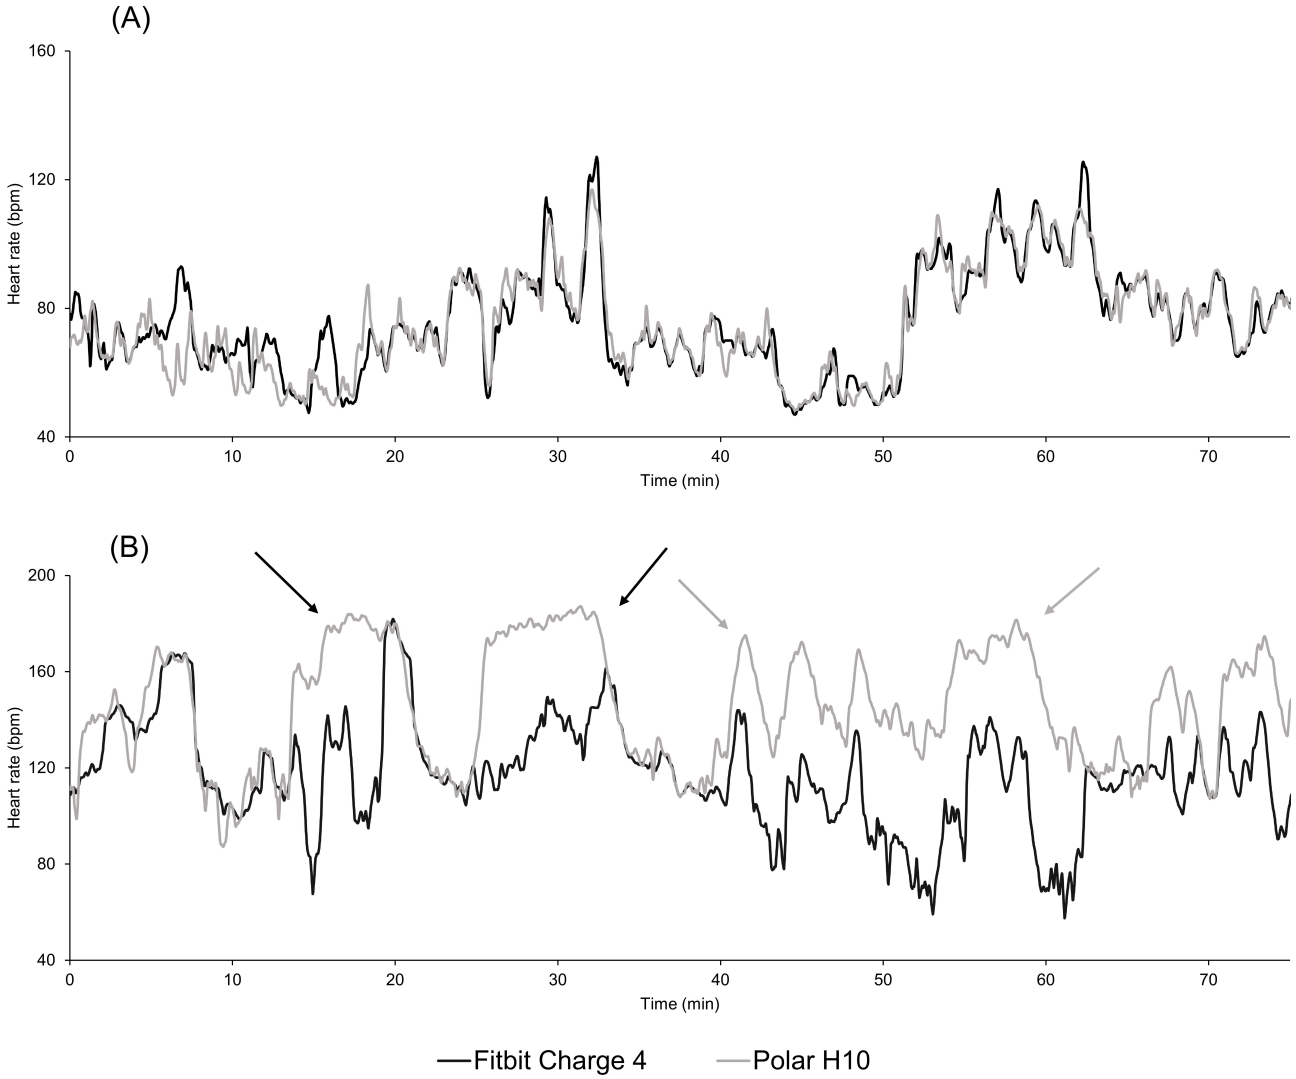
Figure 2. Examples of synchronized heart rate signals (Polar H10: light grey; Fitbit Charge 4: black; A: orienteering running; B: soccer). Soccer heart rate data show recurrent sudden uncoupling between Fitbit Charge 4 and Polar H10 data, as well as heart rate underevaluations by the Fitbit Charge 4 throughout the recording session. bpm: beats per minute.



Overall, artifacts and random movements could highly affect a sensor's precision. Some studies tried to reduce motion artifacts by using novel techniques, such as accelerometry coupling or algorithm-based processing, but there is no consensus yet on which one should be used [38-42]. Even by varying numbers of diodes, lights colors, and algorithms, the technical aspect for measuring HR remains similar, suggesting that some FC4 characteristics could increase the presence of motion artifacts. For example, the materials used for the strap was slippery on skin, amplified by exercise-induced sudation. In addition, from a general standpoint, algorithms used by manufacturers can also affect the recordings, but we did not have access to these proprietary processing scripts.

Limitations

We observed no influence of skin tone on bias, unlike previous works that highlighted some effects on HR error rates [21]. However, our study is in line with another paper that was based on analyses of the signal to noise ratio, which showed no effect of skin tone when using a proper PPG wavelength (520 nm) [15]. More recently, another study did not find an effect of skin tone on beat-to-beat interval quality while separating skin types into two major groups (group 1: 1 to 4 on the Fitzpatrick Skin Scale; group 2: 5 and 6 on the Fitzpatrick Skin Scale) [43]. Even if our study findings are consistent with these results, no generalization can be made, since participants' skin types ranged from 2 (n=6) to 4 (n=3) on the Fitzpatrick Skin Scale. Moreover, we did not take into account physiological and environment factors, such as local temperature, humidity, and sudation, which may impact peripheral vasomotricity and therefore increase or decrease PPG signal intensity [44-46]. It would also have been relevant to assess the influence of motion parameters, such as acceleration measured at the wrist, on HR accuracy and reliability of the FC4; however, we could not access raw data produced by the proprietary processes for further analyses, and it was not possible to use inertial units because these could have resulted in discomfort for the participants, and inertial units are not a commodity among the public. Furthermore, we chose to place the FC4 on the wrist of the nondominant arm, as this placement is recurrent in daily life and research, although we knew that the movements would be inferior to those of the dominant wrist and therefore would reduce the artifact rate. Finally, the low number of participants included for the running activity (n=3) should be considered while interpreting our

XSL•FO
RenderX

results, although the pooled analysis lowered this potential bias while providing similar reliability and accuracy results.

Comparison With Previous Works

A recent study evaluated the accuracy of the FC4 HR sensor against an ECG Holter monitor for activities of daily living (sitting, walking, typing, lying down, etc) and showed acceptable HR measurement capabilities [47]. The added value of our protocol comes from the ecological approach to the gear sensor validation, which included additional physical activities with various intensities and limb movements. To our knowledge, no study has evaluated the FC4 in this manner during multiple sports or activities yet. However, further studies should be conducted to measure the reliability of the FC4 and its parameters for activities of daily living (number of steps, number of stairs climbed, number of calories burned, and quality of sleep), especially among persons or patients whose physical activities are restricted, as observed in sedentary individuals, people with obesity, people with heart failure, etc.

Considering our results (ie, the lack of precision and reliability in specific activities), the FC4 should not be used for research or athlete training purposes, including those related to running, which showed the lowest LOA width and artifact ratio. However, the FC4 could be useful for tracking HR during daily activities, which does not require such accurate monitoring, and it may be considered for patients' reeducation. However, for the latter, further studies should inspect the FC4's reliability according to the characteristics of the population. For example, obesity affects the physiological factors necessary for proper PPG signal intensity and quality, such as capillary density and recruitment, blood flow, and skin thickness [44].

Conclusion

The FC4 shows excellent reliability for measuring HR during activities with slow and predictive arms movements, such as running. However, it should not be used for activities with "sharp" and random arm and wrist movements, such as soccer and racket sports, due to its sensitivity to motion artifacts. Hence, in ecological conditions, this device should not be used for research or training purposes due to the high artifact rate and LOA width.

Authors' Contributions

MC and EH designed the research. MC collected and analyzed the data. MC wrote the manuscript. EH and HD revised the manuscript. All authors have read and agreed to publish this version of the paper.

Trade-Offs Between Simplifying Inertial Measurement Unit–Based Movement Recordings and the Attainability of Different Levels of Analyses: Systematic Assessment of Method Variations

Abstract

Background: Human movement activity is commonly recorded with inertial measurement unit (IMU) sensors in many science disciplines. The IMU data can be used for an algorithmic detection of different postures and movements, which may support more detailed assessments of complex behaviors, such as daily activities. Studies on human behavior in real-life environments need to strike a balance between simplifying the recording settings and preserving sufficient analytic gains. It is poorly understood, however, what the trade-offs are between alternative recording configurations and the attainable analyses of naturalistic behavior at different levels of inspection, or with respect to achievable scientific questions.

Objective: This study assessed systematically the effects of IMU recording configurations (placement and number of IMU sensors, sampling frequency, and sensor modality) on the high temporal resolution detections of postures and movements, and on their lower temporal resolution derivative statistics when the data represents naturalistic daily activity without excessively repetitive movements.

Methods: We used a dataset from spontaneously moving infants (N=41; age range 4 - 18 months) recorded with a multisensor wearable suit. The analysis benchmark was obtained using human annotations of postures and movements from a synchronously recorded video, and the reference IMU recording configuration included 4 IMU sensors collecting triaxial accelerometer and gyroscope modalities at 52 Hz. Then, we systematically tested how the algorithmic classification of postures (N=7), and movements (N=9), as well as their distributions and a derivative motor performance score, are affected by reducing IMU data sampling frequency, sensor modality, and sensor placement.

Results: Our results show that reducing the number of sensors has a significant effect on classifier performance, and the single sensor configurations were nonfeasible (posture classification Cohen kappa<0.75; movement<0.45). Reducing sensor modalities to accelerometer only, that is, dropping gyroscope data, leads to a modest reduction in movement classification performance (kappa=0.50-0.53). However, the sampling frequency could be reduced from 52 to 6 Hz with negligible effects on the classifications (posture kappa=0.90-0.92; movement=0.56-0.58).

Conclusions: The present findings highlight the significant trade-offs between IMU recording configurations and the attainability of sufficiently reliable analyses at different levels. Notably, the single-sensor recordings employed in most of the literature and wearable solutions are of very limited use when assessing the key aspects of real-world movement behavior at relevant temporal resolutions. The minimal configuration with an acceptable classifier performance includes at least a combination of one upper and one lower extremity sensor, at least 13 Hz sampling frequency, and at least an accelerometer, but preferably also a gyroscope (posture kappa=0.89-0.91; movement=0.50-0.53). These findings have direct implications for the design of future studies and wearable solutions that aim to quantify spontaneously occurring postures and movements in natural behaviors.

Introduction

There is a wide interest in studying human activity with inertial measurement unit (IMU)-sensors in a variety of disciplines, including health care, developmental psychology, education, and sociology [1-6]. The objective physical measures of acceleration and gyration from the IMU sensors are considered to provide a significant complement, or alternative, to the traditionally used questionnaires [7] and expert assessments [8], both of which are compromised by subjectiveness and inherent ambiguities. Moreover, the expert-based assessments in the lab or hospital setting are costly and labor-intensive, whereas IMU sensors can be used as wearables to measure human activity in the real world, such as in participants' homes, supporting substantially improved ecological validity of the findings.

Compared with the many other methods used in movement studies, such as surface electromyography, video recordings, or 3D motion capture (3D movement analysis), the currently available IMU sensors allow for an easy-to-use [9], cost-efficient, privacy-preserving [10], and domain-relevant collection of movement data that can be easily deployed for long-form recording. IMU-sensor recordings are well accepted by the participants and their caregivers (in the case of minors), and they are relatively easy to use in long-term naturalistic measurements [11,12]. Moreover, the analyses and interpretability of IMU signals may be considerably easier than analyzing electromyography signals or video recordings obtained in uncontrolled environments.

The traditional approach to IMU-sensor data collection is to measure accelerometry ("actigraphy") signals from a single wrist-, hip, or ankle-worn accelerometer sensor [13], followed by quantifying the amounts of movements as total, with break-down to different levels of activity (eg sedentary, light, or moderate to vigorous), or to indirectly estimate the related energy expenditure [1,14-16]. The single-sensor setups are used in many commercially available wellness products to categorize sustained and repetitive activities (eg, sitting, lying, walking, running, climbing, and cycling [17,18]). Further, the recently introduced parallel gyroscope modality has increased its accuracy [19-21]. This methodologically simple approach reduces movement analysis to amounts of movements or detections of repetitive activities only, both of which fail to account for the frequently changing postures and movements, the key components of all natural human behavior. At the other extreme of recording setups, a very high number of IMU sensors may support detailed skeletal pose modeling [22-24]. However, the technical and analytic complexity of such measurements has limited their use to dedicated laboratory environments only.

An intermediate form between these extremes would be multi-IMU recording setups with a handful (N=2 - 6) of sensors, which have been used increasingly to improve the analytic range of human activity recognition (HAR); however, studies with such setups have used acted-out data collection with predefined activity types (eg, [18,25,26]), which inherently limits their generalizability to real-life measurements [27]. For at-home measurements of naturalistic activity, we have recently developed a multisensor wearable suit for infants (MAIJU, motor ability assessment of infants with a jumpsuit [28-32]), using 4 IMU sensors that collect triaxial accelerometer and gyroscope signals at 52 Hz. The data analysis uses a validated, deep learning–based analytical pipeline to provide a human-equivalent level classification of postures (7 categories) and generic movements (9 categories) for each second of the recording [29]. These high-temporal-resolution/low-analytic-level detections can be used further to build low-temporal-resolution/high-analytic-level assessments of daily activity or motor development [29,30].

In order to maximize the scalability and utility of the novel IMU technology, it would be essential to know the exact trade-offs between simplifying the recording setup and the losses of achievable analyses at different levels of inspection. For example, out-of-lab recordings would benefit from a lower number of sensors that simplify the wearable gear design, or lower data rates that increase the maximum recording lengths and reduce errors in data logistics; meanwhile, well-controlled environments with brief recordings would benefit from redundancy in the setup that increases analytical accuracy. Prior studies have assessed selected aspects of these trade-offs primarily on acted-out or otherwise controlled (ie, nonspontaneous) activities. They have reported that at least 2 sensors with either thigh and ankle [6] or thigh and shoulder [28] positioning are required to achieve adequate posture tracking with a high temporal resolution, and the sampling rate is likely not a significant analytic bottleneck between 10 and 100Hz [18,26,33].

Here, we studied systematically how the recording configurations in naturalistic measurements would affect the accuracy of analytic details at different levels of inspection, ranging from high-temporal-resolution and low-analytic-level detections to low-temporal-resolution and high-analytic-level assessments of spontaneous behavior. The overarching aim was to define which sensor placements, sampling frequencies, and sensor modalities are necessary for different levels of study questions. We used a multisensor IMU dataset with second-by-second level expert annotations of well-defined movements and postures in naturalistic settings, which together provide a rich, previously published and fully generalizable (ie, age-independent) presentation of spontaneously occurring movement behaviors. The novel contribution of this work is the systematic evaluation of the effects of (1) the number of sensors over 4 specific proximal limb locations, (2) sensor modality, and (3) sampling frequency, in the area of classifying posture and movement and their higher-order aggregate and derivative summary metrics for 4 - 18-month-old infants.

Methods

Overview

The overall goal was to study the effect of the recording configuration on the automated, quantified movement and posture analyses. The classifier outputs were assessed at high time resolution using previously developed second-by-second outputs [28,29], followed by assessing summary representations over the recording session (category distributions and scalar projections [29,30]). The ground truth of postures and

XSL•FO
RenderX

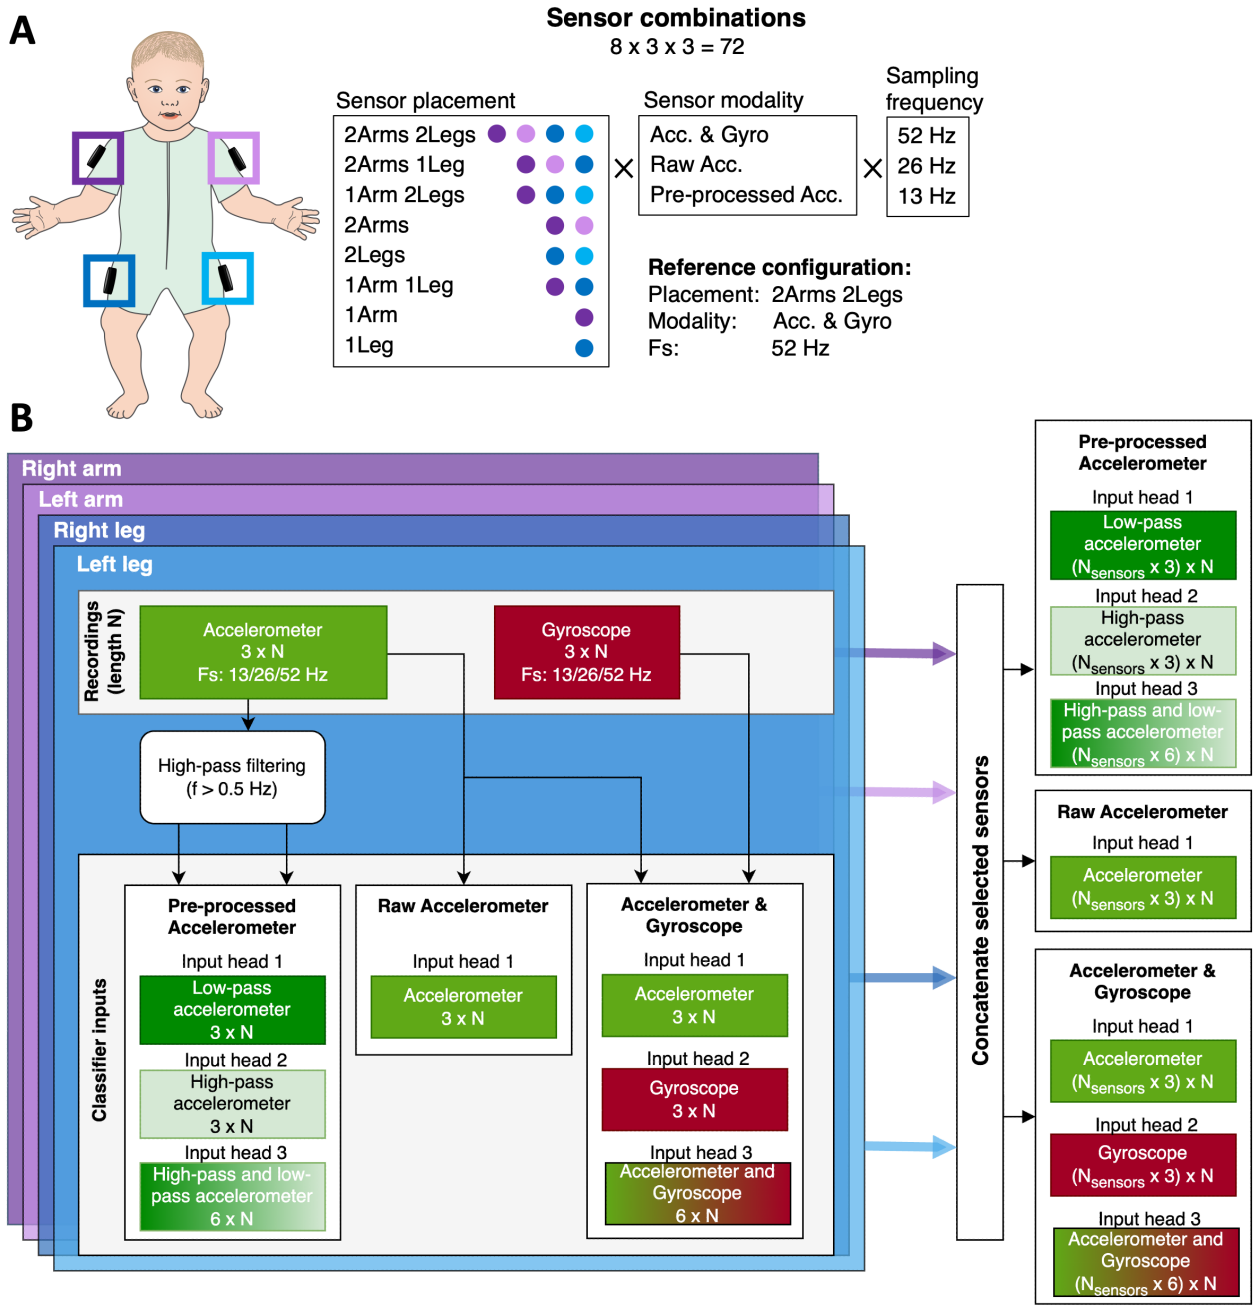
movements was taken from the human inter-rater agreement obtained from independent annotations using IMU-synchronized video recordings.

Data Collection and Recordings

MAIJU Wearable

MAIJU (Figure 1 [28-30]) is a full-body overall akin to a commonplace infant swimsuit that is equipped with 4 movement sensors (Movesense [34]), one proximally placed in each limb. The sensors stream IMU data via a Bluetooth 5.0 low-energy connection into an iOS-based mobile device with a custom-built application, "Maiju logger" (Kaasa GmbH, Düsseldorf, Germany). Data collection is performed with a 52 Hz sampling rate using a triaxial accelerometer (measuring linear acceleration at m/s^2; sensitivity 8 g) and gyroscope (measuring angular velocity at deg/s; sensitivity ±500 deg/s).

Figure 1. Overview of the study. (**A**) Illustration of the studied recording configurations that are obtained by subsampling from the reference configuration data. (**B**) Block diagram depicting the data preprocessing for each configuration. The "raw accelerometer" and "accelerometer+gyroscope" configurations take in the raw inertial measurement unit (IMU) signals (gyroscope with bias removal), whereas the "pre-processed accelerometer" configuration preprocesses the raw accelerometer signal into low- and high-pass parts, after which they are treated as independent data streams.



IMU Recording Configurations

Prior work with the MAIJU recordings has been published with the highest available configuration setup (4 sensors; accelerometer and gyroscope; 52 Hz sampling). This reference configuration was shown to enable classifier performance at a human equivalent level, ie, the agreement between the classifier and a human expert is comparable to human inter-rater

XSL•FO
RenderX

agreement [28,29]. Our previous experiments have shown that classifier robustness can be improved with simulated sensor dropout [31], and other studies on infants have shown that 2 or 3 IMU sensors may provide successful posture classification [4], if the sensors are attached to the unilateral hip, ankle, and waist. Initial experiments with MAIJU demonstrated that an incomplete list of postures is detectable with 2 sensors [28]. These results together suggest that the number of IMU sensors could be reduced from 4. Regarding the sensor locations, the proximal thigh placement (laterally in MAIJU wearable) is identified as the most robust single sensor location for reliable capture of different human activities [17].

In this work, we studied systematically how reductions in recording configurations affect the movement analyses at different levels of inspection, ranging from high-resolution (1 s level) classifications to summary measures of the whole recording session. The tested 3 domains of varying recording configurations were (Figure 1): sensor placement, sensor modality, and sampling frequency. Sensor placement refers to the number of sensors used (from 1 to 4) at the different (proximal-lateral-) limb locations. The recording modality of the sensors can be selected as either an accelerometer, a gyroscope, or both. Since the gyroscope requires orders of magnitude more power compared with the accelerometer, and it does not contain information about the absolute state of orientation, we omitted the gyroscope-only configuration from the study. Since we are using an end-to-end neural network for our classifier, we tested 2 variants of accelerometer-only configurations to reflect the 2 distinct physical sources of acceleration—the gravity component (limb orientation) and limb acceleration—which were obtained by splitting the accelerometer signal into low-pass and high-pass components, respectively.

The “raw accelerometer” variant uses solely the measured accelerometer as such, and in the configuration “pre-processed accelerometer” the low- and high-pass filtered components are fed into separate input heads (Figure 1B). Finally, we test all of the configuration variants with 3 different sampling frequencies supported by the Movesense sensor (52, 26, and 13 Hz), all of which are obtained from the original reference configuration recording by decimation followed by upsampling and low-pass filtering.

Dataset Details

This study uses 29.3 hours (91,449 frames) of previously published data [29] that includes 41 recordings from infants aged 4.5 - 16.6 months. The data, alongside parallel video recordings, were obtained at the infants’ homes (N=17) or at the lab within a home-like setting (N=24) during minimally structured play sessions that lasted from 18 minutes to 74 minutes.

Annotations

We used a previously reported set of human annotations [29] from 3 (N=34) or 2 (N=9) independent annotators. The annotations were performed with the free Anvil software [35], which presents synchronized video and raw signal waveforms to annotate 3 separate tracks: posture, movement, and auxiliary (for details, see [29]). The posture track contains 7 categories (prone, supine, side left, side right, crawl posture, sitting, and standing), and the movement track contains 9 categories (still, proto, elementary, fluent, transition, roll left, roll right, pivot left, and pivot right) (Figure 2). The auxiliary track contained segments where posture and movement annotation could not be performed, viz, infant being carried instead of independent movement and out-of-camera segments. These segments were not included in training or evaluation and have not been counted in the reported dataset size. The baseline Cohen kappa scores for the multiclass inter-rater agreement for the posture and movement annotations were 0.93 (95% CI 0.92 to 0.94) and 0.59 (95% CI 0.57 to 0.62), respectively. As discussed in detail in [28,29], the posture and movement tracks are designed to represent complementary aspects of human movement behavior, and due to the differences in their conceptual clarity and temporal dynamics (Figure 3), the kappa levels between the tracks should not be directly compared. Specifically, the accuracy metrics of the movement track suffer from short bout lengths because the true category transitions cannot be perfectly aligned with the analytic time frames. This unavoidable compromise in temporal accuracy arises from real-world behavior. Notably, our prior work has demonstrated how it is effectively mitigated by using aggregate statistics over the measurement session, yielding unbiased movement track accuracies that are highly comparable with human visual annotations [29] and that have direct utility in describing the gross motor developmental level [36]. Further, our prior work has demonstrated that the movement categories can be meaningfully combined, for example, to denote a dichotomy between “locomotion” and “non-locomotion” [37].

To estimate suitable window lengths for short-term analysis, we studied durations of the posture and movement segments in the data for different categories. In principle, the choice of window length is a compromise of 2 factors: more data in the longer windows would typically improve classifications, however, a too-long window length leads to contamination by different activity types inside the same window. The cumulative distributions for the counts of variable-length annotation segments are presented in Figure 3. The figure shows that almost none of the annotations are less than 1 second in length, whereas especially for movement, there are substantial amounts of segments with duration <2 seconds (≈10% - 40%, depending on the movement category; corresponding roughly to ≈5% - 20% of total time). This suggests that the length of analysis windows should be within 2 seconds to capture all annotated activities. Thus, we used the previously published [28-32], window length of 2.3 seconds (120 samples at 52 Hz) with 50% overlap (1.15 s; 60 samples at 52 Hz).

Figure 2. Example of the raw accelerometer signals and the video-based annotations for posture and movement within a 10-minute recording segment. For each track, the 3 parallel annotations are depicted alongside the training target (obtained with iterative annotation refinement [28]). The classifier outputs are presented with 4 different configurations: 2Arms 2Legs (52 Hz, acc and gyro), 1Arm 1Leg (13 Hz, pre-processed acc), 1 Leg (13 Hz, pre-processed acc), and 1 Arm (13 Hz, pre-processed acc). Note the increasing classification errors when reducing the recording configurations, and the apparently random classification with 1 arm recording.

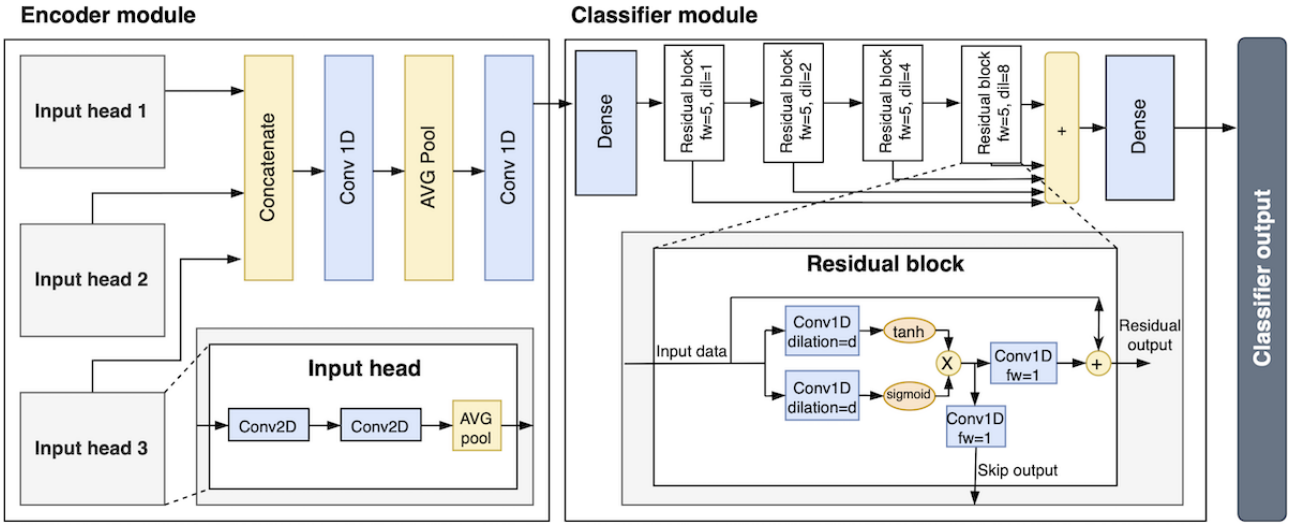
Data Preprocessing and Neural Network-Based Classifier

Data Preprocessing

Windowing

The raw IMU-sensor data is segmented into 2.3 s (120 samples per channel) frames with 50% overlap. The frames are processed and concatenated based on modality (Figure 1B) and then fed into the classifier (Figure 4).

Figure 4. Block diagram depicting the neural network structure for all of the classifiers.



Downsampling

The used Movesense sensor firmware supports measurement at sampling rates starting from 13 Hz. We simulated sampling frequencies lower than 52 Hz (reference configuration) by decimating the original signal by a factor of 2 or 4 (for 26 Hz and 13 Hz, respectively) and then upsampling by the same factor followed by forward-backward low-pass filtering with a sixth order Butterworth filter (with a cut-off frequency of 0.5 * decimated sampling frequency). This was done to keep the classifier architectures identical (ie, each variant takes in frames of 120 samples).

Pre-Processed Accelerometer

In the pre-processed accelerometer modality, the obtained raw accelerometer signal is split into low-pass and high-pass components that are processed in parallel blocks (Figure 4). The low-pass component in accelerometers is primarily caused by the earth's gravity, and it contains information about the absolute orientation of the sensor, whereas the high-pass component primarily contains information about the instantaneous movement. The pre-processed accelerometer signals were obtained by forward-backward filtering the raw accelerometer signals with an eighth-order Butterworth filter with a cut-off frequency of 0.5 Hz (for the low-pass component). The high-pass component was obtained by subtracting the low-pass component from the original signal.

Classifier Architecture

The overall architecture of the end-to-end neural network classifier is presented in Figure 4, and is identical to our earlier experiments [28-32]. The architecture consists of an encoder module (responsible for condensing frame-level information) and a classification module (which performs time-series modeling over the frame-level features). The encoder module has a varying amount of input heads, depending on the chosen modality (1 for raw accelerometer, 3 for the rest). Each input head has a similar architecture but takes as input the concatenated channels of the different sensor modalities (Figure 1B). The modality-level information is combined within the input head to latent representations that are concatenated and further processed in the final layers of the encoder module to obtain a 160-dimensional latent representation for each frame. The classifier module contains stacked residual blocks that do dilated convolutions over the frame-level representations of the data tensor (looking symmetrically into the past and future with a total receptive field of 30 frames=34.6 s).

Training Details

All classifier training experiments were performed with recording-level 10-fold cross-validation with a fixed random seed. Minibatch gradient descent with the ADAM optimization algorithm was used with a weighted categorical cross-entropy loss (batch size=1×100 consecutive frames, learning rate 10^{-4}, $beta_1$=.9, $beta_2$=.999, epsilon=10^{-8}). To mitigate the effects of unbalanced category distributions, each frame's error in the loss functions was weighted with the inverse probability of the target class occurrence. Sensor dropout (P=.3), sample dropout (P=.3), and random Euler rotation (P=.3, ±15 deg) were applied randomly during training to the input signals to enhance model robustness. The training was run for 200 epochs, and held-out validation data (20% of training data) was used to select the best-performing model in terms of the Cohen kappa score.

Levels of Analysis Outputs

Overview

The classifiers for posture and movement produce frame-level information at a rate of 0.87 frames/s. Many use cases, such as health care or developmental research, are interested in holistic

XSL•FO
RenderX

estimates of overall movement performance, and they need summary metrics from the whole recording with a fixed-length feature vector or a scalar value representing the recording. In this study, we used 2 such summary metrics at the level of individual infants: concatenated category distribution vectors and a holistic scalar value, BABA infant motor score (BIMS) [29].

Recording-Level Category Distributions

The classifiers produce a one-hot coded vector (1, N_{cats}) for each frame, where N_{cats} is the number of output categories in the classifier. Thus, for each track in a recording, the classifiers output a matrix of shape (N_{frames}, N_{cats}), where N_{frames} is the number of frames in the recording (at 1.15 s intervals). An automatic carrying detection classifier [32] produces a binary mask of shape (N_{frames}, 1), which is applied as a filter to the posture and movement classifier outputs before computing the distributions. The distribution for each track is computed by taking the mean of the automatic carrying detection-filtered one-hot matrices along the frame axis to yield a vector of shape (1, N_{cats}). It is possible to combine the posture and movement classifications into a single "posture-conditioned movement" representation (ie, prone-still, prone-fluent, standing-still, etc), which yields a total of 27 sensible combinations of motor activity (ie, standing-fluent is a sensible combination, but supine-fluent is not). After obtaining the recording-level distribution value $p'_{c(m_i)}$, where c is the category in question, i is the recording number, and m is the MAIJU recording, the values were concatenated across all recordings into a vector $p'=[p'_{c(m_i)}]$ and compared with the annotation-based reference values $[p_{c(m_i)}]$ with Pearson r. 95% CIs were obtained with bootstrapping (10,000 iterations) at the recording level.

Recording-Level Holistic Assessment

One of the targets of MAIJU recordings is to track the development of gross motor abilities. A novel index BIMS was introduced [29] as a holistic scalar measure for gross motor maturity. BIMS is a normalized (to a scale of [0, 100]), unitless measure defined as the statistical expectation of age that has most likely generated the given measurement. The concatenated recording-level posture and posture-conditioned movement distributions are used as feature vectors within Gaussian process regression [38] for the BIMS computation [30]. Our previous experiments have shown that BIMS correlates well with a conventional assessment battery of gross motor ability (Alberta Infant Motor Scale) [8].

Performance Metrics

Performance for frame-level classification is computed from a compounded confusion matrix where each individual human annotation is compared with the classifier output. For inter-rater agreement, the individual annotations are compared with each other in all combinations. The confusion matrices over all recordings are summed into a single compound confusion matrix, from which the number of true positives (tp), true negatives (tn), false positives (fp), and false negatives (fn) are obtained. Overall performance is reported as Cohen kappa with the formula:

$$k = 2(tp*tn - fn*fp) / (tp+fp)(fp+tn) + (tp+fn)(fn+tn)$$

Due to the unbalanced nature of the category distributions, kappa gives a more informative (compared with accuracy) correlation-like score (in [–1,1]), where a score of 0 denotes chance-level performance.

Statistical Methods

Paired t Test

Two-tailed paired *t* tests are used to test for the null hypothesis that the differences between otherwise equivalent systems' performances are zero when accounting for a single configuration variable. The results are reported with significance levels of (*P<.05; **P<.001; ***P<.0001). To justify the use of the *t* test, the Gaussianity of the differences is verified with a single-sample Kolmogorov-Smirnov test with P>.05.

Pearson r

The aggregate metrics are compared between the annotation-based and classifier-based variants with the Pearson correlation coefficient. This is due to the naturally uneven distribution of category occurrence, which makes straightforward loss metrics such as L1 or L2 loss hard to interpret. Aggregate scores include the category distributions and the BIMS score. The use of Pearson *r* is justified by a strong linear dependency between the tested variables.

Bootstrapping

The basic bootstrapping method is used to obtain 95% CIs for the accuracy, Cohen kappa, and Pearson *r* values. In each case, the sampling (10,000 iterations) is performed at the recording level when computing the compounded result. The *t* test is not used in connection with bootstrapping, where statistical significance is interpreted in terms of the overlap of the CIs.

Ethical Considerations

The study complies with the Declaration of Helsinki, and the research was approved by the Ethics Committee of Children's Hospital (number HUS-1331-2016-8; September 14, 2015), Helsinki University Hospital. A written informed consent was obtained from one of the parents of each participant.

Results

Overview

We present the results of 3 experiments to assess the effects of reducing recording configurations (placement, amount, modality, sampling frequency) to (1) high-resolution classification of posture and movement (1.15 frames per second), (2) to recording-level summary measures, and (3) to holistic assessment on infants' gross motor development. For all experiments, the classifier performance was assessed with recording-level 10-fold cross-validation.

Experiment 1: Effect of Reducing Recording Configuration to High-Resolution Classification

Overview

We trained separate posture/movement classifiers for all reduced IMU sensor inputs to study how the classifier performance

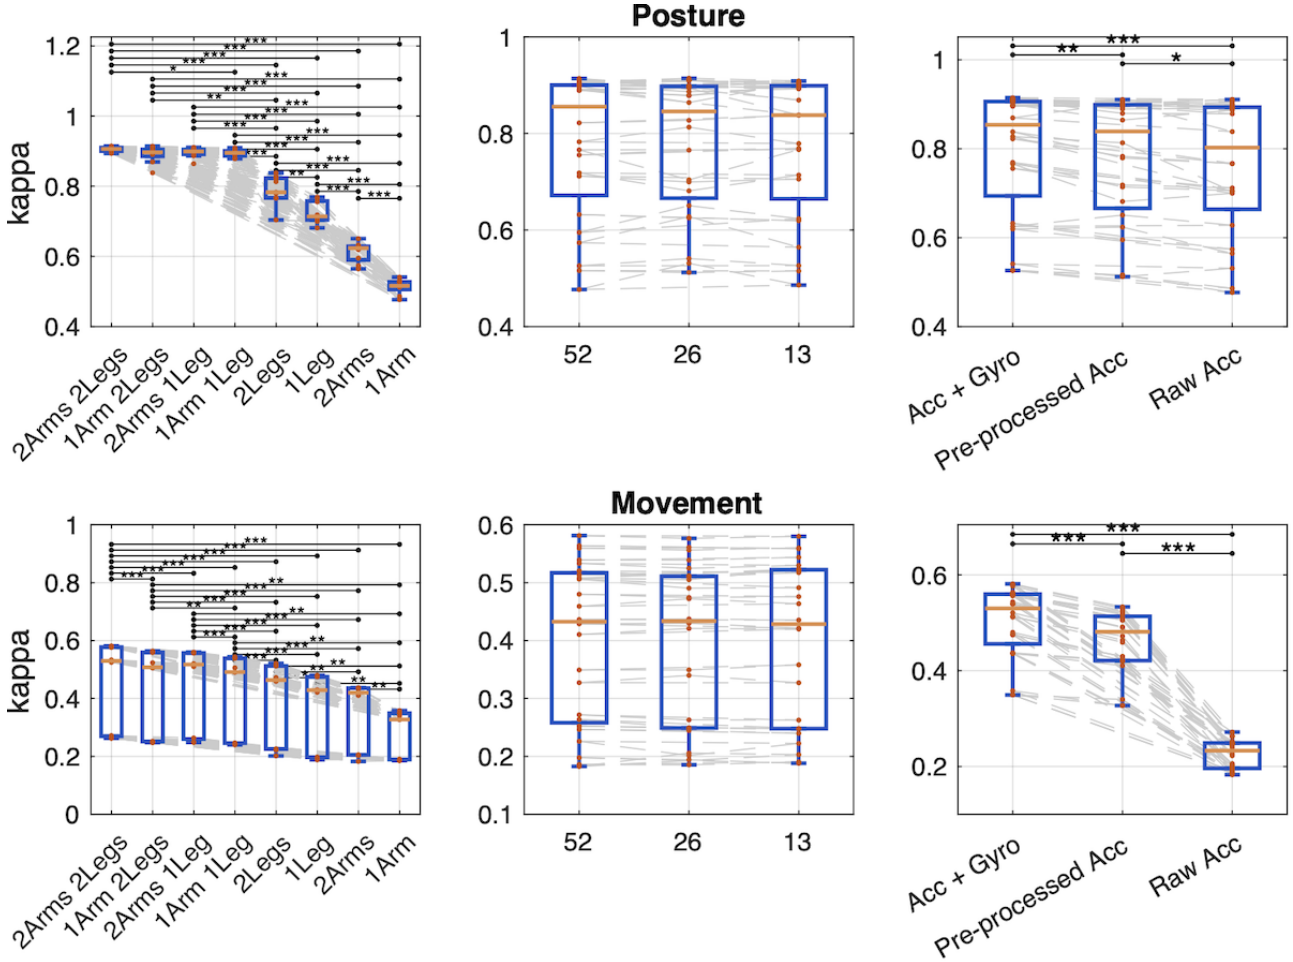
XSL•FO
RenderX

degrades as a function of compromising the IMU configurations. A total number of (8x3×3) 72 classifiers for both tasks (Figure 1) were trained with varying recording configurations, including 8 variants of sensor placement, 3 sampling frequencies (52, 26, and 13 Hz), and 3 alternatives of measurement modality (acc and gyro, raw acc, pre-processed acc) (see Methods section).

Sensor Placement

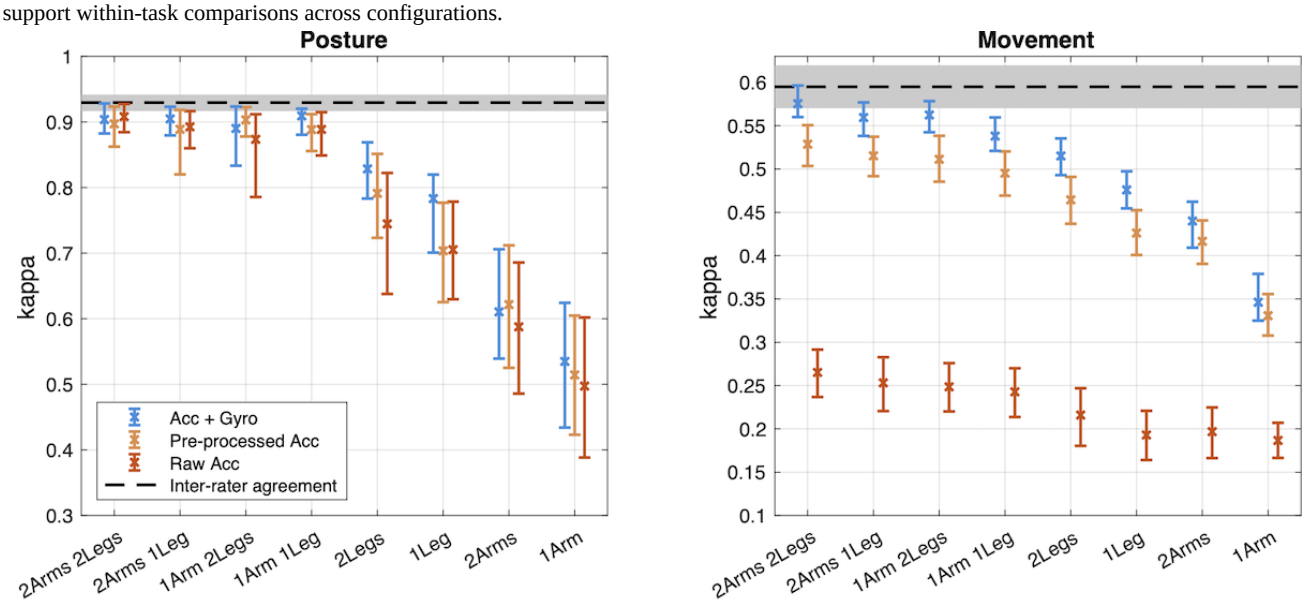
The full classifier performance results are shown in Figures 5 and 6, ordered by descending order of mean kappa levels. Notably, the same rank hierarchy of recording configurations emerges for both posture and movement detections: 2Arm2Leg > 1Arm2Leg > 2Arm1Leg > 1Arm1Leg > 2Leg > 1Leg > 2Arm > 1Arm. For postures, however, the 3 best-performing configurations are not significantly different (t_8 range 0.4 - 2; P=.08-.59). These results together indicate clearly that a combination of upper and lower limb IMU sensors yields the best classification, while IMU sensors in the legs support better classification than IMU sensors in the arms.

Figure 5. Effect of recording configuration to frame-level classification. Effect of sensor placement (left), sampling frequency (middle), and sensor modality (right) on the classification performance (Cohen kappa) for posture (top) and movement (bottom). The boxplots show the median, IQR, and range of experiment values for the cases where the given attribute is held constant. The gray lines connect systems with otherwise equivalent parameters. Two-tailed paired *t* tests are used to test for the null hypothesis that the differences between otherwise equivalent systems' performances are zero (*P<.05; **P<.005; ***P<.001). Please note the different y-axes for posture and movement to support within-task comparisons across configurations.



XSL•FO
RenderX

Figure 6. Effects of sensor modalities on the classifier performance. The findings extend the data presented in this figure by indicating sensor modalities by different colors. The 95% CIs of the performance values (kappa) are drawn with whiskers. The level of human inter-rater agreement (dashed line, 95% CIs depicted with gray) indicates the kappa levels needed to claim human-level accuracy. Please note the different y-axes for posture and movement to support within-task comparisons across configurations.



Sensor Modality

The effect of the sensor modality has the highest discrepancy between posture and movement: For posture, all 3 modalities perform rather acceptably, even though systematic differences can be observed (t_{23} range 2.2 - 3.8; P=.035 to <.001). However, for movement, the performance of the "raw accelerometer" modality plummets (t_{23} range 28 - 30; P<.001; 4 sensors from kappa=0.58 to kappa=0.27). In contrast, the pre-processed accelerometer modality manages to maintain performance in a more robust way when sensors are being reduced from the full setup, although the use of a gyroscope still results in superior performance (t_{23}=14; P<.001).

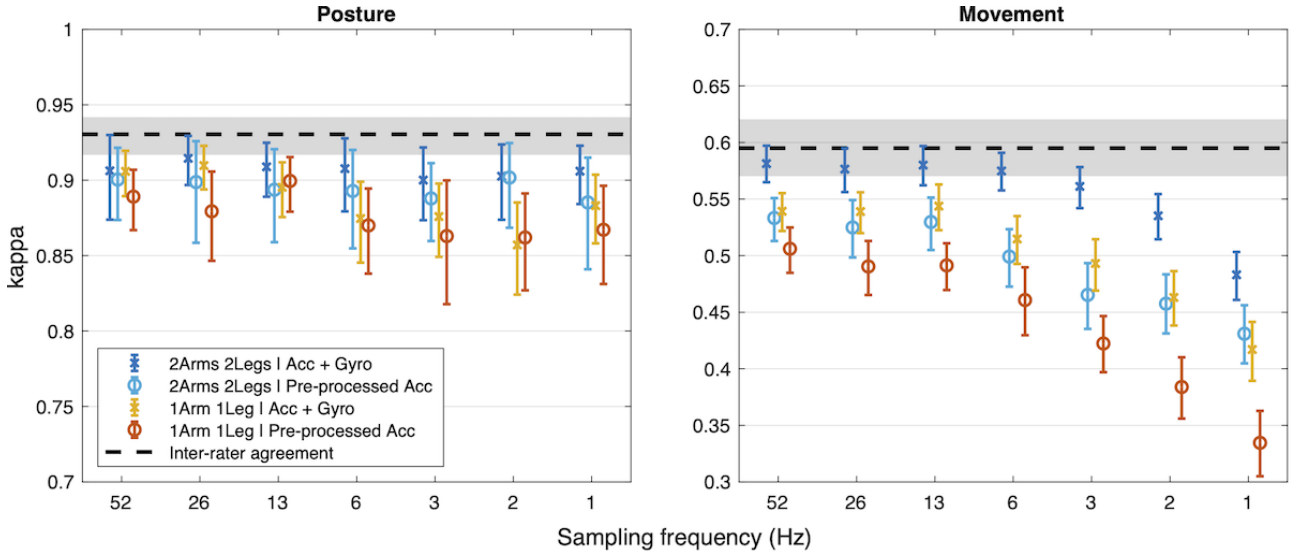
An alternative representation of results is shown in Figure 6. Based on the above findings, the sampling frequencies could be pooled together, and the means of the kappa values and their 95% CIs (obtained by bootstrapping) are presented for recording configuration and modality. For posture detections, the classifier performance remains stable until the 1Arm1Leg sensor placement, and it deteriorates when only one limb type is recorded. For movement detections, however, the overall performance deteriorates gradually with all sensor placements. The CIs overlap for the 4- and 3-sensor placements when the recordings included both acc and gyro modalities. Notably, the reference configuration with acc and gyro modalities is nonoverlapping with all of the pre-processed accelerometer modality recordings.

Sampling Frequency

There were no systematic effects of sampling frequency either for posture or movement classifications within the supported range of the used Movesense sensors (13+ Hz). The median performance ($kappa_{pos}$=0.85 and $kappa_{mov}$=0.43) was slightly higher with 26 Hz, but there were no significant differences (t_{23} range 0.1 - 1.1; P=.30-.90). Because the default sampling rate range did not present a differentiating effect for the posture and movement classification tasks, we conducted a further experiment to assess the effects of extreme downsampling with 4 candidate systems: 2Arms2Legs and 1Arm1Leg with either acc+gyro or pre-processed acc. The results are presented in Figure 7. Strikingly, the 2Arm2Leg system with a gyroscope retained unchanged performance down to a sampling rate of 6 Hz and was comparable to other full-sampled systems even at a 2 Hz sampling rate. We reason this to be the case due to 2 factors. First, even at a 1 Hz sampling rate, the raw accelerometer and gyroscope readings are, in fact, a good feature representation for orientation and movement. The accelerometer always includes the gravity vector, and the gyroscope reading is a good estimate of movement intensity. Second, the used neural network architecture takes consecutive frame-level features into account from a receptive field of 35 seconds, which significantly increases the amount of information available for each frame-level inference (ie, classification of single-frame features without surrounding context would drastically decrease performance).

XSL•FO
RenderX

Figure 7. Effect of extreme sampling rate decimation on selected configurations. Notice the surprisingly high performance in posture detection for sampling rates as low as 1Hz. Please note the different y-axes for posture and movement to support within-task comparisons across configurations.



Experiment 2: Effect of Recording Configuration on Recording Level Category Distributions

Based on the result of experiment 1, we identified the following 4 recording configurations to be the most appealing in terms of maximizing some of the several measurement properties. First, (2Arm2Leg, acc and gyro, 13 Hz) as the best-performing system with the lowest supported sampling rate. Second, (1Arm1Leg, pre-processed acc, 13 Hz) as the best-performing 2-sensor configuration. Third and fourth, (1Arm and 1Leg, pre-processed acc, 13 Hz) as single-sensor configurations with large differences.

Posture and movement category distributions provide a straightforward and explainable summary of the whole recording session. The results are presented in Figure 8. For the distributions of all posture categories, the reference recording configuration was very highly correlated to the distributions obtained from human expert annotations (range r=0.96-0.999; n=41). The sensor placement with 1Arm1Leg showed also a very high correlation (r=0.96-0.999) for all but the Side posture (r=0.73). The single-sensor recordings yielded a considerably lower performance: 1Leg has range (r=0.64-0.996), with most 4 of the categories having r<0.9, and 1Arm has the worst performance with range (r=0.61-0.94), with 5 categories having r<0.8.

The correlation between classifier-based and human expert-based movement category distributions was more variable, and there was also a more gradual deterioration of performance when compromising the recording configuration. Our reference configuration showed a range of 0.67-0.96, with 4 (out of 7) movement categories having r>0.9. For 1Arm1Leg the same metrics are in the range 0.34-0.97 (2 out of 7 categories with r>0.9). Overall, the movement categories “roll”, “fluent”, and “transition” seem to be the most robust in performance, whereas the “proto” category was least correlated to the human annotations.

Figure 8. Effect of recording configuration on recording-level summary metrics. The correlations (Pearson r) between posture (left) and movement (right) distributions obtained using human annotation (REF) and those obtained from IMU recordings and classifier-based (CLS) detections.

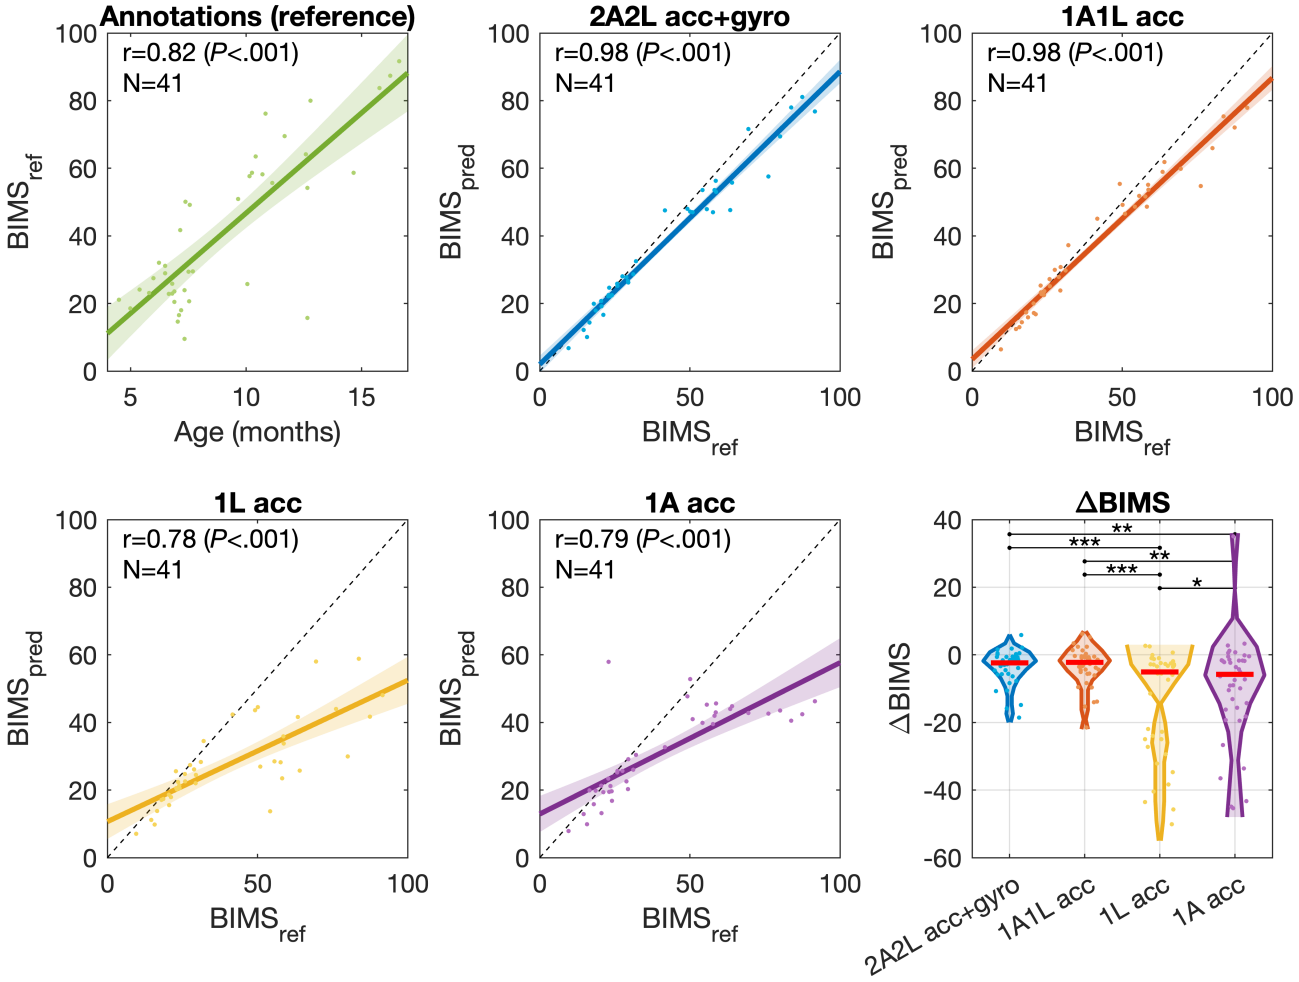
Experiment 3: Effect of Recording Configuration on Holistic Assessment of Motor Development

Figure 9 presents the effect of reducing recording configurations to a holistic measure, here the scalar metric of a motor maturity score (BIMS). The first panel (green) indicates the reference score $BIMS_{ref}$ that is obtained from the annotated distributions as a function of chronological age. The subsequent panels show the correlation of the IMU-recording-based and classifier-derived BIMS scores ($BIMS_{pred}$) to $BIMS_{ref}$. The dashed diagonal lines represent the ideal case where the scores are equal. The results show that the BIMS scores obtained from the 2Arm2Leg configuration are indistinguishable from those of 1Arm1Leg (r=0.98 for both), whereas the single-sensor configurations have clearly lower performance (r=0.78-0.79). Compared with the human expert annotations, the BIMS scores related to older age groups (higher baseline BIMS scores) are more difficult to predict, and this effect is most clearly seen in the 1-sensor variants (see bottom row of Figure 9): 2Arm2Leg median ΔBIMS=–2.4 (range –18 to 5.8), 1Arm1Leg –2.3 (range –21 to 6.8), 1Leg –5.0 (range –50 to 2.7), and 1Arm -5.7 (range –45 to 35). We assume this effect to be caused by the drastic qualitative shifts in gross motor abilities as the infants progress from lower (BIMS<50) to higher motor maturation (BIMS>50); this developmental time window is characterized by a shift from floor-based postures to increasingly upright postures and high postural variability.

Figure 9. Effect of classifier-based inputs on the BIMS score ($BIMS_{pred}$) compared with the reference ($BIMS_{ref}$). Green: Scatter plot and correlation (Pearson r) of $BIMS_{ref}$ compared with the chronological age. Blue, red, yellow, purple: Scatter plots and correlations of $BIMS_{pred}$ compared with $BIMS_{ref}$. Bottom right: Violin plots showing the $\Delta BIMS=BIMS_{ref}-BIMS_{pred}$ for the studied recording configurations. The red lines denote the median difference. Two-tailed paired t tests are used to test for the null hypothesis that the differences between systems' performances are zero (*P<.05; **P<.005; ***P<.001). BIMS: BABA infant motor score.



Summary of Results

Finally, Tables 1 and 2 present the most relevant conclusions from the experiments: Sampling frequency did not have a significant effect on the classifier performance. Sensor modality did affect classifier performance, showing the best results with a combined accelerometer and gyroscope modality. However, a pre-processed accelerometer-only recording with separate low- and high-pass heads may produce reasonably good results with a minimalist measurement setup. For sensor placement, all 4- and 3-sensor configurations reach human equivalence in all measures of results. The best-performing 2-sensor configuration is obtained with a combined 1 arm and 1 leg placement, which has slightly lower-than-human equivalent performance in all other metrics except BIMS estimation. Finally, the one-sensor configurations perform poorly in all comparisons, while the proximal leg position is clearly better than an arm placement.

Discussion

Principal Results

Overview

This study shows that reductions in the IMU recording configurations lead to systemic and predictable compromise at all analytical levels, ranging from high temporal resolution analyses to recording-level statistics and a holistic assessment of motor performance. (Tables 1 and 2). While the present dataset is collected from young infants during their spontaneous activity, the studied movement behaviors [28] present a natural repertoire of well-defined movements and postures at any age. We, therefore, posit that the findings on high-resolution posture and movement detections are generalizable to other age groups as well, though the lower-resolution movement behavior in the older participants is more structured and predictable. Thus, the highly variable infant data provides a stress test for the overall methodology. Most importantly, (1) sensor placement is critical and at least one lower and one upper extremity sensor is essential for all high-resolution detections of posture or movement categories, (2) gyroscope data is significant for classifying movement types, and (3) data sampling rate has no meaningful effect on analyses.

When the analyses are based on complex pipelines, such as machine learning-based classifiers, the links between compromises in data versus results escape heuristic predictions. Instead, direct experimental evidence is needed, preferably in the context of an authentic end-to-end solution, such as the MAIJU recordings for infants' motor assessment used in our work. The strong effects of recording configuration, in particular the very low analytic accuracy of single sensor recordings, may seemingly conflict with the long history of actigraphy recordings [13,17,20]. Our study targeted high-fidelity detections of qualitatively different postures and movements, whereas actigraphy analyses measure the intensity (or amount) of movements to be categorized into different activity levels, such as sedentary, light, or moderate to vigorous activities [15,16].

Our present work does not aim to claim a universal superiority of any recording configurations. Instead, our findings emphasize the tight interplay, or trade-off, between the chosen recording configurations and the attainable analyses and study questions. Another potential comparison is the range of recently launched sport and wellness wearables that use one sensor to provide the user with logs of selected activity types, such as running, walking, or cycling. The apparently successful performance of those applications is based on using very long time-epochs (minutes to tens of minutes) and analyzing only monotonous and rhythmic movement patterns. Our results from human video annotations confirmed that the behaviorally relevant time resolution needs to be in seconds rather than minutes, and a significant part of the natural movement and posture categories of daily activity are not monotonous or rhythmic, at least in the studied infant population. While the present results and the presently studied movement measures are directly generalizable to any age group, it is important to note that studies using other movement categories (ie, other analysis targets) would benefit from their respective trade-off analyses.

The main purpose of reducing the recording configuration is to simplify movement studies for wider scalability and easier analytics:

Sampling Frequency and Data Rate

We show that the data rate can be reduced without loss of analytic gain from the original setup to 13 Hz, 2-sensor acc only recordings, corresponding to a compression factor of 16 (from 1248 numbers per second; 5.0 kilobytes/s with 32-bit floats to 78 numbers per second; 0.4 kilobytes/s). Furthermore, our results suggest that an even more radical reduction of the sampling rate to 2 - 6 Hz is feasible, especially if a higher number of sensors can be maintained. This is a novel finding that might have significant ramifications for future research directions, however, the current findings are directly applicable to the specific movement and posture categories used in our study pipeline. Other HAR classification targets with a wider dynamic range of physical movements may be more sensitive to lowering the

XSL•FO
RenderX

sampling rate. Lower sampling rates improve the pipeline at all levels: First, smaller IMU data files per time enable storage of longer recordings in the sensor memory [39]. Compared with real-time data streaming, local storage is easier for the user, and it yields substantial savings on the sensor battery (–96.8 µA) [40]. Second, the transmission of the recorded data over a wireless connection becomes much faster, and in the case of continuous streaming, it improves the stability of the wireless connection (here Bluetooth 5.0 low-energy was used).

Sensor Modalities

Reduction in sensor modalities to accelerometer only has direct effects on power consumption because gyroscopes consume considerably more power than accelerometers (approximately 5 times in the used Movesense sensor; 46 µA for 13 Hz acc, 227 µA for 52 Hz acc+gyro [40]). Additionally, dropping the gyroscope will also halve the data rate.

Sensor Number and Placement

Reduction in the number of sensors without significant effects on analysis performance gives 2 kinds of advantages: First, data recorded with initially higher sensor numbers can be used even in the event of sensor dropouts, either due to an actual recording failure of individual sensors or due to rejection by quality control afterward. Second, a lower number of sensors will also imply cheaper construction and easier use of the wearables. Here, we showed that a 2-sensor configuration is feasible in most situations if the data is reliably collected from at least one upper and one lower limb; yet, additional sensors are always improving the robustness by providing redundancy in case of technical failures that may be unpredictable in real-world environments.

Limitations

While our results contain readily translatable interpretations to wider use cases, the exact experimental design implies some limitations. First, our reference IMU data were obtained using a recording setup that was previously optimized for infant studies. Other anatomic locations (eg, distal limbs, trunk, or head [41,42]) could add further insights for use cases outside of the infant gross motor assessment. Our own unpublished studies indicated that distal sensor placements would not improve analytic reliability enough to justify the extra practical challenges coming from adding distal IMU sensors in wearable suits. Additionally, distal placements would come at the cost of far higher movement complexity in most activities. Regarding trunk and hip placement, our data does not inform it, but the lateral proximal sensor location in the leg comes close to hip placement.

Second, our work focused on posture and movement classifications of infants from the age they begin moving until they walk fluently. The apparently canonical postures and movements used in our classifier task [29] are likely applicable to any age group, but other groups were not explicitly assessed. However, we posit that naturalistic IMU datasets from adults including substantial sedentary behavior could well lead to better performance with more reduced recordings [27]. Nevertheless, we suggest that our present results and the conclusions thereof should be taken primarily as recommendations for a “safely sufficient” recording setup for the universally applicable posture and movement categorization task. Finally, it is important to note that our classifiers did not extend to more subtle movement characteristics, such as symmetry or synchrony between limbs, which may be important in the medical context [43]. Such analyses, however, require symmetrical sensor placements and preferably high sampling rates, such as our 4-sensor reference configuration.

Comparison With Prior Work

Our findings are fully in line with a larger body of prior literature (both for infants [6,28] and for adults [41,42,44]) and with the intuitive reasoning that reductions in the recorded data would compromise the analytically extractable information. However, we are not aware of prior studies performing so an extensive and systematic study, including so widely ranging recording configurations and diverse analytical outputs, where data collection has been based on naturalistic observation of behavior. Our results need to be compared with prior work separately for each study dimension. Regarding sensor number and placement, our findings are fully compatible with prior studies showing that 3 to 4 sensors in infants [4,6,28], or at least 2 sensors in adults [41,42], may provide sufficient analysis of postures at lower time resolutions. Our findings extend prior work by showing that 2-arm or 2-leg only setups are not adequate. We also extend our analysis outputs to movement classification, where the gyroscope supports clearly better analytic accuracy. Regarding the resolutions of our movement classifier, our study extends significantly the prior works by using a very high temporal resolution as well as discrimination between widely varying movement types [29]. Our algorithms operate at the second-by-second level for both posture and movements, whereas prior studies have provided multisecond [4,6], or more often multiple-minute resolution [45], or even coarser than that in many consumer electronic applications. It is clear that averaging movement data over longer time windows will improve classification, but this comes at the cost of losing the natural behavioral variability. Here, we showed empirically using video-based annotations that natural behavior is characterized by altering postures and movements at the level of seconds. Thus, an ecologically valid and informative movement analysis must also work at the same time resolution. It is striking in this context that most of the published HAR research has used “acted out” data collection, where the classifiers are trained (and validated) using movement recordings where participants’ performance is instructed (eg, [4,17,42,46,47]). Such classifiers may perform seemingly well, but they grossly simplify the naturalistic human movement activity behavior, leading to significant concerns about the lack of real-world validity and applicability when using the common recording configurations and analytic approaches [27]. The need for higher quality validation protocols, improved gold-standard reference methods (eg, video), and more realistically assigned classification targets [29] is imperative when the movement recordings are applied to assessing real-world behavior using wearable systems. A recent thorough review by Giurgiu et al [27] concludes with the statement (sic): “Future research should strongly aim at biological state and posture or activity outcomes and strive for standardized protocols embedded in a validation framework”, which is precisely addressed by this article.

XSL•FO
RenderX

Conclusions

This study identified the minimalist setup for adequate posture and movement tracking as: at least a combination of one upper and one lower extremity sensor, 13 Hz sampling frequency, and at least an accelerometer, but preferably also a gyroscope. However, optimizing recording configurations always comes at a price, and striking the balance between gains and losses must be done with respect to each analysis target and the study question. For instance, a posture-based behavioral assessment may benefit from a very long recording time, even up to a week, supporting the use of the minimalist setup. However, thorough characterization of gross motor performance needs high accuracy in both posture and movement measures, while it does not benefit from excessively long recording times [29,30]. For the particular purpose of infant recordings with optimal analytic gain, it is recommended to use the full reference configuration (as in the MAIJU wearable setup [29]), including 4 sensors with both accelerometer and gyroscope modalities. The systematic assessment of analytic compromises provides future IMU sensor users with an evidence-based guide to optimize their recording configurations for each particular use case.

Acknowledgments

The authors wish to thank the Finnish CSC-IT Center for Science for the scientific computing resources used to perform the experiments. This work was supported by the Finnish Academy (314602, 335788, 335872, 332017, 343498), Finnish Pediatric Foundation (Lastentautiensäätiö), Suomen Aivosäätiö, Sigrid Juselius Foundation, and HUS Children's Hospital/HUS diagnostic center research funds. Open access was funded by the Helsinki University Library. The funding organizations had no role in the design or conduct of the study; in the collection, analysis, or interpretation of the data; in the decision to submit the article for publication; or in the interpretation, review, or approval of the article. Generative artificial intelligence was not used in any form to generate or ideate the text or the visualizations within the manuscript.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request. Please contact SV (sampsa.vanhatalo@helsinki.fi) for requests.

Authors' Contributions

MA, OR, and SV conceptualized the study. MA performed all the experiments, analyses, and visualizations. MA wrote the initial draft, and OR and SV critically edited and revised the final manuscript.

Abstract

Background: Air pollution is a major environmental cause of premature deaths, responsible for around 7 million deaths annually. In this context, personal air pollution exposure (PAPE), the product of pollutant concentration and minute ventilation (*V'm*), is a crucial measure for understanding individual health risks. Standard exposure techniques do not address the space-time variability of air pollution, both indoor and outdoor, and the intra- and intersubject variability in *V'm*.

Objective: This study evaluates the feasibility of using a wearable body sensor network (BSN) to estimate PAPE in real-life settings, assess its capability to detect spatiotemporal variations in pollution levels, and compare inhaled dose estimates from the BSN with those from fixed monitoring stations and standard *V'm* values. The study also examines the system's usability.

Methods: The system, a BSN capturing physiological (pulse rate [PR] and respiratory rate [RR]) and environmental data, including health-affecting pollutants (particulate matter [PM] 1, PM2.5, PM10, CO_2, CO, total volatile organic compounds, and NO_2), was tested in a 4.5 km walk in Milan by 20 healthy volunteers. PR and RR collected by the system were used, together with biometric data and forced vital capacity estimations, in a model for *V'm* estimation to compute PAPE. Pollution levels were compared between morning and afternoon measurements, as well as between indoor and outdoor settings.

Results: Variations in RR were found among volunteers and at different locations for the same participant. Significant differences (P<.001) in pollutant concentrations were observed between morning and afternoon for CO_2 (higher in the morning) and PM (higher in the afternoon). Spatial variability along the walking path was also detected, highlighting the system's high spatiotemporal resolution. Indoor environments showed high variability in CO_2 and total volatile organic compounds, while outdoor settings exhibited elevated and variable PM levels. The mean PAPE to PM2.5 estimated with tabulated *V'm* and fixed station data was 13.31 (SD 4.16) µg while the one estimated with the BSN was 16.27 (SD 9.78) µg, 2.96 µg higher (22.3%; 95% CI −6.55 to 0.63; P=.05) than the former one, and with a broader IQR. Nevertheless, the 2 estimation methods show a good and strongly significant correlation (r=0.665; P<.001). The system's usability was generally rated as good.

Conclusions: The BSN provides high-resolution spatiotemporal data on personal exposure, capturing differences in pollution levels dependent on time, location, and surrounding environment, along with individual physiological variations. It offers a more accurate estimation of inhaled dose in real-life settings, supporting personalized exposure assessments and potential applications in activity planning and complementing epidemiological research.

air quality; body sensor network; personal exposure; cardiorespiratory monitoring; wearable system

Introduction

Air pollution is the main environmental trigger for premature deaths worldwide. A total of 9 out of 10 people breathe highly polluted air, as stated by the Organization for Economic Co-operation and Development Outdoor and household air pollution causes around 7 million deaths every year, 90% of which occurs in low- and middle-income countries because of open fires and stoves used for cooking purposes [1].

Reducing environmental pollution is a widespread concern and the United Nations has included it among the Sustainable Development Goals, more specifically in relation to the third goal about good health and well-being.

In this alarming scenario, accurate monitoring of the air we breathe is fundamental, both from an individual point of view, as a way of enhancing awareness and promoting a healthy lifestyle, and from a collective point of view, to foster new public policy oriented towards improving air quality. For instance, in the context of public intervention, monitoring and control over air pollution are among the foundation stones of smart cities [2,3].

XSL•FO
RenderX

Nowadays, there are various technologies for monitoring air pollution. Fixed stations are located in various geographical areas to assess the environment, which in turn is characterized by different predominant emission sources and different distribution and density of buildings. In addition, in some countries, such as Italy, mobile stations are used for a predetermined period (eg, 2 weeks) to investigate pollution variability during the year and examine specific situations, following notification by the municipal administrations [4]. Moreover, satellite observations help identify large areas of pollution. For instance, the Sentinel-5 Precursor satellite from the European Space Agency produces one image per day for different pollutants. These measurements are crucial for protecting public health, preserving the environment, guiding policy decisions, mitigating climate change, and promoting sustainable development, but operate at a macro-geographical and population level and give little insight into more specific data at the individual level.

Generally, studies conducted at the individual level approximate a person's level of exposure to various pollutants to the outdoor pollution level at their residential address. As demonstrated by Lu [5], ignoring human motion and spatiotemporal variability of air pollution could lead to differential exposure misclassification, potentially biasing health risk assessments. This happens because standard monitoring techniques are not sufficient to account for the great space-time variability of pollution [6]. Indeed, air quality can drastically change over short distances, lower than 100 m [7], and short time intervals [8] due to its pronounced dependence on both pollution sources and air circulation. As an example, "urban street canyons", that is, streets lined with tall buildings that impede air circulation, can give rise to a pollution scenario that can be completely different from the surrounding one.

As mentioned before, indoor air quality must be monitored as well, as demonstrated in multiple research studies [9,10]. In fact, people spend between 80% and 90% of their time in closed environments and the World Health Organization reports 1.6 million premature deaths caused by indoor air pollution [11].

However, focusing solely on indoor exposure results in a significant underestimation of exposure levels [5]. For example, particulate matter [PM] 2.5 exposure measured exclusively in indoor environments is estimated to be 61% lower than actual exposure for commuting distances exceeding 30 km. For these reasons, a personal air quality monitor is suggested to accurately assess exposure to pollutants, taking into account the participant's mobility between indoor and outdoor environments [12].

Various companies have developed portable systems capable of monitoring key air pollutants [6]. Among them, it is worth mentioning the Atmotube PRO (Atmotech Inc), which provides continuous monitoring of PM and volatile organic compounds (VOCs), and Flow (Plume Labs) which measures PM, VOCs, and nitrogen dioxide (NO_2). Further examples include the Wynd Air Quality Tracker (WYND), which specializes in PM monitoring, and Aeroqual's portable air quality monitor (Aeroqual), which supports the integration of different sensors in a limited configuration.

Nevertheless, for an accurate assessment of the pollution that effectively infiltrates human organisms, the respiratory activity of the participant assumes a crucial role. To consider the whole phenomenon, personal air pollution exposure (PAPE) is the appropriate measure, as proposed by Arano et al [8]. PAPE is evaluated considering a respiratory factor and an environmental factor. It is calculated with the following formula:

$$(1) PAPE(p)=SZ(p)*V'm$$

Where V′m is minute ventilation in m^3/min and SZp is the fully aggregated pollution value in a certain period *p*, calculated as:

$$(2) SZp=\sum t=1n12(Zti+1+Zti)(ti+1-ti)$$

Where Zti+1 and Zti are the specific pollutant concentrations in the time instants of ti+1 and ti, with ti+1−ti should be lower than 10 minutes.

Hence, a wearable system following the person everywhere, monitoring both indoor and outdoor environments and the cardio-respiratory activity of the person, can represent a robust solution for the accurate assessment of PAPE. In this study, we have carefully structured our experimental design to systematically address multiple research questions. Our primary objective is to evaluate the feasibility of using a body sensor network (BSN) of wearable devices to estimate personal pollutant exposure in real-life settings. To validate the performance of the BSN, we compare the inhaled dose [13] calculated from the system's measurements with the dose derived from fixed monitoring station data and tabulated Vm′ values. Furthermore, we assess the system's ability to detect variations in pollution levels across different times and locations. Additionally, we seek to determine the usability of the BSN in both indoor and outdoor environments. These distinct yet interconnected objectives are central to advancing our understanding of the system's potential applications and limitations. In section II, the novel system and the experimental protocol involving 20 healthy participants are detailed. Results about pollutant distributions and evaluation of PAPE to air pollutants are reported and discussed in section III. In section IV conclusions are drawn, highlighting limitations and future developments.

Methods

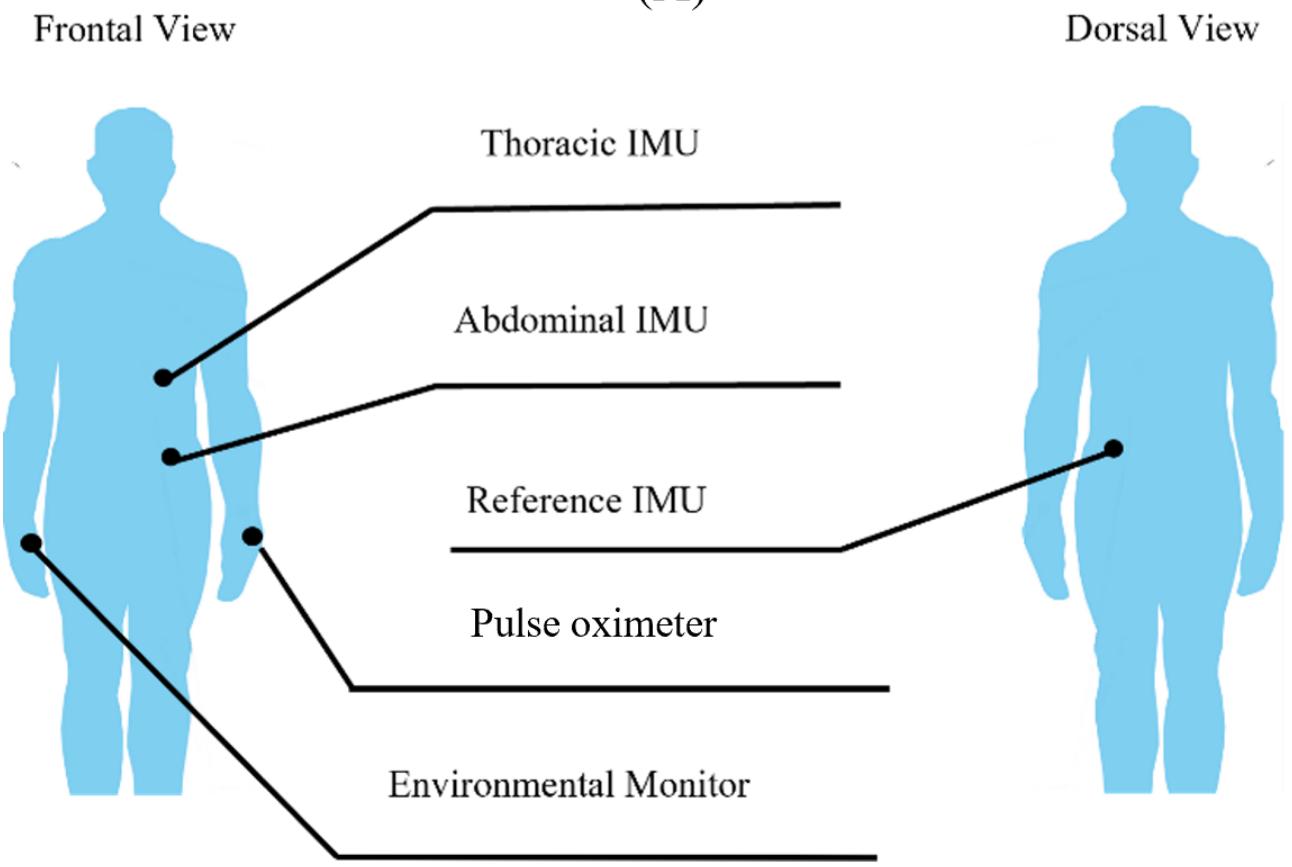
Environmental Monitor and Cardio-Pulmonary Monitoring Platform

The developed wearable environmental monitor, shown in Figure 1A, is designed to be worn on the wrist or on the arm to track the pollutant concentrations to which the participant is exposed [14].

XSL•FO
RenderX

Figure 1. (A) Wearable device for environmental monitoring; (B) Body sensor network composed of 3 IMUs, a wrist-worn pulse oximeter, and a wrist-worn environmental monitor. IMU: inertial measurement unit.

(A)



(B)

The monitored pollutants are PM (specifically PM1, PM2.5, and PM10; where the number indicates the diameter of the particle in µm), CO_2, total volatile organic compounds (tVOCs), carbon monoxide (CO), and NO_2. The PM sensor is the SPS30 by Sensirion (accuracy of ±10 µg/m^3 for PM1 and PM2.5, ±25 µg/m^3 for PM10) [15], the CO sensor is the SCD41 (±40 ppm of accuracy) [16], the tVOC sensor is the SGP30 (1.3% of measured value with Ethanol and H_2) [17], and the CO and NO_2 sensor is the MICS-6814 by SGX [18]. Atmospheric parameters such as temperature, humidity, and pressure are also detected using the Bosch BME280 sensor. The environmental monitor node is integrated into a BSN, shown in Figure 1B, aimed at collecting cardio-respiratory data. The BSN is composed of 3

XSL•FO
RenderX

devices each embedding an inertial measurement unit (IMU), positioned one on the thorax, one on the abdomen, and a reference one on the back [19-21], and a wrist-worn pulse oximeter [22], in addition to the environmental monitor.

During the experimental campaign, data recorded by all the nodes of the BSN were exploited to evaluate the PAPE. The sample frequency of the 3 IMUs and the pulse oximeter is 10 Hz for each of them and data are sent through the ANT communication protocol in a shared channel network configuration. Instead, the environmental monitor has a sampling frequency of 0.042 Hz and sends a new set of data every 24 s in an independent channel for data transmission to the master which, in our case, is a smartphone. An Android application displays environmental data in real time and geolocates them using the integrated smartphone GPS. Both environmental and physiological data are saved in a cloud-hosted database (ie, Google Firebase) for later analysis.

Inclusion and Exclusion Criteria

Volunteers were eligible to participate if they were between 18 and 75 years of age. However, individuals were excluded if they exhibited any physical deformities in the upper limbs that might compromise the validity of the data obtained. Anyone with gait impairments likely to interfere with the ability to complete the study protocol was also excluded.

Experimental Campaign

The experimental protocol consisted of a walk over 4.5 km in the university area of Politecnico di Milano, passing through some specific places. The full path is reported in Figure 2. Two different types of acquisition were performed as follows: static and dynamic. Static acquisitions consisted of 5 minutes of recording of the overall system in a static condition in 7 acquisition points. Each point represents a distinct microenvironment: a laboratory (A), a gas station (B), a park (C), an intersection with traffic light (D), a train station (E), a small park (F) in which there is also a fixed station of the Lombardy regional agency for environmental protection (Agenzia Regionale per la Protezione Ambientale; ARPA) and a low traffic street (G). Participants were seated in points A, F, and G, and standing in points B, C, D, and E. Dynamic acquisitions involved only the environmental monitor and consisted of the recording of pollutant concentration while walking from one static point to the other. Most acquisitions were performed in November 2022. Two time slots per day were available, one in the morning around 10:00 AM and one in the afternoon around 2:30 PM. This choice was made to avoid peak traffic hours and keep as much as possible the same conditions during all the acquisitions.

Figure 2. Route of the experimental campaign with static acquisition points highlighted. They are (A) inside a laboratory, (B) near a gas station, (C) in a park, (D) at an intersection with traffic lights, (E) near a train station, (F) in a small park where there is also an ARPA station, and (G) in a low traffic street. ARPA: Agenzia Regionale per la Protezione Ambientale.

RenderX

Preprocessing and Normalization of Environmental Data for Comparative Analysis

Environmental data were resampled with a sampling frequency of 1 Hz. Then, the entire acquisition was segmented using time stamps registered during the acquisition protocol when arriving at and leaving each acquisition point. This process generates 7 arrays for static conditions and 7 arrays for dynamic acquisition for each participant, serving as a means of space normalization to facilitate the comparison of acquisitions across different volunteers. In fact, given the hypothesis of variability in pacing among volunteers and that an uncontrolled environment is susceptible to random events (eg, red traffic lights or crowds affecting walking speed), this approach ensures a more consistent basis for comparison.

A linear interpolation that takes 3 samples per minute is applied to obtain the same number of samples for each participant in each segmented array.

After these processing steps, different pollutants and their variation along the path were plotted and visually inspected. Considering that ARPA provides a single daily value for PM2.5 and PM10, our comparison with data recorded by the fixed station (F) focused on acquisitions conducted in the morning and afternoon of the same day.

Personal Air Pollution Exposure

The assessment of the inhaled dose, or PAPE, involved the use of Equation (1) and was computed for PM1, PM2.5, PM10, tVOC, and CO_2. The minute ventilation in (1) is computed as the product of the respiratory rate (RR) and tidal volume. Since tidal volume information are not provided by the system, a model proposed by Greenwald et al [23] was instead deployed for the respiratory factor. This model is in the form of a power function, reported in (3), based on a large, pooled dataset, with a median percent error of 1.20% (IQR 37.9%).

$$(3)\quad V'm = e^{-8.75} HR^{1.72} RR^{0.611} age^{0.298} sex^{-0.206} FVC^{0.614}$$

Where V′m is the value of minute ventilation expressed in L/min, HR is the heart rate in beats per minute, and RR is the respiratory rate in breaths per minute, and FVC is the forced vital capacity in L. Pulse rate (PR) data are recorded by the pulse oximeter and are used instead of HR, whereas the 3 IMUs monitor RR. In this paper, FVC was evaluated using the Global Lung Function Initiative method from the European Respiratory Society [24]. The remaining variable is sex (1 for men, 2 for women).

For what concerns the environmental factor, it consists of a mean of the values acquired during 1 minute of measurement for all 5 minutes in the different static acquisition points. PAPE to PM2.5, assessed using data obtained from wearable sensors, was compared with what is hereafter referred to as the “Standard Method.” This method estimates PAPE based on tabulated values for V′m, and daily pollutant concentration data from ARPA fixed monitoring stations. Specifically, in the Standard Method, V′m values were derived from tables considering age range, sex, and activity level [25].

In our study, we opted to align with an activity level of 3, characterized by METs typically falling within the range of 2 to 4, as an approximation to our experimental conditions. In fact, the trial encompassed brisk walking, an activity associated with a MET value of 5, and standing and seated positions, corresponding to MET values of 1.8 and 1.3, respectively. The tabulated minute ventilation for an activity level of 3 is 13.26 L/min for women and 15.14 L/min for men. These values were used as respiratory factors in the Standard Method.

Questionnaire

At the end of the experimental protocol, a questionnaire, reported in Table 1, was verbally administered by the principal investigator or his collaborators to the participants to assess satisfaction with device usability. Answers were recorded, transcribed, and then the audio recordings were deleted. The recording was convenient as it allowed the participants to walk while answering, ensuring that the process did not interrupt the experimental activities and reducing the overall time required for the protocol.

Table . Items of the wearability questionnaire.

Item number	Item	Ideal scores
I1	I think the device is simple to wear	5
I2	I think I would be able to use the device autonomously	5
I3	I found the fixing method uncomfortable	1
I4	I would have preferred to remove the device during the test	1
I5	I think I could wear the device for a long time	5
I6	I think using the device would negatively affect my daily activities	1
I7	I think I would be able to use the smartphone app autonomously	5
I8	I think the data shown are easy to read	5
I9	I think the device has a functional design	5

XSL•FO
RenderX

Participants were asked to give a score between 1 (completely disagree) and 5 (completely agree) to the 9 statements. The collected responses were compared with the ideal scores (reported in Table 1) to evaluate satisfaction with the device, and the results were visualized using a radar plot.

Statistical Analysis

First, the statistical difference in pollutants' concentration and physiological parameters between the 7 static acquisition points was assessed. After checking the normality of the distributions through the Shapiro-Wilk test, a Friedman test was performed. If the null hypothesis was rejected, a post-hoc test was performed to assess between which acquisition points there was a statistical difference in pollutants' concentration and physiological parameters and the entity of this difference.

Then, concentrations of the morning and afternoon acquisitions of the same day were compared by means of a Wilcoxon signed rank test, aiming to assess potential statistical differences between these time intervals.

RR of the different participants was analyzed using Kruskal-Wallis one-way ANOVA on Ranks to determine the presence of any statistical differences. This assessment aimed to gauge whether a standard value of RR could effectively serve as a proxy for the actual real-time RR recorded during the protocol.

Ethical Considerations

The experimental protocol was approved by Politecnico di Milano Ethics Committee (approval number 39/2022; date of approval October 10, 2022) and involved 20 healthy volunteers, who gave their informed consent. Participants retained the right to withdraw from the study protocol at any time, as outlined in the informed consent. Participant data were safeguarded through a process of pseudonymization, whereby each participant was assigned a unique identifier, with the key linking identifiers to individual identities securely maintained by the principal investigator. Participants were recruited through word of mouth and did not receive any financial compensation for their participation.

Results

Participants

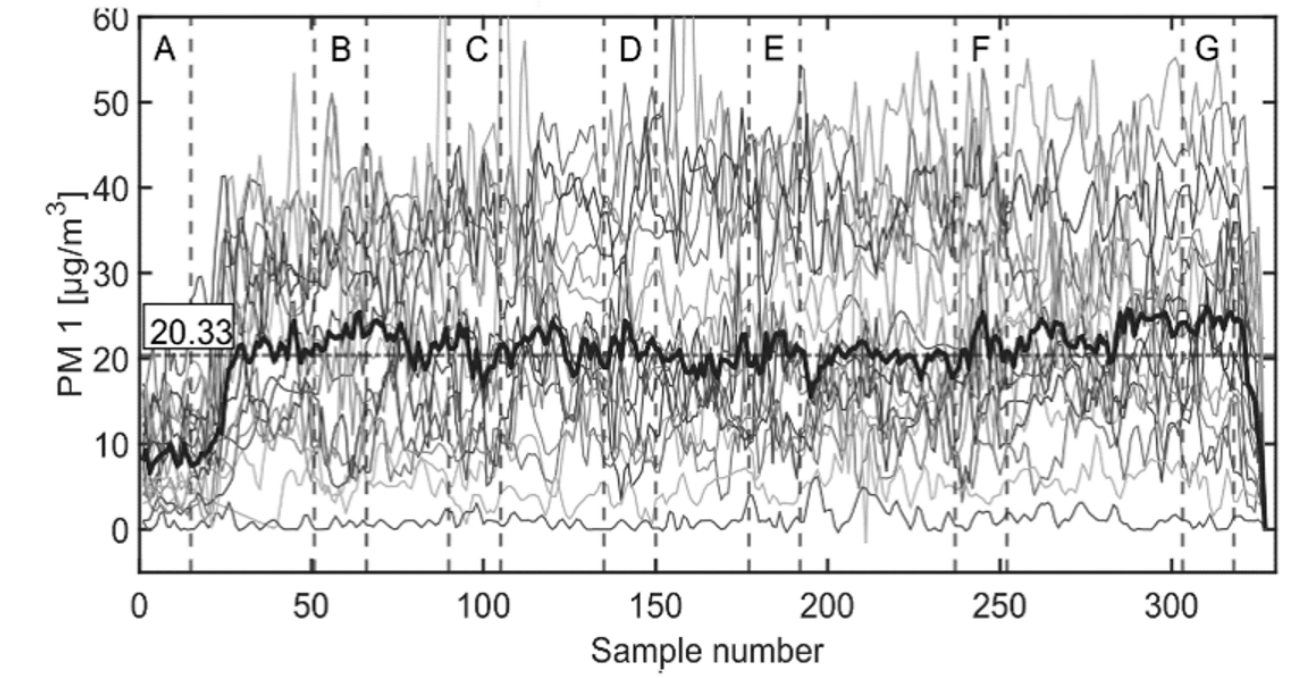
The population consisted of 14 male and 6 female participants. The median of the age distribution was 25.5 years with an IQR of 3 years, with 3 outliers at 32, 46, and 55 years. The median body weight was 70 (IQR 67.5-76.5) kg and the median height was 179 (IQR 168.0-180.5) cm.

Pollutant Concentration Trends: Indoor Versus Outdoor and Temporal Comparisons

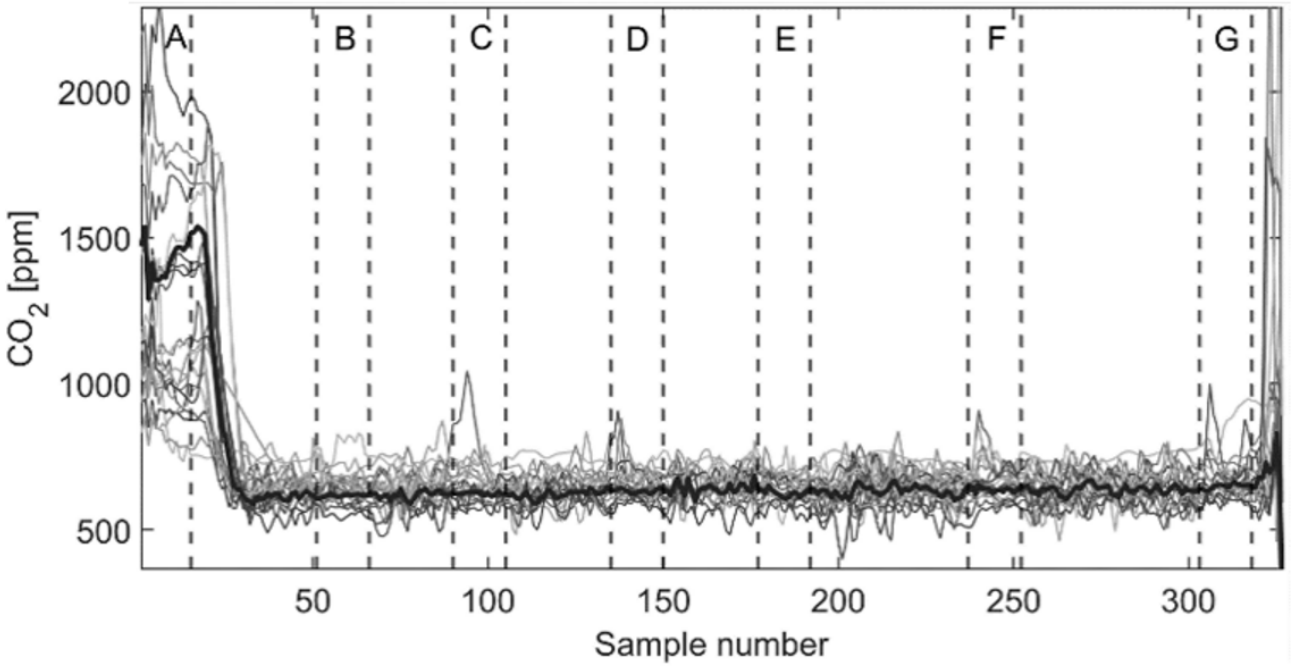
In Figure 3A and B, PM1 and CO_2 concentrations, respectively, of the whole acquisitions are reported, with the median curve represented by the bold line. As expected, there is a strong variation moving from the indoor environment (acquisition point A, inside a laboratory) to the outdoor environment (all other acquisition points). Specifically, PM1 exhibits a significant increase outdoors, whereas CO_2 shows the opposite trend. Inside the laboratory, significant variability and numerous high peaks of CO_2 can be observed.

XSL•FO
RenderX

Figure 3. PM1 (A) and CO_2 (B) concentration along the route for the 20 participants. The median is represented by the bold line. The vertical dashed lines show the 7 specific acquisition points, denoted by capital letters A through G: point A, inside a laboratory; point B, near a gas station; point C, in a park; point D, at an intersection with traffic lights; point E, near a train station; point F, in a small park where there is also an ARPA station; and point G, in a low traffic street. ARPA: Agenzia Regionale per la Protezione Ambientale; PM: particulate matter.



(A)



(B)

Substantial variability in PM was observed for the outdoor segment of the acquisition path. This variability is evident in Figure 4, which illustrates PM2.5 concentrations for 2 participants tested on the same day during the morning (Figure 4A) and the afternoon (Figure 4B). For instance, it can be noted that along the same street, from acquisition point B to E, concentrations span from very low (0 - 12 µg/m^3) to very high (55 - 150 µg/m^3) values. Moreover, Figure 4 also shows a generally lower concentration of PM2.5 in the morning with respect to the afternoon for a representative day. All these considerations are true also for PM1 and PM10.

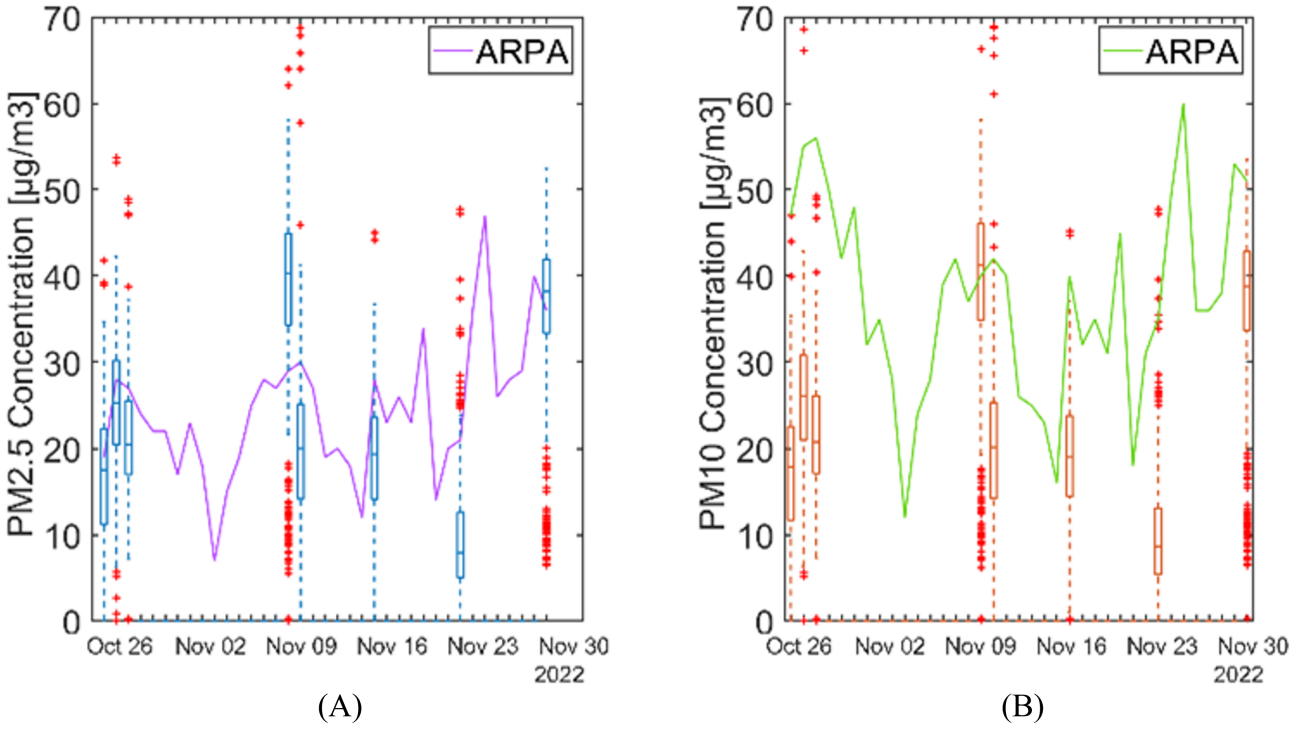
XSL•FO
RenderX

In Figure 5, boxplots of the new device measurements and a solid line for ARPA values are reported. It can be observed that concentrations captured by the new device are often lower than the mean value of the day reported by ARPA.

NO_2 and CO levels never overcame the detection limit of 20 ppb during our acquisitions.

Figure 4. Map of the PM2.5 concentration during (A) morning acquisition and (B) afternoon acquisition of 2 participants, tested the same day. The 7 specific acquisition points are denoted by capital letters A through G: point A, inside a laboratory; point B, near a gas station; point C, in a park; point D, at an intersection with traffic lights; point E, near a train station; point F, in a small park where there is also an ARPA station; and point G, in a low traffic street. ARPA: Agenzia Regionale per la Protezione Ambientale; PM: particulate matter

Figure 5. PM2.5 (A) and PM10 (B) concentrations' comparison between ARPA values taken from the fixed station in point F (continuous line) and data recorded by our device when 2 participants were tested on the same day (boxes). ARPA: Agenzia Regionale per la Protezione Ambientale; PM: particulate matter.



Quantitative Analysis of Pollutant Concentration and Physiological Parameters

For each pollutant, the Friedman test showed a statistical difference between acquisition points. In fact, for each gas and particulate, there was a statistical difference between the indoor environment and the outdoor environment. A higher value of CO_2 and tVOCs was found inside the laboratory with respect to all other outdoor acquisitions. Instead, PM was higher outdoors and lower indoor. Medians and IQRs for each pollutant together with RR and PR in the different acquisition points are reported in Table 2.

XSL•FO
RenderX

Table . Concentrations of CO_2, total volatile organic compounds (tVOCs), particulate matter (PM) 1, PM2.5, PM10, respiratory rate (RR), and pulse rate (PR) in the 7 specific acquisition points.

	CO_2 (ppm), median (IQR)	tVOCs (ppb), median (IQR)	PM1 (µg/m^3), median (IQR)	PM2.5 (µg/m^3), median (IQR)	PM10 (µg/m^3), median (IQR)	RR (breaths/min), median (IQR)	PR (beats/min), median (IQR)
A	1010.4 (214.2)	586.1 (207.5)	8.4 (7.8)	9.9 (8.6)	10.4 (8.9)	24.0 (16.9)	86.7 (13.1)
B	615.9 (56.3)	167.7 (215.0)	22.7 (22.8)	24.2 (16.0)	24.6 (16.9)	17.1 (16.6)	98.8 (19.2)
C	628.7 (73.5)	161.8 (254.2)	19.7 (23.3)	23.0 (17.5)	23.3 (17.3)	14.3 (9.67)	98.1 (18.6)
D	619.4 (74.7)	160.4 (259.9)	21.5 (24.8)	21.7 (16.9)	22.0 (18.9)	14.6 (9.6)	97.7 (19.0)
E	628.5 (72.0)	86.1 (134.7)	20.7 (23.5)	23.3 (21.9)	23.7 (21.6)	14.3 (9.7)	105.1 (21.0)
F	626.6 (64.6)	134.5 (319.6)	21.7 (20.2)	21.8 (17.0)	22.1 (17.1)	11.1 (8.6)	99.0 (21.5)
G	650.0 (79.1)	205.8 (440.0)	24.4 (17.8)	26.2 (15.1)	26.6 (15.1)	11.3 (9.6)	101.0 (25.0)

In addition to the significantly different results between indoor and outdoor acquisition points, other statistically significant differences were detected between the distributions. For CO_2, the acquisitions in point G, outside the laboratory in the parking lot near a low-traffic street, differ with a $P<.05$ from all the other acquisition points. The great variability of the indoor CO_2 concentration, assessed visually in Figure 1, was confirmed also by a quantitative analysis, showing a wider IQR in the indoor acquisition of all participants with respect to all the other outdoor acquisitions. For what concerns tVOCs, point E near the train station, which is highly ventilated, shows significantly lower values with respect to point G ($P<.001$). PM concentration was significantly higher in point G ($P<.001$ for all PMs) with respect to the gas station (B), the park (C), and the intersection with traffic lights (D).

About the comparison between morning and afternoon acquisitions, significantly higher values of concentration were found in the afternoon ($P<.001$) for all the pollutants except CO_2, which was higher in the morning ($P<.001$).

Regarding physiological parameters at various acquisition points, several noteworthy observations emerge.

The median RR at the initial acquisition point (A) was notably higher compared with all others, exhibiting a significant difference from points C, E, F, and G (with P values respectively $P_{AC}=.002$, $P_{AE}=.001$, $P_{AF}<.001$, $P_{AG}=.001$). In points C, D, and E, RR values are slightly higher than those in points F and G, although not significantly except for the couple CF ($P_{CF}=.049$, $P_{CG}=.33$, $P_{DF}=.26$, $P_{DG}=.30$, $P_{EF}=.647$, $P_{EG}=.94$).

Turning our attention to PR data, a remarkable disparity exists between point A and all other acquisition points ($P<.001$). Both RR and PR values showed great variability among participants, confirmed also by the Kruskal-Wallis one-way ANOVA on Ranks ($P<.001$ in both cases).

Inhaled Dose

A participant-specific comparison of PAPE to PM2.5 computed with tabulated data for V′m of an activity level of 3 (13.26 L/min for women and 15.14 L/min for men) and ARPA daily concentration values (indicated by the subscript “STD”), and the assessment derived from the wearable system (indicated by the subscript “NEW”), is reported in Table 3.

XSL•FO

[a]C: concentration.

[b]ID: inhaled dose.

Computed V′m has a great variability among the different participants as highlighted by median values, but also intrasubject variability as can be observed analyzing the reported IQRs. It can be observed that the IQR values of C_{NEW} are very high, reaching a maximum of 10.2 µg/m^3. This proves the great spatial and temporal variability of PM2.5 along the 4.5 km path and the ability of the developed wearable environmental monitor to account for that.

It is calculated that using ARPA values of concentration and tabulated values of minute ventilation led to a mean PAPE to PM2.5 (ID_{STD} in Table 3) of 13.31 µg with a SD of 4.16 µg, whereas the PAPE obtained with our BSN (ID_{NEW} in Table 3) had a mean of 16.27 µg and a SD of 9.78 µg. They are strongly positively correlated (r=0.665, P<.001), indicating that when the dose estimated from wearable devices increases, the dose calculated from standard data also tends to increase; similarly, when there is a decrease in one measure, the other decreases as well. This alignment suggests a consistent relationship between the 2 methods, with changes in wearable-derived data generally reflecting those in the standard measurements, however, the method with wearable data exhibits higher variability in the estimations. The paired *t* test applied to the 2 normal distributions reveals that on average, the PAPE to PM2.5 with standard data underestimates by 2.96 µg the PAPE evaluated with recorded data coming from the proposed wearable system (22.3% difference; 95% CI −6.55 to 0.63, *P*=.05). Boxplots comparing the PAPE of PM2.5 are reported in Figure 6. In Table 4 the medians and IQRs of aggregated data of PAPE for the different acquisition points for CO_2, VOC, PM1, PM2.5, and PM10 are reported.

XSL•FO
RenderX

Figure 6. Boxplots representing PAPE to PM2.5 computed with standard data, which are ARPA values for pollutant's concentration and tabulated values for minute ventilation, and with wearable data detected by the proposed wearable system. ARPA: Agenzia Regionale per la Protezione Ambientale; PAPE: personal air pollution exposure; PM: particulate matter.

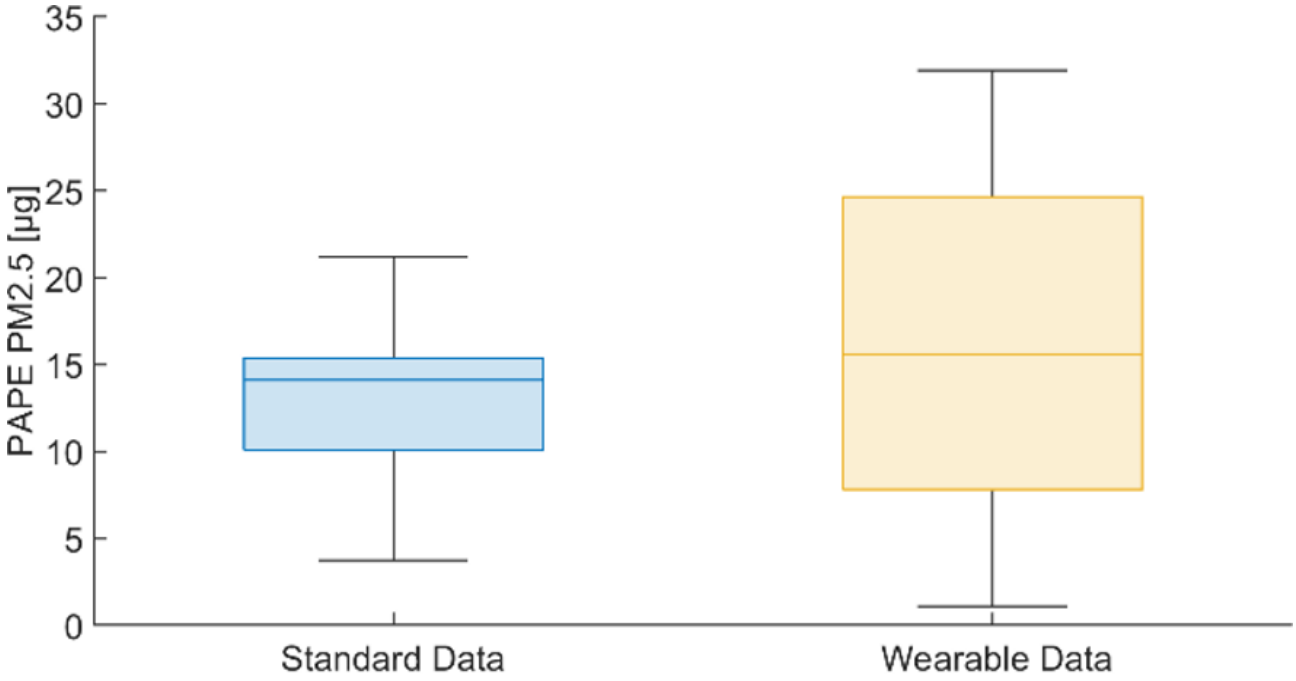

Table . Personal air pollution exposure of CO_2, total volatile organic compounds (tVOCs), particulate matter (PM) 1, PM2.5, and PM10 in the 7 acquisition points.

	CO_2 (pp•mm^3), median (IQR)	tVOCs (pp•bm^3), median (IQR)	PM1 (µg), median (IQR)	PM2.5 (µg), median (IQR)	PM10 (µg), median (IQR)
A	108.3 (59.3)	108.3 (59.3)	0.7 (1.3)	0.8 (1.4)	0.9 (1.5)
B	69.9 (52.0)	69.9 (52.0)	1.8 (3.1)	2.1 (2.9)	2.4 (3.2)
C	80.1 (22.5)	80.1 (22.5)	2.5 (2.6)	2.3 (2.5)	2.6 (2.6)
D	65.8 (18.7)	65.8 (18.7)	2.4 (3.1)	2.3 (2.9)	2.5 (3.2)
E	72.2 (35.0)	72.2 (35.0)	2.5 (3.8)	2.5 (3.5)	2.7 (3.8)
F	67.3 (20.0)	67.3 (20.0)	2.6 (1.9)	2.1 (1.8)	2.4 (1.9)
G	71.2 (20.0)	71.2 (20.02)	2.5 (2.5)	2.2 (2.5)	2.4 (2.8)

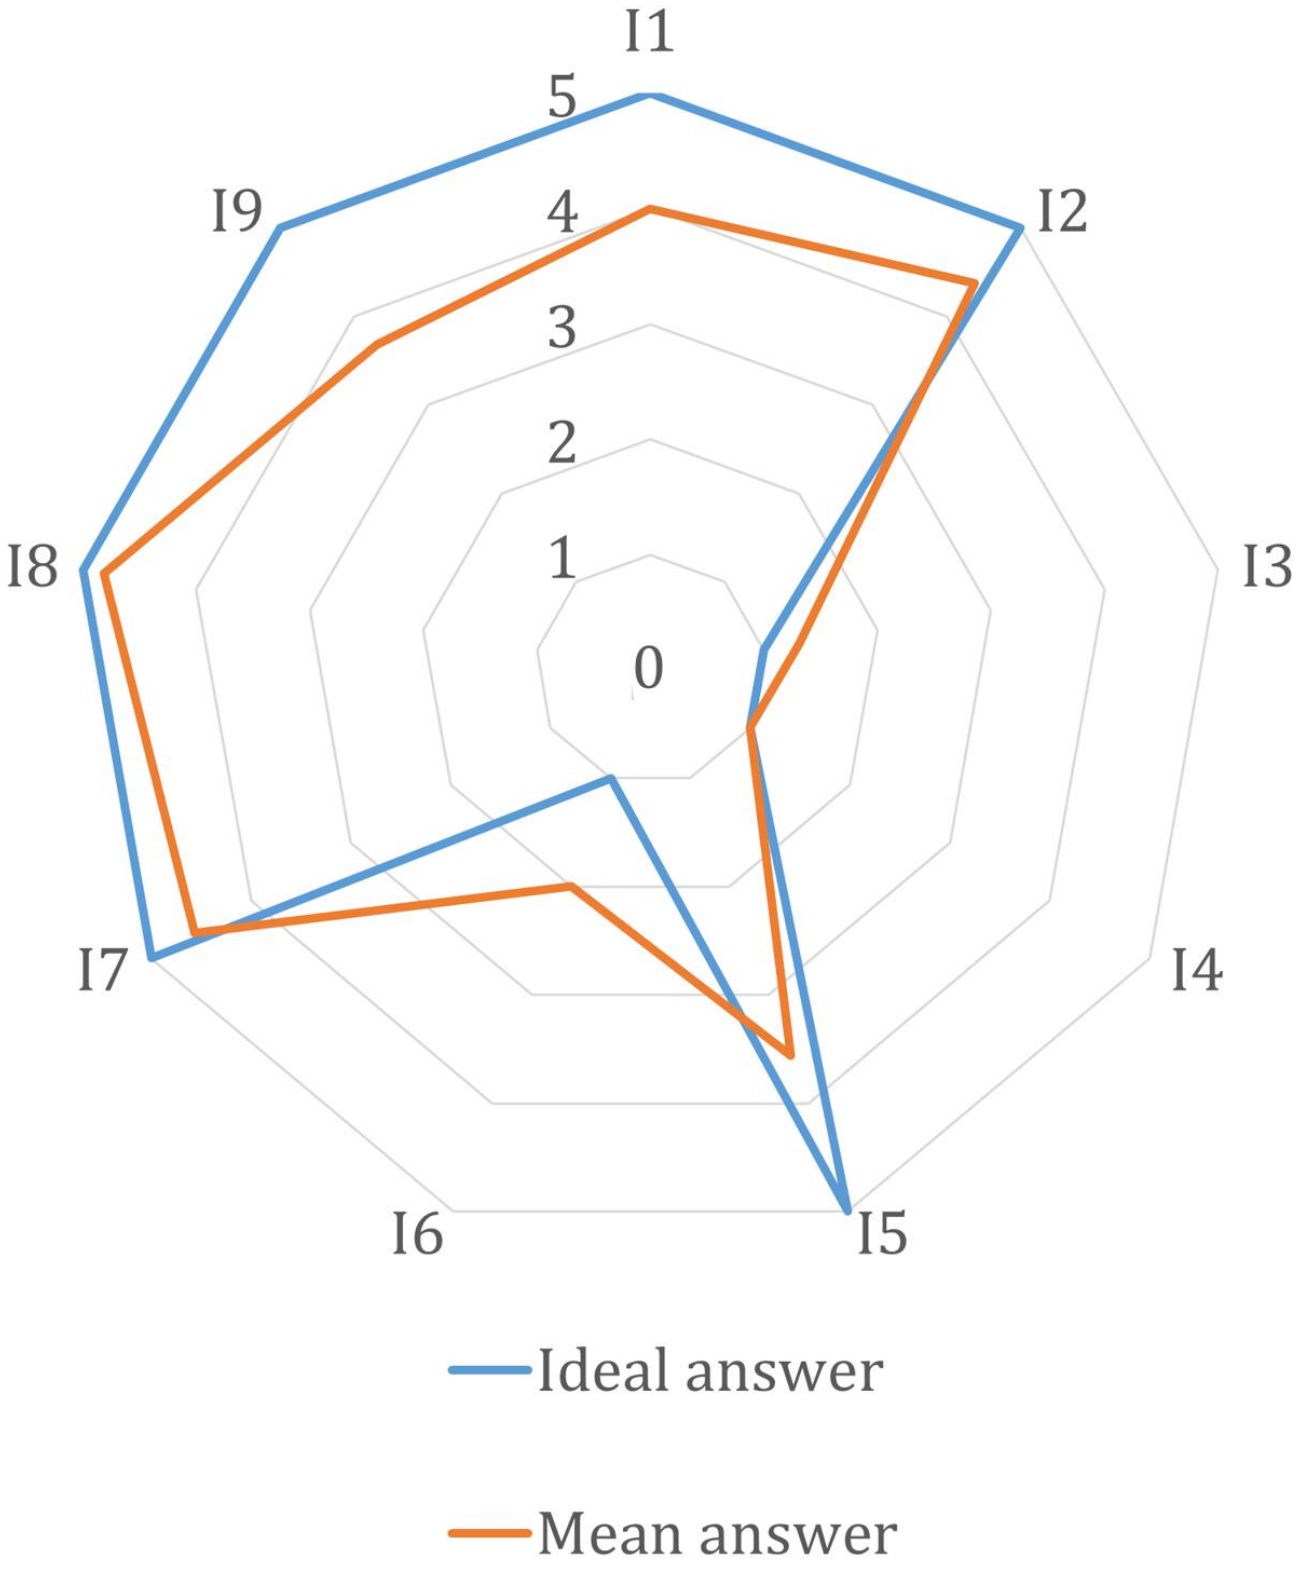
The Friedman test resulted in a significant difference in PAPE between acquisition points for all the pollutants, with a $P<.001$. The post-hoc analysis on PAPE, with the Bonferroni correction, revealed that the only point that is statistically different from all the others is point A, which was expected since it is the only indoor location of the experimental campaign. Some considerations, even though not statistically significant, can be added. PAPE to CO_2 is higher ($P=.12$) in point C (park) with respect to point F (small park with ARPA station). The situation is analogous for tVOCs ($P=.10$), with the additional factor that trees contribute to their emissions. Considering PAPE to PM near the station (E), higher values with respect to the other points were reached, even if statistically significant only compared with point C ($P_{BE}=.88$, $P_{CE}=.03$, $P_{DE}=.19$, $P_{EF}=.58$, $P_{EG}=.91$).

Questionnaire Results

The results of the questionnaire are presented in the radar plot in Figure 7, which displays both the collected scores and the optimal/ideal scores for each item. The lowest scores are obtained for statements regarding wearability over a long period and the functionality of the hardware design. Despite these concerns, high scores were obtained for the question addressing the comfort of the fixing method (I3 in Table 1). Additionally, the way data are presented in the accompanying application was appreciated, as demonstrated in I8.

XSL•FO
RenderX

Figure 7. Radar plot of questionnaire results. Ideal scores are indicated with the blue line while in orange mean scores collected during the campaign.



Discussion

Main Results

This study aimed to determine the feasibility of using the proposed BSN for estimating inhaled pollutant doses in real-life settings. Additionally, it sought to assess whether the system could detect differences in pollution levels between morning and afternoon, evaluate variations across predefined locations with different pollution sources regardless of the time of day, and examine the suitability of the BSN for both indoor and outdoor measurements. The study also compared the system's data with those from an ARPA fixed station and assessed the overall usability and user acceptance of the proposed solution.

The feasibility of using the proposed BSN for estimating the inhaled dose of pollutants in real-life settings is supported by the lightweight of the devices and their complete wearability.

XSL•FO
RenderX

For what concerns the environmental monitor, the sensors chosen are specifically suited for high temporal resolution sampling, making the system well-equipped to track the substantial spatial and temporal variability of air pollution. This is particularly relevant given that pollutant concentrations can vary significantly over small spatial scales (<100 m) and short time periods due to emission dynamics, such as traffic peaks during rush hours. As highlighted in the literature, fixed monitoring stations may fail to capture these variations adequately, reinforcing the need for a high-resolution mobile system [7]. For comparison, commercial environmental monitoring instruments typically offer a measurement every minute at best, and more commonly, one sample every 5 minutes. Our device, which samples environmental parameters nearly 3 times faster than the fastest commercial options, is thus well-suited to capture the detailed spatial and temporal information required in environments like those tested. Moreover, the system includes units capable of synchronously retrieving RR and PR already aligned with the pollution data [26]. These units were already tested both in static [22] and dynamic conditions [27] in previous works. The synchronized data collection of the system allows for an accurate evaluation of the inhaled dose, calculated as the product of pollutant concentration and V′m. Furthermore, the smartphone app has been thoroughly tested and performed reliably throughout the different tests. Therefore, the system is well-suited for estimating the inhaled dose of pollutants in real-life settings. It is worth noting that, although the sample size was determined by practical considerations, it also aligned with the sample sizes typically used in comparable studies focused on wearable prototypes or exposure assessment [22,28,29].

The system demonstrated its capability to study differences in pollution levels between morning and afternoon. CO_2 was found to be higher during morning acquisitions with respect to afternoon acquisitions on the same day, both excluding and including the indoor environment in the analysis. This result is also confirmed in the literature. In fact, outdoor concentrations of CO_2 exhibit daily and diurnal variations, with fluctuations ranging from 50 to 100 ppm in large urban centers, as was observed in a study in Baltimore [30]. CO_2 concentrations tend to be lower in the afternoon and higher in the morning. Instead, PM concentrations were statistically higher in the afternoon compared with morning measurements. This trend aligns with the influence of traffic, which significantly elevates PM levels during peak hours such as lunchtime, coinciding with school dismissal and workers' breaks.

The BSN effectively evaluated differences at predefined points along a walking path, each with potentially distinct pollution sources, regardless of the time of day. During the study, substantial fluctuations in PM were observed within a single data acquisition session, underscoring the limitations of stationary monitoring stations in capturing nuanced air quality dynamics. Indeed, over a short 4.5 km walk, individuals encounter diverse pollution levels, challenging the notion of a single daily concentration value as representative of actual exposure. For instance, in a low-traffic street in a parking lot (acquisition point G), PM levels were unexpectedly high, surpassing those at more conventionally polluted locations such as intersections with traffic lights. This elevated pollution was likely due to the architectural configuration around the parking lot, which impeded air recirculation, emphasizing the value of having a device that provides objective measurements rather than relying on subjective impressions. Physiological parameters further illustrate the system's effectiveness in individually evaluating PAPE. At the initial acquisition point A indoors, participants showed a significantly higher RR, likely due to heightened anxiety due to the start of the experimental acquisition or the high CO_2 concentration in the room. Currently, the system cannot distinguish between these factors because additional sensors, such as those measuring galvanic skin response, are needed to properly assess the participants' stress levels. However, the system shows potential for future developments in this area. Furthermore, the transition from point A to point B, which involved ascending a flight of stairs, contributed to the observed higher, even if not significant, RR at point B with respect to the other acquisition points. RR further decreased at subsequent points, particularly where participants were seated, such as at points F and G. PR data showed lower values at point A, with consistent increases as participants moved and engaged in brisk walking, reflecting expected physiological responses. Additionally, variations in CO_2 and tVOCs levels were observed across different points. Point C, a park with dense tree cover, had significantly higher CO_2 and tVOCs readings compared with point F, a smaller park with less tree coverage. Studies suggest that VOCs from trees may have beneficial effects, such as enhancing cognitive functions and reducing mental fatigue [31]. Consequently, understanding whether a sensor can detect tree-derived VOCs—and at what concentrations—is essential for making informed decisions about exposure and potential benefits. For PM, the highest IQR was recorded at point E, near a train station, influenced by factors such as nearby taxis and varying traffic conditions. This variability, along with differences in physiological responses, underscores the importance of the BSN's ability to provide nuanced data across various environments. Overall, the system's capacity to detect and analyze these spatial and temporal variations confirms its effectiveness in evaluating pollution and exposure differences at multiple predefined points along a walking path.

The system has proven to be suitable for both indoor and outdoor measurements. Indoor measurements indicated significantly higher concentrations of CO_2 and tVOCs, with considerable variability observed even within short, 5-minute intervals. This variability was particularly notable among different participants and can be attributed to varying conditions of air recirculation and fluctuations in the number of individuals in the room. In contrast, PM concentrations were generally lower indoors, consistently with expectations. Outdoors, the system detected notable variability in PM levels across different days and even within the same day, highlighting its capability to capture dynamic changes in air quality. This ability to effectively monitor and account for fluctuations in both indoor and outdoor environments confirms the system's versatility and suitability for comprehensive air quality assessment. Given that urban populations spend most of their time indoors, where pollutant concentrations often exceed outdoor levels, the ability to monitor

XSL•FO
RenderX

both environments is essential for accurately assessing personal exposure [7,32].

The data obtained from the new device show notable variability when compared with values reported by the ARPA fixed station. The new device typically recorded lower pollutant concentrations compared to the ARPA mean values. This discrepancy is primarily due to the experimental protocol, which intentionally avoided peak traffic hours, resulting in data collection during periods of lower pollutant concentrations. This highlights the limitations in time resolution of fixed stations, which may not fully capture the real exposure levels experienced by individuals. Moreover, fixed monitoring stations are often limited in their spatial representativeness, as air pollution levels can vary significantly even over small distances due to local emission sources, urban morphology, and meteorological conditions. The presence of street canyons, for example, can lead to pollutant accumulation, while open areas may experience greater dispersion. Consequently, a mobile system such as the one used in this study provides a more accurate representation of personal exposure by capturing both spatial and temporal variations that fixed stations may not be able to detect [7].

Additionally, PR and RR varied significantly among different participants and even in the same participants at different acquisition points. This variability was reflected in V′m data, which were computed using a model based on these physiological measurements. Unlike previous studies that assign standard Vm′ values based on activity type [33], our approach accounts for individual physiological variations [34], improving the accuracy of inhaled pollutant dose estimation [8,32]. This individualized evaluation of inhaled dose is especially important, as shown in studies of athletes, where factors such as physical activity and ventilation rate significantly impact exposure levels, emphasizing the need for personalized assessment to better reflect real exposure [35]. Exemplary comparison of inhaled doses of PM2.5—calculated as the product of V′m and pollutant concentrations—revealed an average overestimation of 2.96 µg with the new wearable system compared with ARPA data and standard tables for V′m, and also a higher variability in the measurements obtained from the BSN. These observations highlight the system's ability to capture fine temporal and spatial variations in air quality and physiological parameters, demonstrating its potential for more accurate real-time monitoring compared with traditional fixed stations combined with tabulated data.

The usability of the proposed system was positively received by the tested population. The results from usability satisfaction questionnaires indicate an overall favorable perception of the system. Participants found it acceptable and expressed strong interest in its functionality. This positive feedback underscores the system's practicality and user appeal and indicates its potential for broader application and adoption.

Limitations

A limitation of the work is that physiological data were collected only in static positions, while the environmental monitor continuously detects pollution values. In fact, to properly assess PAPE during the testing session, also dynamic acquisitions with physiological parameters need to be performed, and future implementations should account for that. However, the collected dataset was enough to demonstrate significant variability in V′m among different participants, and also for the same participant. Future research should also include activities other than walking, such as cycling to enhance a wider range of minute ventilation values. Additionally, incorporating simultaneous measurements of 2 or more individuals walking the same route could provide further insights into individual variations in exposure to micro-environmental pollution and physiological responses. This approach could be considered for future experimental trials to better highlight the need for personalized environmental exposure and health impact assessments.

In reference to the usability satisfaction questionnaires, some limitations were evident. Wearability over prolonged durations and device functionality emerged as pivotal aspects, emphasizing the necessity for a more compact and lighter device. It is worth noting that the device was consistently worn at the level of the wrist during all acquisitions. However, alternative configurations, such as attaching it to a belt or to an armband, can be implemented for enhanced comfort. Despite differences in pollution levels observed over distances of several meters, the relatively small distance between the mouth or nose and the device in these configurations suggests that any of these placements could accurately measure pollutant exposure and reliably support PAPE assessment.

Conclusions

Traditional air pollution exposure estimation methods fail to account for the dynamic variability in air pollution both indoors and outdoors, as well as the variations in minute ventilation among individuals. To overcome such limitations, our study introduces a novel wearable PAPE evaluation system consisting of a BSN collecting both physiological and environmental parameters, as concentrations of pollutants that have a known adverse effect on human health. Statistically significant differences in pollutant concentration were found between morning and afternoon but also between acquisition points in the same test session.

To estimate V′m, we used a pre-existing model described in the literature. The PAPE was then computed by integrating over time the product of V′m and pollutant concentrations sampled by the developed system. As an example, PAPE to PM2.5, evaluated with fixed station's concentration and standard values of V′m for the 20 participants, was significantly lower with respect to PAPE obtained with the proposed wearable system. Despite the study's participants pool was limited, it effectively highlighted the variability in V′m among individuals and fluctuations in pollutant concentration.

Future improvements involve incorporating an active air recirculation system to mitigate micro-environmental effects inside the device's 3D-printed case over temperature and humidity and advancing device miniaturization.

In conclusion, this system demonstrates high spatial and temporal resolution, positioning it as a valuable tool that may supplement epidemiological studies and empower the public

XSL•FO
RenderX

with data to enhance pollution awareness and acceptability towards policies aimed at reducing air pollution.

Acknowledgments

We gratefully acknowledge Stefano Canali for his invaluable support and insightful suggestions, which significantly enhanced the quality of this work. This work was funded by the National Plan for NRRP Complementary Investments (PNC, established with the decree-law 6 May 2021, number 59, converted by law number 101 of 2021) in the call for the funding of research initiatives for technologies and innovative trajectories in the health and care sectors (Directorial Decree number 931 of 06-06-2022), project number PNC0000003—Advanced Technologies for Human-Centred Medicine (project acronym: ANTHEM). Abstract

Background: Diabetic foot ulcers (DFUs) are a life-changing complication of diabetes. There is increasing evidence that remote plantar temperature monitoring can reduce the recurrence of DFUs. Monitoring of foot temperature once a day is the current guideline for identifying early signs of foot inflammation. However, single readings of physiological signals can increase the risk of misdiagnosis when the signals fluctuate throughout the day.

Objective: The aim of this study was to evaluate whether intraday temperature asymmetry signals were stable or varied as a function of time in individuals at risk of DFUs.

Methods: In total, 64 participants with diabetes (mean age 68, SD 13.8 y) were provided with multimodal sensory insoles (Orpyx Sensory Insoles) to monitor continuous temperature data at a frequency of once per minute at 5 plantar locations in a 90-day study window. The augmented Dickey-Fuller test was used to determine whether the temperature asymmetry signals were stationary (ie, indicating constant mean and variance over time) or nonstationary (ie, indicating time-varying behaviors or trends in the signal).

Results: The study included 43 participants, 1080 data days, and 5400 contralateral temperature asymmetry signals. Most (4428/5400, 82%) of the temperature asymmetry signals were nonstationary, with intraday fluctuations likely influenced by physiological and environmental factors. Of the nonstationary signals, nearly half (1948/4428, 44%) fluctuated above and below the concerning asymmetry threshold of 2.2 °C. The intraday variability underscores the potential for false-positive and false-negative hot spot detection with once-daily measurements. Substantial variability was observed in stationarity patterns both within and across participants. Notably, concerning asymmetries in nonstationary signals occurred at different time points across participants, measurement windows, and days.

Conclusions: Our findings highlight the value of continuous plantar temperature monitoring for diabetic foot health management, relative to once-daily measurements. Several repeated measurements throughout the day increase confidence with regard to the accuracy of observed plantar physiology trends. Continuous monitoring may improve the accuracy of plantar temperature measurement, unlock new diagnostic capabilities, and support personalized care.

Introduction

Background

Diabetic foot ulcers (DFUs) are open wounds on the foot caused by neuropathy, poor circulation, or repetitive stress to the foot tissue [1]. DFUs are a devastating foot complication in individuals with diabetes, with 1 in 5 ulcers resulting in severe infection and amputation [2]. Fortunately, 75% of DFUs are preventable when the risk factors are detected and treated early [3]. Remote plantar temperature monitoring has been proposed as a preferred method for DFU prevention, as tissue inflammation (indicated by warmth) can precede wound formation [2].

Current international guidelines suggest once-daily foot temperature monitoring to identify early signs of foot inflammation [3,4]. Once-daily plantar temperature measurements can be captured with handheld thermometry [5] or with sensor-based digital health technologies (eg, sensory

XSL•FO
RenderX

insoles [6], smart mats [7], or sensor-embedded socks [8]). Daily temperature asymmetry measures (difference between similar regions on 2 feet) are typically compared to an established asymmetry threshold of 2.2 °C to identify a trend of concern (ie, a temperature hot spot) [7-10]. While studies informing once-daily plantar temperature measurements have shown most success in DFU risk reduction when managed with marked reductions in activity [5], there are concerns that once-daily plantar temperature measurements may not provide a comprehensive view of foot temperature dynamics. Once-daily measurements may also lack the accuracy needed to limit false negatives (which could result in missed, concerning trends) or false positives (which could unnecessarily recommend sedentary behavior in a diabetic population). Key fluctuations in temperature asymmetry that indicate early-stage complications may occur outside the once-daily measurement [11,12].

Single readings of health measurements increase the risk of misdiagnoses due to false-positive and false-negative test results. Many physiological signals fluctuate throughout the day as a function of behavior, activity, environment, circadian rhythms, and other factors [13-15]. While single health measurements remain valuable in some contexts, repeated or continuous measurements are now being taken to improve accuracy. For example, rather than a single blood pressure measurement, at least 4 daily home blood pressure measurements over 2 days are recommended to accurately diagnose out-of-clinic hypertension [14]. For glycemic management, continuous glucose monitoring has become a widely adopted supplement to intermittent capillary blood glucose testing as it more accurately reflects how lifestyle factors impact glucose fluctuations, reducing the risk of hypo- and hyperglycemia events [16,17]. For outpatient fever monitoring in high-risk patients, continuous temperature monitoring, rather than daily oral temperature assessment, has been shown to detect fever onset more accurately and with greater lead time [18].

Wearable devices that facilitate continuous plantar temperature monitoring have shown that absolute plantar temperatures can vary as a function of foot and body posture, limb perfusion, activity levels, disease status, and other factors [12,19]. For example, Beach et al [12] used a wearable device for continuous plantar foot temperature monitoring to calculate dynamic temperature parameters (eg, rise time) in the sitting and standing positions in participants with diabetes and healthy controls. Foot temperature rise times were significantly higher in participants with diabetes, potentially due to differences in soft tissue biomechanics and vascularization. The authors concluded, “temperature monitoring for DFUs focuses on a single snapshot of temperature differences, which may not represent the more complex dynamics of temperature change present in those with diabetes” [12].

Objective

It remains unknown if plantar temperature *asymmetries*, the key biomarker in remote temperature monitoring for DFU management protocols, vary throughout the day. The aim of this analysis was to evaluate whether intraday plantar temperature asymmetries vary as a function of time in individuals with diabetes and a history of DFUs.

Methods

Study Design

The following sections describe a secondary analysis of a broader clinical study evaluating the use of the Orpyx Sensory Insole (Orpyx Medical Technologies Inc.) system as an adjunct to diabetic peripheral neuropathy standard of care. The primary outcome of the broader clinical study was to observe the clinical advantages of the sensory insoles alongside the standard of care. This study was reported in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines (Checklist 1).

Participants

In total, 64 participants with type 1 or 2 diabetes, peripheral neuropathy, and a history of a previous plantar foot ulcer (mean age 68, SD 13.8 y) were enrolled through a prospective, observational cohort study. Participants were recruited from a single podiatry clinic in Ohio, United States, from April 2022 to January 2023. The exclusion criteria included the presence of active ulcers or other open chronic wounds, severe vascular disease (defined as an ankle-brachial index [ABI] of ≤0.6 or an ABI of ≥1.2, or adequate lower extremity perfusion per physician discretion), a history of nonneuropathic foot ulcers (ie, arterial or venous insufficiency ulcers), or significant balance disorders.

Technical Implementation

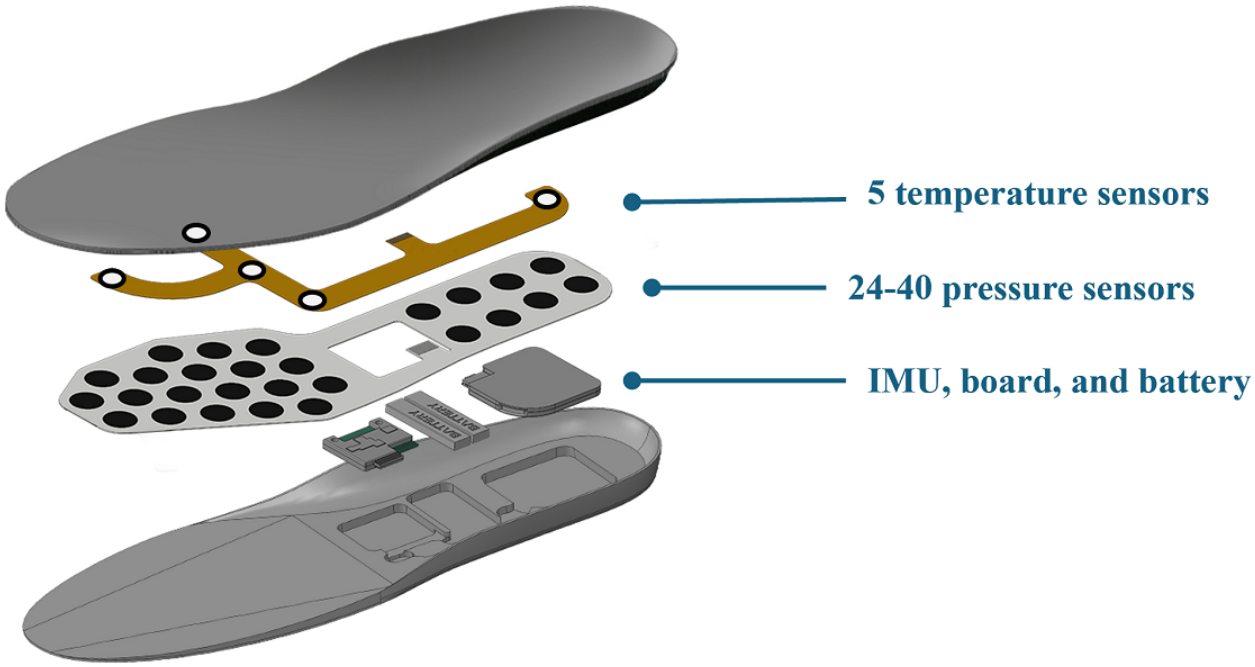
Custom sensory insoles (Orpyx Sensory Insole) were used for data collection. The Orpyx Sensory Insole is a standard-of-care, custom orthotic combined with a technology layer that enables patient-facing biofeedback and remote patient monitoring services.

The custom insoles comprised a custom contoured layer manufactured using a direct milling CAD/CAM (computer-aided design/computer-aided manufacturing) process. When requested by the provider, the insoles were then further modified to accommodate any foot abnormalities. The insole materials and fabrication process meet HCPCS A5514 requirements.

The technology layer included multiple sensors and electronics that enable multimodal, continuous, underfoot data collection (Figure 1). Depending on the size of the insole, the technology layer contains between 24 and 40 pressure sensors. In addition, 5 temperature sensors are embedded and positioned at the big toe; metatarsal heads 1 (Meta 1), 3 (Meta 3), and 5 (Meta 5); and the heel (the areas of bony prominence) that are the most frequent locations for DFU formation. Finally, the electronics assembly includes an inertial measurement unit (IMU) that enables the ability to track steps and wear time.

XSL•FO
RenderX

Figure 1. The multimodal Orpyx Sensory Insole system includes custom-milled insoles that are placed into the participants' shoes. The insoles include a technology layer to enable multimodal monitoring and biofeedback to participants and providers. The technology layer includes temperature sensors, pressure sensors, and an inertial measurement unit (IMU) sensor. For this analysis, only temperature data measured by the 5 temperature sensors were used.



Data Collection and Analysis

Participants wore the sensory insoles for up to 90 days in standardized diabetic footwear, with a recommended daily adherence of 4.5 hours per day [20]. Participation in the study concluded at the end of the 90-day period, upon the development of a plantar foot ulcer within the monitoring window or if the participant withdrew for another reason. Participants were also provided remote patient monitoring services through the in-house remote patient monitoring service at Orpyx Medical Technologies. A case series, focused on the value of multimodal sensing across multiple physiological domains for managing diabetic foot health, was previously published for 3 participants from this study cohort [21].

Plantar temperature data, logged at a frequency of once per minute, were the only parameter used for this analysis. The daily contralateral temperature asymmetry time-series signal was calculated as the difference between continuous temperatures at the corresponding left and right foot regions. Therefore, each sensory insole pair provided 5 temperature asymmetry signals. A series of data-cleaning steps corrected the underlying signal bias and masked portions of the time-series signals that were unreliable measures of foot skin temperature (eg, periods surrounding insole donning and doffing). The remaining signals were smoothed using a rolling window mean (window size=10 minutes).

For this analysis, participants were excluded if they withdrew from the study before insole dispensing, withdrew after minimal device use (defined as no data day with a temperature asymmetry measurement >2 h), or were enrolled as unilateral users, as these participants did not generate plantar temperature asymmetry data. Participants with previous minor lower-limb amputations (eg, removal of the first digit) were also excluded from this specific analysis to control for the potential impact of missing foot anatomy on temperature asymmetry signals. Furthermore, short-duration temperature asymmetry measurements (<2 h) were excluded from this analysis. The short-duration measurement exclusion criteria were specifically to accommodate this exploratory statistical analysis and were more rigorous than what were used in our remote temperature monitoring protocol for DFU management.

Statistical Analysis and Outcomes

A stationarity test was conducted to assess whether the time-series temperature asymmetry signals remained constant over time. Specifically, we used the augmented Dickey-Fuller (ADF) test, performed in Python (version 3.10) with the adfuller function from the statsmodels Python package (version 0.13.2), to evaluate the stationarity of each daily temperature asymmetry time series [22,23]. The ADF test evaluates the null hypothesis that a unit root is present in the time series, indicating nonstationarity due to a stochastic trend [23,24]. In our analysis, we specified regression="c" to assume the data may have a nonzero mean but no trend term. Maximum lag was not manually defined (maxlag=None), while the test automatically selected the optimal number of lags based on the Akaike information criterion (AIC) by setting autolag="AIC," which

XSL•FO
RenderX

balances model fit and complexity. The test yields a test statistic, which is compared against critical values from simulated distributions to assess statistical significance. A *P* value ≤.05 was considered evidence against the null hypothesis, indicating that the time series is "weakly stationary." This infers that certain statistical properties, such as mean, variance, and autocovariance remain constant over that wear period. For this paper, we refer to contralateral temperature time series from the data days in which the ADF test rejects the null hypothesis at a *P* value threshold ≤.05 as "stationary" and in which the ADF test fails to reject the null hypothesis at a *P* value threshold >.05 as "nonstationary."

The stationarity result of all daily signals was aggregated for each participant to calculate the percentage of stationary versus nonstationary signals over their adherence days in the 90-day study period. Individual data days were reviewed to determine if the signals at all 5 plantar locations were consistently stationary, consistently nonstationary, or a mixed result (some stationary and others nonstationary).

Given that nonstationary temperature asymmetry signals will exhibit trend and variability, further analysis was conducted to determine the proportion of measurements within a day that were symmetric versus asymmetric. As no established threshold currently exists for defining concerning asymmetry in *continuous* temperature monitoring, the established threshold for once-daily temperature monitoring (2.2 °C) was used [7-10]. For nonstationary signals with one or more temperature asymmetry measurements exceeding this threshold, the percentage of intraday measurements with "concerning asymmetry" (defined as asymmetry >2.2 °C) was calculated, similar to how continuous glucose measurements are classified as "time in range" and "time above or below range" [17].

Finally, nonstationary signals with at least one concerning asymmetry measurement were qualitatively examined to determine the time of day at which these concerning asymmetrical measurements occurred. This analysis provided insights into whether periods of concerning asymmetry were consistent and repeatable or temporally dispersed between days and across participants.

Ethical Considerations

This study was approved by the WCG Institutional Review Board (20220828) on October 3, 2022. Informed consent was obtained from all participants. The original informed consent permitted secondary analyses without requiring additional consent from participants. Participant data were stored on secure, access-controlled servers. Data were deidentified for this analysis and only accessible by authorized research personnel. Participants did not receive any financial compensation for participation in this study.

Results

Participant Characteristics

A total of 43 participants were included in this analysis (Table 1; Figure 2), of which 21 participants were excluded: 8 participants withdrew from the study before insole dispensing, 2 participants withdrew after minimal device use, 1 participant enrolled as a unilateral user, and 10 participants had previous minor lower-limb amputations.

Across the 43 participants, 1429 data days with temperature asymmetry measurements were considered for further data cleaning and analysis (Figure 2); 313 short-duration data days (<2 h) were discarded, in addition to 36 low-quality data days that had no remaining measurements after data cleaning (Figure 2). Ultimately, 43 participants and 1080 data days provided 5400 temperature asymmetry signals for statistical analysis (Figure 2).

Across the 64 participants enrolled in this study, 4 participants developed a plantar ulcer within the 90-day study period. Of the 4 participants who ulcerated, two were in a cohort excluded from this analysis and two were in the included cohort.

Table . Participant characteristics.

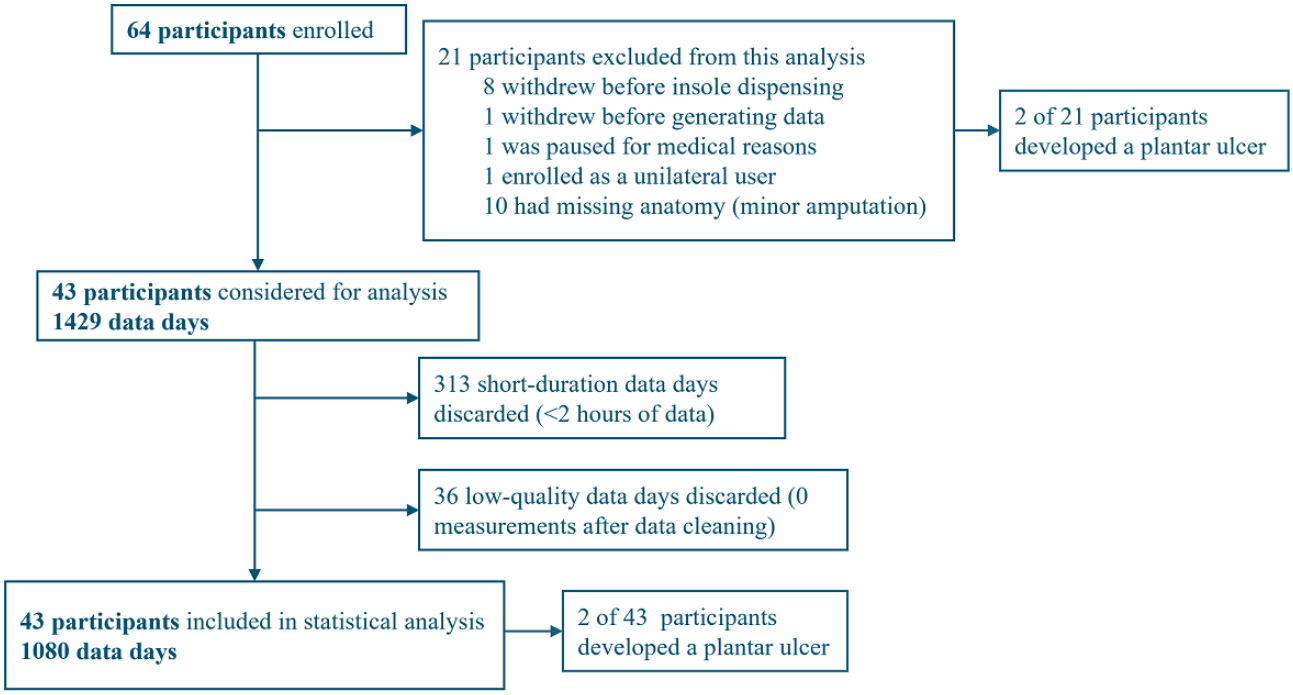
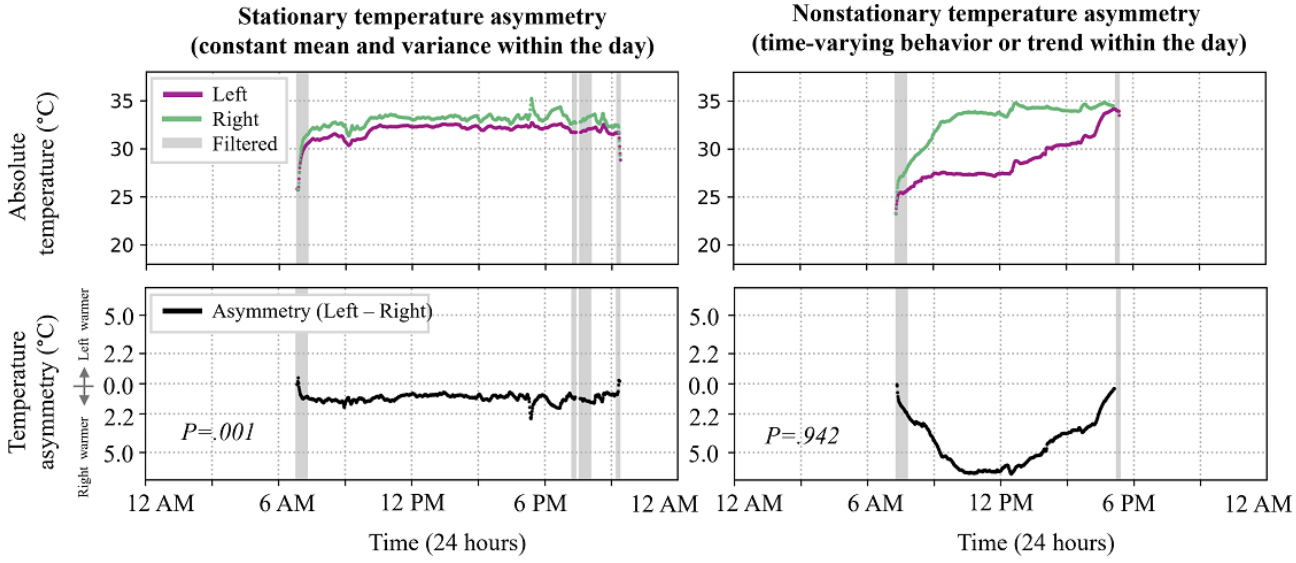
Figure 2. Flowchart of the process used in selecting participants and data days for inclusion in the study analysis.



Summary of Stationary Versus Nonstationary Temperature Asymmetry Signals

Across the 5400 temperature asymmetry signals analyzed, 82% (n=4428) were nonstationary. Figure 3 shows an illustrative stationary and nonstationary temperature asymmetry signal.

Figure 3. Illustrative stationary (indicating constant mean and variance over time) and nonstationary (indicating time-varying behaviors or trends in the signal) plantar temperature signals. Continuous time series for left (purple) and right (green) plantar temperature measurements (upper row); corresponding left versus right plantar temperature asymmetry (lower row). The gray bars show the masked portions of the time-series signals during the data-cleaning steps. The two illustrative days are from two different participants. *P* values indicate the test result from the augmented Dickey-Fuller test on the temperature asymmetry signal. Signals with a *P* value ≤.05 were considered stationary.

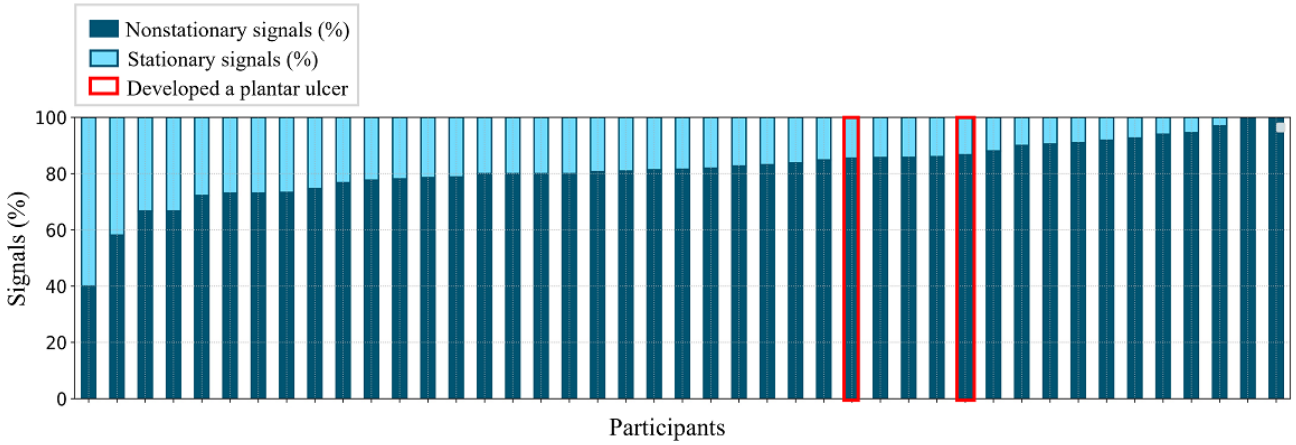


Stationarity of Temperature Asymmetry Signals in Individual Participants

For a given participant, 40% to 100% of their temperature asymmetry signals were nonstationary (Figure 4). No participant exhibited entirely stationary data throughout the 90-day study period. For the 2 participants who developed a plantar ulcer in this study, >80% of their temperature asymmetry signals were nonstationary.

XSL•FO
RenderX

Figure 4. For each participant (n=43), most of the temperature asymmetry signals were nonstationary (indicating time-varying behaviors or trends in the signal). For a given participant, 40% to 100% of their temperature asymmetry signals were nonstationary (dark blue bars) and the remaining signals were stationary (light blue bars). Most of the temperature asymmetry signals were nonstationary for the 2 participants who developed a plantar ulcer (identified with red bars). Participants were visually sorted from lowest to highest percent of nonstationary signals.

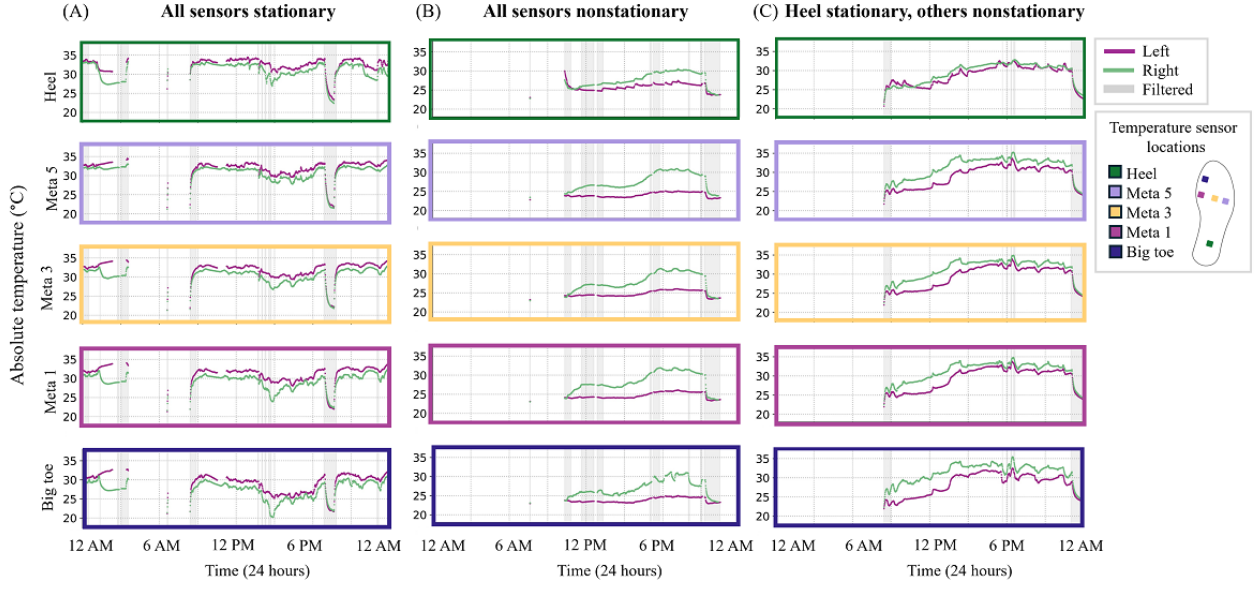


Stationarity of Temperature Asymmetry Signals at Different Plantar Locations

Pooling all participants' data days, the percentage of nonstationary temperature asymmetry signals was similar at each plantar sensor location: 83% of data days at heel, 82% at Meta 1, 82% at Meta 3, 80% at Meta 5, and 82% at the big toe region.

When analyzing individual participant data, some individuals exhibited a consistent stationarity result across all sensor locations (Figure 5A and B). However, others showed a mix of stationary and nonstationary signals across plantar sensor locations (Figure 5C). For example, in 1 participant, the forefoot sensor (Meta 1, Meta 3, Meta 5, and big toe) signals were nonstationary for >90% of data days, whereas heel temperature asymmetry signals were nonstationary for only 64% of data days. Therefore, this participant often exhibited stationary heel temperature asymmetry while other plantar sensor locations showed nonstationary signals.

Figure 5. Stationarity of plantar temperature asymmetry signals sometimes varied across sensor locations. Across sensor locations, some data days displayed consistently stationary temperature asymmetry signals (**A**), some displayed consistently nonstationary temperature asymmetry signals (**B**), and others displayed a mix of stationary and nonstationary signals across sensor locations (**C**). The 3 illustrative data days are from 3 different participants.

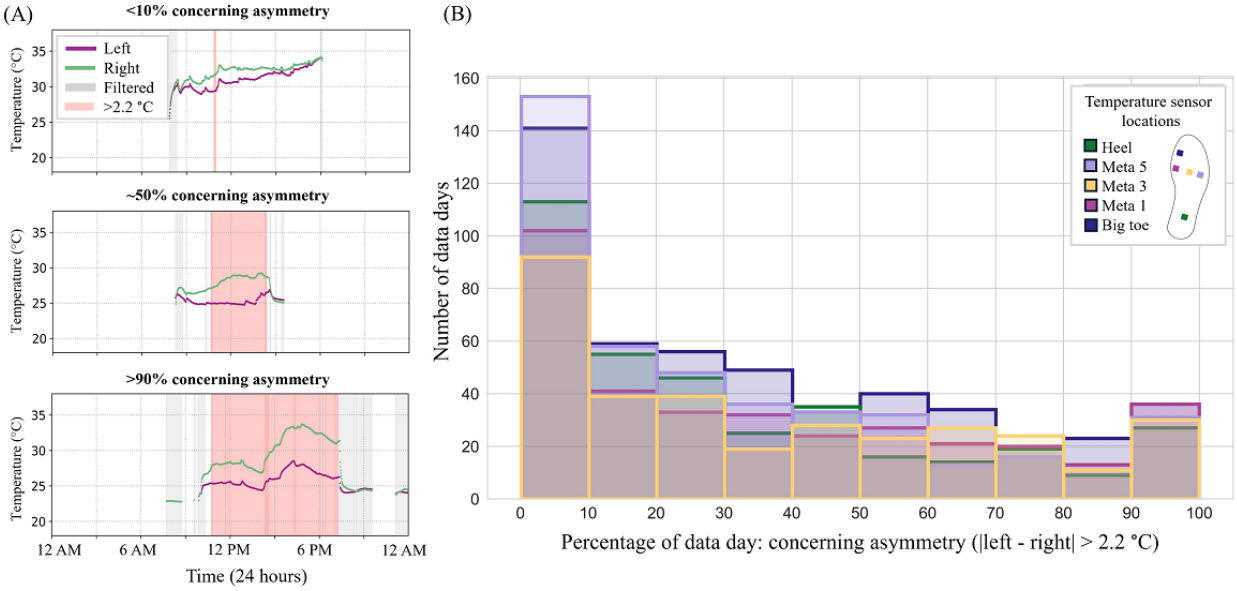


Temperature Trends of Concern in Nonstationary Signals

Of the total, 44% of the nonstationary signals included one or more temperature asymmetry measurements that exceeded a 2.2-°C asymmetry threshold for a data trend of concern. The total number of data days with at least one measurement of concerning asymmetry was 359 for the heel, 431 for Meta 5, 332 for Meta 3, 349 for Meta 1, and 487 for the big toe. The percentage of measurements within a day that exceeded the 2.2-°C threshold varied from very few measurements to nearly all of the daily measurements (Figure 6).

XSL•FO
RenderX

Figure 6. Of the total, 44% of nonstationary signals included one or more concerning temperature asymmetry measurements (>2.2 °C). (**A**) Three illustrative data days showing varying percentage of concerning temperature asymmetry (red shaded region); (**B**) frequency of data days with different percentages of concerning temperature asymmetry measurements at each sensor location.

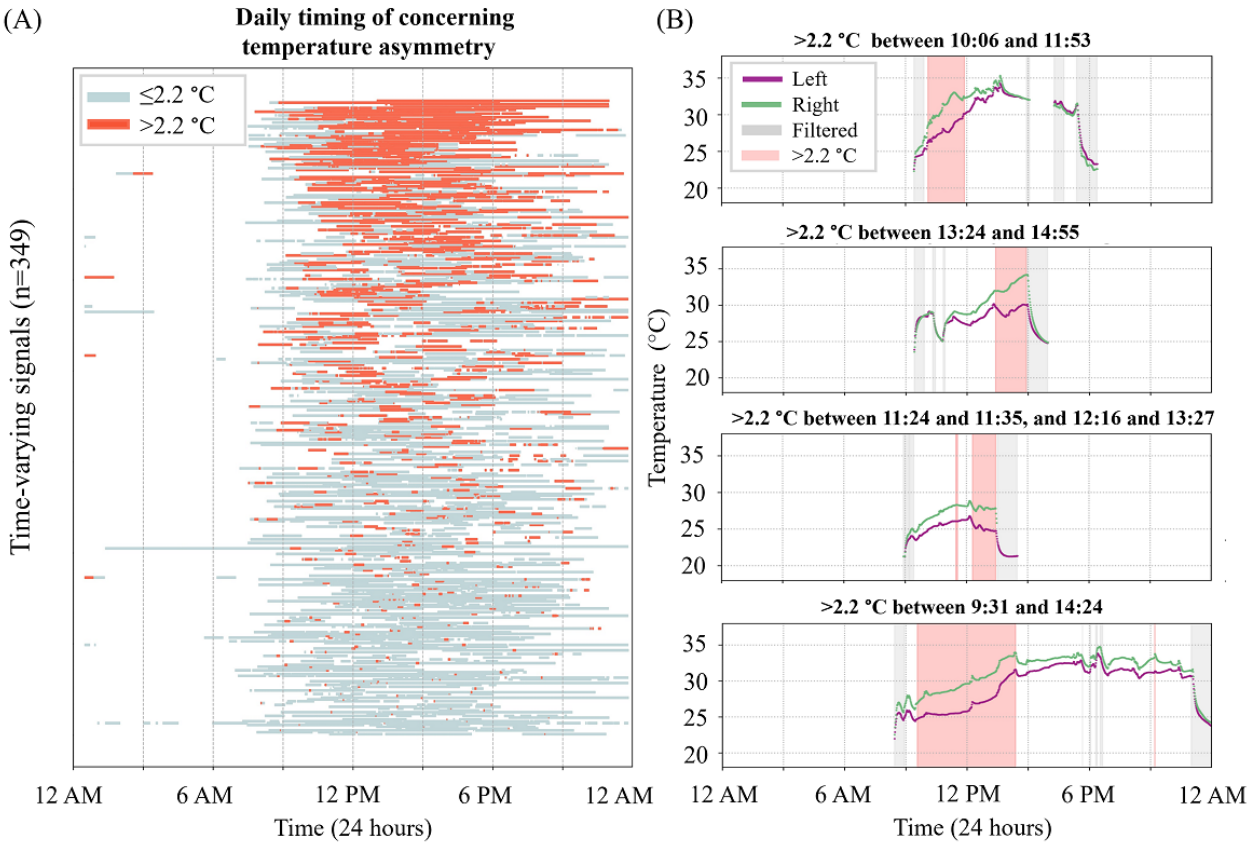


Temporally Dispersed Concerning Temperature Asymmetry

A visual inspection of nonstationary data days with one or more temperature asymmetry measurements exceeding the 2.2-°C threshold revealed that the periods of concerning temperature asymmetry were temporally dispersed across participants, time windows, and data days (Figure 7A and B).

XSL•FO
RenderX

Figure 7. Temporally dispersed concerning temperature asymmetry. (**A**) The distribution of nonconcerning (≤2.2 °C, light blue bands) and concerning (>2.2 °C, red bands) temperature asymmetry measurements across 349 plantar temperature signals that included at least one concerning temperature asymmetry measurement. The results are for one representative sensor location (Meta 1). Each horizontal bar is the usage duration for a data day. The data days were visually ordered based on the duration of the concerning asymmetry. (**B**) Four illustrative data days with at least one concerning temperature asymmetry measurement. Concerning temperature asymmetries occurred at different times of the day.



Discussion

Principal Findings

The primary finding of this study was that most (4428/5400, 82%) of the plantar temperature asymmetry signals were nonstationary. Temperature asymmetry fluctuations occurred throughout the day, likely influenced by underlying physiological and environmental factors. About half (1948/4428, 44%) of the nonstationary temperature signals included a mix of concerning (>2.2 °C) and nonconcerning (≤2.2 °C) temperature asymmetry measurements. Single or intermittent measurements of temperature asymmetry are therefore at risk of over- or underestimating plantar hot spots and DFU risk. These results highlight the value of continuous remote temperature monitoring in the management of diabetic foot disease.

Leveraging Continuous Monitoring to Improve Accuracy

Modest success in DFU risk reduction has been demonstrated with intermittent plantar temperature monitoring [5]. A meta-analysis of 5 randomized controlled trials (n=772) demonstrated that single time-point foot temperature monitoring and reduction of ambulatory activity in response to hot spots (temperature asymmetry >2.2 °C on 2 consecutive days) reduced the risk of developing a DFU by approximately 50% [5]. However, the overall certainty of this evidence was low. Intermittent monitoring protocols may miss transient but clinically relevant changes that occur between measurements.

Of the total, 44% of nonstationary data days included one or more temperature asymmetry measurements that exceeded a 2.2-°C threshold, indicating a data trend of concern. On these days, relying on a single, once-daily snapshot risks both false-negative and false-positive assessments (Figures 6 and 7). Multiple studies have demonstrated the limitations of once-daily temperature monitoring. In a study [7] using a thermometric foot mat to assess once-daily temperature asymmetry (one 20 s measurement), the authors reported a false-positive rate of 57% and false-negative rate of 3% for predicting ulcer development with an average lead time of 37 days. Another study [25] found that in the 2 months preceding ulceration, only 8 (28%) participants had a true hot spot, while 7 (24%) had false hot spots and 14 (48%) had no detectable hot spot, challenging the assumption that once-daily measurements consistently identify impending skin breakdown. Similarly, a post hoc analysis [26] of foot thermograms from 15 individuals with diabetes identified hot spots (asymmetry >2.2 °C) in 20% of regions of interest, yet none of the participants developed ulcers. While several factors likely contribute to the high rate of false positives and false negatives reported, one explanation

XSL•FO
RenderX

may be that single snapshot measurements fail to capture the inherent variability of intraday plantar temperature asymmetries.

Several repeated measurements throughout the day, rather than a once-daily measurement, increase confidence with regard to the accuracy of observed plantar physiology trends. The recommended frequency of daily plantar temperature measurements may need to be increased to provide a more holistic view of a patient's foot health.

Uncovering New Diagnostic Opportunities

Across participants, 40% to 100% of temperature asymmetry signals were nonstationary (Figure 4), and individual participants displayed different distributions of stationary versus nonstationary signals at each plantar location (Figure 5). Numerous factors such as activity, foot care practices, vascular disease status, history of ulceration, foot posture and gait, and foot deformities may contribute to the observed temperature signal patterns [19,27]. While current remote temperature monitoring protocols emphasize the *magnitude* of temperature asymmetry, it is possible the *pattern* of temperature asymmetry also offers diagnostic value. As a secondary, exploratory analysis, we examined 3 illustrative participants to explore potential associations between participant-level factors and patterns of temperature asymmetry.

Case 1 is a participant with comorbid peripheral vascular disease. Continuous plantar temperature monitoring may be particularly valuable for individuals with peripheral vascular disease, a common comorbidity of diabetes, as limb temperature can also serve as a surrogate measure of limb perfusion [28]. The most recent vascular assessment for this participant (approximately 4 mo before enrollment in the study) showed a right ABI of 1.3, suggesting arterial calcification and noncompressibility, and a left ABI measurement of 1.16, within the normal range (Figure 8A). Interestingly, the sensory insole typically measured lower temperatures in forefoot regions on the right foot, aligning with the presumed calcification in that limb. Temperature asymmetry was nonstationary at the forefoot sensor sites (Meta 1, Meta 3, Meta 5, and big toe) but not at the heel. This pattern may reflect the impact of greater vessel length supplying the forefoot compared to the heel, which is served by separate, more proximal arterial branches. It should be noted that this participant was excluded from the primary study analysis due to a right fourth toe amputation (Figure 2), but it is reported here as an exploratory example to illustrate the potential relationship between vascular disease status and temperature asymmetry profile.

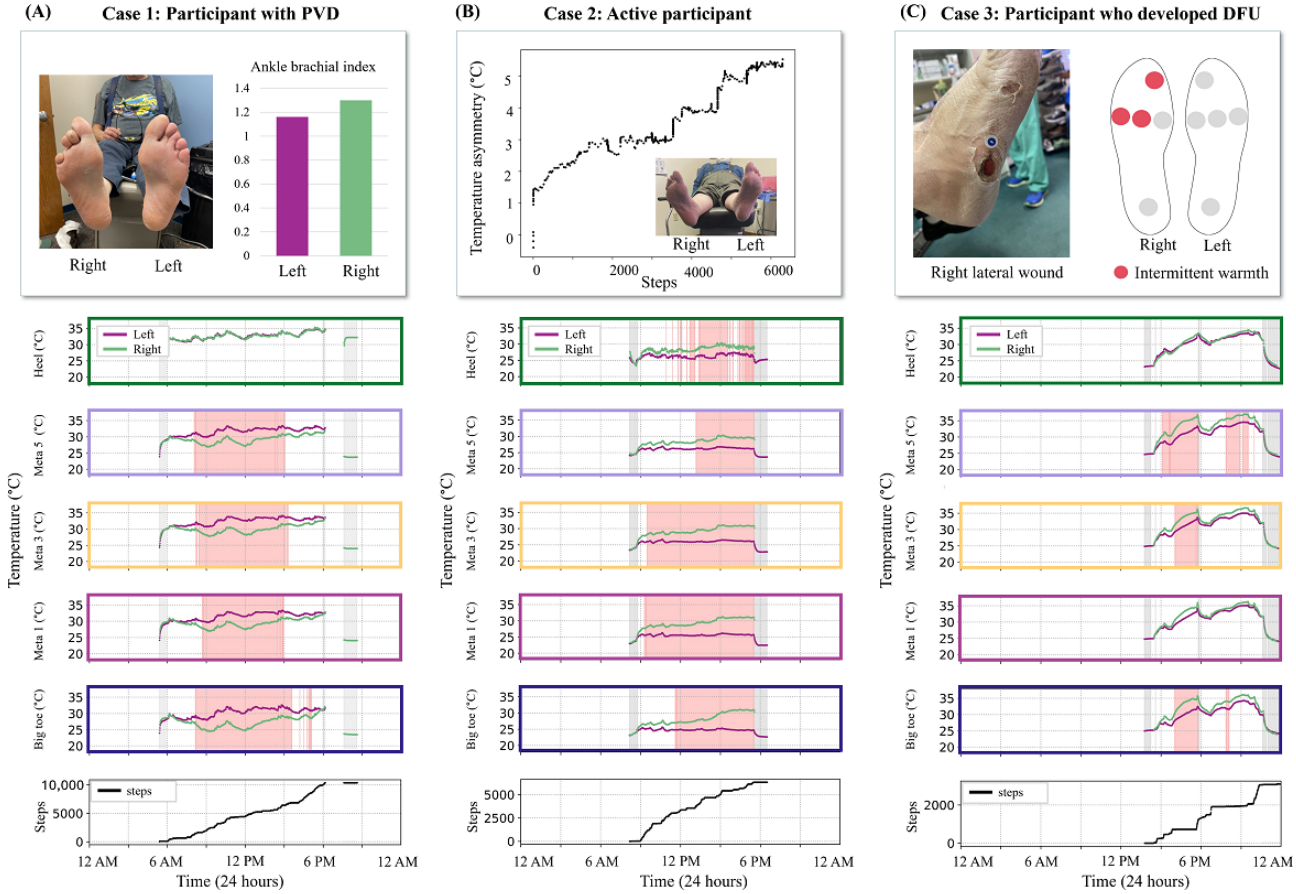
Case 2 is a participant with bilateral hammertoes and high daily step counts. The participant exhibited nonstationary temperature asymmetry patterns at all foot regions (5 sensor locations), with the right limb typically presenting as warmer. Interestingly, the magnitude of temperature asymmetry increased progressively with time and cumulative steps throughout the day (Figure 8B). We suspect that the correlation between temperature asymmetry and activity may reflect asymmetrical loading or altered biomechanics from the underlying foot deformities, potentially leading to increased tissue stress and localized inflammation on the right side. This participant was not reported to have underlying vascular disease.

Case 3 is a participant who developed an ulcer at the lateral aspect of the right foot during the study. Notably, the participant exhibited nonstationary temperature asymmetry patterns with episodes of temperature asymmetry exceeding the concerning threshold of 2.2 °C intermittently throughout the day (Figure 8C). The location of intermittent warmth (Meta 3, Meta 5, and big toe) did not exactly correspond to the reported ulcer location (ie, the lateral aspect of the foot). However, these transient temperature elevations, with the right forefoot being relatively warmer, would have been at risk of being missed by once-daily temperature assessments, highlighting the advantage of continuous intraday temperature monitoring. No meaningful data trends were observed for the other participant who developed an ulcer during the study, likely due to poor adherence to the sensory insoles, which were worn for only 3 days.

Exploratory observations from these representative cases highlight the potential for continuous temperature monitoring to offer insights that go far beyond those provided by once-daily measurements. We hypothesize that the ongoing collection of multimodal, continuous plantar data will uncover meaningful associations and previously unrecognized patterns that link temperature asymmetry with vascular status, activity, wound risk, or other factors. Continuous data may enable more personalized and timely interventions based on when and where risk emerges.

XSL•FO
RenderX

Figure 8. Three illustrative participants to demonstrate potential associations between participant-level factors and patterns of temperature asymmetry. DFU: diabetic foot ulcer; PVD: peripheral vascular disease.



A Step Toward Personalized Monitoring

Once-daily foot skin temperature monitoring is a clear, concise, and achievable guideline [7]. However, such one-size-fits-all guidelines may not be appropriate for all patients. In this study, a review of all data days that included one or more measurements exceeding the threshold of concern suggested there was not a consistent time of day when concerning temperature asymmetries typically occurred (Figure 7). A fixed, single time point for monitoring temperature asymmetry risks under- or overestimating risk.

Greater visibility into the day-by-day temperature asymmetry fluctuations may be meaningful to providers and patients, similar to how continuous glucose monitoring information and a core set of glucose level statistics overcame the limited information provided by isolated glucose readings [29]. Such continuous monitoring may better support health care providers to personalize care for the individual. We anticipate that continuous temperature asymmetry signals will be used increasingly in clinical trials for managing diabetic foot health.

Limitations and Future Opportunities

Many unknowns remain regarding the underlying physiological and environmental factors that contribute to intraday fluctuations in plantar temperature asymmetry. Additional clinical trials are necessary to determine the degree to which continuous temperature monitoring improves DFU detection compared to once-daily temperature measurements. While ongoing research is necessary to better understand these mechanisms, we remain confident that continuous, repeated measurements throughout the day build more confidence for clinical decision-making.

Further research is needed to determine if and how plantar temperature warning thresholds should be adapted for continuous monitoring. Current guidelines, based on clinical trials using once- or twice-daily measurements, recommend a hot spot indicator threshold of 2.2 °C for 2 or more consecutive days. However, with the recent availability of continuous plantar temperature monitoring, it may be necessary to reconsider this fixed threshold. A variable or individualized threshold, accounting for factors such as activity levels, comorbid peripheral vascular disease, previous ulcer locations, and environmental influences, may be more appropriate.

Moreover, continuous temperature monitoring provides an opportunity to move beyond the static threshold-based criteria to other statistical strategies, such as time in range versus time above threshold, intraday trend and variability metrics, or interday temperature profile comparisons. This evolution parallels the development of extended analytics during the transition from discrete self-monitoring of blood glucose to continuous glucose monitoring systems [16,17]. Developing updated reporting standards will require further research and multidisciplinary collaboration to achieve consensus. Ultimately, we envision a future in which continuous temperature monitoring and its associated analytics become as ubiquitous and clinically valuable as continuous glucose monitoring and other continuous physiologic monitoring tools.

XSL•FO
RenderX

Conclusions

This study demonstrates the high prevalence (82% of data days) of nonstationary temperature asymmetry signals in individuals with diabetes and history of ulceration. Our results highlight the value of continuous plantar temperature monitoring for diabetic foot health management, relative to once-daily measurements. Continuous monitoring may improve the accuracy of plantar temperature measurement, unlock new diagnostic capabilities, and support personalized monitoring. Future research is required to better understand the underlying mechanisms of plantar temperature asymmetry fluctuations and to prove the clinical value of continuous monitoring for reducing the risk of DFU formation. Continuous monitoring is an exciting advancement in remote temperature monitoring for diabetes health span extension.

Abstract

Background: Pregnancy and childbirth involve significant health challenges, including preventable maternal deaths, severe complications, and disparities tied to social determinants, emphasizing the need for improved maternal care. Pregnancy could benefit from a more comprehensive, continuous care model that captures dynamic changes and enhances maternal-fetal outcomes.

Objective: This large-scale, real-world, high-density study aims to use wearable data to investigate maternal biobehavioral trajectories for pregnancies leading to loss, preterm, and term births, exploring how demographic factors like age and body mass index (BMI) affect these trajectories.

Methods: Retrospective observational analysis of pregnancies from a sample of 10,318 and 18- to 51-year-old female Oura Ring users (324 preterm births, 5039 term births, 4955 pregnancies ending in loss before 20 weeks of gestation). Oura biobehavioral data were analyzed across a 64-week window encompassing 8 weeks prepregnancy, through pregnancy, and post partum, via generalized estimating equation (GEE) statistical modeling.

Results: Gestational age emerged as a significant factor across all domains among term pregnancies (P<.001). During the first trimester, participants experienced marked sleep changes, peaking around week 9 and characterized by more time in bed (+30 min), asleep (+15 min), and awake (+15 min) compared with prepregnancy. Metrics declined and stabilized in the second trimester; by the third trimester, time in bed returned to baseline, while sleep remained reduced and wakefulness elevated. At birth, time in bed and wakefulness peaked, and sleep duration reached its minimum, with nighttime wake exceeding 3 SDs above baseline. Temperature changes were more pronounced, sustained, and occurred earlier than sleep changes—becoming evident by week 4, peaking at +0.3 °C above baseline by week 9, and showing a steady decline until birth. A secondary, modest increase (+0.1 °C) was observed near birth, followed by a decline postpartum. Heart rate (HR) increased steadily, peaking at +10 bpm above baseline at week 32, while HR variability declined by >15 milliseconds in a mirrored pattern. Respiratory rate peaked around week 9 and declined thereafter. Step count declined in the first trimester, with a ≈2000-step reduction at around week 8. After a slight rebound midpregnancy, activity declined again, reaching its lowest point near birth, with >2500 fewer steps than prepregnancy. Age and BMI showed significant but modest interaction effects (all P<.01). In pregnancies ending in loss, deviations emerged up to 2 weeks prior. Time in bed decreased starting ≈2 weeks before loss (P<.001), followed by reductions in sleep duration (P<.001), temperature trends (P<.001), respiratory rate (P=.019), HR (P=.005), and awake time (P=.033).

Conclusions: These findings highlight the complex dynamics underlying changes in participants' sleep, temperature trends, cardiorespiratory, and activity data throughout pregnancy, involving extensive adaptations. A deeper focus on normative changes can advance maternal-fetal medicine, improve clinical outcomes, and address scientific gaps.

Introduction

More than 4 births occur every second of every day worldwide. In the United States alone, more than 10,000 babies are born (live births) each day [1]. According to the World Health Organization, approximately 287,000 women died during pregnancy or childbirth in 2020, equating to one maternal death every 2 minutes [2]. Data from the 2017-2019 Maternal Mortality Review Committees in the United States showed that over 80% of pregnancy-related deaths (occurring during pregnancy, delivery, and up to a year postpartum) were determined to be preventable [3]. Beyond mortality, millions of women experience severe maternal morbidity, including life-threatening complications such as hemorrhage, preeclampsia, and infections. For example, in the United States, as many as 60,000 women per year are affected by severe maternal morbidity, most of which could have been avoided with timely interventions [4]. Miscarriage (loss of a fetus before the 20th week of pregnancy) and stillbirth (loss of a fetus after 20 weeks of pregnancy) are common and represent significant emotional and physical trauma. Importantly, maternal health outcomes are deeply tied to social determinants of health. Women in underserved communities face higher risks due to limited access to health care, systemic inequalities, and a lack of prenatal care.

Pregnancy represents a highly complex physiological state, characterized by extensive biological, hormonal, and behavioral adaptations that optimize maternal and fetal development. Current prenatal care is largely centered on assessing health and screening for disease at discrete time points during scheduled visits, focusing on key physical markers such as blood pressure, weight, and fetal growth. In the United States, standard prenatal care varies based on a woman's risk profile. Standard prenatal care globally includes relatively few touchpoints compared with the length of pregnancy and the significant physiological and emotional changes that occur. Postpartum, care and connection often drop off, with sometimes only a single visit after delivery. Those considered high-risk may require more frequent visits and ad hoc interventions depending on the severity and progression of pregnancy-associated factors, but the care, nevertheless, is brief and infrequent [5].

While valuable, this episodic approach often fails to capture the dynamic and continuous nature of physiological, behavioral, and psychosocial changes throughout pregnancy. Critical fluctuations or early signs of atypical trajectories may go unnoticed between visits. Notably, it overlooks individual trajectories relative to one's baseline, potentially missing significant deviations that, while within population norms, may still indicate important risks or shifts in health status. This limitation underscores the need for a more comprehensive, individualized, longitudinal model of prenatal care, incorporating continuous monitoring and integrating emerging biobehavioral and contextual data. Such an approach would provide a deeper understanding of pregnancy as an evolving process and improve maternal-fetal outcomes.

Traditional maternal health research has been instrumental in shaping our understanding of pregnancy, providing critical insights into fetal development, maternal physiology, and the factors contributing to pregnancy outcomes. Through clinical assessments and structured studies, this body of work has established foundational knowledge and improved care practices.

Thanks to the advancements in sensor technology and digital health, multisensor consumer wearables (ie, smartwatches, smart rings, and other health trackers) in particular, present an opportunity to complement and extend traditional research approaches. However, this line of work is still in its infancy, and more research is needed to understand their role in supporting the reproductive life course [6-8]. By enabling passive, large-scale monitoring of biobehavioral data—such as sleep, temperature trends, cardiorespiratory, and activity patterns—wearables could provide a dynamic and real-time perspective on maternal health throughout pregnancy. Wearables demonstrate feasibility in estimating ovulation compared with calendar-based fertility tracking [9], presenting a potential avenue to support women's fertility journeys. Grant and Smarr [10] showcase the possibility of passive early pregnancy detection through continuous analysis of distal skin temperature, while others suggest the use of a wearable to proxy the clinically estimated delivery date [11,12]. Other studies showcase the potential to use wearables in relation to pregnancy risks (eg, classification of healthy pregnant vs nonpregnant women) [13] and complications, including gestational diabetes [14], gestational hypertension [15], preterm labor [11,16], and postpartum depression [17].

The maternal health market is evolving rapidly, with a growing focus on digital health solutions and consumer-centric innovations to address the diverse needs of pregnant women and new mothers. While the role of consumer wearable in maternal health is still unclear, initial feasibility for continuous high-resolution passive monitoring of pregnancy using a multisensor consumer wearable device has been shown by Keeler et al [18]. In that study, biobehavioral data collected via the Oura Ring Gen2 and questionnaire data were analyzed from 120 pregnancies, including 97 full-term pregnancies and 23 cases of pregnancy loss. Two additional recent studies evaluating signals before, during, and after pregnancy highlight changes across 3 distinct physiological states. A retrospective analysis of sleep data from 2540 Fitbit users in the US and Canada examined patterns 12 weeks before pregnancy, throughout gestation, and during the first 20 weeks postpartum [19]. Similarly, an evaluation of 757 pregnancies for Apple Watch users described trends in sleep, as well as exercise minutes, steps, and physiologic signals such as heart rate (HR) and respiratory rate (RR) [20]. Overall, these studies demonstrated that high-resolution data throughout pregnancy offer valuable insights into temporal and individual variability, as well as differences across different biobehavioral data, such as, sleep, temperature trends, cardiorespiratory, and activity.

This work aims to extend the study by Keeler et al [18] by conducting a large-scale mapping of biobehavioral changes across pregnancy—from preconception to postpartum—for pregnancies ending in loss (before 20 weeks), preterm birth, and term birth, using data from a large sample of 10,318 Oura Ring users. This retrospective observational study—the largest compilation of pregnancies using wearable data to date—aims

XSL•FO
RenderX

to delineate the physiological and behavioral characteristics of pregnancy and to evaluate whether factors such as advanced maternal age and overweight status influence biobehavioral data trajectories during pregnancy. For example, existing literature indicates that advanced maternal age [21] and overweight/obesity [22] significantly increase the risk of adverse maternal outcomes; however, this study uniquely leverages wearable technology to provide continuous, real-world biobehavioral data across pregnancy, offering novel insights into how age and BMI impact sleep, activity, and cardiorespiratory patterns throughout gestation.

Methods

Dataset

A cohort of Oura Ring users was included in the study. Users were eligible if they self-identified as female (ie, sex assigned at birth), were pregnant between May 2023 and November 2024, and were aged 18 to 51 years. The date range was selected to ensure that participant data were collected using the latest Oura algorithms and Gen3 hardware. The final sample included 10,318 unique pregnancies. Among these, 5363 pregnancies led to live births (324 preterm and 5039 at term), while 4955 ended in loss before 20 weeks of gestation (eg, miscarriage or other early pregnancy losses).

Ethical Considerations

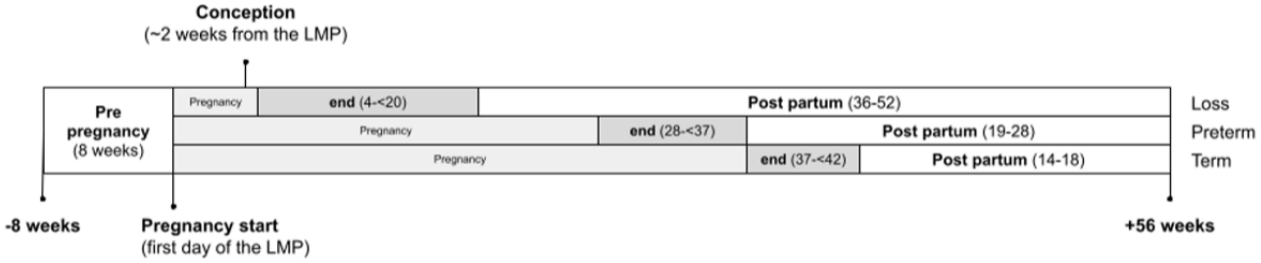
This study involved secondary analysis of data from adult users of the Oura Ring, collected by Oura Health Oy (Oulu, Finland) in accordance with its Terms of Use [23] and Privacy Policy [24], which users consent to prior to data collection. By agreeing to the Privacy Policy, users consented to the use of their data for research and analytical purposes. All data used in this study were fully deidentified and aggregated in accordance with Oura's internal data governance protocols. The research protocol was reviewed and approved by Oura's internal science and legal teams, which oversee regulatory and ethical compliance for research activities. The study was deemed exempt from formal ethics board review as it involved only secondary analysis of anonymized, nonidentifiable data. Additional safeguards included restricted data access solely for verification and analytical accuracy. No compensation was provided to participants.

Procedure

This is a retrospective observational study on Oura users who opted to use the Oura App's Pregnancy Insights feature (see below) during pregnancy. Sleep, temperature trends, cardiorespiratory, and activity data from Oura Ring were accessed for a 64-week window encompassing the period from 8 weeks prior to the estimated start of pregnancy (the first day of the last menstrual period [LMP]) to 56 weeks following that.

Participants were grouped based on self-reported pregnancy outcomes and the gestational age at pregnancy end, that is, pregnancies ending in loss versus live births (with live births further categorized into preterm and term births (Figure 1).

Figure 1. Schematics of the data collection timeline across pregnancies resulting in loss, preterm birth, and term birth are provided. The start and end of pregnancy, as well as the estimated time of conception, are highlighted in the graph. LMP: last menstrual period.



Gestational age was also used to classify pregnancy into 3 trimesters. Trimester 1 included weeks 0 days to 13 weeks 6 days of gestation. Trimester 2 ranged from 14 weeks 0 days to 27 weeks 6 days. Trimester 3 covered 28 weeks 0 days until 40 weeks 6 days of gestation.

Oura Bio-Behavioral Data Collection

All participants wore an Oura Ring Gen3 (Oura Health Oy, Oulu, Finland), a noninvasive, water-resistant, and commercially available multisensor device that continuously measures finger blood flow, peripheral oxygen saturation, skin temperature, and movement via photoplethysmography green, red, and infrared LEDs, a negative skin temperature coefficient thermistor (±0.1 °C resolution), and 3D accelerometry. Oura Ring connects to mobile platforms via Bluetooth Low Energy, and data are transmitted to secure cloud-based servers for processing and storage. Oura Ring battery lasts up to 7 days.

By using proprietary algorithms, Oura Ring measures several health-related indices. Please refer to de Zambotti et al [25] for an overview of consumer wearable sleep metrics and their operationalization. A list of Oura Ring metrics used in this study is provided in Table 1.

XSL•FO
RenderX

Table 1. Oura Ring Gen3 metrics.

Measure	Description
Sleep	• Daily Time in bed (hours), asleep (hours), awake (hours), and time spent in "light" sleep (equivalent of PSG[a] N1+N2 sleep; % time asleep), "deep" sleep (equivalent of PSG N3 sleep; % time asleep) and rapid-eye-movement (REM) sleep (% time asleep), for the Oura classified main nocturnal sleep (>3h sleep duration). For each participant, single daily measures of overnight sleep measures were obtained. These metrics are calculated between the Oura Ring's automatically detected onset and offset of nocturnal sleep windows, approximating individuals' bedtimes and wakeup times via proprietary algorithms that combine features from PPG[b], temperature trends, and accelerometer sensors, trained on expert-scored PSG sleep records. The performance of Oura Ring for sleep measurement has been evaluated across multiple peer-reviewed studies across different demographics, providing overall good agreement with the gold standard PSG [26-31]. In the most recent Oura-sponsored performance evaluation of Oura Ring Gen3 [29], Oura Ring achieved a sensitivity of 73.0% for wake, 76.7% for "light" sleep, 64.0% for "deep" sleep, and 72.6% for REM sleep, in healthy individuals.
Temperature	• Daily peak sleep skin temperature (°C). For each of the participants, a single daily measurement of peak sleep skin temperature during sleep was obtained. Oura internal validation (unpublished company data) [32] shows good concordance of the skin temperature sensor with reference standards in both laboratory and free-living conditions.
Cardiorespiratory	• Daily average sleep PPG-based HR[c] (bpm) HRV[d] (ms). For each of the participants and night, HR and HRV have been averaged across the Oura Ring's classified main nocturnal sleep to provide a daily measure. Oura Ring Gen3 estimates HR at 30s resolution and time-domain HRV, that is, the root mean square of successive differences between normal heartbeats (RMSSD) for consecutive 5-minute windows during the nocturnal sleep. RMSSD captures the high-frequency component of HRV reflecting vagal autonomic nervous system function. Please see Shaffer and Ginsberg [33] for an overview of HRV assessment and meaning. As a note, the term HRV is used for consistency, considering that Oura Ring measures pulse rate variability from PPG signal, which reflects variation in blood flow and does not directly measure heart's electrical depolarization signal. Average-per-night test comparing Oura Ring versus reference standard electrocardiogram-based HR and HRV metrics, shows good level of concordance with low mean biases [34]. • Daily average respiratory rate (RR; breaths/min). RR is measured by computing PPG-HR time series data during nocturnal sleep. For each of the participants and night, RRs have been averaged across Oura classified main nocturnal sleep to provide a daily measure.
Activity	• Daily total steps (number). Oura Ring calculates the number of daily steps within the time period spanning across the 24h. For each of the participants, a single daily measure of total steps was obtained. • Oura activity data show good concordance for laboratory and free-living testing when compared with reference standards, particularly when considering group-level comparisons [35].

[a]PSG: polysomnography.

[b]PPG: photoplethysmography.

[c]HR: heart rate.

[d]HRV: heart rate variability.

Oura App and the Pregnancy Insights Feature

The Oura App Pregnancy Insights feature is designed to provide data-driven information (how sleep and other biometrics change with pregnancy) and in-app education to help users navigate their pregnancy. The feature tracks gestational age, providing weekly updates about physiological changes detected by the Oura Ring. Pregnancy Insights requires a user to turn on the feature in the "Women's Health" settings of the app, confirming pregnancy. The feature enables self-report of estimated due date and first day of the last period, as well as date of birth or pregnancy loss.

Age, prepregnancy height and weight, and country of residence have been extracted from the Oura App users' profiles. BMI has been calculated as weight (kg) × height $(m)^{-2}$.

Data Preprocessing

Oura Ring Data

This step included the generation of "local" date-time indexing, removal of duplicate time points, and for sleep, temperature trends, and cardiorespiratory data, time points not belonging to main sleep periods (eg, naps, diurnal sleep) have been removed. In addition, pregnancies with less than 40% of Oura Ring data available [18], for prepregnancy and for each trimester during pregnancy, were excluded.

Identifying Pregnancy Start and End Date for Pregnancies Leading to Birth and Early Pregnancy End

Pregnancy start (standardized point for estimating gestational age) is operationalized as the first day of the LMP, which differs from conception (biological event), that is, the moment when the sperm fertilizes the egg, typically occurring around 14 days after the start of the LMP in a standard 28-day cycle. Pregnancy start is computed based on self-reported expected due date if known (expected due date minus 280 days; 5090/10,318, 49.3% pregnancies) or directly based on their self-reported first day of their last period (5228/10,318, 50.7% pregnancies). Pregnancy end was operationalized based on self-reported data, either as a birth date or as an early pregnancy loss.

Statistical Analysis

A first statistical analysis was conducted to evaluate patterns of change in Oura bio-behavioral data throughout pregnancy,

XSL•FO
RenderX

specifically focusing on pregnancies leading to term births. All bio-behavioral data were first aligned to the estimated start of pregnancy. The analysis was performed on average weekly bio-behavioral data from Oura, encompassing both the pregnancy and postpartum periods. To account for inherent interindividual variability in baseline physiological levels, each metric was normalized to a prepregnancy baseline. This baseline was defined as the average value over the 4 weeks preceding the estimated pregnancy start. Normalization was performed by calculating Z-scores, representing the number of SDs a value deviated from the mean of its respective prepregnancy baseline. This standardization allowed for a more focused capture and comparison of trends and patterns of physiological change throughout pregnancy across the cohort.

To appropriately account for the longitudinal within-subject correlation structure inherent in repeated measurements from the same individual, a generalized estimating equation (GEE) statistical modeling framework was used [36]. An exchangeable working correlation structure was specified for the GEE. This choice assumes a constant correlation between any 2 measurements within the same individual, regardless of the time interval between them, and is commonly used for its robustness. The GEE framework provides consistent estimates of population-averaged effects and computes robust standard errors, which are valid even if the assumed working correlation structure is not perfectly specified.

The nonlinear relationship between each normalized physiological metric and gestational age (our time variable) was modeled using B-spline basis functions. The specific flexibility of the curve was determined by using 8 degrees of freedom for the B-spline. This choice of degrees of freedom was guided by a balance between capturing complex nonlinear patterns (assessed through visual inspection of predicted fits) and maintaining statistical stability.

Subsequently, the impact of continuous covariates, specifically maternal age and prepregnancy BMI, as well as their interactions with gestational age, was investigated. This was achieved by extending the primary GEE model to include corresponding B-spline terms for these covariates and tensor product spline interaction terms with gestational age. These tensor product splines allowed for the characterization of how the nonlinear trend of each physiological metric over gestational age might vary across different levels of age and BMI.

The statistical significance of effects was assessed using Wald tests. First, for the gestational age-only model, a joint Wald test was performed on the set of B-spline coefficients for gestational age. A significant *P* value indicated a statistically significant nonlinear population-level trend in the physiological metric throughout pregnancy. Then, for models incorporating maternal age and BMI, joint Wald tests were conducted on the sets of coefficients corresponding to their main effect B-spline terms and interaction terms with gestational age. A statistically significant *P* value for these interaction terms indicated that maternal age or BMI had a significant moderating effect on the physiological trend over gestational age.

All tested effects (including the main trends over gestational age, and the main and interaction effects of age and BMI) were found to be statistically significant (*P* values <.05). However, it was observed that the magnitude of some of these effects (ie, the effect size) was small in practical terms, which was further explored through visualization of predicted trends and quantification of absolute differences over each trimester.

A second statistical analysis was conducted to evaluate differential trajectories in Oura bio-behavioral data between pregnancies ending before 20 weeks and those resulting in term live births, focusing on the period immediately preceding early pregnancy end. Specifically, we investigated how pregnancy outcome influenced physiological metrics during the 28 days leading up to the day of early pregnancy end. Prior to analysis, data underwent preprocessing, including linear interpolation for missing values and subsequent normalization via z-scoring with respect to each individual's prepregnancy baseline (defined as the average over the 4 weeks preceding pregnancy start). For each pregnancy that ended before 20 weeks, we extracted bio-behavioral data for the 28 days immediately preceding the end of pregnancy. To establish a time-matched control, data from a randomly sampled pregnancy resulting in a term live birth were selected for the equivalent gestational age (eg, if a pregnancy end occurred at 7 weeks 1 day estimated gestational age, data from 3 weeks 2 days to 7 weeks 1 day were extracted for both the early pregnancy end case and its matched control).

A GEE model, like that used in the first analysis, was applied. In this model, the day relative to pregnancy end served as the primary independent variable to predict each normalized physiological metric, while simultaneously controlling for pregnancy outcome (pregnancy end before 20 weeks or term live birth). The nonlinear relationship between each normalized physiological metric and the day relative to a pregnancy ending before 20 weeks was modeled using a B-spline with 3 degrees of freedom. The model also included a linear term for pregnancy outcome and a linear interaction term between pregnancy outcome and the day relative to early pregnancy end. To determine if the physiological trajectory for pregnancies resulting in loss was statistically different from the trajectory for pregnancies resulting in a term live birth, we assessed the overall effect of pregnancy outcome using a joint Wald test on both the linear term for pregnancy outcome and the linear interaction term. Effect sizes were quantified as the mean difference between the modeled responses for pregnancies resulting in term live birth and those ending before 20 weeks, calculated across 2 distinct periods: the entire 28 days preceding early pregnancy end, and specifically during the 7 days immediately prior to the early pregnancy's end.

All models were implemented using the Python package statsmodels [37]. This study is reported in accordance with the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines. A completed STROBE checklist is provided in Multimedia Appendix 1.

Results

Demographics and Pregnancy Characteristics

Participants in the study had a mean age of 32.2 (SD 4.5) years and a mean BMI of 25.3 (SD 5.4) kg/m², based on data collected prior to pregnancy.

Participants in the study represented various regions, including the United States (7398/10,318, 71.7% participants), the European Union (1104/10,318, 10.7% participants), the United Kingdom (351/10,318, 3.4% participants), Canada (320/10,318, 3.1% participants), Australia (155/10,318, 1.5% participants), and other countries (371/10,318, 3.6% participants). For 619 out of 10,318 (6.0%) participants, the location was unknown.

Distribution of Oura Ring sizes in the study population were the following: Size 6 (856/10,318, 8.3% participants), Size 7 (2270/10,318, 22% participants), Size 8 (3281/10,318, 31.8% participants), Size 9 (2384/10,318, 23.1% participants), Size 10 (1011/10,318, 9.8% participants), Size 11 (382/10,318, 3.7% participants), Size 12 (103/10,318, 1% participants), and Size 13 (31/10,318, 0.3% participants).

The distribution of pregnancies as a function of the estimated gestational age at which the pregnancy ended, for pregnancies ending in loss, preterm birth, and term birth, is provided in Multimedia Appendix 2. Self-reports of early pregnancy end did not differentiate between types of loss, such as spontaneous abortion, ectopic pregnancy, molar pregnancy, or pregnancy termination; therefore, this study does not adjust for the specific etiology of pregnancy loss. The distribution of participants' age and BMI for pregnancies ending in loss, preterm birth, and term birth is provided in Multimedia Appendix 3.

Prepregnancy age (Kruskal-Wallis, P=.44) and BMI (Kruskal-Wallis, P=.08) did not significantly differ between pregnancies ending in loss, preterm, or term birth.

Pattern of Changes in Oura Bio-Behavioral Data Throughout Pregnancy in Pregnancies Leading to Term Births

Overview

Absolute changes in Oura data throughout pregnancy are provided in Multimedia Appendix 4. The number of women contributing valid data at each gestational week is shown in Multimedia Appendix 5. Detailed results for the GEE model are provided in Multimedia Appendices 6 and 7. Changes in normalized Oura bio-behavioral data throughout pregnancy are displayed in Figure 2 (sleep), Figure 3 (temperature trends), Figure 4 (cardiorespiratory), and Figure 5 (activity).

XSL•FO
RenderX

Figure 2. Changes in Oura sleep data throughout pregnancy. Data (Z-scores - normalized data based on prepregnancy individuals' baseline) are plotted as the weekly median (thick line) and the 50th percentile range, separately for pregnancies leading to loss (N=4955), preterm births (N=324), and term (N=5039) births. Gestational age 0 (the start of pregnancy) is defined as the first day of the last menstrual period. The red, purple, and green vertical bars delineate the mean pregnancy end and one SD for pregnancy loss, preterm birth, and term birth, respectively.

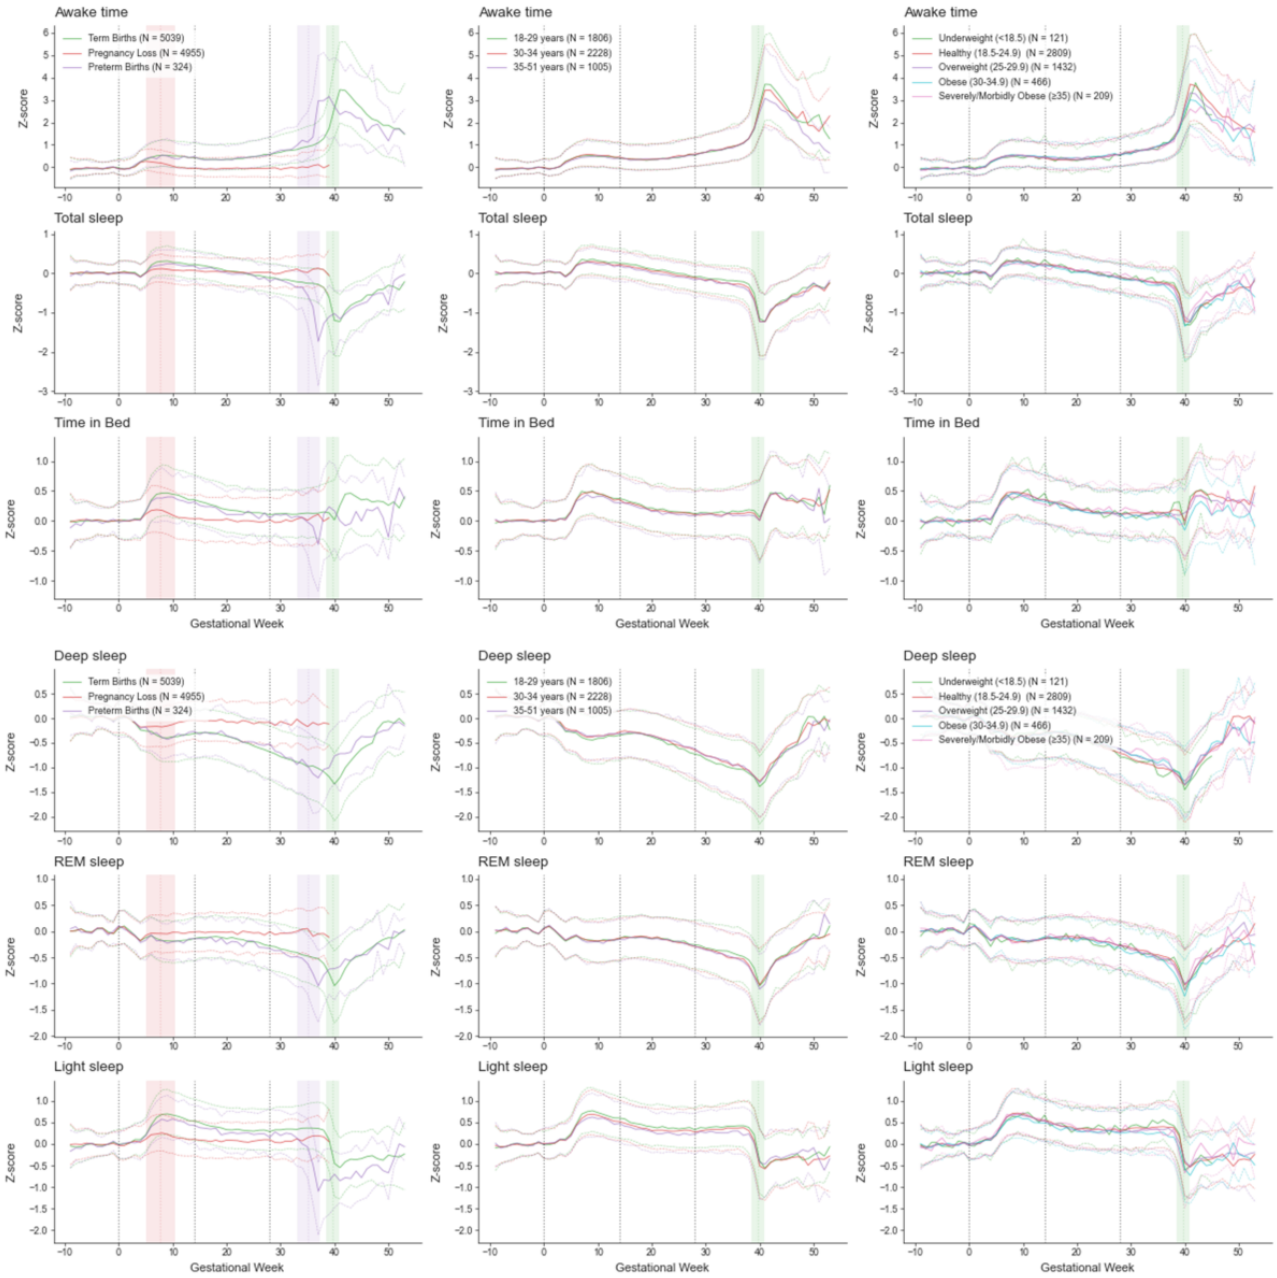

Figure 3. Changes in Oura temperature trends data throughout pregnancy. Data (Z-scores - normalized data based on prepregnancy individuals' baseline) are plotted as the weekly median (thick line) and the 50th percentile range, separately for pregnancies ending in loss (N=4955), preterm births (N=324), and term (N=5039) births. Gestational age 0 (the start of pregnancy) is defined as the first day of the last menstrual period. The red, purple, and green vertical bars delineate the mean pregnancy end and one SD for pregnancy loss, preterm birth, and term birth, respectively.

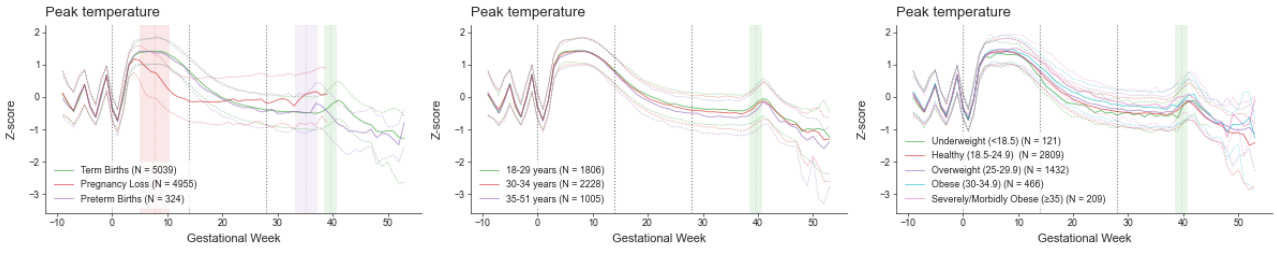

XSL•FO
RenderX

Figure 4. Changes in Oura cardiorespiratory data throughout pregnancy. Data (Z-scores - normalized data based on pre-pregnancy individuals' baseline) are plotted as the weekly median (thick line) and the 50th percentile range, separately for pregnancies ending in loss (N=4955), preterm births (N=324), and term (N=5039) births. Gestational age 0 (the start of pregnancy) is defined as the first day of the last menstrual period. The red, purple, and green vertical bars delineate the mean pregnancy end and one SD for pregnancy loss, preterm birth, and term birth, respectively.

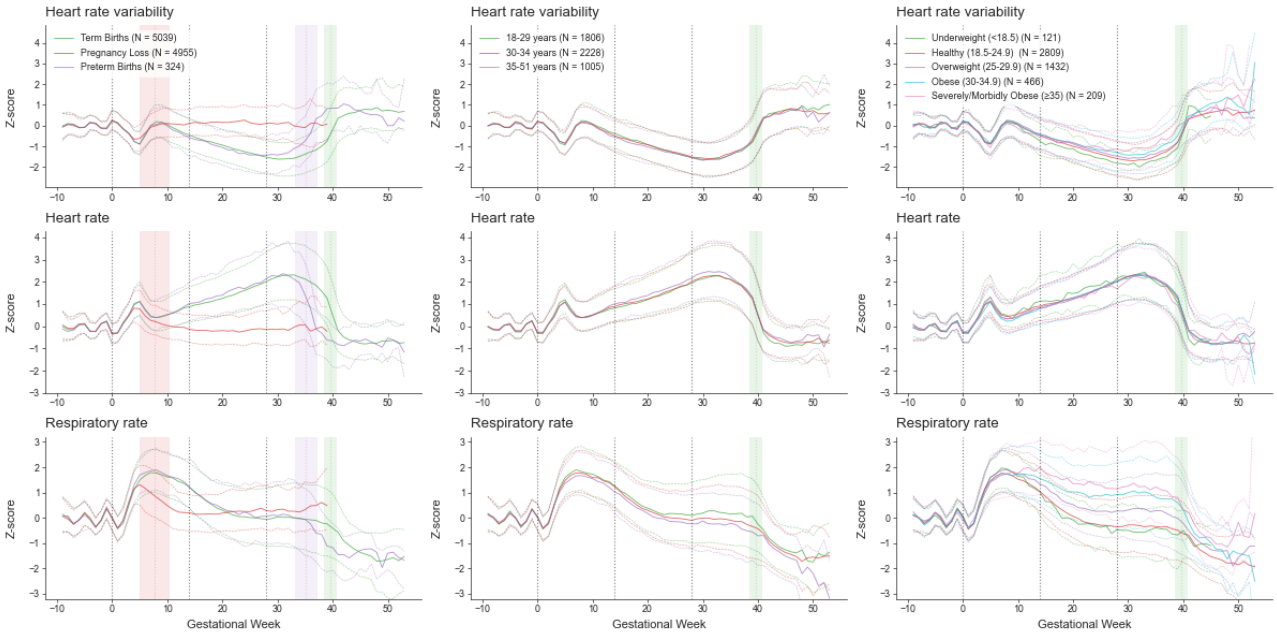

Figure 5. Changes in Oura activity data throughout pregnancy. Data (Z-scores - normalized data based on prepregnancy individuals' baseline) are plotted as the weekly median (thick line) and the 50th percentile range, separately for pregnancies ending in loss (N=4955), preterm births (N=324), and term (N=5039) births. Gestational age 0 (the start of pregnancy) is defined as the first day of the last menstrual period. The red, purple, and green vertical bars delineate the mean pregnancy end and one SD for pregnancy loss, preterm birth, and term birth, respectively.

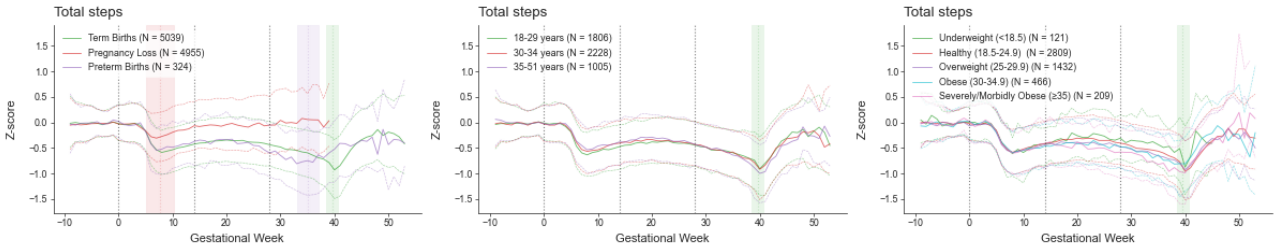


While analyses focus on term births, the figures provide a visual comparison with pregnancies ending in loss and preterm birth. Pregnancies ending in loss (occurring between estimated gestational ages of 4 to 20 weeks) exhibit significant deviations from the trajectories of pregnancies resulting in birth at the same gestational age. In contrast, pregnancies resulting in preterm birth closely mirror Oura data trajectories of term births, except that the physiological changes associated with birth occur at an earlier gestational age.

Sleep

GEE results indicate a significant gestational age main effect for time in bed, time asleep, and time awake at night (all *P* values <.001). From the onset of pregnancy, time in bed, time asleep, and time awake all rise and reach a first peak around week 9. They then decrease and stabilize in the second trimester. In the third trimester, while time in bed returns to approximately pre-pregnancy level, time awake remains elevated and time asleep reduced. Around birth, sleep patterns change, with time in bed and time awake increasing to their peaks, while time asleep decreases to its lowest point, all occurring at week 40. Notably, participants' time spent awake at around birth exceeds 3 SDs over baseline. GEE results indicate statistically significant gestational age-by-maternal-age and gestational age-by BMI interaction for each sleep metric (all *P* values <.01). However, the effect sizes are relatively modest except for differences following birth. We do see a slightly increased time asleep in younger compared with older participants from week 9 up to birth, with respect to prepregnancy level.

Similarly, significant gestational age main effects were observed for sleep stages (all *P* values <.001). Deep and rapid-eye-movement sleep both decreased throughout pregnancy, reaching a nadir around birth before recovering postpartum. Light sleep increased during the first trimester, reaching a peak around week 9, remained stable for most of pregnancy, and then declined postpartum. While statistically significant gestational age-by-maternal-age and gestational age-by BMI interactions were also found for these sleep stages (all *P* values <.01), their effect sizes were relatively modest. A subtle increase in light sleep and a decrease in deep sleep were noted in younger participants compared with older participants from week 9 until birth, relative to prepregnancy levels. There was a slight increase in rapid-eye-movement sleep from around

XSL•FO
RenderX

week 33 until birth for younger participants compared with older participants.

Temperature Trends

GEE results indicate a significant gestational age main effect (*P* value <.001). From the start of pregnancy, temperature trends increase sharply at around conception (around 2-week gestational age), until it reaches a max peak around 9-week gestational age. It then gradually decreases to below prepregnancy levels. Around birth, temperature trends slightly increase, peaking at week 41, and afterward, it drops again below prepregnancy baseline levels. There are statistically significant but modest effects associated with age and BMI (all *P* values <.001). While the peak in temperature around week 9 is roughly the same across age groups, we do see a slightly less pronounced downward trend in temperature during the second and third trimesters for younger compared with older participants. The temperature peak around week 9 is slightly lower for participants with lower BMI compared with those with higher BMI, and there is a more significant drop in temperature during the second trimester for lower compared with higher BMI participants. This difference between lower and higher BMI participants persists through the third trimester.

Cardiorespiratory

GEE results indicate a significant gestational age main effect for HR and heart rate variability (HRV), as well as statistically significant interactions with age and BMI (all *P* values <.001). From the beginning of pregnancy, HR rises and reaches a first peak at week 5. After a small trough at week 9, it continues rising, peaking at week 32, then drops sharply at birth and stabilizes in the postpartum period. The HRV trajectory mirrors the opposite pattern of HR. Older participants exhibit a slightly larger rise in HR in the second and third trimesters (until approximately week 33), and have a slightly larger drop in HRV between the end of the first trimester and the first half of the second trimester (approximately from week 12 through week 24). Participants with lower BMI experienced a greater drop in HRV during the second trimester compared with those with higher BMI.

GEE results indicate significant gestational age main effect, gestational age by maternal age interaction, and gestational age by BMI interaction for RR (all *P* values <.001). From the onset of pregnancy, RR increases, peaking at 9 weeks of gestational age. It then steadily declines, stabilizing during the second and third trimesters. Following birth, RR experiences a sharp drop, falling below baseline levels. Interaction effects indicate that after reaching the first peak, RR decreases less in participants with a higher BMI and in younger participants.

Activity

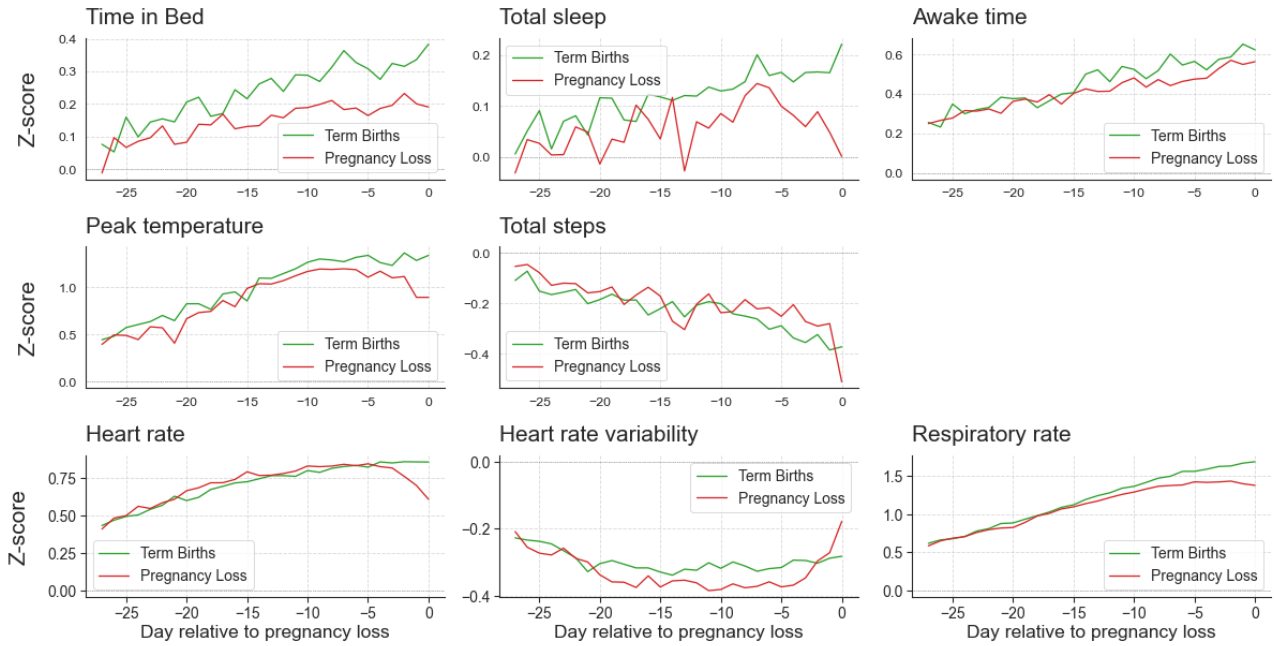
GEE results indicate significant gestational age effects for total numbers of steps (*P* values <.001). From the start of pregnancy, the number of steps decreases, reaching a trough at gestational week 8 and then increases slightly until 21 weeks of gestational age (middle of the second trimester) before decreasing again until birth, reaching the min level of activity. GEE results indicate significant interactions between gestational age and both maternal age and BMI for the total number of steps (all *P* values <.001). Though statistically significant, the effect size for the maternal age interaction is modest. There is a greater decrease in steps starting in the second trimester for participants with higher BMI compared with those with lower BMI. There is also a slightly larger drop in steps for younger participants starting at the trough at gestational week 8, with the difference between younger and older participants disappearing by the end of the second trimester.

Oura Biobehavioral Signatures Preceding Pregnancy Loss

Detailed results for GEE are provided in Multimedia Appendix 8. Changes in Oura bio-behavioral data for 28 days preceding and following the end of pregnancy are displayed in Figure 6. The number of women contributing valid data at each gestational week is shown in Multimedia Appendix 5.

XSL•FO
RenderX

Figure 6. Changes in Oura sleep, temperature trends, activity, and cardiorespiratory data across 28 days preceding the end of pregnancy, for pregnancies ending in loss (N=4955), compared with Oura data trajectories matching the same gestational age, for a randomly chosen pregnancy leading to birth (N=4955).



The GEE model, comparing the loss versus nonloss curves, shows that the time in bed starts decreasing about 2 weeks prior to pregnancy loss (*P* values <.001), while total sleep time starts to decrease one week before (*P* values <.001). Awake time drops around the same period (*P*=.033). Temperature trends also show a significant effect (*P* values <.001), with peak temperature trends decreasing a week before pregnancy loss. Average HR drops a few days prior to pregnancy loss (*P*=.005), and RR drops one week before loss (*P*=.019). Steps and HRV effects were not statistically significant in the GEE models.

Discussion

In this comprehensive, real-world, observational, retrospective study, we analyzed data from 10,318 pregnancies, providing the first large-scale examination of multimodal physiological and behavioral metrics recorded across the entire pregnancy continuum—from prepregnancy through conception and into the postpartum period. The novelty of the study lies in the high-density analysis of key biobehavioral aspects of pregnancy (sleep, temperature trends, cardiorespiratory, and activity data), mapping their trajectories over time and highlighting the complex, domain-specific temporal dynamics that characterize the multitude of biological and behavioral changes accompanying a woman's pregnancy journey.

Changes that women experience throughout pregnancy are largely driven by hormonal shifts and can be viewed as adaptive responses designed to support a successful pregnancy and birth while protecting the mother [38,39]. Our results indicate that during the first trimester, participants experienced significant sleep alteration, peaking at week 9 and being characterized by increased time in bed (≈ +30 min), asleep (≈ +15 min), and awake (≈ +15 min) compared with prepregnancy levels. These changes align with rising progesterone levels, which have both thermogenic and soporific effects and can promote sleepiness and increase total sleep time, but also contribute to sleep disruption. While sleep duration returned to baseline (or lower) in the second trimester, wake time remained elevated, likely due to physiological adaptation to pregnancy as well as known factors such as increased frequency of nocturnal urination [40]. In the third trimester, sleep disturbances worsened, possibly driven by increased physical discomfort, fetal movements, or additional increases in nocturnal urination. After birth, sleep deteriorated dramatically, with wake time rising by ≈90 min and time spent asleep dropping ≈70 min below prepregnancy levels, possibly reflecting infant care demands, postpartum hormonal shifts, and disrupted circadian rhythms [41].

Temperature changes were more pronounced, sustained, and occurred earlier than sleep changes, becoming evident by 4 weeks estimated gestational age (≈+0.3 °C above baseline), mapping early hormonal shifts, particularly rising progesterone, which is known to increase basal skin temperature via thermogenic effects. These changes persisted throughout the first trimester. In the second trimester, temperature trends declined as maternal adaptation mechanisms, such as increased blood volume and improved thermoregulation (eg, response to increased metabolic heat produced by the fetus) [38], took effect, stabilizing below baseline in the third trimester. At birth, a slight skin temperature rise (≈+0.1 °C) may reflect labor-associated metabolic demands (eg, increased physical activity with uterine contractions) and hormonal fluctuations, followed by a drop postpartum as pregnancy-related thermogenic effects subside [38]. The postpartum return to monthly cyclical temperature oscillations (ie, the resumption of menstrual cycles) is not observed within the analyzed time window, which is limited to a few months after birth for live births. Given that menstruation gradually resumes, varying among individuals and influenced by factors such as lactation practices and hormonal

XSL•FO
RenderX

fluctuations—none of which are captured in the current dataset—this process remains beyond the scope of our analysis.

Changes in cardiorespiratory data are consistent with the dynamic cardiovascular adaptations that occur throughout pregnancy to support the increasing metabolic demands of both the developing fetus and the mother [42]. Oura HR and HRV, that is, indices reflecting autonomic modulation, show profound changes across gestational age; they exhibit inverse patterns, characterized by a biphasic fluctuation in the first trimester—an initial HR peak exceeding 4 bpm above baseline and an HRV drop of >10 milliseconds at week 5, followed by a trough at week 9. These changes suggest early significant maternal physiologic preparatory changes to pregnancy, that is, happening before the end of the embryonic period, with HR rises following systemic vasodilation [43-45]. During the second trimester, HR increases linearly, peaking at >10 bpm above baseline, while HRV declines, reaching a minimum of >15 milliseconds below baseline, possibly reflecting decreases in parasympathetic cardiovascular control, as evaluated via standardized autonomic tests [46]. In the third trimester, these trends begin shifting earlier, with a marked drop in HR and a rise in HRV around birth, ultimately approaching prepregnancy levels.

The pulmonary system undergoes significant mechanical and functional changes during pregnancy. Notably, ventilation and tidal volume increase by approximately 20%-50% from prepregnancy levels [47]. Changes in RR are less well-defined in the literature; when reported, increases are typically modest, ranging from 1 to 2 breaths per minute. In our study, RR shows a slight increase during the first trimester, peaking around 8 weeks at approximately 1 breath per minute above baseline. This initial rise may reflect the stimulating effect of progesterone. Subsequently, the RR decreases and stabilizes by the mid-second trimester, returning to prepregnancy baseline levels, and remains unchanged until birth. After delivery, the RR may drop below baseline levels as the body readjusts to the nonpregnant state.

Our data indicate a decline in step count during the first trimester of pregnancy, with a notable dip around 8 weeks—a reduction of approximately 2000 steps compared with prepregnancy levels. This decline may be attributed to a combination of physiological, psychological, and social factors driven by hormonal fluctuations and early maternal adaptations. For example, elevated levels of human chorionic gonadotropin contribute to common pregnancy symptoms such as nausea, dizziness, and fatigue, which may lead to reduced physical activity [48]. Additionally, other factors such as worsening sleep quality and increased psychological stress may further contribute to decreased activity levels during this period. Cardiovascular adjustments can also impact energy levels. Following a slight increase in the second trimester, physical activity declines again, reaching its lowest point near birth, with step counts dropping by more than 2500 steps. This reduced activity in the third trimester may be explained by factors such as reduced mobility due to the mechanical strain, such as increased lordosis and laxity of joints, as well as increased effort on the cardiorespiratory system to sustain exercise under peak cardiometabolic demand as the maternal body supports rapid fetal growth, increased oxygen consumption, and metabolic adaptations to prepare for labor [42].

The use of passive, continuous longitudinal data collection in free-living conditions during pregnancy remains limited. However, our findings align with recent studies using consumer-grade devices. For example, 2 studies—one involving a limited sample of 17 (88%) US Hispanic women wearing Oura Ring devices [49] and another with a convenience sample of 20 Finnish women using Garmin Vivosmart bands [50]—revealed similar overall trajectories in sleep duration, activity levels, and HR increases through pregnancy. Focusing on photoplethysmography-based HR and a comprehensive set of time-domain and frequency-domain HRV metrics, Sarhaddi et al [51] analyzed data collected from 58 Finnish pregnant women, including those with high-risk pregnancies, using the Samsung Gear Sport smartwatch. Like our results, their findings reveal measure-specific changes in HR and HRV. Additional similar studies include pregnancy analyses based on Ava Fertility Tracker data in 23 women [52] and WHOOP 2.0 data in 18 healthy women [53]. These studies vary in sample characteristics, methodology, and purpose (eg, narrow focus on specific events during pregnancy), relying on small sample sizes and often lacking early pregnancy and prepregnancy baseline data, making direct outcome comparisons challenging. Additionally, many of these studies were conducted during the COVID-19 pandemic, which may have influenced pregnant women's behaviors throughout pregnancy.

Notably, recent analyses of wearable biobehavioral data in 2540 Fitbit users [19], primarily focused on sleep, and an analysis of 733 Apple Watch users [20] revealed similar temporal patterns across the health metrics examined. Likewise, Keeler et al [18] analyzed Oura-derived biobehavioral trajectories in 97 full-term pregnancies and 23 early pregnancy losses. Our analysis builds upon and extends these findings by offering significantly greater temporal resolution, analyzing a substantially larger and more diverse sample, and uniquely including pregnancies ending in loss or preterm birth. These contributions allow for a more comprehensive characterization of physiological changes across pregnancy and highlight early, modality-specific deviations associated with nonviable outcomes. Importantly, similar to others [18,20], our results did not show large variation in Oura biobehavioral trajectories throughout pregnancy as a function of factors such as maternal age and prepregnancy BMI status. This aspect needs to be further explored. Notably, our evaluation of BMI was limited to prepregnancy status, and it is likely that different weight trajectories during pregnancy—such as the rate and pattern of weight gain—may affect pregnancy biometrics.

In our observations, we detected changes in sleep and downward shifts in temperature, RR, and HR preceding the reported early end of pregnancy, with most signal deflections beginning approximately 7 days before the event. These biobehavioral changes suggest the potential utility of continuous monitoring for identifying early indicators of pregnancy failure. Specifically, we were unable to determine the underlying cause or classification of these outcomes (eg, spontaneous miscarriage, ectopic pregnancy, molar pregnancy) due to the lack of diagnostic or medical metadata. As such, while we observed biobehavioral deviations in pregnancies not resulting in live

XSL•FO
RenderX

birth, these findings should be interpreted as preliminary and hypothesis-generating. Future studies incorporating clinical validation and diagnostic classification are critical to elucidate whether specific biobehavioral patterns reliably differentiate among types of pregnancy loss, and to explore their potential for early detection of adverse outcomes.

Several limitations should be acknowledged. A major limitation of this work is the lack of detailed information on sample characteristics, pregnancy complications, and other biopsychosocial factors, which limits our ability to fully understand the complex influences on trajectories of sleep, temperature trends, cardiorespiratory function, and activity patterns throughout pregnancy. In addition, the observational design of the study does not allow for control of external variables or inference of causal relationships between biobehavioral changes and maternal outcomes. This is a retrospective analysis of data from Oura Ring users who engaged with an in-app feature specifically developed to support women during pregnancy. The sample likely overrepresents individuals with access to wearable technology and higher levels of health literacy, introducing demographic bias and limiting generalizability—particularly to underserved or marginalized populations. As such, the sample may not reflect the characteristics of the general population. For instance, while 71.7% of participants are based in the United States, only 13% meet the criteria for obesity—substantially lower than the 40.3% prevalence reported by the US Centers for Disease Control and Prevention among adults aged 20 years and older [54]. Furthermore, several key variables were self-reported, including prepregnancy BMI and the date of pregnancy end (eg, birth or loss), increasing the potential for recall bias and misclassification. The absence of clinical validation limits the applicability of these findings in medical settings and underscores the need for complementary studies that integrate health records and diagnostic assessments to enhance the translational utility of wearable-based monitoring.

This study also has inherent technological limitations. Wearable devices may be subject to measurement error and limited clinical validation—including during pregnancy, which involves profound physiological changes. Device accuracy may fluctuate across the pregnancy continuum, potentially masking some underlying physiological effects. These and other limitations of consumer wearable technology have been extensively discussed in recent literature [25,55,56]. In this study, in an attempt to control for potential confounders, we limited variability in device model and algorithm version by including only Oura Ring Gen3 users following the latest algorithm updates.

Future studies would also benefit from a multimodal data collection approach that combines passive wearable monitoring with ecological momentary assessments in more diverse populations. This would enable contextualization through variables such as reproductive history, lifestyle habits, occupational and relationship status, perceived support, health conditions, light exposure, physical activity not captured by the wearable (eg, activities performed when the wearable is not worn or not detected by the device), medication use, weight changes, and the presence or treatment of sleep disorders (eg, sleep-disordered breathing, restless legs syndrome). At the same time, this will be essential to improve generalizability and ensure that findings are applicable to racially, socioeconomically, and geographically diverse populations. Such enriched datasets would allow for nuanced characterization of the individual pregnancy experience and support the development of predictive models for both adverse pregnancy outcomes and natural events such as labor onset or early indicators of abnormalities—factors known to influence maternal and infant morbidity and mortality.

While outside the scope of this study, emerging evidence also highlights the potential relevance of circadian biology in shaping pregnancy outcomes. The reproductive system is tightly coupled to circadian regulation, and disruptions in maternal circadian timing—such as those caused by irregular light-dark cycles or shift work—are associated with negative pregnancy outcomes [57,58]. The placenta exhibits circadian gene expression, and disturbances in maternal circadian alignment may interfere with fetal-maternal signaling, nutrient transfer, and developmental timing [59]. There is evidence of a relationship between disturbed sleep during and after pregnancy and negative pregnancy outcomes, such as depression [60], anxiety [61], and gestational diabetes [62]. Going forward, incorporating circadian-focused assessments using wearable devices may provide novel insight into modifiable risk factors affecting both maternal well-being and fetal development. Although this study did not examine circadian-related metrics, wearable-derived data streams—such as nighttime temperature rhythms, intraindividual variability in sleep timing, and rest-activity rhythm—may offer promising noninvasive proxies for circadian alignment [25]. Future work should explore whether these features can serve as digital biomarkers of circadian misalignment and help identify individuals at higher risk for adverse pregnancy outcomes.

To conclude, this comprehensive exploration provides valuable insights into the physiological trajectories of pregnancy within a real-world population—information that until now, has not been widely available. By integrating passive sensing data with clinical information on reproductive history, pregnancy progression, and outcomes, this approach has the potential to advance our understanding of maternal health, enabling more personalized monitoring and improved pregnancy care. Beyond the continuous, automatic collection of relevant health metrics, this method allows for the examination of patterns relative to an individual's baseline, rather than solely determining whether a single data point falls within a population range, irrespective of personal variation.

Data Availability

The dataset analyzed during this study is not publicly available due to privacy protections for participants, but may be made available, in deidentified form, at Oura's sole discretion.

Authors' Contributions

RA, MdZ, NT, KP, AC, and NG contributed to the conceptualization of the study. RA, MdZ, NT, and KP contributed to the methodology. RA and KP contributed to data curation and formal analysis, with KP also responsible for validation. KP and MdZ contributed to the visualization. MdZ, RA, and KP drafted the original manuscript. RA, NT, AC, NG, KP, and MdZ reviewed and edited the manuscript. MdZ provided supervision.

Conflicts of Interest

AC, NG, KP, and MdZ are employees of Oura Health Oy or any of its affiliates. RA and NT were employees at Oura Health Oy at the time of their contribution to this study, which predates their transition to Apple Inc (RA) and Bayesian Health (NT). While the authors have a professional affiliation with these companies, they have conducted this research with the highest standards of scientific integrity and transparency. Oura has a portfolio of patents and patent applications [63] that includes coverage of women's reproductive health, which may be broadly relevant to the topic of this study. The authors confirm that this intellectual property interest has not influenced the study design, data collection, analysis, or interpretation of the results. MdZ has received research funding unrelated to this work from Noctrix Health Inc and Verily Life Science LLC.

Multimedia Appendix 1
STROBE checklist - cohort studies.
[DOCX File , 27 KB - mhealth_v13i1e80213_app1.docx]

Multimedia Appendix 2
Distribution of volume of pregnancies as a function of gestational age at which pregnancies end, for pregnancies ending in loss, preterm births and term births.
[PNG File , 21 KB - mhealth_v13i1e80213_app2.png]

Multimedia Appendix 3
Distribution of age and body mass index (BMI) of participants with pregnancies ending in loss, preterm births and term births.
[PNG File , 129 KB - mhealth_v13i1e80213_app3.png]

Multimedia Appendix 4
Absolute changes in Oura data (sleep, temperature trends, cardiorespiratory, and activity) throughout pregnancy. Data are plotted as the weekly median (thick line) and the 50th percentile range, separately for pregnancies ending in loss (N = 4955), preterm births (N = 324), and term (N = 5039) births. Gestational age 0 (the start of pregnancy) is defined as the first day of the last menstrual period. The red, purple and green vertical bars delineate the mean pregnancy end ± one standard deviation for pregnancy loss, preterm birth, and term birth, respectively.
[PNG File , 345 KB - mhealth_v13i1e80213_app4.png]

Multimedia Appendix 5
The number of women contributing valid data at each gestational week for pregnancies ending in loss, preterm births and term births.
[PNG File , 22 KB - mhealth_v13i1e80213_app5.png]

Multimedia Appendix 6
Detailed results for Generalized Estimating Equation (GEE) model for analyses evaluating pattern of changes in Oura bio-behavioral data throughout pregnancy, in pregnancies leading to term births. REM, Rapid-Eyes-Movement-Sleep. Maximum effect sizes are summarized per trimester; however, the statistical model was fit over the entire pregnancy duration.
[DOCX File , 21 KB - mhealth_v13i1e80213_app6.docx]

RenderX

Multimedia Appendix 7
Detailed results for Generalized Estimating Equation (GEE) model for analyses evaluating effect of Body Mass Index (BMI) and maternal age on Oura bio-behavioral data throughout pregnancy, in pregnancies leading to term births. Maximum effect sizes are summarized per trimester; however, the statistical model was fit over the entire pregnancy duration.
[DOCX File , 25 KB - mhealth_v13i1e80213_app7.docx]

Multimedia Appendix 8
Detailed results for Generalized Estimating Equation (GEE) model for analyses evaluating pattern of changes in Oura bio-behavioral data for the 28 days preceding pregnancies ending in loss. The effect size is calculated over the 28 and 7 days preceding the pregnancy ending before 20 weeks and represents the average difference with respect to corresponding biometrics over the same period from randomly selected full-term pregnancies.
[DOCX File , 19 KB - mhealth_v13i1e80213_app8.docx]

Abstract

Background: Recent studies demonstrated the validity, reliability, and accuracy of consumer smartwatches for measuring daily steps in people with Parkinson disease (PD). However, no study to date has estimated the minimal clinically important difference (MCID) for average daily steps (avDS), measured through a consumer smartwatch in people with PD.

Objective: This study aimed to calculate the MCID of avDS, measured through a commercial smartwatch (Garmin Vivosmart 4) in people with PD.

Methods: People with PD with a disease stage <4, without cognitive impairment, and who were able to walk unaided, wore a Garmin Vivosmart 4 smartwatch for 5 consecutive days on the wrist least affected by the disease, allowing the computation of avDS. To define the 3 levels of MCID for avDS, we used an anchor-based method linked to: (1) scales capturing subtle changes in global mobility and motor functions, (2) clinical and health-related measures, and (3) disease-related patient-reported outcomes. Linear regressions, Student *t* test, and ANOVA were used to estimate the minimal change in avDS based on anchors relevant change. For each level, the overall MCID was calculated as the average of the variables included, and the range was reported.

Results: A total of 100 people with PD were enrolled. Participants took on average 5949 (SD 3034) daily steps, ranging from 357 to 12,620. The MCID of avDS anchored to standardized measures of motor symptoms and mobility was 581 steps/day (range 554 - 608) or around 10% of mean avDS in our population. The MCID of avDS anchored to clinical and health-related variables was 1200 steps/day (range 350 - 1683), or around 20% of mean avDS in our population. Finally, the MCID of avDS anchored to disease-related patient-reported outcomes was 1592 steps/day (range 594 - 2589), or around 27% of the mean avDS in our population.

Conclusions: These findings could be relevant for designing future clinical trials involving avDS as a digital mobility outcome in daily life for people with PD and evaluating the effectiveness of the intervention promoting free-living walking in this population.

Introduction

Parkinson disease (PD) is a neurodegenerative disease characterized by both motor and nonmotor symptoms. Among the motor manifestations of PD, gait disturbances are notably prevalent and encompass a variety of issues, such as a shuffling gait, reduced step length and diminished automaticity, decreased arm swing, increased double support time, altered cadence, and periodic episodes such as freezing of gait (FOG) [1]. Walking, a fundamental daily activity, is crucial for maintaining functional

XSL•FO
RenderX

independence and social well-being [2]. Gait disturbances, therefore, represent a particularly disabling category of symptoms in PD, significantly impacting the autonomy and quality of life of patients [3].

Gait characteristics can be examined through various methods, both in controlled and ecological settings. Recently, the use of wearable inertial sensors for gait analysis has gained considerable traction [4-6]. Specifically, the daily step count serves as an indirect yet rather easily obtainable indicator of walking and physical activity [7]. While this metric does not provide detailed gait analysis, there is established evidence linking a reduced daily step count to a range of health issues, including oncological and cardiovascular diseases [8], dementia [9], as well as an elevated risk of overall mortality [10-13]. In the context of PD, studies have consistently demonstrated a correlation between a decrease in daily steps and increased disease severity [14] as well as with levels of physical activity [15,16]. These studies have also proposed a minimum daily step goal of around 4200 to align with physical activity recommendations in the early stages of PD [17].

Step measurement can be accomplished using either research-grade or consumer devices. Research-grade devices are specifically developed for use by professionals in research or clinical settings and are generally recognized for their superior accuracy and reliability [18-21]. Despite this, they come with drawbacks such as higher costs, limited market availability, the need for specialized expertise for operation, and less focus on aesthetic appeal and user-friendliness. In contrast, consumer wearable devices are designed for the general public. These devices are easily accessible in the market and user-friendly, requiring no specialized knowledge for operation. However, they typically lack validation for research purposes and often do not include sophisticated algorithms or analysis software [22]. Despite this, there is an increasing focus in the literature on using consumer wearables for data collection and monitoring in neurological patients [23-25]. Both device types demonstrate reliable step counting in individuals with normal gait patterns [26], though research-grade devices show higher reliability across a wider range of conditions [27]. However, for individuals with nonphysiological gait, such as those with reduced walking speeds or those using walking aids, the performance of consumer wearables tends to diminish [18,28-31].

PD poses a unique challenge for gait analysis, as its associated disturbed gait patterns could adversely impact the reliability of device algorithms. Furthermore, the occurrence of tremors and dyskinesias in patients with PD may introduce additional background noise in recordings, potentially resulting in an overestimation of step counts [31,32]. Conversely, the presence of rigidity and bradykinesia, characteristic of PD, might lead to an underestimation of steps, especially when the activity monitor is worn on the wrist [33].

In our previous in-laboratory study involving 47 people with PD, we demonstrated a good criterion validity (intraclass correlation coefficient=0.76) and an acceptable level of error (mean absolute percentage error=5%) in step counting using a consumer smartwatch (Garmin Vivosmart 4), when worn on the side least affected by the disease and under well-controlled pharmacological conditions [31]. In the context of real-life settings, a separate study underscored the criterion validity of average daily steps (avDS) measured by several wrist-worn consumer devices (Fitbit Alta [Google] and Fitbit Inspire 3 [Google]) in 28 people with PD at home, compared with a research-grade device (Dynaport movemonitor) [34]. We recently replicated these results, using Garmin Vivosmart 4, in a proof-of-concept experiment [35]. Beyond criterion validity, the reliability of a measurement tool—the consistency of repeated measures in unchanged individuals—is equally crucial. In this regard, our recent findings indicate that a minimum of 4 days is necessary to obtain a reliable estimate of avDS recorded by a consumer smartwatch (Garmin Vivosmart 4) in free-living conditions [36].

An essential additional metrological characteristic of an activity monitor is its capability to reliably capture changes in measured parameters and the clinical significance of these changes. In this context, the minimum detectable change (MDC) and the minimal clinically important difference (MCID) are 2 key metrics and are pivotal for calculating clinical trial sample sizes and assessing the effectiveness of interventions [37,38]. On the one hand, MDC denotes the smallest change that can be confidently identified beyond the measurement error of the instrument used for a specific parameter [37]. In a recent work of ours on 56 individuals with mild-to-moderate PD, we found that for a monitoring period of at least 4 days, the MDC for the Garmin Vivosmart 4 ranged between 1198 and 1524 steps/day, averaging at 1366 steps/day [36]. On the other hand, MCID represents the smallest difference in a parameter that is meaningful from a clinical perspective [38]. In fact, a statistically significant change after an intervention may not represent a modification that has a real impact on the patient's condition and, ultimately, might not be perceived by individuals. Therefore, a measure for clinical significance is required. MCID can be estimated in different ways, and there is no definite consensus for the best method [39,40]. Globally, two calculation methods exist: (1) distribution-based and (2) anchor-based. Distribution-based methods rely on the statistical characteristics of the variables of interest within the given population to identify the magnitude of change that would be unlikely to be observed by chance. Spread parameters, such as SD and SE of measurements, are commonly used indices to calculate MCID using distribution-based methods [39,40]. However, several authors underlined the limitation of distribution-based methods in capturing truly meaningful change and considered the use of these techniques only as an addition to anchor-based methods [39,41].

Anchor-based methods compare the change in patients' variable of interest with how patients score on a second, explicit metric of improvement (ie, the anchor) [39,40,42]. Usually, when applying the anchor-based method, improvement is evaluated longitudinally following an intervention and a time period for which a change in the anchor measure is expected [39]. However, cross-sectional evaluation is also possible, as reported by Motl and collaborators [43]. With this second approach, a value, or a range of values, is defined for the anchor that corresponds to the MCID and then the target score of the variable of interest that corresponds to the anchor value is

XSL•FO
RenderX

calculated. With the cross-sectional method, the between-subjects variability in the relationship between the anchor and the new measure is often high; therefore, multiple anchors are often needed to provide a well-triangulated MCID value [39]. However, this could offer the advantage of delineating several levels of MCID depending on their specific goals and expected outcomes, providing a more versatile framework [43]. While generally considered more reliable than distribution-based methods, potential limitations of anchor-based methods include recall bias and the need for at least a moderate correlation between the anchor and the variable of interest [39].

As of now, there are no published studies that have evaluated the MCID for avDS in people with PD. Therefore, considering these identified research gaps and the clinical significance of the psychometric and clinometric properties of daily steps measured by consumer smartwatches in free-living conditions for people with PD, the objective of this study was to determine the MCID of avDS as recorded by a consumer smartwatch in real-world settings for this population of individuals.

Methods

Population

Participants were recruited at the Movement Disorder Outpatient Service of the Sant'Andrea University Hospital, Rome, Italy, in the period between March 2023 and February 2024. Inclusion criteria were (1) diagnosis of idiopathic PD according to Movement Disorder Society criteria [44], (2) aged 18 years or older, (3) disease stage <4 according to the modified Hoeh and Yahr scale (mHY; "severe disability; still able to walk or stand unassisted") [45], and (4) ability to perform the experimental procedure. Exclusion criteria were (1) cognitive impairment as defined by a Montreal Cognitive Assessment score < 21, and (2) orthopedic, rheumatologic, or systemic conditions affecting mobility as judged by the assessor.

Ethical Considerations

This cross-sectional study was performed in accordance with the ethical standards as laid down in the 1964 Declaration of Helsinki and its later amendments. Approval was granted by the local Ethical Committee of Sapienza, University of Rome (Reference 0372/2022). Data collection and processing followed the current European regulation for data protection. All participants provided written informed consent (Multimedia Appendix 1) before the beginning of measurements. All data were deidentified. Participants did not receive any form of compensation.

Demographic and Clinical Data

Participants were evaluated during scheduled visits. Demographics (age and sex) and anthropometric measures (weight, height, and BMI) were collected. Disease duration, disease stage according to the mHY scale, and levodopa equivalent daily dose (LEDD) [46] were also collected. Participants were then evaluated with the following rating scales:

The sum of the Movement Disorder Society Unified Parkinson's Disease Rating Scale (MDS-UPDRS) [47] parts I and II was used to assess the impact of motor and nonmotor symptoms on daily life [48]. MDS-UPDRS part III was used to assess the severity of motor symptoms. From MDS-UPDRS part II and III scores, participants were classified into tremor dominant (TD), postural instability and gait disorder (PIGD), or indeterminate disease subtypes, according to Stebbins et al [49]. Participants were also grouped in those with mild and moderate disease severity based on the MDS-UPDRS score as proposed by Martínez-Martín and colleagues [50]. The Parkinson's Disease Questionnaire-39 was used to evaluate participants' quality of life [51]. The Short Physical Performance Battery (SPPB) was used to assess lower limb function and general physical capacity [52]. The Wearing-Off Questionnaire-19 was used to assess the presence of wearing off. A score ≥2 was used as a cutoff to define the presence of wearing off [53]. The Fatigue Severity Scale was used to assess fatigue severity; a score ≥4.67 was used to define clinically relevant fatigue [54]. The item 1 of the New Freezing of Gait Questionnaire [55] was used to assess the presence of FOG, defined as a score >0. Finally, the MDS-UPDRS item 2.10 was used to assess the absolute presence or absence of tremor as reported by participants.

Experimental Procedure

Participants then received the smartwatch Garmin Vivosmart 4 to be worn at home for 5 consecutive days, including at least 1 weekend day, on the wrist of the body side least affected by the disease [31]. Participants were instructed to wear the smartwatch at all times during the day and night and remove it only when involved in water activities (eg, bathing, showering, and swimming). Participants were also asked to perform daily activities as usual. No additional reminder or instructions were provided to participants during the monitoring period. We chose a 5-day period since we demonstrated previously that a minimum of 4 days of monitoring is needed to reliably estimate daily step count in people with PD [36]. Each smartwatch was configured according to the producer's recommendations by indicating the patient's age, height, weight, and the wrist on which the smartwatch was worn (ie, left or right). During the monitoring period, participants could access information on the smartwatch screen, including the total number of steps, heart rate, and sleep time. The device did not provide instructions, alerts, or other messages to participants.

After 5 days, they returned the smartwatch to the hospital. From the smartwatch dashboard, the total daily number of steps for each day was recorded, and the avDS were calculated [36]. Compliance was assessed based on the participants' dashboard data. We could assess that the device was worn through heart rate and activity data. We considered all recording days with ≥80% wear time while awake to be valid. We estimated the awake time as 24 hours minus the total sleep time as indicated by the device.

Data and Statistical Analysis

The statistical analyses were performed using JASP v0.18.3.0 (JASP Team, University of Amsterdam), R v4.0.3 (R Core Team), and RStudio v2022.07.1+554 for Windows (R Foundation for Statistical Computing). Descriptive statistics were calculated for the examined variables. Normality of

XSL•FO
RenderX

distributions was assessed by histogram and residual plots inspection.

To define MCID, we used an anchor-based method identifying three levels of variables, following the approach of Motl and collaborators [43]: (1) scales capturing subtle changes in global mobility and motor functions (ie, MDS-UPDRS part III and SPPB); (2) clinical and health-related measures including disease duration, mHY, LEDD, PD subtype, disease severity as assessed by MDS-UPDRS, age, sex, and BMI; and (3) disease-related patient-reported outcomes (PROs) including MDS-UPDRS parts I and II, the Parkinson's disease questionnaire-39, presence of FOG, presence of wearing off, presence of fatigue, and presence of tremor.

Such an approach could provide ranges of MCIDs and options for MCID selection that are appropriate for specific populations and circumstances, including both assessor-based and PROs, in clinical trials and interventions involving people with PD [39].

Since previous studies have recommended a correlation coefficient of at least 0.3 - 0.35 between the change score and the anchor [56], we first conducted a correlation analysis between avDS and the included variables using the Spearman test. Only associations with a correlation coefficient >0.3 were considered for MCID estimation.

We then conducted a linear regression between avDS and MDS-UPDRS part I+II and part III, mHY, SPPB, LEDD, and age for estimating the incremental change in daily steps per relevant variable change. To evaluate the relevant change, we used the already known MCID for each scale included in the regression analysis. Scales for which an MCID was not reported were excluded from the analysis. In case of asymmetric MCID (ie, different values for improvement and deterioration), we used the average value rounded to the higher next whole number.

For the remaining variables, we calculated mean and SE differences in avDS between groups by performing between-subjects ANOVA with Bonferroni-Holm post hoc pairwise comparisons in case of overall significance, when the variables included more than 2 classes. For 2-class variables, we used the Student *t* test for independent groups to compute the mean differences and SE in avDS. Cohen *d* was used to estimate the standardized effect size. MCID for the 3 levels was then calculated, and the average of the included variables and range was reported. The level of significance was set at α<.05.

Results

Overview

A total of 100 people with PD were enrolled in the study. All participants were monitored through Garmin Vivosmart 4 at home for a period of 5 consecutive days. No participants or days were excluded based on the prespecified compliance criteria. Participants took on average 5949 (SD 3034) daily steps, ranging from 357 to 12620. Details of demographic, anthropometric, and clinical variables in the enrolled population are illustrated in Table 1.

MCID

Global Mobility and Motor Functions

All included variables showed a correlation coefficient >0.3 with avDS. The 2 linear regression models between avDS and MDS-UPDRS-III and SPPB were statistically significant (MDS-UPDRS-III: $F_{1,98}$=20.46, P<.001, R^2=0.16; SPPB: $F_{1,98}$=19.84, P<.001; R^2=0.16) (Figure 1).

The resulting regression equations indicated that every 1-point increase in MDS-UPDRS-III corresponded to a 152 steps/day decrease (avDS=9778−152×MDS-UPDRS-III). MCID for MDS-UPDRS was reported as 3.25 for score decrease and 4.63 for score increase [57]; therefore, we calculated a rounded average of 4 points, and we estimated a 608 steps/day modification for each 4-point change in MDS-UPDRS-III. Finally, each 1-point increase in SPPB score corresponded to an increase of 554 steps/day (avDS=503+554×SPPB). A change of 1 point is also the reported MCID for SPPB in older adults; therefore, we adopted this value [58]. Overall, the mean MCID across the 3 clinical scales that capture meaningful changes in motor and mobility condition was 581 steps/day (range 554 - 608), corresponding to 10% of the avDS in our population.

XSL•FO
RenderX

Clinical and Health-Related Measures

All included variables except BMI showed a correlation coefficient >0.3 with avDS. Regression models of mHY, LEDD, age, and disease duration were statistically significant (mHY: $F_{1,98}$=26.26, P<.001, R^2=0.20; LEDD: $F_{1,98}$=12.97, P<.001, R^2=0.11; age: $F_{1,98}$=18.22, P<.001, R^2=0.15; disease duration: $F_{1,98}$=7.01, P=.009, R^2=0.06) (Figure 2).

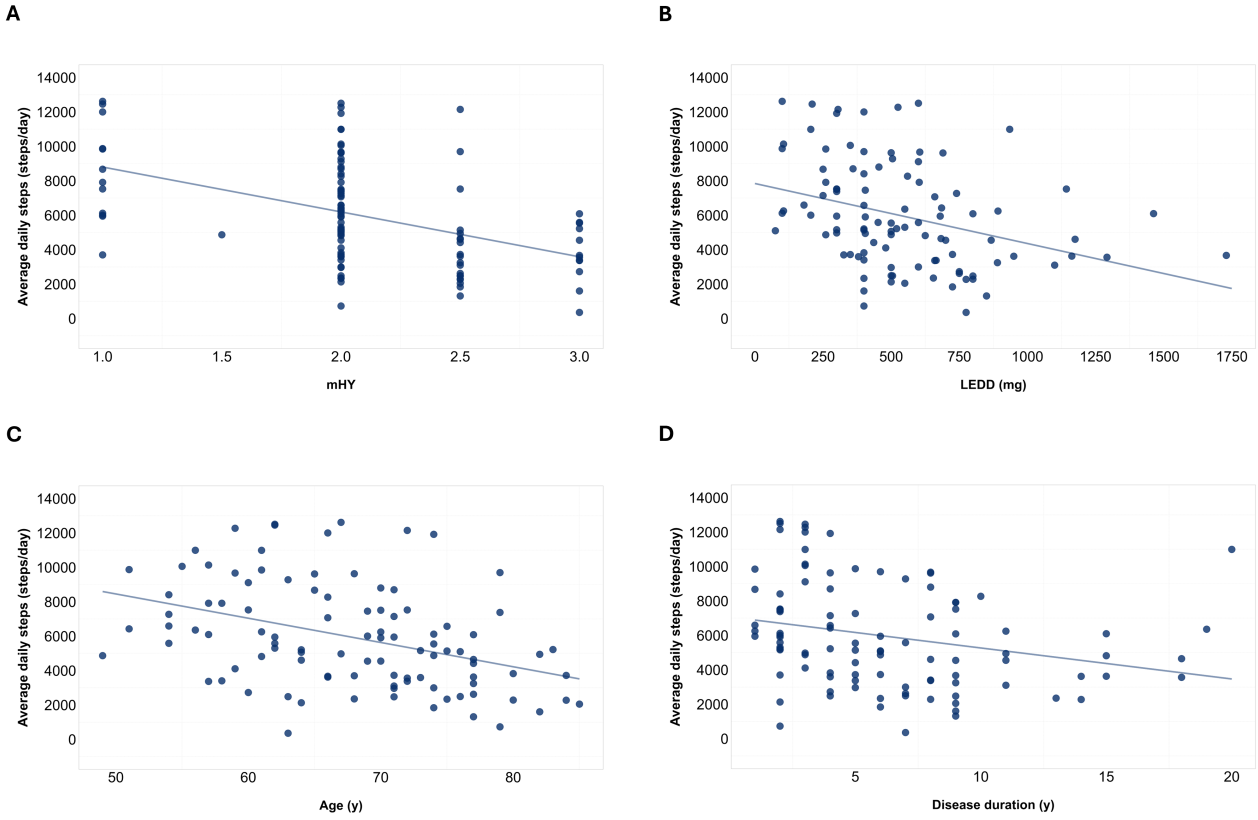
The resulting regression equations indicated that every 1-point increase in mHY stage yielded a reduction of 2607 steps/day (avDS=11,409−2607×mHY). Since mHY included 0.5 steps increases between scores 1 and 3, we calculated that each step corresponded to a 1304 steps/day reduction.

For LEDD, regression equations indicated that every 1 equivalent mg increase led to a reduction of 3.5 steps/day (avDS=7846−3.5×mHY). Since the usual single dose of levodopa corresponds to 100 mg, we used this value as a reference, and we estimated a 350 steps/day modification for each 100 mg change in LEDD.

For age, regression equations indicated that a 1-year increase in age yielded a reduction of 141 steps/day (avDS=15,512−141×age). Furthermore, 10-year increases are usually used to divide participants in age groups; therefore, we estimated a 1410-step/day modification for each 10-year change of age.

For disease duration, regression equations indicated that a 1-year increase in disease duration resulted in a reduction of 180 steps/day (avDS=7071−180×age). We chose 5 years as a significant increment in disease duration since this was a common cutoff to categorize disease duration in previous studies [59-61]. Therefore, we estimated a 900-step/day modification for each 5-year change of disease duration.

Figure 2. Correlation of average daily steps with modified Hoehn and Yahr stage, levodopa equivalent daily dose, age, and disease duration. Scatterplots are reported showing correlation between average daily steps and modified Hoehn and Yahr stage (panel A), levodopa equivalent daily dose (panel B), age (panel C), and disease duration (panel D). A linear regression line was added to show the linear tendency. LEDD: levodopa equivalent daily dose; mHY: modified Hoehn and Yahr stage.



Considering categorical descriptors, ANOVA showed a significant difference in avDS among participants with TD, PIGD, and indeterminate participants ($F_{2,97}$=4.55, P=.01). Post hoc pairwise comparisons showed a significant difference between participants with TD and PIGD (t_{90}=2.60, P=.03) with a mean difference of 1683 (SD 646) steps/day and a moderate effect size (Cohen d=0.57) (Figure 3A).

The Student t test showed a significant difference between mild and moderate disease severity, as categorized based on MDS-UPDRS cutoffs (t_{98}=2.54, P=.01) with a mean difference of 1554 (SD 612) steps/day and moderate effect size (Cohen d=0.53) (Figure 3B).

No significant differences were found between males and females (t_{98}=−0.12, P=.90).

Overall, the mean MCID across the clinical and health-related variables was 1200 steps/day (range 350 - 1683), corresponding to 20% of the avDS in our population.

RenderX

XSL•FO
RenderX

Disease-Related PROs

Only MDS-UPDRS I+II showed a correlation coefficient >0.3 with avDS and was included in the regression analysis. Regression models of MDS-UPDRS part I+II were statistically significant (MDS-UPDRS I+II: $F_{1,98}$=7.03, P=.009, R^2=−0.06) (Figure 4).

For MDS-UPDRS I+II, regression equations indicated that every 1-point increase led to a reduction of 99 steps/day (avDS=7188−99×MDS-UPDRS I+II). For the sum of MDS-UPDRS I and II, the reported MCID is 5.73 points for improvement and 4.70 points for worsening; therefore, we calculated a rounded average of 6 points, and we estimated a 594 steps/day modification for each 6-point change in MDS-UPDRS I+II.

The Student t test showed a significant difference between patients reporting tremor and those not reporting it (t_{98}=−4.67, P<.001) with a mean difference of 2589 (SD 554) steps/day and a large effect size (Cohen d=−0.94) (Figure 5).

No significant differences were found in avDS between participants with and without FOG (t_{98}=0.74, P=.46), between participants with and without fatigue (t_{98}=0.61, P=.55), between participants with and without wearing-off (t_{98}=−0.39, P=.70)

Overall, the mean MCID across the disease-related PROs variables was 1592 steps/day (range 594 - 2589), corresponding to 27% of the avDS in our population.

The 3 calculated MCIDs, as well as the anchors and the avDS modification related to anchors significant changes, are reported in Table 2.

Discussion

Principal Findings

In this cross-sectional study, we aimed to calculate, for the first time, the MCID for avDS as an indicator of free-living walking behavior in people with PD using a consumer smartwatch under real-world conditions. We identified 3 distinct levels of MCID for avDS. The first level, of around 580 steps/day, is anchored to standardized measures of motor symptoms and mobility. The second level, of around 1200 steps/day, is based on clinical and health-related variables. Finally, the third level, of around 1590 steps/day, is anchored on disease-related PROs.

Globally, the MCID values ranged from 581 to 1592 steps/day, representing 10% - 27% of the average in our study population. We used the method used by Motl and colleagues [43], which offers the advantage of delineating distinct levels of clinically meaningful changes in real-world walking behavior for people with PD. These 3 thresholds provide a versatile framework for assessing the impact of clinical interventions in people with PD, depending on their specific goals and expected outcomes. Furthermore, the MCID estimates for avDS can be used either independently or in conjunction with other MCIDs, as presented in this manuscript for clinical assessment tools, to offer a more comprehensive evaluation of clinically meaningful changes in individuals with PD.

Our results suggest that a value of around 580 steps/day might reflect the smallest clinically meaningful change in avDS when measured by a consumer smartwatch and should be considered when designing a study including interventions focused on mobility or motor condition improvement. Differently, when global disease and health status are the main outcomes, our results showed that a larger value of around 1200 steps/day might be considered to define a clinically meaningful change.

In the last decades, a growing importance has been attributed to PROs, such as patient-reported scales, quality of life questionnaires, etc, as vital indicators of people's perception of their own condition [62]. PROs are often central outcomes in patients' perspectives and might capture some aspects that cannot be evaluated through objective measurements. The use of these outcomes is encouraged to guide research and clinical practice in the context of a patient-centered model of care, and several PROs were included in a recent consensus on outcome measures for PD [63]. To this end, in this paper, we calculated that a change of around 1590 steps/day might be considered to define a clinically meaningful intervention when patients' self-perception is the main outcome.

XSL•FO
RenderX

It is also vital to consider the feasibility of achieving changes in avDS of the magnitudes identified in this study. Previous research has explored interventions in people with PD that use daily steps as an outcome measure [17,64]. In 1 study by Handlery and colleagues [17], people with PD who initially took fewer than 4200 steps per day managed to increase their daily step count by approximately 1250 steps/day 6 months after participating in high-intensity treadmill exercises [17]. Similarly, another randomized controlled trial by Ellis and colleagues [64] involving 44 people with PD found that participants who initially averaged fewer than 7500 steps per day increased their avDS by about 763 steps/day over a year, following a mobile health–supported exercise program. These findings suggest that achieving changes comparable with the MCID values identified in our study is feasible through interventions aimed at promoting physical activity.

Nevertheless, the capability of consumer devices to accurately detect changes of the magnitude reported here is crucial for their clinical utility. In a recent study of ours, we found that for a monitoring duration of at least 4 days, the MDC for the Garmin Vivosmart 4 ranged between 1198 and 1524 steps/day, averaging at 1366 steps/day [36]. This MDC value is higher than the smaller MCID we calculated, indicating that any observed change exceeding this threshold is not only beyond the realm of measurement error but also clinically significant. However, this also implies that the device might not be sensitive enough to consistently detect subtler yet clinically meaningful changes in avDS, as indicated by the lower MCID limit of approximately 580 steps/day. Consequently, while the Garmin Vivosmart 4 can be effective in measuring significant differences in avDS in people with PD, for smaller anticipated changes, other instruments with higher reliability need to be considered. Future research should therefore investigate the performance of various consumer smartwatches and other devices such as smart socks, insoles, etc, and their applicability across different neurological conditions to validate, refine, and possibly extend our findings.

Limitations

We recognize certain limitations in our study. First, the people with PD included in our study displayed relatively high levels of physical capacity, as evidenced by a median SPPB score of 10 (IQR 9-12), and adequate cognitive functions, due to our exclusion of participants with a Montreal Cognitive Assessment score below 21. In addition, those with more advanced disease stages or requiring walking aids were not part of our study group. This selection criterion potentially limits the generalizability of our findings to only mild-to-moderate people with PD. Indeed, in a population of individuals with worse cognitive and motor conditions, we might expect lower accuracy and reliability of avDS estimates by smartwatches and fewer steps/day due to greater walking impairments [65-67]. Therefore, higher absolute and relative MCID values as well as different anchor combinations could be observed. Nevertheless, the sample in our study can be seen as representative of the typical target demographic for interventions using consumer-grade wearable technology. In fact, including people with PD with a disease stage greater than 3, those using walking aids, or with more severe cognitive impairments poses significant challenges in the use of consumer technology and was beyond our study's scope. Eventually, the evaluation of people using walking aids with commercial out-of-the-shelf devices, without more advanced data processing, might not even be feasible due to the potential inadequate accuracy of a smartwatch for measuring daily steps among this patient population, whose mobility characteristics differ substantially from those of individuals with physiological ambulation [68]. Future research incorporating participants with PD with lower functional scores, increased disease severity, and more pronounced cognitive impairments would be valuable.

In addition, while we incorporated a range of general and disease-specific measurements, other factors that might affect daily life mobility, such as fear of falling, frontal executive cognitive dysfunction, and objectively measured gait parameters (eg, gait speed, cadence, and step length), were not examined. Furthermore, specific subdomains of adopted measurement tools could be further explored (eg, walking speed or balance subitems of SPPB and PIGD subscore of MDS-UPDRS part III). Further studies exploring the relationship between these factors and smartwatch-recordable parameters are recommended to provide a more comprehensive understanding of mobility in people with PD.

In addition, we did not extract the raw data from the smartwatches, but used the information reported by the device's dashboard. While acknowledging the technical limitations of this approach, we designed the study to mimic as closely as possible the actual use of the device in a real-world context and to use parameters as similar as possible to those that a general user would have access to. Finally, in this work, we used an anchor-based cross-sectional method to define different levels of MCID as presented by Motl et al [43]. However, other anchor-based methods are available. In particular, a widely used method consists of the longitudinal calculation of MCID following an intervention [39,40]. However, while this latter method could allow for drawing more sound conclusions, it must be considered that it might be dependent on the type of interventions used, thus hampering the generalizability. Furthermore, previous evidence highlighted the sample-specificity of MCID estimates (particularly for distribution-based methods) [69] and the dependency on the baseline scores of the enrolled population [70]. This further stresses the importance of conducting future longitudinal, multicenter studies in a free-living context, including independent cohorts of people with PD with different clinical baseline conditions, from different clinical centers—and even different countries—and using different evaluation tools to confirm and expand the results hereby presented. In addition, since different methods to calculate MCID could lead to different results [71], using different techniques and comparing them will be important to provide the best scientific evidence on this topic. Nevertheless, we considered it relevant to provide researchers with a first indication of MCID for avDS as measured by a consumer smartwatch in order to build a framework to interpret findings in studies incorporating this outcome measure. In fact, researchers designing a study (eg, a clinical trial that aims at assessing the effectiveness of an intervention specifically designed to increase physical activity in PD) and incorporating smartwatch-based avDS as an outcome

XSL•FO
RenderX

measure of physical activity will be able to define end points that are clinically relevant, beyond statistical significance. Furthermore, based on the other included endpoints (ie, mobility, clinical indicators, or PROs), investigators will be able to select the more appropriate MCID level.

Conclusions

We reported 3 levels of MCID for avDS measured through Garmin Vivosmart 4, for 5 consecutive days, 1 of approximately 580 steps/day (or about 10% of our population's average), anchored to standardized measures of motor symptoms and mobility. A second, of around 1200 steps/day (or about 20% of the mean in our population), anchored to clinical and health-related variables. Finally, a third, or around 1590 steps/day (or about 27% of the mean in our population) anchored to disease-related PROs. Considering that the previously reported MCD for Garmin Vivosmart 4 was 1366 steps/day, this indicates that any observed change exceeding this threshold is not only beyond the realm of measurement error but also clinically meaningful. Furthermore, based on previous studies, we could suppose that achieving changes comparable with the smaller MCID identified in our study might be feasible following interventions aimed at promoting physical activity in people with PD. These findings, together with existing evidence for reliability and validity on consumer smartwatches, could be relevant for designing future clinical trials involving avDS as an outcome measure of real-world walking behavior in PD, and evaluating the effectiveness of intervention promoting free-living walking.

Acknowledgments

The authors sincerely thank all people that were involved in the data collection, from study participants to students who aided and assisted the assessments. This research was performed as part of Edoardo Bianchini's PhD (Sapienza University of Rome, Italy & University Grenoble Alpes, France) and funded through Doctoral Bursary from Sapienza University of Rome (Student 1472455). The research was supported by Sapienza University of Rome as part of the program Sapienza Research Call 2020, grant AR120172B97AF626 and Research Call 2022, grant AR222181683A15AA and by the French National Research Agency (ANR) in the framework of the Investissements d'avenir program (ANR-10-AIRT-05 and ANR-15-IDEX-02), and the MIAI Cluster (ANR-23-IACL-0006). This work also forms part of a broader translational and interdisciplinary GaitAlps research program (NV).

Data Availability

The data presented in this study are available on reasonable request from the corresponding author.

Authors' Contributions

EB, FEP, and NV designed the study. DR, MA, and SG helped with patients' recruitment and data collection. EB performed data analyses. EB, CH, FEP, and NV wrote the first draft of the manuscript. DR, MA, SG, AZ, AS, and MS reviewed manuscript draft. NV supervised the study. All authors contributed to the article and approved the submitted version.

Abstract

Background: With the continuous evolution of technology, wearable accelerometers have become one of the most popular means of measuring daily physical activity (PA) levels. Despite the conventional use of the nondominant wrist as a device placement in numerous PA studies, the impact of wrist-worn accelerometer placement on PA data outcomes remains uncertain.

Objective: This study aimed to examine the degree of agreement between accelerometry data collected from CentrePoint Insight Watches (CPIWs; ActiGraph) worn on the dominant and nondominant wrists of young adults in free-living conditions.

Methods: Twenty-nine participants (mean age 20.2, SD 1.6 years; 23 females) simultaneously wore an ActiGraph CPIW on both dominant and nondominant wrists for 7 consecutive days during waking hours. A sampling frequency of 32 Hz and Montoye 2020 cut-points were used to categorize activity intensity based on counts per minute. Data validity criteria included (1) ≥600 minutes per day of monitor wear time for both wrists, (2) a daily wear time difference of <1% of the average wear time between the dominant and nondominant wrists, and (3) a minimum of 3 valid days of monitor wear for both wrists. Bland-Altman plots and intraclass correlation coefficient (ICC) analyses were performed to compare the accelerometry data between the two device placements.

Results: Average daily monitor wear time was 789.6 (SD 86.1) minutes per day for the dominant wrist and 793.0 (SD 91.8) minutes per day for the nondominant wrist. All accelerometer variables, including sedentary time (ST), light PA, moderate-to-vigorous PA (MVPA), steps, triaxial counts, and vector magnitude (VM), showed good-to-excellent levels of reliability between the two measurements (ICC >0.88 for all; P<.001). Bland-Altman analysis calculated mean bias and SD between the two device placements as follows: ST (−18.8, SD 27.6 min/d), light PA (2.7, SD 15.9 min/d), MVPA (12.7, SD 26.7 min/d), steps (218.1, SD 476.6 counts/d), x-axis (99.4, SD 188.8 counts/min), y-axis (73.9, SD 147.0 counts/min), z-axis (107.6, SD 183.5 counts/min), and VM (161.2, SD 273.4 counts/min). Bland-Altman plots revealed that the upper and lower limits of agreement across most variables were considerably wide.

Conclusions: Our findings partially align with previous research, demonstrating higher MVPA and step counts on the dominant wrist, while the nondominant wrist produced a higher level of ST. Despite the acceptable level of reliability between the two placements based on ICC analyses, the dominant wrist tended to produce greater outcomes as the intensity of PA increased, highlighting the need for careful consideration when determining the wear location of CPIWs and interpreting data outcomes.

Introduction

Participation in regular physical activity (PA) contributes substantial benefits to overall health, such as weight control, brain health, bone and muscle strengthening, and emotional regulation [1,2]. For this reason, PA levels primarily serve as an informative gauge of general health status for both the public and health care practitioners [3,4]. The 2018 National PA Guidelines for Americans suggest that adults should participate in at least 150 minutes of moderate-to-vigorous PA (MVPA) or 75 minutes of vigorous-intensity PA per week, along with additional muscle-strengthening activities, to achieve health benefits [5]. Accurately quantifying PA levels is a key component in developing and analyzing public health initiatives to promote regular PA participation in the general population [6,7]. Among numerous approaches for PA measurement and estimation, accelerometer-derived outcomes not only help individuals objectively recognize their PA levels but also build foundational knowledge for organizations and communities to develop health intervention plans for specific populations [8,9].

With the continuous evolution of technology, sensor-based ecological measurement has emerged, and wearable activity trackers have become one of the most popular means of measuring daily PA levels [10]. Global health technology companies, including Apple, Garmin, and Fitbit, have revolutionized the market for commercially available activity or fitness-tracking devices by making them affordable, easily accessible, and compatible with other electronic devices and applications [11]. Despite their widespread use, commercial wearable devices have shown limited accuracy in estimating PA levels in free-living environments, largely due to relatively low intradevice reliability and limited criterion validity. Most available studies have been conducted in controlled laboratory settings, focusing primarily on basic metrics, such as step counts and distance, rather than comprehensive assessments of PA parameters [12]. Moreover, their measurement accuracy varies significantly by device brand and type, and the criterion validity of comparative data is relatively poor [12,13]. ActiGraph triaxial accelerometers (ActiGraph LLC) have been used extensively by researchers across the world to estimate various PA parameters across diverse clinical and nonclinical populations, with high reliability and validity in both laboratory and free-living conditions [14]. Although limited affordability and a lack of real-time feedback are recognized as drawbacks compared to consumer-level devices [15], ActiGraph accelerometers remain among the most widely used research-grade instruments for PA measurement [16].

Due to poor compliance of wear time during the measurement period, which often results in inaccurate classification or misrepresentation of physical behaviors (eg, overrepresentation of MVPA or underrepresentation of sedentary time [ST]), an increasing number of research studies are exploring the use of wrist-worn accelerometers instead of waist-worn devices [17]. Nonetheless, there is a lack of agreement in current literature as to how the placement of wrist-worn devices (eg, dominant vs nondominant or right vs left) affects the accuracy and interdevice reliability of accelerometer data outcomes. A few studies have used earlier models of ActiGraph triaxial accelerometers (eg, GT3X, GT3X+, and GT9X) to compare specific PA outcomes collected from both the dominant and nondominant wrists in free-living settings [18,19]. Buchan et al [18] reported no significant differences between the two device placements for wear time and MVPA; however, they monitored the behavioral outcomes during waking hours for only 1 day. Park et al [20] also compared the two device placements during waking hours in a single-day, free-living setting and found that the dominant wrist tended to yield higher step counts compared with the nondominant wrist. Interestingly, a similarly designed study using comparable data collection protocols (eg, 24-hour monitoring) revealed that there was no substantial difference in PA levels measured by ActiGraph GT3X accelerometers on both wrists [19]. A recent systematic review also examined how ActiGraph accelerometry compares to popular commercial wrist-worn devices for estimating step counts, energy expenditure, and heart rate, highlighting the dearth of validity evidence for their usability in free-living settings [13]. Few attempts have been made to investigate the impact of accelerometer placement on measurement outcomes in free-living conditions using research-grade accelerometry with a 7-day monitoring protocol, which can significantly increase the reliability of predicting and representing an individual's habitual behaviors [21,22]. A recent study by Buchan et al [7] compared 7-day wear time between the dominant and nondominant wrists. The results suggested that the intensity gradient may be equivalent between both wrists, but average acceleration was slightly higher on the dominant wrist.

Given the increasingly dominant use of wearable technologies to monitor and estimate PA levels, it is important to clarify the discrepancy in the literature and verify the conventional use of the nondominant wrist as the preferred device placement in PA measurement studies. The objective of this study was to examine the degree of agreement between PA data collected from accelerometers worn on the dominant and nondominant wrists of young adults in free-living environments. This study used one of ActiGraph's newest models, the CentrePoint Insight Watch (CPIW; ActiGraph LLC), which features a unique user-centered band design and high-resolution raw acceleration data that may improve participant comfort and data reliability. In addition, the relatively new, cross-validated vector magnitude (VM) count cut-points by Montoye et al [23] were used to determine and classify activity intensity, improving the practical implications of the study findings.

Methods

Participants

Twenty-nine young adults (mean age 20.2, SD 1.6 years; 23, 79.3% females) from a Midwestern university in the United States were recruited for this study. Flyers were posted around the university campus during the spring term, and prospective participants were encouraged to contact the research team for the eligibility screening. Inclusion criteria were as follows: (1) aged 18 - 25 years, (2) ability to follow study protocols and independently provide informed consent, and (3) walking as a primary form of ambulation without the use of assistive devices.

XSL•FO
RenderX

Individuals with a mobility impairment (eg, use of a wheelchair or crutches) or a history of cardiovascular disease were excluded from this study. Prospective participants were invited to an individual meeting with the research team, during which study procedures were thoroughly reviewed for all participants.

Procedures and Instruments

Self-administered demographic and general health information was obtained from the participants with the assistance of a trained student investigator. This included date of birth, biological sex, height, weight, and hand dominance, which were used to initialize the ActiGraph CPIWs (dimensions: 1.97×1.35×0.41 in and weight: 14 g) for each participant. Prior to the accelerometry data collection, participants attended a training session on how to wear and care for the device. Specifically, the research team emphasized wearing and removing both accelerometers simultaneously and placing them high on their wrists with appropriate tightness to prevent slippage during movement or daily activities. They were asked to ensure the accelerometers were placed at the same relative positions on the dorsal aspect of their wrists, as variations in proximity to the hand could affect acceleration and activity counts. Participants were also asked to carry out their normal activities of daily living while wearing the accelerometers. To avoid the risk of water damage to the devices, participants were asked to take the devices off during any water-based activities, such as swimming and bathing, as well as during sleep. Participants wore an ActiGraph CPIW on both their dominant and nondominant wrists during waking hours for 7 consecutive days, for at least 10 hours per day. The watch displayed only the date and time without any interpretive information on participants' PA levels, which is an intentional design feature to minimize reactivity to accelerometer-based measurement [24]. In addition, remote synchronization and notification features of the ActiGraph CPIW were disabled to avoid influencing participants' habitual behaviors and PA engagement. ActiGraph CPIW enables PA data collection for up to 30 days without charging, and thus, participants were not instructed on how to charge the devices.

For this study, accelerometers were programmed to record acceleration data at a default sampling frequency of 32 Hz using 60-second epochs, which were subsequently converted to counts per minute (CPM) based on the Montoye et al [23] VM count cut-points to classify the activity intensity. Specifically, the CPM cut-points included sedentary (<2860 CPM), light PA (2860 - 3940 CPM), and MVPA (≥3941 CPM). Accelerometer activity count of three axes (ie, vertical, horizontal, and mediolateral) is a measure that indicates quantified acceleration within a designated epoch length [25,26]. For data processing, accelerometer data were first saved in the CentrePoint portal (ActiGraph LLC) and later exported to ActiLife (version 6.14.0; ActiGraph) to validate the wear time and score the collected datasets based on the predetermined CPM cut-points. The wear criteria threshold for both wrists was set at ≥600 minutes per day, and nonwear time was defined as ≥90 minutes of consecutive zero counts with an allowance of 2-minute spike tolerance [27]. After the 7-day data collection period, participants attended a debriefing meeting with the research team to return the accelerometers. In addition, perceived PA level was assessed using a 4-category classification approach outlined in the Physical Activity Guidelines for Americans (PAGA), 2nd edition, which includes the following PA levels: inactive, insufficiently active, active, and highly active [5].

Statistical Analysis

PA as a variable was measured using the following parameters: step counts per day, time spent at each PA intensity, including light PA and MVPA (min/d), activity counts from 3 axes, and VM CPM. VM was calculated using the following formula: $|V| = \sqrt{(\text{Axis } X^2 + \text{Axis } Y^2 + \text{Axis } Z^2)}$, to describe in-depth analyses of sampled accelerations of movement detected from both device placements. Considering that reactivity to accelerometer measurement is most pronounced at the beginning of the PA data collection [24], the first day of the 7-day accelerometry data was intentionally removed from the analyses. Data validity criteria included: (1) ≥600 minutes of monitor wear time per day for both wrists, (2) a daily wear time difference of less than 1% of the average wear time between the dominant and nondominant wrists, and (3) a minimum of 3 valid days of monitor wear for both wrists during the same periods. Of the 30 participants who completed the entire study, 29 participants met all 3 data validity criteria and were included in the analyses. One participant was excluded for having only one valid day of monitor wear. Each participant generated 3-6 valid days of monitor wear, and the total number of valid days included in the analyses was 153. We calculated the average of each data metric across valid days for each participant and compared the data outputs from the 2 device locations on the individual level. Paired samples *t* tests were performed to examine differences in PA and ST data collected from dominant and nondominant wrists. Bland-Altman plots and intraclass correlation coefficients (ICCs) were used to determine the degree of agreement between the two device placements. The ICC value ranges from 0 to 1, where <0.5=poor, 0.5 - 0.74=moderate, 0.75 - 0.9=good, and >0.9=excellent reliability [28]. In addition, linear regression analyses were conducted to assess the relationship between the magnitude of measurements and individual bias. The coefficient of determination (R^2) was interpreted as follows: ≤0.01=small, ≈0.09=medium, and ≥0.25=large effect size [29]. As a follow-up analysis, the equivalence test, also known as the two one-sided test (TOST), was performed to determine whether the means of the two different measures were equivalent within a 5% margin and whether any found differences were clinically significant. To conclude significant equivalence within the specified margin, both one-sided tests (ie, upper and lower bounds represented as t_1 and t_2) must reject the null hypothesis of nonequivalence (ie, unequal to zero). All statistical analyses were performed using IBM SPSS Statistics version 28, and the significance level was set at $P<.05$.

Ethical Considerations

Written informed consent was obtained from all participants prior to their participation in this study. All participants received a US $20 prepaid debit card as an incentive at the end of their study participation. The institutional review board at the University of Minnesota approved this study (STUDY00017556).

Results

Participant characteristics are shown in Table 1. The average weight of the participants was 63.6 (SD 8.3; males: 70.7, SD 5.1; females: 61.8, SD 8.0) kg. Except for 2 (6.9%), most participants (n=27; 93.1%) were nonsmokers at the time of study participation. Of the 29 participants, 2 (6.9%) indicated left as their dominant wrist or hand. Average daily monitor wear time was 789.6 (SD 86.1) minutes per day for the dominant and 793.0 (SD 91.8) minutes per day for nondominant wrists, respectively. The average number of valid monitor wear days was 5.3 (SD 1.3; median 6, IQR 2) days.

The descriptive accelerometry data between dominant and nondominant wrists and the results of the paired samples *t* tests are shown in Table 2. According to the ICC analyses, all accelerometer variables, including ST, light PA, MVPA, steps, triaxial counts, and VM, showed good to excellent levels of reliability between the two device placements (ICC >0.88 for all; *P*<.001; refer to Table 3).

[a]Average measures with a two-way mixed effects model were used.

[b]ICC: intraclass correlation coefficient.

[c]ST: sedentary time.

[d]LPA: light physical activity.

[e]MVPA: moderate-to-vigorous physical activity.

[f]CPM: counts per minute.

[g]VM: vector magnitude.

Bland-Altman analysis calculated mean bias and SD between the two device placements as follows: ST (−18.8, SD 27.6 min/d), light PA (2.7, SD 15.9 min/d), MVPA (12.7, SD 26.7 min/d), steps (218.1, SD 476.6 counts/d), x-axis (99.4 SD 188.8 counts/min), y-axis (73.9, SD 147.0 counts/min), z-axis (107.6 SD 183.5 counts/min), and VM (161.2, SD 273.4 counts/min). Figures 1 and 2 display individual-level biases with upper and lower limits of agreements. It is estimated to have proportional bias when there is a linear tendency in the discrepancies between the two measures, which is often represented by the slope of the regression or R^2 that significantly differs from zero [30]. Proportional bias was considered present in steps (R^2=0.091) and light PA (R^2=0.105), given the medium effect sizes for the regression coefficients, coupled with the progressive divergence in the generated plots. However, follow-up TOSTs with a 5% equivalence margin revealed that none of the accelerometry variables showed statistically significant equivalence between the means of two device placements: t_1 and t_2 for ST=0.33 and −1.90; light PA=1.08 and −0.52; MVPA=1.59 and 0.68; steps=0.73 and −0.22; x-axis=1.70 and 0.21; y-axis=1.06 and −0.08; z-axis=2.03 and 0.29; and VM=1.57 and 0.10 (all $P>.05$).

Figure 1. Bland-Altman plots were used to assess data agreement between the dominant and the nondominant wrists in measuring sedentary time, light physical activity, moderate-to-vigorous physical activity (min/d), and steps per day. Each red circle represents the individual-level difference between the two device placements for the 29 participants. Two dotted black lines indicate the limits of agreement (mean difference ±1.96× SD of the differences), and a solid black line indicates the mean bias between the two measures. LPA: light physical activity; MVPA: moderate-to-vigorous physical activity; ST: sedentary time.

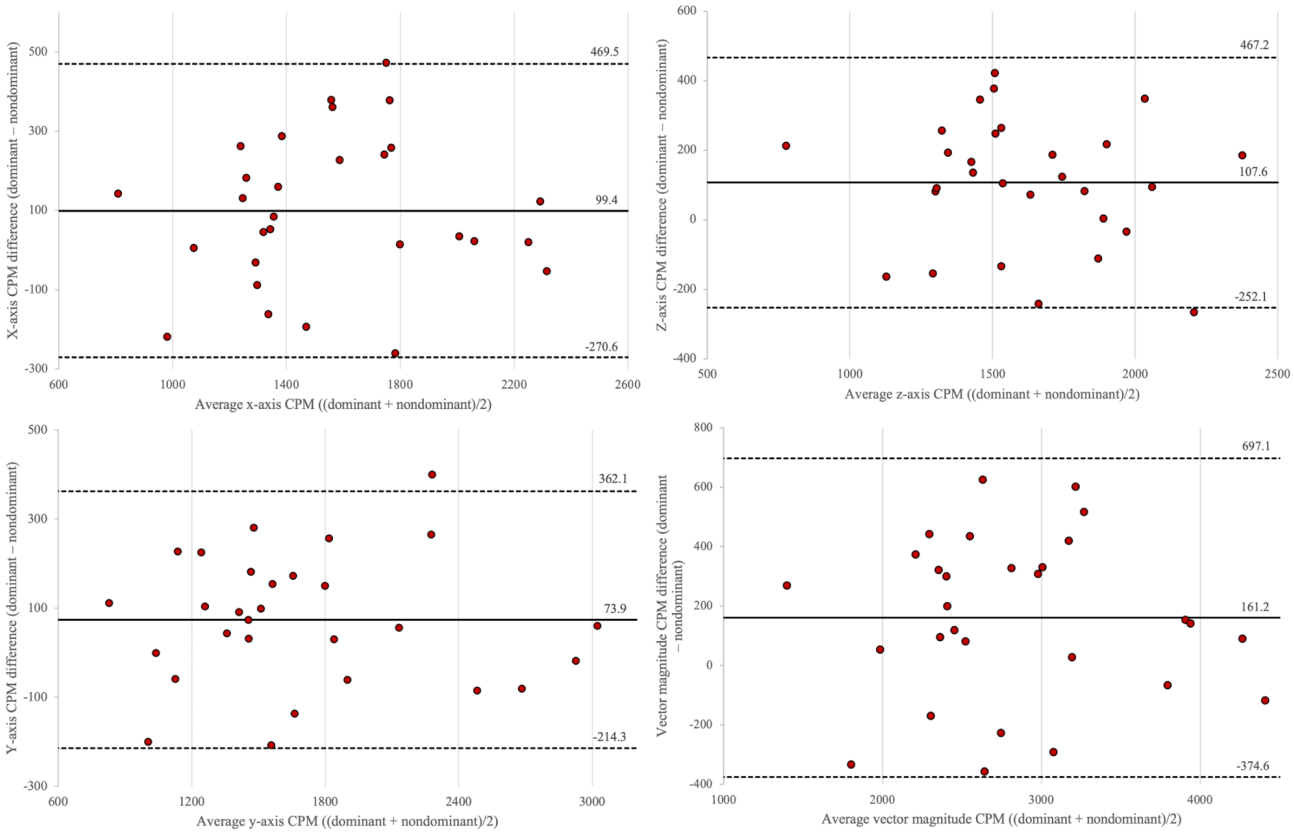
Figure 2. Bland-Altman plots were used to assess data agreement between the dominant and the nondominant wrists in measuring x, y, and z axes, as well as vector magnitude (counts per minute). Each red circle represents the individual-level difference between the two device placements for the 29 participants. Two dotted black lines indicate the limits of agreement (mean difference ±1.96× SD of the differences), and the solid black line indicates the mean bias between the two measures. CPM: counts per minute.



Discussion

Principal Findings

The objective of this study was to examine the degree of agreement between accelerometry data collected from ActiGraph CPIWs worn on the dominant and nondominant wrists of young adults in free-living conditions. This study comprehensively compared accelerometry variables, including ST, light PA, MVPA, and steps, as well as activity counts of 3 axes and VM, between the two device placements. Despite statistically significant differences observed through paired *t* tests, all outcome variables between the two placements showed good-to-excellent levels of comparability. However, the limits of agreement were considerably wide across all variables except ST, highlighting the need for cautious interpretation of these mixed findings.

Overall, previous research comparing PA data collected from the dominant and nondominant wrists revealed mixed results with limited consistency. A recent study examined PA data from ActiGraph GT9X accelerometers worn on both wrists for a 1-day data collection period and reported that the dominant wrist consistently produced higher step counts than the nondominant wrist in free-living conditions [20]. This result aligns with our findings, wherein the dominant wrist produced relatively higher outcomes of MVPA, light PA, and steps than the nondominant wrist. Conversely, an earlier study used a nearly identical protocol and found that device placement had no impact on the average daily PA outcomes, regardless of the axis examined in free-living environments [19]. Our study partly supports this finding, as all accelerometer variables, including the 3 axes and VM, exhibited excellent ICC values between the two measurements. However, proportional bias was considered present in steps (R^2=0.091) and light PA (R^2=0.105). This implies that the dominant wrist tended to produce higher step counts as the average step level increased, while the opposite trend was predicted for light PA. Given that 7 consecutive days of monitor wear are recommended for investigating representative and predictable PA behaviors, differences in wear periods (eg, 1 d vs 7 d) and the use of different ActiGraph models (eg, GT9X and GT3X vs CPIW) may contribute to the inconsistent results [31,32].

As explained by the paired *t* test results, MVPA, steps, and all axis-related variables showed statistically significant differences between the two placements, in which the dominant wrist produced relatively higher levels of outcomes compared to the nondominant wrist. Interestingly, the opposite result was observed in ST, whereby the nondominant wrist produced a higher level of outcome than the dominant wrist. Montoye et al [33] compared research-grade accelerometers (ie, GENEActiv; Activinsights Ltd) worn on both wrists for measuring PA and sedentary behavior. Their findings underscored higher sensitivities and specificities (eg, 97%) in predicting sedentary behavior as well as low-intensity activities using the left wrist-worn accelerometer (left hand was indicated as the nondominant hand among most participants), compared to the right wrist-worn accelerometer. Meanwhile, the right

XSL•FO
RenderX

wrist-worn accelerometer (mostly the dominant wrist among participants) produced significantly lower sensitivity and specificity for MVPA, which was overly misclassified as light PA due to underestimation of MVPA. Similarly, Fraysse et al [34] used GENEActiv accelerometers to compare the classification accuracy between dominant and nondominant wrists in free-living environments. While their sample consisted of older adults (ie, ≥70 years of age), significantly higher ST and lower MVPA were linked to the dominant wrist compared to the nondominant wrist. Once again, these mixed results may be attributed to the use of different accelerometer brands (eg, ActiGraph vs GENEActiv) that can result in varying raw acceleration outputs [35]. More comprehensive cross-validation studies are needed to determine the degree of agreement among a variety of research-grade accelerometer brands and models according to specific movement contexts and populations.

It should be noted that the paired *t* test considers only the overall bias of two measures; thus, this approach may not fully address how rejecting the null hypothesis corresponds to the degree of agreement between the two measurements [36]. As such, we implemented follow-up TOSTs with an equivalence margin of 5% to determine whether the observed difference between the two device placements is clinically significant. None of the included variables rejected the null hypothesis of nonequivalence for both one-sided tests, indicating insufficient evidence to declare statistically significant equivalence between the two placements within the specified margin. In line with the TOST results, ICC values for all accelerometer measures indicated good-to-excellent correlation (>0.88), suggesting strong agreement between the two placements. Moreover, Bland-Altman plots of all variables showed that the individual differences between the dominant and nondominant wrists mostly fell within the limits of agreement, which highlights the comparable estimations of variables between the two placements [37]. However, given the volume of average accelerometry outcomes (ie, ST=536.3 min/d, light PA=153.3 min/d, and MVPA=101.8 min/d), the discrepancy between the two measurements may not be at the acceptable level. The mean bias for MVPA (12.7 min/d) was comparable to that for ST (−18.8 min/d), indicating lower interdevice comparability in estimating MVPA. Wrist-worn devices are often recommended to capture lower-intensity activities, especially those mainly involving upper-body movements such as household chores [38]. Therefore, our findings emphasize the practical comparability (eg, sedentary-to-light activities vs MVPA) between the two device placements in free-living conditions, in which the intensity of the activity determines the degree of agreement or discrepancy between the two placements: the higher the intensity of PA, the greater the discrepancy in outcomes between the dominant and nondominant wrists.

The current and previous findings underscore the need for cautious interpretation of ICC and Bland-Altman plots when comparing the PA data of multiple measurements [39,40]. It is critical to note that although the mean bias for most accelerometry variables may seem marginal, the limits of agreement between the two measurements were considerably wide for PA variables, spanning over 104.8 minutes per day range for MVPA (−39.7 to 65.1 min/d), nearly 2000 steps per day for walking steps (−716.1 to 1152.3 steps/d), and more than 1000 VM CPM per day (−374.6 to 697.1 CPM/d). A similar result was observed by Pfister et al [39], in which the research team examined the comparability between the waist-worn ActiGraph GT3X+ and the thigh-worn activPal3 (PAL Technologies Ltd). While the ICCs for all PA and ST variables between the two devices were generally high and consistent, statistically significant—albeit small—differences in MVPA were found between the GT3X+ VM, vertical axis, and activPal3 at the group level. Further, the limits of agreement between the two accelerometer types were generally wide at the individual level, restricting the interchangeable use of these devices [39]. Regardless of the ICC analysis results, the degree of agreement may need to be determined by the overall mean bias in comparison to the range of the limits of agreement.

When it comes to the objective measurement of physical behaviors, the anterior waist or hip has been a conventional placement in earlier studies. Karaca et al [41] compared step counts measured by wGT3X-BT (ActiGraph) in five different body locations, including both right and left wrists, and found that the waist and right upper arm showed low mean absolute percentage error compared to other placements. In addition, waist-worn accelerometers tended to provide more accurate estimates of sedentary behavior that engaged the lower extremities exclusively, compared to wrist-worn devices [42]. However, the shift to using wrist-worn accelerometers over the past decade has demonstrated relative advantages over standard waist-worn devices. Despite the lower-performing algorithm compared to waist or hip location and a lack of criterion validity, particularly in free-living settings, wrist-worn devices can enhance participant acceptability given their familiarity with a wristwatch and enable increased data collection within 24-hour movement and sleep studies [43,44]. The use of the wrist as a device placement is often preferred over the waist because wrist-worn devices are generally less intrusive and often result in higher compliance with study protocol [45,46]. Although there is a lack of scientific consensus on cut-points for categorizing activity intensities in wrist-worn accelerometers, including CPIW, it is understood that devices on the nondominant wrist are likely to ensure higher measurement accuracy than those on the dominant wrist in free-living settings [33]. Given the high variability of movement and participants' unfamiliarity with wearing devices on the dominant wrist, the nondominant wrist may be a more reliable choice for assessing levels of PA and ST in real-world settings.

Limitations and Strengths

It is important to acknowledge the methodological limitations that may have affected the interpretation of our findings. The use of wrist-worn accelerometers may lead to underestimation or overestimation of PA levels, as they are limited in detecting nonambulatory activities (eg, cycling and yoga) and distinguishing between varying postures (eg, sitting vs standing) [38]. This limitation should be considered when interpreting PA estimates derived from wrist-based measurements. Although it was possible for participants to wear the accelerometers in the water, we intentionally advised them to remove the monitors during water activities and sleep to minimize potential malfunction or improper device positioning, which may have

XSL•FO
RenderX

underestimated their PA levels and the discrepancies between the two measures. Longer device wear time, especially during unstructured movements such as taking a shower or pool-based activities, could increase the likelihood of movement discrepancies between the two limbs. According to our follow-up survey, 1 participant consistently wore the monitors and engaged in water-based PA despite the instructions from the research team. Sensitivity analyses excluding this participant revealed that their inclusion had a minimal impact on the results. Without detailed logs of specific activities of daily living, such as brushing teeth, washing dishes, and driving, it is difficult to systematically examine differences related to hand dominance. Another limitation of this study is the use of the nondominant wrist-specific cut-points to classify activity intensities for both wrist placements. While dominant wrist–specific cut-points have been proposed using alternative metrics such as Euclidean Norm Minus One (ENMO) [47], these may not be directly comparable due to fundamental differences in data processing and calibration methods. The lack of validated CPM-based cut-points for the dominant wrist in adults highlights the need for further calibration studies to improve comparability across wear locations between the two wrists. Finally, the sample recruited in this study may also have introduced potential bias. Most participants in this study were women with relatively high levels of PA participation, as many were college students majoring in Exercise and Rehabilitation Sciences. This group included a few student-athletes who regularly engage in intensive training sessions, which may not be representative of average young adults. Prior studies suggest that there exists gender- and age-related variability in arm movement patterns and movement efficiency. Specifically, females tend to exhibit significantly less arm swing asymmetry, while males show more lateralized, asymmetric arm movements during walking [48]. Aging is also associated with reduced arm swing amplitude and less efficient arm movement coordination [49]. Thus, our sample of young adults may not accurately capture the variability in wrist-worn accelerometer–based PA estimates that could frequently occur in older populations. We acknowledge the growing importance of using open-source, monitor-independent metrics, such as ENMO, mean amplitude deviation, and Monitor-Independent Movement Summary, to enhance reproducibility and cross-study comparability in accelerometry research [50-52]. While Migueles et al [47] demonstrated that ENMO may yield greater agreement across wrist placements and proposed dominant wrist-specific cut-points, future research is warranted to directly compare these emerging metrics with VM counts across diverse device placements and evaluate their implications for interpreting accelerometry outputs in surveillance and intervention studies. Post hoc power analyses revealed that both the paired *t* tests and equivalence tests were underpowered, with estimated power ranging from 6% to 47% across primary accelerometry outcomes (eg, ST, MVPA, and steps). As such, these findings should be interpreted with caution given the limited sample size.

Despite the limitations, this study demonstrates notable strengths. First, this study used a standard 7-day data collection protocol in free-living conditions to provide more transferable knowledge for determining the use of the nondominant wrist as device placement. Moreover, the use of a user-friendly, relatively new CPM cut-point method [23] to classify ST and PA intensities is a major study strength. Past PA measurement studies have been interpreted with caution due to the misuse of the cut-points that were developed for waist or hip locations, different age groups (eg, adults vs children), different axial outputs (eg, uniaxial vs triaxial), or structured laboratory settings [53]. Our study findings, which leveraged the cross-validated cut-points, provide practical implications for future studies that adopt research-grade wrist-worn accelerometers.

Conclusions

This study aimed to examine the degree of agreement between accelerometry data collected from ActiGraph CPIWs worn on the dominant and nondominant wrists of young adults in free-living environments. The current findings align partially with previous research, demonstrating higher step counts, MVPA levels, and axis-related outcomes on the dominant wrist, while the nondominant wrist produced a higher level of ST compared with the dominant wrist. Although we observed excellent levels of reliability based on ICC across most accelerometry outcomes, the intervals between the upper and lower limits of agreement were considerably wide, particularly in steps and MVPA, along with the potential proportional bias in steps and light PA. It is estimated that the intensity of PA determines the degree of discrepancy between the dominant and nondominant wrists (eg, the dominant wrist tends to produce greater outcomes as the intensity of PA increases). These findings emphasize caution in interpreting ICC and Bland-Altman plots when comparing PA data from multiple wear locations. Taken together, the nondominant wrist could offer a reliable option for measuring physical behaviors in free-living environments; however, potential underestimation of MVPA and overestimation of ST should be considered when interpreting data outcomes and selecting the device placement.

Abstract

Background: The administration of incentives to promote physical activity, such as the amount or timing, can vary depending on target health behaviors, research settings, intervention delivery channels, and participants' preferences. Interventions implemented at scale necessitate the consideration of potential fiscal constraints for public health promotion. Since limited funding is a barrier to implementing community-based interventions, examining both immediate and sustained effects of temporary incentive increases on physical activity is important.

Objective: This study aimed to evaluate the effect of a 1-week double-point event on increasing physical activity among low-engaged individuals in the context of a community-based mobile intervention.

Methods: Using retrospective data from a Seoul Metropolitan Government mobile health (mHealth) intervention, we evaluated the effects of a 1-week double-point incentive on participants' physical activity. During 3 registration phases from November to December 2021, a total of 50,145 individuals enrolled. Our analysis focused on the low-engaged group (n=27,833, 55.5%), who averaged fewer than 3 days per week of meeting the daily step challenge (at least 7000 steps) before the intervention. We performed a segmented regression analysis to assess changes in physical activity before and after the event. Multivariable logistic regression and Cox proportional hazards models were used to identify factors associated with improving and maintaining physical activity after starting the intervention.

Results: Of 27,833 low-engaged participants, only 13.7% (n=3835) improved their physical activity. Daily challenge engagements per week increased by 2.53 times, and average daily steps increased by 1924.97 (standardized mean difference 0.55, 95% CI 0.51 - 0.58). In multivariable logistic regression, older age was significantly associated with improved physical activity immediately after starting the intervention. However, 50% (1918/3835) of the improved group was likely to return to low engagement 3 weeks after the intervention ended. Older age and use of certain wearable devices were associated with maintaining physical activity after the intervention.

Conclusions: Double-point incentives in the short term may serve as a cue-to-action to motivate low-engagement targets; however, they do not seem to guarantee long-term maintenance in the context of community-based mHealth interventions. Further research is needed to identify additional strategies beyond monetary incentives to sustain long-term healthy behavior.

KEYWORDS

community-based interventions; physical activity; engagement; financial incentive; relapsed period; mobile phone

Introduction

Physical inactivity is the fourth leading cause of global mortality, contributing significantly to the global health burden [1]. As of 2016, a total of 27.5% of the global population was physically inactive, a prevalence that has persisted since 2001 [2]. This widespread inactivity poses health risks and results in substantial health care costs for governments and other stakeholders [3]. Achieving the recommended levels of physical activity remains challenging; for example, in 2018, a total of 39.5% of Americans aged 18 years and older did not meet the aerobic activity guidelines [4]. To combat this, many countries have implemented community-based mobile interventions, such as the Carrot Rewards program in Canada and the National Steps Challenge Season 3 in Singapore, which have successfully increased physical activity [5-7].

Despite the promising effect of community-based mobile interventions, encouraging properly those whose engagement waned during the intervention remains challenging. To address this challenge, providing financial rewards or incentives is considered a good way, demonstrating up to 2.5-fold greater effectiveness in promoting physical activity engagement compared to nonincentivized conditions [8-10]. A meta-analysis revealed that among studies only targeting physically inactive populations, financial incentives improved a mean increase of 1150 steps per day [6].

The administration of incentives, such as the amount or timing, can vary depending on target health behaviors, research settings, intervention delivery channels, and participants' preferences [5,11-13]. Interventions implemented at scale necessitate the consideration of potential fiscal constraints for public health promotion. Thus, the incentive operation may change during the intervention administration due to business or financial decisions, and these changed rewards may impact user engagement [14]. In a longitudinal study with 55,000 users of a commercial physical activity application, reducing incentive size over time was associated with lowering user engagement [15]. Another longitudinal study revealed that adding a team-based incentive policy to the conventional individual-oriented policy contributed to improving daily step counts [16]. Additionally, a study with 1600 users reported that their physical activity decreased after reducing incentives [14].

The previous studies allowed us to examine the relationship between incentive changes and user behaviors in a real-world context [17]. However, further elucidation is needed regarding the effect of intentional, theory-based changes to incentive policies on user engagement within community-based mobile physical activity interventions. Specifically, as limited funding is a barrier to implementing community-based interventions, examining both immediate and sustained effects of temporary incentive increases on physical activity is important [18]. Therefore, our study aimed to evaluate the effect of a 1-week double-point event on increasing physical activity among low-engaged individuals in the context of a community-based mobile intervention. We also identified which participants increased their activity due to the event and assessed how long these improvements lasted.

Methods

Study Population

This retrospective cohort study used data from "On Seoul, Health On (OSHO)," a 9-month community-based mobile health (mHealth) intervention program organized by the Seoul Metropolitan Government from November 2021 to July 2022. The analysis focused on a subset of participants who were categorized into the low-engaged group in terms of physical activity during the program's initial phase (1 month). The low-engaged group was defined as individuals who engaged in the daily step count challenge (completing at least 7000 steps) for an average of less than 3 days per week. Several studies suggest that taking 7000 steps per day is a minimum recommended level of physical activity to reduce the risk of morbidity or mortality in adults [19-21]. Moreover, the government aimed to facilitate the participants' self-efficacy by setting achievable goals for a wide range of age groups [22,23]. Additionally, setting it to 7000 steps per day can be reasonable considering that the average number of steps for Koreans is 5755 [24], and it is usually recommended to increase the target setting by about 10% - 15% [6]. A total of 50,145 participants registered for the program, and 27,833 (55.5%) individuals in the low-engaged group during the initial phase of the program were included in this study (Figure S1 in Multimedia Appendix 1).

Description of the OSHO Program

The OSHO program aimed to enhance physical activity levels of individuals in Seoul, South Korea. Eligibility for the program required participants to be adults aged 19 - 64 years, residing or working in Seoul, and owning a mobile device compatible with at least Android (version 5.0; Google LLC) or iOS (version 10.0; Apple). Recruitment was conducted through the program's official homepage, media coverage, and advertisements in subway stations. During 3 registration phases spanning November to December 2021, a total of 50,145 individuals registered to participate. Upon registration, participants were provided with 1 of 4 different wearable devices free and asked to install a mobile app for the program. All wearable devices measured steps in real time, but the shape (band-like or watch-like) and the availability of additional functions (body composition, heart rate, etc) varied depending on the brand. Detailed specifications of each wearable brand are presented in the supplementary materials (Table S1 and Figure S2 in Multimedia Appendix 1). The mobile app enabled participants to monitor their step counts as recorded by the wearable device. To encourage participation, individuals received 200 points,

XSL•FO
RenderX

convertible to an equivalent amount of cash (KR ₩200, approximately US $0.20), for every 7000 steps or more per day. The points could be redeemed to promote their health at pharmacies, sports facilities, and other designated health care businesses.

"Spring Walk Campaign": Additional Financial Incentive Event

Approximately 4 months after the start of the program, the "Spring Walk Campaign" (SWC) was introduced as a special 1-week event, starting on March 21, 2022. The SWC was intended to encourage physical activity among participants who remained inactive during the initial intervention by providing additional financial incentives. The SWC was advertised to OSHO participants through the mobile app and the official website. During the event, those who engaged in the daily step challenge were awarded double points (400 points) to encourage physical activity. We anticipated that the SWC, a temporary incentive increase, could motivate the low-engaged participants based on a behavioral mechanism that combines "loss aversion" and "scarcity effects" [25]. Although the intervention offered additional rewards rather than removing existing ones, which is not a classical use of loss aversion, the limited-time nature may have triggered similar urgency effects associated with perceived opportunity costs.

Outcomes

The primary outcome was the immediate change in physical activity during the SWC event. Physical activity was evaluated using steps counted by wearable devices. Individuals who succeeded in the daily step challenge (>7000 steps) for at least 3 days a week were considered the improved group. The secondary outcome was the maintenance of improved physical activity among participants who transitioned to the improved group during the SWC after the removal of additional incentives.

At the time of registration for this program, sociodemographic information, including sex, age, and occupation, was assessed. The BMI and comorbidities were also assessed. Physical activity levels at enrollment were assessed using the International Physical Activity Questionnaire-7 Short Form [26]. This measure is a self-administered tool that focuses on the frequency and duration of walking, moderate to vigorous intensity activities, and sedentary time over the past 7 days. In this study, we adapted the instrument by using 6 items while excluding 1 item that assessed sedentary behavior. Responses were converted to metabolic equivalent of task (MET)–minutes per week, an objective metric that quantifies the energy cost of physical activities [27]. One MET is defined as the amount of oxygen consumed while sitting at rest and equals 3.5 mL O_2 per kg body weight×min [28]. Based on MET-min/wk values, participants' physical activities were categorized into 3 levels—low, moderate, and high. The criteria for these categorizations are detailed in Table S2 in Multimedia Appendix 1. Step count data recorded in real time through wearable devices were summarized and shared as daily cumulative figures. All distributed devices were manufactured by Korean companies and had obtained KC (Korea Certification) for product safety and qualification testing. Only authorized personnel had access to the data on the OSHO administration server, and the research team obtained deidentified data.

Statistical Analyses

Descriptive analyses were performed to summarize participants' baseline characteristics. Significance tests were conducted using the chi-square test (for categorical variables) or *t* test (for continuous variables), and the standardized mean difference (SMD) was estimated to present the magnitude of the difference between the 2 groups, considering this study's population size.

We performed a segmented regression to analyze changes in daily user engagement trajectories before and after the SWC. An equation of the regression model was considered to define levels (eg, y-intercepts) and slopes for each time segment (before vs after starting the SWC). Time started from 0, and the intervention was coded as 0 (before starting the SWC) and 1 (after starting the SWC). Time since the intervention was measured in days post the SWC. The model was fitted using the restricted maximum likelihood method, including the autoregressive error term. The autocorrelation value was calculated using the Durbin-Watson test. After fitting, we presented a graphical depiction of the data points and trend lines. Multivariable logistic regression was used to identify the factors associated with improved physical activity (the improved group) after the event. This model was adjusted for potential confounders, including age, sex, BMI, physical activity level at enrollment, chronic diseases, OS type, and wearable device type. The inclusion of OS type was due to its potential to reflect individual behavior disposition [29] or varying motivations for healthy behavior change among users [30]. Additionally, we considered that heterogeneity across wearable brands may result in different user experiences and satisfaction with the OSHO program [31,32]. This was because certain brands had high dropout rates in the exploratory analysis, which may be a confounder or attrition bias (Table S3 in Multimedia Appendix 1). Technological features are also known to influence user engagement [33]. Kaplan-Meier survival curves were plotted to estimate the time to the first occurrence of relapse to the low engagement level in the improved group, with weekly time points. Differences between curves were assessed using the log-rank test. All statistical analyses were conducted using R (version 4.3.1; R Foundation for Statistical Computing). Statistical significance was defined as a 95% CI and a *P* value of <.05.

Ethical Considerations

This study was approved by the institutional review board of the Samsung Medical Center (SMC 2022-07-073). All individuals who participated in the OSHO program provided informed consent for the program registration. However, our research uses retrospective data containing anonymized personal information and has received a waiver of additional informed consent for the analyses from the participants. Participants received 200 points (equivalent to 200 Korean Won or approximately USD 0.20) for each day they achieved 7,000 steps or more. These points could be redeemed at pharmacies, sports facilities, and other designated health-related businesses.

Results

Comparison of Demographic Characteristics Between Those With Improved Physical Activity During the SWC and Those With No Improvement

Of 27,833 participants included in the analysis, 3835 (13.7%) showed improved physical activity during the SWC (Figure S1 in Multimedia Appendix 1). The improved group members were older (39.4 vs 37.4 years, SMD=0.194) and especially included more adults aged 40 years and over, compared to the nonimproved group (SMD=0.215, Table 1). The BMI (SMD=0.031) and physical activity level at baseline (SMD=0.054) were similar between the 2 groups.

Table . Difference in demographic characteristics by improved physical activity during the Spring Walk Campaign.

	Overall (N=27,833)	Improved physical activity during the Spring Walk Campaign		Standardized mean difference
		Yes (n=3835)	No (n=23,998)

Factors Associated With Moving to the Improved Group During the SWC

In multivariable logistic regression, participants in their aged (years) 30s (adjusted odds ratio [aOR] 1.40, 95% CI 1.27 - 1.54), 40s (aOR 1.79, 95% CI 1.62 - 1.97), 50s (aOR 1.73, 95% CI 1.53 - 1.95), and 60s (aOR 1.82, 95% CI 1.48 - 2.23) were more likely to show improved physical activity during the SWC (Table 2). Additionally, those who had minimal physical activity levels assessed using the International Physical Activity Questionnaire-7 Short Form at baseline (aOR 1.16, 95% CI 1.07 - 1.26) or used android-powered smartphones

XSL•FO
RenderX

compared to iOS (aOR 1.20, 95% CI 1.11 - 1.30) were more likely to show improved physical activity. However, those who received wearable B (aOR 0.89, 95% CI 0.81 - 0.97) or wearable D (aOR 0.63, 95% CI 0.57 - 0.70) were less likely to show improved physical activity.

[b]N=27,715, eliminated 118 missing values.

Immediate Changes in Physical Activity After Starting the SWC

Daily activity challenge achievement rate (%) tended to decrease by 0.18 units per day at 27.45 (Figure 1). After starting the SWC, the achievement rate immediately increased by 8.16 (P<.001). Especially, those with improved physical activity during the SWC increased their weekly engagement from an average of 1.76 to 4.29 times (SMD=1.81, 95% CI 1.76 - 1.86, Table 3). Concerning average step count, there was an increase of 1924.97 steps in those with improved physical activity during the SWC (SMD=0.55, 95% CI 0.51 - 0.58).

Table . Changes in the number of daily challenge engagement per week and average daily step counts before and during the Spring Walk Campaign.

	Before the Spring Walk Campaign, mean (SD)	During the Spring Walk Campaign, mean (SD)	Mean difference	Standardized mean difference (95% CI)
The number of daily challenge engagements per week				
Overall	0.57 (0.87)	0.77 (1.56)	0.20	0.17 (0.16 to 0.18)
Improved group (N=3835)	1.76 (0.83)	4.29 (1.22)	2.53	1.81 (1.76 to 1.86)
Nonimproved group (N=23,998)	0.38 (0.71)	0.21 (0.54)	−0.17	−0.26 (−0.27 to –0.25)
Average step counts per day				
Overall	2857.22 (3724.84)	2243.80 (3714.70)	−613.42	−0.18 (−0.19 to –0.17)
Improved group (N=3835)	6769.13 (3640.74)	8694.10 (2857.22)	1924.97	0.55 (0.51 to 0.58)
Nonimproved group (N=23,998)	2232.08 (3337.30)	1213.01 (2643.52)	−1019.07	−0.32 (−0.34 to –0.31)

Sustaining Improved Physical Activity After the SWC Ended

After starting the SWC, the decreasing slope of the completion rates improved from −0.18 to −0.02 (P<.001, Figure 1). The Kaplan-Meier curve showed that half of the improved group were likely to return to low engagement in physical activity 3 weeks after the SWC ended (Figure 2). In the multivariable Cox proportional hazards model, participants in their aged (years) 20s (adjusted hazard ratio [aHR] 1.44, 95% CI 1.19 - 1.75) or 30s (aHR 1.27, 95% CI 1.05 - 1.53) had a higher risk of returning to low engagement in physical activity after the SWC ended (Table 4). Moreover, users of wearable B (aHR 1.12, 95% CI 1.03 - 1.21) and wearable D (aHR 1.15, 95% CI 1.04 - 1.27) had a greater risk of returning to low engagement compared to users of wearable A.

Figure 2. Kaplan-Meier curves for time to return to low engagement in physical activity after the Spring Walk Campaign ended among the improved group. SWC: Spring Walk Campaign.

[a]The improved group (N[1]=3820).

[b]Eliminated 15 missing values.

[c]Crude model represents the crude hazard ratio (95% CI).

[d]Adjusted Model included age group, sex, BMI, physical activity level, chronic diseases, OS type, and wearable device type.

Discussion

Principal Findings

In this study, we evaluated the effect of a 1-week double-point event on increasing physical activity among low-engaged individuals in the context of a community-based mobile intervention. We also identified which participants increased their activity due to the event and assessed how long these improvements lasted. We found that 14% (n=3835) of those who were in the low-engaged group with the intervention improved their physical activity during the SWC. However, the effect diminished in 50% (1918/3835) of the participants within 3 weeks, with those in their 20s and 30s showing a more rapid return to preintervention levels.

Immediate Effects of a 1-Week Double-Point Incentive Event on Change of Physical Activity

In our study, the OSHO program provided a stream of small-size incentives (US $0.20 per day) for achieving the daily physical activity challenge. However, participants' physical activity or engagement with the program declined over time. We found that temporarily increasing incentives could help improve intervention engagement, potentially leading to physical activity improvement. Immediately after starting the SWC, the achievement rate of the daily activity challenge increased by 8.16%. In the low-engaged group of 27,833 people, approximately 14% (n=3835) showed an improvement in their physical activity during the SWC. In general, larger absolute amounts of financial incentives tend to ensure greater user engagement with mobile interventions [5,8]. However, recent

XSL•FO
RenderX

evidence highlights that considering how to design an incentive structure is more important than securing a larger amount of incentives. A study using real-world data from 54,817 Canadians found that decreasing incentives over time can lead to lower user engagement in mobile health programs [15]. Another real-world study found that policy change toward increasing the uncertainty of obtaining incentives led to decreased physical activity among users [14]. A randomized controlled trial in which the total amount of incentives was the same but the structure was different found that a constant incentive rate was more effective than increasing or decreasing rates over time [34]. Therefore, considering our research and previous studies, it would be necessary to develop and evaluate effective incentive policies to increase user participation. However, since the overall effect size of SWC was low (SMD=0.17) and certain participants responded to it, multiple incentive structures should be established within an intervention [35].

Lasting Effects of a 1-Week Double-Point Incentive Event on Change of Physical Activity

Although 14% (n=3835) of the low-engaged group became more active during the SWC, 50% (1918/3835) of them relapsed into the low-engaged group within 3 weeks after the event. This suggests that the temporary incentive increase does not ensure long-term effects on physical activity. Participants may feel that the end of SWC was akin to a withdrawal of an incentive. Though attitudinal assessment of participants was not a primary focus of this investigation, study of participants' attitudes toward the SWC will be important in future initiatives.

Eventually, this may lead to lowering their motivation. In previous studies, financial incentives rarely led to long-term behavior change; particularly, people tended to revert to their initial behaviors soon after the incentives stopped [36]. A large randomized clinical trial evaluating the effects of a fitness tracker and various incentive structures on physical activity found that those who received cash incentives were more physically active than the control group for 6 months [5]. However, the effect diminished over the 6 months after the incentives ended. A meta-analysis also indicated that only 4 of the 18 studies exhibited positive effects following the end of the interventions. These interventions include various types of incentives, such as immediate rewards, team-based incentives, loss-framed incentives, etc, based on a randomized controlled trial [6]. In general, monetary incentives could encourage extrinsic motivation while discouraging intrinsic motivation [37]. Therefore, strategies are needed that can quickly convert extrinsic rewards provided within a temporary event into intrinsic motivation [36-38]. For instance, combining wearable technology with regular counseling produced higher engagement rates, indicating that integrating financial incentives with personalized support and feedback may be a good option [39].

Impact of Age and Technology-Related Factors on Physical Activity Changes

In our study, we found that the older age group had greater responsiveness to the SWC and were more likely to maintain their improved physical activity. These findings are supported by previous studies that have noted greater participation among older adults in physical activity interventions [8,40]. According to a study using combined data from 8 studies with 100,000 participants, older age was a significant factor associated with retention in remote digital health studies [41]. Another longitudinal study with 1000 participants found that older age was positively associated with consistent and continued use of mobile health apps after becoming a user [42]. A possible reason is that older people are relatively more responsive to health care services, so their satisfaction and perceived benefits from mHealth may have been well maintained [43]. This may reflect the older population's greater temporal flexibility compared to younger individuals constrained by occupational commitments. Another possible explanation may be that older people placed a higher value on the use of incentives provided in our study. According to the administrative manual of the OSHO program, the places where the points could be redeemed were limited to pharmacies, sports facilities, and other designated health care businesses to improve their health. This may not have been appealing to younger participants. Indeed, an exploratory study with Israeli adults (n=379) aged 20 - 89 years reveals that while participants in the young age group (ages 20 - 39 years) rated 4 factors—affiliation, competition, appearance, and mastery—as more important. In contrast, the older age group (ages 61 - 89 years) rated health benefits as more important than the other age groups [44]. For younger participants, strategies such as group exercises, challenges, and sharing achievements on social media could be effective to encourage intrinsic motivation. Hence, it would be necessary to consider tailored strategies to balance extrinsic and intrinsic motivation for each age group [38].

Although we did not directly evaluate the participants' user experience or investigate technological problems, it is possible that participants had negative experiences with certain brands of wearable devices. The Seoul Metropolitan Government tried to distribute devices with similar specifications, but our exploratory analysis discovered that brands A and B had higher dropout rates. This suggests that compatibility issues with the OSHO app or other technological problems with the devices may have negatively affected the user experience. In fact, heterogeneity between devices and systems for a single service can easily create compatibility problems [45]. This may have affected engagement with the intervention and, eventually, motivation for physical activity [33]. Therefore, rather than solely considering incentives as a means of increasing physical activity, it is important to incorporate design and administrative considerations that ensure consistent performance and user experience across platforms and devices.

Limitations

Limitations of the current study may include confounding by unmeasured variables. The Seoul Metropolitan Government did not measure baseline health conditions such as weight, BMI, or average steps before starting this promotion. We applied retrospective analyses to evaluate a specific intervention with a large population in a real-world setting where experimental manipulations are not feasible. However, this approach may also have limitations in clearly identifying the causal effects of the intervention due to unclear or selective exposure to the intervention. To better validate the efficacy of additional financial incentives, conducting a randomized controlled trial

XSL•FO
RenderX

will be needed. Behavioral aspects related to physical activity, which could impact participants' motivation in the SWC, were also not considered. The use of wearable devices or smartphone apps to track physical activity may result in technological limitations or inaccuracies in data collection. The OSHO program provided all participants with wearable devices to monitor daily activities. However, there may still be a possibility of underestimation of daily steps if participants did not consistently wear the device. Additionally, not all participants had equal access to or familiarity with the technology, potentially affecting the results. Moreover, this study may not have adequately measured or addressed variations in participant engagement and adherence to the intervention, which could have affected the outcomes. Future research should explore methods to improve and measure engagement to enhance the effectiveness of similar interventions. Finally, the sample consisted solely of Seoul citizens, where the walkability index ranks among the top 10 cities in the world [46]. The generalizability of our findings could vary depending on the infrastructure of a given location. Future studies should replicate and extend the current findings using more diverse and representative samples from different regions to enhance the generalizability of the results.

Conclusions

In conclusion, we found that the double-point incentive motivated only a small subset of participants, leading to significant short-term increases in physical activity. However, only a small proportion of participants maintained these behavioral changes, indicating that sustaining such changes typically requires longer or repeated interventions and personalized strategies to enhance both engagement and long-term adherence. Financial incentives alone may not be sufficient to promote sustained physical activity. Other factors, such as personalized support, behavioral change techniques, and environmental modifications, should be considered to effectively enhance physical activity levels. Integrating these elements can provide a more comprehensive approach to motivate individuals and sustain healthy behaviors.

Acknowledgments

There is no declaration for acknowledgments. This research was supported by the Seoul Metropolitan Government (20220435393-00) and the SmartTech Clinical Research Center (SCRC), funded by the Ministry of Health & Welfare, Republic of Korea (RS-2023-KH142023).

Data Availability

Data and codes supporting the findings of this study are available from the corresponding author on reasonable request.

Authors' Contributions

JJ, ML, and JC conceptualized this study. ML, JT, and JC worked on the methodology and validated this study. JJ and ML did the data curation, formal analysis, visualization of this study; and wrote and prepared the original draft. All authors reviewed and edited the writing. JC supervised and obtained funding for this study.

Conflicts of Interest

The authors declare no conflicts of interest. However, JC, ML, and JY participated in this research project, which was conducted with support and funding from the Seoul Metropolitan Government. Therefore, to ensure the transparency and independence of the research project, data curation and analyses were performed and reviewed together with external experts who were not involved in the research project. None of the authors received any financial benefits from the funder, including royalties, incentives, stocks, or stock options.

Abstract

Background: Tools for measuring clinical disability status in people with multiple sclerosis (MS) are limited. Accelerometry objectively assesses physical activity and circadian rhythmicity profiles in the real-world environment and may potentially distinguish levels of disability in MS.

Objective: This study aims to determine if accelerometry can detect differences in physical activity and circadian rhythms between relapsing-remitting multiple sclerosis (RRMS) and progressive multiple sclerosis (PMS) and to assess the interplay within person between the 2 domains of physical activity (PA) and circadian rhythm (CR) in relation to MS type.

Methods: This study represents an analysis of the baseline data from the prospective HEAL-MS (home-based evaluation of actigraphy to predict longitudinal function in multiple sclerosis) study. Participants were divided into 3 groups based on the Expanded Disability Status Scale (EDSS) criteria for sustained disability progression: RRMS-Stable, RRMS-Suspected progression, and PMS. Baseline visits occurred between January 2021 and March 2023. Clinical outcome measures were collected by masked examiners. Participants wore the GT9X Link ActiGraph on their nondominant wrists for 2 weeks. After adjusting for age, sex, and BMI, a logistic regression model was fitted to evaluate the association of each accelerometry metric with odds of PMS versus RRMS. We also evaluated the association of accelerometry metrics in differentiating the 2 RRMS subtypes. The Joint and Individual Variation Explained (JIVE) model was used to assess the codependencies between the PA and CR domains and their joint and individual association with MS subtype.

Results: A total of 253 participants were included: 86 with RRMS-Stable, 82 with RRMS-Suspected progression, and 85 with PMS. Compared to RRMS, participants with PMS had lower total activity counts (β=−0.32, 95% CI −0.61 to −0.03), lower time spent in moderate to vigorous physical activity (β=−0.01, 95% CI −0.02 to −0.004), higher active-to-sedentary transition probability (β=5.68, 95% CI 1.86-9.5), lower amplitude (β=−0.0004, 95% CI −0.0008 to −0.0001), higher intradaily variability (β=4.64, 95% CI 1.45-7.84), and lower interdaily stability (β=−4.43, 95% CI −8.77 to −0.10). Using the JIVE model for PA and CR domains, PMS had higher first joint component (β=0.367, 95% CI 0.088-0.656), lower PA-1 component (β=−0.441, 95% CI −0.740 to −0.159), and lower PA-2 component (β=−0.415, 95% CI −0.717 to −0.126) compared to RRMS. No significant differences were detected between the 2 RRMS subtypes except for lower relative amplitude in those with suspected progression (β=−5.26, 95% CI −10.80 to −0.20).

Conclusions: Accelerometry detected differences in physical activity patterns between RRMS and PMS. More advanced analytic techniques may help discern differences between the 2 RRMS subgroups. Longitudinal follow-up is underway to assess the potential for accelerometry to detect or predict disability progression.

Introduction

Multiple sclerosis (MS) is a chronic disease affecting the central nervous system in which those affected typically have intermittent neurologic symptoms and signs early in the course (relapsing-remitting multiple sclerosis [RRMS]) but often, subsequently (or, less commonly, from onset), slowly accumulate disability (progressive multiple sclerosis [PMS]). Currently available tools to measure disability in MS are limited. The Expanded Disability Status Scale (EDSS) is the most widely used clinical outcome measure and is considered by the Food and Drug Administration to be the gold standard for phase 3 trials in PMS. The EDSS, however, is semiquantitative, has limited reliability, and only captures a person's state at one short point in time during a clinical visit [1]. People with MS may have different disability states at different times throughout the day, as symptoms can fluctuate with temperature, fatigue, stress, and other factors [2,3]. The limitations of the EDSS lead to long delays in confirming that a person has transitioned from RRMS to PMS and also inflate the sample size and follow-up time required for MS trials for which disability progression is the primary end point [4,5].

Triaxial accelerometry is a safe and relatively inexpensive tool that may offer an objective and sensitive measure of disability in people with MS. With the use of an accelerometer worn on the wrist, real-time information about physical activity and circadian rhythmicity patterns can be collected in a person's natural environment. Such data may allow detection of variation in activity that may be missed during clinical visits [6,7]. Several studies have looked at the use of accelerometry in MS to identify associations with sleep, fatigue, depression, or disability outcomes (EDSS and Patient-Determined Disease Steps); however, whether wrist-worn accelerometry can differentiate between people with RRMS and PMS remains an existing question [8-16]. We hypothesized that people with RRMS and PMS have different physical activity and circadian rhythmicity patterns. Due to the interplay between physical activity and circadian rhythm domains within person, we also aimed to study joint and individual variations in these 2 domains and their associations with MS subtype.

Methods

Participant Selection and Study Design

This study includes an analysis of the baseline data from the longitudinal observational study HEAL-MS (home-based evaluation of actigraphy to predict longitudinal function in multiple sclerosis; Figure S1 in Multimedia Appendix 1). Eligible participants followed at the Johns Hopkins Multiple Sclerosis Precision Medicine Center of Excellence were recruited between January 2021 and March 2023. Participants had to have a diagnosis of MS, were aged ≥40 years, had no apparent comorbidities that may limit physical activity (eg, heart failure and end-stage renal disease), had no MS relapse within the last 6 months prior to enrollment, and had baseline EDSS score ≤6.5. These criteria were chosen so that the participants with RRMS were of the age at which transition to PMS might begin within the next few years, the changes in accelerometry measures were more likely to be due to MS and not comorbid conditions, and the baseline measures were not affected by recovery from a recent relapse. Medical records were reviewed by an MS-trained neurologist to ensure eligibility.

Participants were divided into 3 groups with a target of 85 participants each: those with stable RRMS who had no suspected or confirmed progression (RRMS-Stable), those with PMS who had confirmed disability worsening on EDSS (PMS), and those with RRMS who were suspected to be progressing clinically (inferred by an MS-trained neurologist from medical record notes or personal knowledge of the participant) but did not have sustained disability worsening on exam (RRMS-Suspected progression). Confirmed disability worsening on exam was defined as an EDSS change of ≥1.0 point if baseline EDSS was ≤5.5, or of ≥0.5 points if baseline EDSS was ≥6.0; this change should be sustained for ≥24 weeks, not in the context of an explanatory relapse. The 2 RRMS groups were matched based on age (target ±2 years with prespecified ability to relax the criterion if necessary), sex at birth, race or ethnicity, and efficacy class of current disease-modifying therapy (no treatment, first-line treatment [injectables and oral therapies (except for cladribine or ofatumumab)], or higher-efficacy treatment [infusion therapies and cladribine]). The PMS group was expected to be a little older and to be prescribed different (or even no) medications due to the likely lack of neuroinflammation and relapse activity in this group. However, enrollment of a comprehensive cohort of participants with respect to sex and race or ethnicity was attempted.

Clinical Measures

The EDSS exam was conducted after the fitting of the accelerometer and was performed by a masked EDSS-trained physician. A modified multiple sclerosis functional composite (MSFC), which includes the 9-hole peg test, the timed 25-foot walk test, the high- and low-contrast letter acuity (binocular, 2.5% contrast Sloan charts), and the Symbol Digit Modalities Test, was performed by a masked, trained study team member. Participants also completed patient-reported outcomes such as the International Physical Activity Questionnaire (IPAQ).

Accelerometry Measures

Accelerometry metrics were derived from accelerometry data collected with the GT9X Link ActiGraph using a built-in triaxial accelerometer [17]. All participants were instructed to wear the ActiGraph device on the wrist of their nondominant hand for 24 hours a day over a duration of 2 weeks. Accelerometers were set to capture 3D acceleration at 30 Hz with the acceleration range of ±8 G. The raw acceleration data (.gt3x) were downloaded from the device using ActiLife v6.134 Lite Edition. Binary raw activity data (Hz-level accelerometry data) were read by read.gt3x package into an R data frame (R Foundation for Statistical Computing) and transformed into 60-second epochs activity count data in 1440 minutes per day (12 AM to 11:59 PM) analytic format. The activity counts are vector magnitude-based activity counts.

The following criteria were applied to define valid days: (1) intervals of 90 minutes or longer with all minute-level activity counts equal to 0 were defined as nonwear intervals [18], (2)

XSL•FO
RenderX

valid days were defined as those with total wear-time ≥90% of the day (≥1296 minutes of wear), and (3) each participant should have ≥3 valid days of accelerometry data.

When a wear period overlapped with the transition to or from daylight saving time, the following adjustments were made. If the clock was set 1 hour forward, 1 hour of data were missing, so imputation was used by averaging the same hour from other valid days for this participant. If the clock was set 1 hour back, duplicate data were generated for that hour; in this instance, we used the average of the duplicated hour, and the loss of 1 hour on the final day was imputed by averaging the same hour from the other valid days for this participant. The wear period overlapped with the transition to or from daylight saving time for only 5 participants.

Accelerometry measures in this study are presented as averages over all valid days and included (1) measures of volume and intensity: total activity count (TAC; daily and 2-hour specific), total log-transformed activity count (TLAC), the total daily number of nonactive minutes, the number of minutes spent in moderate to vigorous physical activity (MVPA), and the number of minutes spent in light intensity physical activity (LIPA); (2) measures of composition: MVPA/LIPA (the ratio of the time spent in MVPA over the time spent in LIPA) and MVPA/nonactivity (the ratio of the time spent in MVPA over the time spent nonactive); (3) measures of fragmentation: sedentary-to-active transition probability (SATP) and active-to-sedentary transition probability (ASTP) [19,20]; and (4) diurnal landmarks of rest-activity rhythms: average log acceleration during the most active 10 hours of the day (M10), midpoint of M10, average log acceleration during the least active 5 hours of the day (L5), midpoint of L5, daytime activity ratio estimate (DARE), amplitude, relative amplitude (RA), midline estimating statistic of rhythm (MESOR), acrophase, intradaily variability (IV), and interdaily stability (IS) [21].

The following sample-specific cut points were developed for discriminating between nonactive, LIPA, and MVPA minutes: (1) nonactive minute was defined as a minute with activity counts ≤2000, (2) LIPA minute was defined as activity counts >2000 and ≤6750, and (3) MVPA minute was defined as activity counts >6750. These cut points were specific to our cohort and defined based on an internal calibration procedure that maximized concordance between accelerometry-based estimates and the participants' self-reported physical activity outcomes in the IPAQ (Table S1 and Figure S2 in Multimedia Appendix 1 [22]). Our derived cut points were similar to those defined in other population cohorts [22-24]. Rather than using predetermined cutoffs reported in the literature, we believe this method was more suitable for this study due to different cohort demographics and clinical conditions that may alter average physical activity intensity.

Statistical Analyses

All statistical analyses were conducted using R (version 4.3.1; R Foundation for Statistical Computing). Descriptive statistics of the demographics, clinical data, and accelerometry measures for each of the 3 groups were summarized as mean (SD) or median (IQR). Differences between the combined RRMS group (RRMS-Stable and RRMS-Suspected progression) and PMS group were compared using *t* tests and Pearson χ^2 test as appropriate. After adjusting for age, sex, and BMI, a logistic regression model was fitted to evaluate the association of each accelerometry metric with odds of PMS (vs RRMS). We also evaluated the association of accelerometry metrics in differentiating the RRMS subtypes (RRMS-Suspected progression vs RRMS-Stable). To account for differences in duration and timing of sleep, sensitivity analyses were performed by re-exploring the same accelerometry-derived measures within the most active 10 hours of each day (M10) rather than the 24-hour daily total.

Functional Principal Component Analysis

Functional principal component (fPC) analysis, applied to diurnal rest-activity rhythms (minute-level activity profiles), captures main patterns of temporal allocation of activity and provides important diurnal landmarks. The choice of the first 5 fPCs as measures of circadian rhythmicity is based on 2 factors. First, they capture most of the diurnal variability (76%) in our data. Second, the use of fPC analysis in accelerometry studies of diurnal rest-activity rhythms in large national cohorts such as the National Health and Nutrition Examination Survey (NHANES) and the UK Biobank mostly focuses on the first 4 fPCs since functional principal components beyond the 4th typically capture a relatively low proportion of variance in the data, and their shapes tend to be very difficult to interpret due to their very dynamic shape [25-27]. Nevertheless, in our case, the fifth fPC explained a significant proportion of the total variability (4%) and was also included. Figure S3 in Multimedia Appendix 1 shows that the additional fPCs beyond the 5th did not provide meaningful explanations of variability.

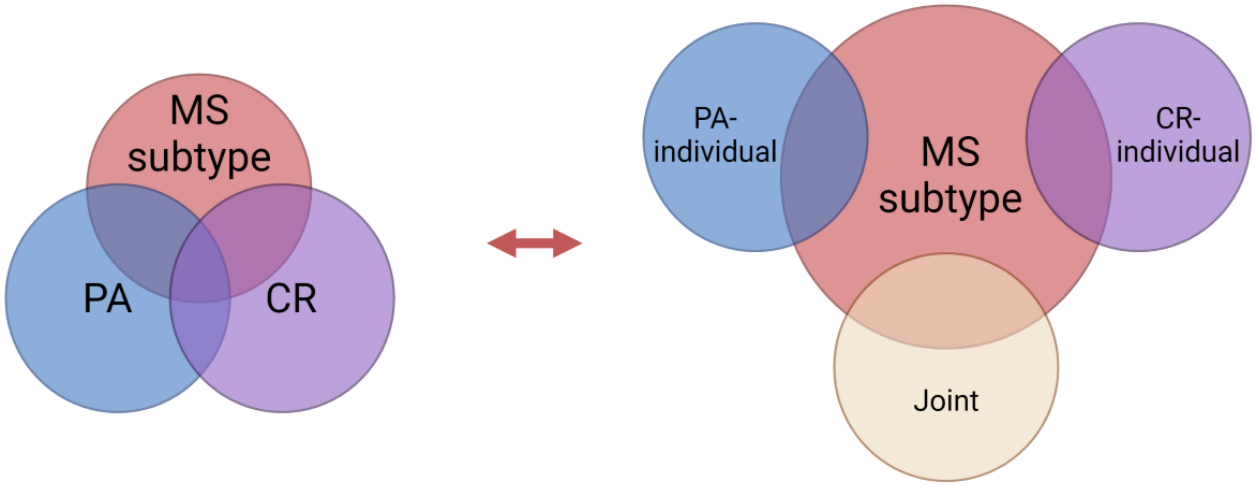
Joint and Individual Variation Explained

The Joint and Individual Variation Explained (JIVE) is an integrative dimension reduction technique that can be applied to multiple features grouped within several domains [28]. The physical activity (PA) domain was characterized by measures of total volume of physical activity, times spent in different intensities of activity and composition ratios of those times, measures of activity fragmentation/continuity, and temporal-local measures of total activity presented in 2-hour bins. The circadian rhythmicity (CR) domain was characterized by measures of the strength of circadian rhythms (RA and related components such as M10 and timing of M10), measures of variability including IS and IV, parametric measures extracted from the cosinor model (MESOR, amplitude, acrophase), and the first 5 fPCs. There is a significant amount of interdependence between the PA and CR domains since the measures belong to the same participants over the same time frame. Variations in PA and CR domains that are independent from each other are also expected. JIVE is a model developed to explore such situations and to decompose the joint and individual effects [29]. Figure 1 demonstrates the conceptual representation of the benefits of JIVE to better understand the association between MS subtype and the joint and individual variation of PA and CR domains. We applied JIVE to the domains of PA and CR to create three groups of latent variables that explain (1) joint variation shared across PA and CR, (2) individual variation

XSL•FO
RenderX

specific to each of the domains, and (3) remaining unexplained variation.

Figure 1. Conceptual representation of associations between multiple sclerosis (MS) subtype and the physical activity (PA) and circadian rhythm (CR) domains performed in standard regression modeling (left) versus the associations between MS subtype and 3 sets of independent (uncorrelated) latent variables representing joint-PA-CR, individual-PA, and individual-CR information after JIVE (Joint and Individual Variation Explained) decomposition (right). Regression analysis with JIVE components as predictors can reveal and distinguish joint and individual associations between the PA and CR domains and MS subtype.



Ethical Considerations

The study was approved by the institutional review board at Johns Hopkins University (IRB00243681). All participants provided written informed consent and had the ability to opt out at any point. All data are stored on REDCap (Research Electronic Data Capture), and only study members who are approved by the institutional review board have access to the data. The data are deidentified to the greatest extent possible. All participants received US $40 as compensation for the baseline visit to offset study-related travel and parking costs. All study procedure costs, including shipping of the ActiGraph, were covered as part of the study.

Results

Demographics and Clinical Outcomes

A total of 275 people with MS completed a baseline study visit as part of the HEAL-MS study; 253 had retrievable accelerometry data and were included in this baseline analysis (16 never returned the device, while 6 had insufficient valid days). Participants were divided into three groups: 86 with RRMS-Stable, 82 with RRMS-Suspected progression, and 85 with PMS. Baseline visits occurred between January 2021 and March 2023. Table 1 shows the demographic and clinical data for the 3 groups.

Accelerometry Measures Over 24 Hours

Figure S4 in Multimedia Appendix 1 shows the raw accelerometry data for 1 participant over the course of the week. The fPCs captured important temporal or diurnal landmarks (Figure 2) and are comparable to those captured in large national surveys such as UK Biobank and NHANES [25,27]. Accelerometry metrics for the 3 groups are shown in Table 2. TAC and MVPA, the 2 main measures of daily physical activity volume, as well as M10, amplitude, and MESOR, measures of circadian rhythmicity, were significantly different between the RRMS and PMS groups, with greater intensity of activity in

XSL•FO
RenderX

the RRMS groups compared to the PMS group. ASTP was also significantly different, with higher values (more frequent transitions to sedentary time) in the PMS group. When TAC was divided into 2-hour windows, it was significantly lower in the PMS group at specific times of the day (6 AM to 12 PM and 2 PM to 10 PM; Figure 3). Figure S5 in Multimedia Appendix 1 demonstrates the correlation plot for all accelerometry measures; the green box demonstrates the temporal profiles of the circadian measures associated with TAC over 24 hours. MESOR, amplitude, and fPC1 are highly correlated with TAC between 9 AM and 8 PM.

As an additional reference, the logistic regression *P* values are shown with the TAC 2-hour intervals used as predictors, after adjusting for age, sex, and BMI. MS: multiple sclerosis; PMS: progressive multiple sclerosis; RRMS: relapsing-remitting multiple sclerosis.

In multivariable-adjusted models (Table 3), participants with PMS had lower TAC (β=−0.32, 95% CI −0.61 to −0.03; *P*=.03), lower MVPA (β=−.01, 95% CI −0.02 to −0.004; *P*=.004), lower M10 (β=−0.0006, 95% CI −0.001 to −0.0002; *P*=.003), and higher ASTP (β=5.68, 95% CI 1.86-9.50; *P*=.004) when compared to those with RRMS. PMS (vs combined RRMS) was also associated with lower TAC from 8 AM to 12 PM and from 2 PM to 8 PM (Figure 3). Lower values of compositional ratios MVPA/LIPA and MVPA/nonactive were also associated with PMS (vs RRMS), indicating that individuals with PMS tend to spend relatively less time in moderate/vigorous activity compared to the time in light intensity activity or nonactivity (Table 3). Participants with PMS also had lower amplitude (β=−0.0004, 95% CI −0.0008 to −0.0001; *P*=.01), lower MESOR (β=−0.0009, 95% CI −0.002 to −0.0002; *P*=.01), higher IV (β=4.64, 95% CI 1.45-7.84; *P*=.004), lower IS (β=−4.43, 95% CI −8.77 to −0.10; *P*=.045), and lower fPC1 (β=−0.39, 95% CI −0.69 to −0.09; *P*=.01) (Table 3). There were no significant associations of accelerometry measures between RRMS subgroups except for a difference in RA (β=−5.26, 95% CI −10.80 to −0.20; *P*=.049), with lower RA in RRMS-Suspected progression (Table 3; Figure S6 in Multimedia Appendix 1).

Accelerometry Measures Within M10

To account for differences in duration and timing of sleep, the accelerometry metrics were explored within the M10 period. The results are summarized in Table S2 in Multimedia Appendix 1. TAC, MVPA, and ASTP remained significantly different between the RRMS and PMS groups. Additionally, the PMS group displayed more nonactive time compared to the RRMS group. Logistic regression identified significant associations between the MS subtype (PMS vs RRMS) and TAC, MVPA, nonactive minutes, ASTP, and MVPA/LIPA (Table S3 in Multimedia Appendix 1). No significant associations were identified when comparing the 2 RRMS subgroups.

The JIVE Components

We also applied JIVE, a novel integrative dimension reduction technique. Figure 1 presents the conceptualized diagram of JIVE decomposition and how JIVE can be used to better understand codependencies between PA and CR domains and their joint and individual association with MS subtype. Figure 4 shows the estimated JIVE components obtained from the accelerometry-derived domains of PA and CR. The directions of loadings (+ or −) and squares of loadings for the estimated JIVE joint component and individual PA and CR components are shown in Tables 4 and 5, and Table S4 in Multimedia Appendix 1, respectively. Higher positive scores of the first joint JIVE component primarily represent lower volume of physical activity (captured by TAC) and weaker circadian rhythms (captured by M10, MESOR, amplitude, and fPC1) (Table 4). Higher positive individual PA-1 scores capture less frequent transitions to active behavior (SATP), less time spent in LIPA (LIPA, LIPA/nonactive, TLAC), and more time spent nonactive. Higher positive individual PA-2 scores capture more time spent in MVPA (MVPA, MVPA/LIPA, MVPA/nonactive) and more activity in the morning and evening hours (TAC 8 to 10 AM and TAC 6 PM to 12 AM) (Table 5). Joint JIVE component and individual PA-1 and PA-2 components were found to be significantly associated with MS subtype (Table 6). No significant associations were identified when comparing the 2 RRMS subgroups.

Discussion

Principal Findings

This cross-sectional analysis was conducted to determine if a set of detailed accelerometry-derived summary measures of physical activity and circadian rhythmicity distinguishes between MS subtypes. As an extension of the work we and others had previously published, in which physical activity counts were on average lower in those with MS who were more disabled [9-11], we show here that participants with PMS exerted less total daily volume of physical activity than those with RRMS, and that these differences seemed more pronounced during specific times of the day. Sensitivity analyses to account for differences in timing and duration of sleep using the accelerometry metrics during the M10 period demonstrated very similar findings, which, if confirmed in subsequent studies, might help improve the feasibility of data collection (eg, if participants are not eager to wear the device overnight).

This work newly demonstrates that beyond average overall activity measures, specific PA indices had stronger discriminative properties than others in distinguishing PMS from RRMS. For example, those with PMS were more likely to transition from active to nonactive behavior (higher ASTP) and had less time spent in MVPA, instead favoring a greater amount of time in which they are inactive or only lightly active. ASTP may be a complementary measure of functionality to the measures of volume of daily activity such as TAC and MVPA. In the general population, higher ASTP is associated with worse health and functional status and higher fatiguability in older adults [20]. Our findings are consistent, as people with PMS have overall greater disability and symptoms. Therefore, it may be useful for future studies to explore novel measures of fragmentation of physical activity to determine indices that could better distinguish MS subtype.

Although differences in patterns of activity were demonstrated between the PMS and RRMS subgroups, exploring accelerometry-measured sleep and circadian/diurnal rhythmicity may discern even more significant differences. For example, we previously demonstrated that among people with MS, diurnal variability is greater in those with higher EDSS [9]. Herein, we confirmed that differences in TAC within specific times of the day (8 AM to 12 PM; 2 PM to 8 PM) appeared to drive the daily average activity measures. Participants with PMS also had higher IV and lower IS, further demonstrating the importance of detecting differences in diurnal rhythmicity between the 2 groups. The observed differences in our cohort herein serve as motivation for further exploration with more advanced analytical techniques beyond the use of averages of daily CR measures. Our next steps will include further investigation of more complex measures of fragmentation of physical activity, distributional and temporally local distributional characteristics of activity, and parameters of sleep and circadian disruptions [19,28,30-32].

An application of JIVE demonstrated a significant overlap between variation in physical activity and circadian rhythmicity domains. Joint component 1 was significant and was primarily driven by the total volume of PA along with measures of strength of CR (M10, fPC1, MESOR, amplitude), suggesting that a joint study of these 2 domains may provide a more accurate picture and capture the interdependence between the domains and their combined association with MS subtype. The significant association of MS subtype with the individual PA-1 and PA-2 components confirmed the results from the standalone associations of individual measures with MS subtype. Specifically, more fragmented physical activity profiles with

XSL•FO
RenderX

lower times spent in MVPA and LIPA can be used to differentiate PMS and RRMS.

Accelerometry did not distinguish between the RRMS subgroups cross-sectionally. Correctly classifying people with MS as having transitioned from RRMS to PMS often takes several years and is usually done retrospectively [33]. In designing this cohort, we hypothesized that data acquired in the early phase of cohort follow-up would predict subsequent worsening as measured by EDSS and that accelerometry may help to reduce the time of diagnostic uncertainty. Since we report only cross-sectional data, we did not expect substantial differences between the RRMS groups, especially as these groups were matched for key characteristics (age, sex, race or ethnicity, and disease modifying therapy class). Longitudinal tracking of the participants will allow for tracking within-person changes in disability trajectories. Whether including additional features of accelerometry data, such as more advanced measures of sleep or circadian rhythm, will better distinguish RRMS subpopulations even at a single time point will be an important next step.

Finally, although our findings are currently not immediately applicable in clinical practice, the study suggests it may be possible to alert clinicians about certain patterns in 24-hour behaviors that may affect the lives of people with MS. Though it can be difficult to clinically distinguish PMS from RRMS, accelerometry measures appear to detect distinct patterns of activity. People with PMS seem to have increased variability and fragmentation of their activity patterns, and intermittently reduced function is commonly reported, subjectively, by people with more advanced MS during clinical visits. This increases the confidence that accelerometry can in fact measure clinically meaningful patterns in people with MS. It is important for future efforts to recapitulate these findings with commercial accelerometers in order to support scalability and to translate the findings into results that clinicians and patients can easily understand and monitor over time. For instance, the increased variability in people with PMS indicates that their experience of their disease may be very different from the clinical picture evident during their clinical visits. A discussion with patients regarding their physical activity, supplemented by accelerometry data, could shed light on other aspects of their lives that should be acknowledged. Understanding when patients are likely to be at their peak activity levels may help plan their day better (when to plan effortful tasks or schedule breaks) and may inform lifestyle modifications such as exercise or even physical therapy interventions to evaluate for improvements.

Limitations

There are limitations to the study. The classification of RRMS as stable versus suspected progression is subjective, and it is likely that some of these individuals were misclassified, where a stable person was deemed as having suspected progression or vice versa, which could contribute to the lack of ability to detect differences in accelerometry measures between the 2 RRMS groups. We chose to create this subclassification to mirror the "clinical intuition" whereby physicians and, often, their patients worry they are progressing even if they do not meet the criteria for sustained EDSS worsening, and we wanted to be sure that sufficient numbers of such people were enrolled in the study. The longitudinal trajectories of the participants with RRMS will be informative; since all are at risk, based on age, of transitioning to a PMS phenotype, we can evaluate this risk as it relates to accelerometry measures not only using these subjective subtypes but also using a more agnostic, data-driven approach within the participants with RRMS subgroup as a whole. Another potential bias related to our study is the Hawthorne effect, where participants could potentially alter their physical activity because they were being monitored. Although this risk cannot be eliminated, it was minimized by disabling the features that display activity levels on the ActiGraph monitors (ie, the number of steps); only the time of day was displayed. It is possible that relevant comorbidities were missed during chart review although this is unlikely to affect a substantial enough proportion of individuals to meaningfully have influenced results. Finally, this is a cross-sectional study, and we will be able to better explore the dynamic changes in activity measured by accelerometry as well as fluctuations in the EDSS with the longitudinal follow-up, which will provide deeper insight into the evolution of MS progression measures.

Conclusions

In conclusion, accelerometry-derived measures captured differences in physical activity and circadian rhythm profiles between people with PMS and RRMS. Further analytic approaches that consider more sophisticated approaches to time (such as circadian patterns) may help further refine the ability to detect differences between these subgroups at a single time point, whereas longitudinal follow-up is most likely to allow for the identification of accelerometry patterns that portend subsequent disability worsening as defined by EDSS. We specifically hypothesize that the measures that distinguish PMS from RRMS at baseline will be those to change first in the participants with RRMS who transition to PMS in the longitudinal follow-up of this cohort. Enabling the identification of MS progression or risk may help with clinical decision-making (such as choosing an appropriate disease-modifying therapy for a given person) or may enable advancements in telemedicine by tracking functions remotely. More importantly, these technologies will likely facilitate therapeutic development for PMS by improving disability detection and worsening, alone or in combination with other metrics such as neuroimaging, which will enable faster and smaller trials of promising interventions.

Abstract

Background: Older adults with a history of falling often encounter challenges in participating in group exercise programs. Recent technological advances, such as activity trackers, can potentially enhance home-based exercise programs by providing continuous physical activity monitoring and feedback.

Objective: The aim of the study is to explore whether integrating wearable activity trackers with a home-based exercise intervention is effective in reducing fear of falling and improving physical function in older adults.

Methods: This was a 12-week, parallel-group, randomized controlled trial involving 30 older adults (≥60 years) with a history of falling. Participants were randomly assigned in a 1:1 ratio to either a group combining an activity tracker with a home-based multicomponent exercise intervention, which included in-person exercise sessions, exercise videos, and objective feedback via phone calls (AT+EX group) or to a group using the activity tracker only for self-monitoring (AT-only group). The primary and secondary outcomes included fall-related parameters (fear of falling assessed by the Activities-Specific Balance Confidence [ABC] and the Falls Efficacy Scale-International [FES-I] scales), depression (Short Geriatric Depression Scale), cognition (Montreal Cognitive Assessment), physical function (grip strength, Short Physical Performance Battery, Timed Up and Go [TUG] test, and 2-Minute Step Test), and body composition. Changes in the average daily step count were monitored and analyzed.

Results: Overall, 28 (mean age 74.0, SD 6.4 years; n=23, 77% female) participants completed the 12-week follow-up period (28/30, 93%). In the activity tracker and exercise group (AT+EX group), significant improvements were observed in fear of falling (15.5 points of ABC: *P*=.002; –5.1 points of FES-I: *P*=.01). The activity tracker alone group (AT-only group) also showed a significant improvement in FES-I score (–5.5 points: *P*=.01). Physical function significantly improved in the AT+EX group (1.1 points of Short Physical Performance Battery: *P*=.004; –1.4 seconds of TUG; *P*=.008; and 26.7 steps of 2-Minute Step Test: *P*=.001), whereas the AT-only group showed significant improvement only in the TUG test (–1.3 seconds: *P*=.002). However, no significant between-group differences were observed in the ABC score, FES-I score, or physical function. Despite no significant increase in daily step counts, both groups maintained close to 10,000 steps per day throughout the 12 weeks.

Conclusions: Both groups showed improvements in the FES-I and TUG test scores without significant between-group differences. Wearable technology, with or without an exercise intervention, seems to be an effective tool in reducing the fear of falling and improving physical function in older adults susceptible to falls.

Introduction

Falls are a significant health issue in older adults and are among the most prevalent geriatric syndromes [1]. The consequences of falls can be severe, resulting in injuries such as fractures, bleeding, and disability, leading to increased health care costs [2]. Falls increase the likelihood of nursing home admissions among older adults and are a leading cause of accidental death [3]. According to the Centers for Disease Control and Prevention, 27.6% of individuals aged >65 years in the United States reported falling during the previous year, and 38,742 (78.0 per 100,000) died from unintentional falls in 2020 [4]. In Korea, the 2017 National Survey of Korean Elderly reported that 15.9% of older adults experienced falls in the past year, with an average of 2.1 falls per person [5]. A history of falls is a significant risk factor for future falls, as approximately 1 in 2 individuals who have experienced falls may experience recurrent falls [6]. Additionally, the fear of falling, characterized by anxiety concerning falling or a loss of confidence in certain activities, leads to decreased physical activity and an increased risk of further falls [7].

Numerous studies have demonstrated the effectiveness of exercise interventions in preventing falls and improving physical function in older adults [8,9]. Each type of exercise (ie, resistance, aerobic, and balance training) has specific benefits, and incorporating high-challenge balance training in exercise programs is particularly emphasized for fall prevention [9,10]. Resistance training is reportedly effective in preventing age-related decline in muscle function, especially with high-intensity training [11]. Clinical guidelines from leading health and geriatric organizations recommend that older adults participate in multicomponent exercise programs, including balance and resistance training, as well as aerobic and flexibility activities, to improve physical function and reduce the risk of falls [12-14].

Effective doses and consistent exercise are crucial for maintaining health in older adults [9]. However, adherence to home-based exercises is typically lower compared to that for community-based exercises, and self-reported physical activity levels often exceed actual levels [15]. Although many group exercise programs have been conducted for older adults in the community, the onset of the COVID-19 pandemic has made it challenging to continue group exercise sessions [16]. Moreover, factors, such as low confidence in physical activity and self-efficacy, further hinder participation in group exercises [17]. Older adults also face restrictions in participating in physical activity programs because of physical and mental health issues (ie, risk of injury, joint pain, and fear of falling) and structural and organizational barriers (ie, access to facilities, limited infrastructure, and cost) [18].

Recently, various wearable devices have been developed and are increasingly used as popular devices for monitoring physical activity. Activity trackers provide individuals with objective measures of physical activity levels and enable health professionals to offer precise feedback and sustained support [19]. The use of activity trackers, either as the primary element or within a broader behavioral intervention, effectively increases physical activity participation [20]. Moreover, integrating activity trackers with traditional intervention components is more effective than using an activity tracker alone [21].

Despite these advancements, there is a lack of research on the integration of activity trackers with other multifaceted interventions for falls in older adults [22,23]. Furthermore, to date, no study has evaluated the effect of combining activity trackers with home-based multicomponent exercises in older adults. Therefore, our aim was to assess the effectiveness of integrating activity trackers with home-based interventions in older adults with a history of falls. We hypothesized that combining an activity tracker with a home-based multicomponent exercise intervention (activity tracker and exercise group [AT+EX group]) would result in greater improvements in fall-related parameters and physical function compared to using an activity tracker alone (activity tracker alone group [AT-only group]).

Methods

Study Design

This 12-week, parallel-group, randomized controlled trial involved older adults aged ≥60 years with a history of falls and COVID-19 in Anyang, Gyeonggi-do, South Korea. Participants were randomly assigned in a 1:1 ratio to either the AT+EX or AT-only group. The AT+EX group received multicomponent exercise sessions, exercise videos, and objective feedback from an activity tracker, whereas the AT-only group received activity trackers without additional interventions. A CONSORT (Consolidated Standards of Reporting Trials) checklist was completed to guide the design, analysis, and reporting of trial findings (Checklist 1).

Participants

Participants were recruited through poster advertisements, flyers, word-of-mouth referrals, and visits to local senior welfare centers. Eligible individuals met the following criteria: (1) aged ≥60 years, (2) history of COVID-19 infection within 1 year from their first study visit, (3) experience with falls, (4) ownership of a smartphone compatible with wearable devices, (5) ability to walk independently without assistance, and (6) voluntary decision to participate in the study with a signed informed consent form before participation. The exclusion criteria were as follows: (1) diagnosis of cognitive decline or dementia and (2) contraindications to exercise, including myocardial infarction within the last 3 months, unstable angina pectoris, uncontrolled diabetes, or musculoskeletal disease that prevented exercise.

Sample Size Calculation and Randomization

According to Giné-Garriga et al [24], the difference in Activities-Specific Balance Confidence (ABC) scale scores between the functional circuit training group and the routine daily activity control group was 6.65 points [24]. Based on this score difference, assuming a type 1 error of 0.05, statistical power of 80%, and an anticipated dropout rate of 20%, 26 (13 per group) participants were required. Therefore, 30 participants were recruited, 15 of whom were assigned to each group. The research team recruited the participants for the trial. A person

XSL•FO
RenderX

who was not involved in the trial carried out randomization. After completing the baseline surveys, the participants were randomly assigned to the intervention (AT+EX group) or control group (AT-only group) using block randomization and randomly selected block sizes of 2, 4, or 6. Blinded assessors evaluated fall-related parameters, body composition, and the data of mean daily step counts from activity trackers.

Intervention

All participants were provided with a wearable activity tracker (HL5, Seven Elec) and its corresponding application. The participants received an individual information session on how to use, pair, and charge the activity tracker during their first visit and were advised to wear the tracker on their wrists throughout the 12-week study period. The activity tracker data were paired and synchronized with the Health & You app on a mobile device. The daily step goal was set at 10,000 steps, and adjustments were made only if necessary, based on the participant's physical ability and current activity levels. The step goals remained consistent throughout the 12 weeks. Participants could track their daily steps via the activity tracker and mobile phone app and were required to synchronize their device with the app at the end of each day. The researcher could view the participants' activity tracker data on the admin page.

The AT-only group received education on the use of an activity tracker and educational materials for general fall prevention exercises. This group focused on self-monitoring using a wearable device to increase daily physical activity and did not receive any exercise interventions or feedback. Participants in the AT-only group visited the clinic at baseline and after 12 weeks.

The participants randomized to the AT+EX group received an activity tracker and participated in a home-based fall exercise intervention program. The exercise intervention included 4 in-person sessions (weeks 1, 3, 6, and 9) conducted at either a hospital or a senior welfare center. Each session was conducted by a certified exercise trainer and at least 1 assistant, with 1 - 6 participants. The exercise protocol was specifically designed to prevent falls in older adults, including balance, resistance, aerobic, and multitask training, which are effective in preventing falls [9,10,13]. Each 1-hour exercise session consisted of 5 minutes of stretching, 15 minutes of balance training, 15 minutes of strength training, 15 minutes of gait and aerobic exercise, and 10 minutes of multitask training. Over the 12-week intervention period, the exercise protocol consisted of 3 phases (first, second, and third stages), with a gradual increase in intensity between each phase. The detailed exercise program for each level is described in Multimedia Appendix 1. All participants in the AT+EX group were provided exercise equipment (step boxes, TheraBands, and yoga mats). To support consistent exercise at home, the participants received exercise videos that followed the same protocol as the in-person sessions. They were asked to exercise at least thrice a week to meet the physical activity recommendations for older adults [13]. Throughout the 12-week study period, the participants received 6 physical activity counseling phone calls (weeks 2, 4, 5, 7, 10, and 11). Phone calls were conducted by a researcher (YK) with a master's degree in exercise physiology, who followed the same protocol for all participants. Each call included feedback on physical activity levels derived from their activity trackers, aiming to motivate participants to initiate and sustain their physical activity and exercise routines. Additionally, the participants were asked concerning their recent health status, barriers to participation in the study, and any issues with using their wearable devices.

Fall-Related Parameters

The primary outcomes were fall-related parameters, including fear of falling, depression, and cognitive function, all evaluated using the Korean version and measured at baseline and 12 weeks. Fear of falling was measured using the ABC scale and Falls Efficacy Scale-International (FES-I). The ABC scale was used to assess the individuals' confidence in performing various activities without losing balance or falling [25]. The questionnaire included 16 items, with scores ranging from 0%=no confidence at all to 100%=completely confident. The overall score was calculated by averaging the scores for all 16 items. The FES-I measures self-efficacy and fear of using 16 items, each rated on a scale of 1=not at all concerned to 4=very concerned. The total score ranged 16 - 64 points, with higher scores indicating a greater fear of falling [26]. Depression, which is closely related to the fear of falling among older adults, was assessed using the Short Geriatric Depression Scale (SGDS), a reliable and valid self-administered questionnaire designed to screen for depression in older adults [27]. The SGDS comprises 15 yes-or-no questions, with higher scores indicating a more depressed mood. The Montreal Cognitive Assessment, a tool for screening mild cognitive impairment, was used to assess cognitive function. Scores range 0 - 30 points, with scores of ≤22 points indicating mild cognitive impairment [28].

Physical Function

Physical function was assessed at baseline and 12 weeks by the same assessor using the same protocol. Grip strength is a key measure used to assess overall health and muscle strength, particularly in older adults [29]. This was assessed using a calibrated digital dynamometer (Takei 5401-C; Takei Scientific Instruments; in kilograms). Individuals were asked to squeeze the dynamometer with maximum effort, performing 3 alternating measurements on each side. The highest values obtained from these trials were used in this study. According to the Asian Working Group for Sarcopenia, low grip strength is defined as <28 kg for male and <18 kg for female participants [30]. The Short Physical Performance Battery (SPPB) is used to assess lower-extremity function and physical performance in older adults [31]. The SPPB includes 3 components: balance tests (side-by-side, semitandem, and tandem stances), a gait speed test (4-m distance), and a 5-time sit-to-stand test. Each component was scored 0 - 4 points, with a total score ranging 0 - 12 points. Higher scores indicate better performance. A change of ≥1 point in the SPPB score was considered a clinically important difference [32]. The Timed Up and Go (TUG) test was used to assess balance and mobility. Each individual was asked to rise from a chair and walk 3 m, turn around, walk back to the chair, and sit down. The time taken to complete the task was measured in seconds. A shorter time indicated better mobility. Scores of ≥13.5 seconds indicate a high risk of falling

XSL•FO
RenderX

[33]. The 2-Minute Step Test (2MST) was used to assess aerobic capacity and endurance as an alternative aerobic endurance test in environments with limited space [34]. The participants were instructed to march in place for 2 minutes, lifting their knees midway between the patella and the iliac crest as many times as possible. Performance was measured by counting the number of right-sided steps completed within the 2-minute period. Higher step counts indicated better aerobic endurance.

Body Composition

Anthropometric measurements were obtained from the participants at baseline and at 12 weeks while wearing light clothes and no shoes, except for height, which was measured only at baseline. Height measurements were recorded to the nearest 0.1 cm using a stadiometer, while weight measurements were recorded to the nearest 0.1 kg with a digital scale. BMI was calculated by dividing weight by height squared (kg/m^2). Body composition was assessed using a dual-energy x-ray absorptiometry scanner (Lunar Prodigy Advance; GE Healthcare Technologies). The total fat, total lean, and appendicular muscle masses were determined. Appendicular muscle mass was calculated as the sum of the lean mass in both arms and legs divided by the square of height (kg/m^2).

Demographics

Basic demographic factors were assessed at baseline and included age, sex, marital status (single, married, widowed, or divorced), education level (college or higher, high school, middle school, or elementary school), occupation (working or not working), number of falls in the previous year, and the presence of comorbidities (eg, hypertension, diabetes, cancer, and other chronic diseases, such as cardiovascular and musculoskeletal disorders).

Mean Step Counts

The mean daily step count was assessed using data from activity trackers and was calculated based on the number of steps recorded over a specific week. The baseline step count was defined as the mean number of daily steps in the first week (days 1 - 7) after the initial visit. Subsequent steps were recorded as the daily average steps between each exercise session (weeks 1, 3, 6, and 9), and the final average steps were recorded from the fourth exercise session to the final visit (week 12). For the AT-only group, average daily step counts were recorded during the same period as those for the AT+EX group, specifically at weeks 1, 3, 6, 9, and 12. Participants with <50% wear days during these periods were excluded from the analysis. Additionally, days with <500 steps were considered nonwear days and excluded from the step count calculations [35].

Statistical Analysis

Continuous variables are presented as means and SDs, while categorical variables are presented as frequencies and percentages. The baseline characteristics of the AT+EX and AT-only groups were examined using independent 2-tailed *t* tests for continuous variables and chi-square tests for categorical variables. Outcome data, including all available data, were analyzed using the intention-to-treat approach. When data were missing due to dropouts of participants, we used the last observation carried forward method to impute missing values. Initially, independent 2-tailed *t* tests or Mann-Whitney *U* test were used to determine whether there were any significant baseline differences between the 2 groups in fall-related outcomes, physical function, and body composition. Subsequently, to compare changes from baseline to 12 weeks (Δ values) between the groups, independent 2-tailed *t* tests or Mann-Whitney *U* tests were conducted. Paired 2-tailed *t* tests or Wilcoxon signed rank tests were used to evaluate within-group changes from baseline to 12 weeks. The change in average daily step count over the 12-week study period was analyzed using a mixed-effects model for repeated measures to account for within-participant correlations. The change in the average daily step count was calculated by subtracting the mean step count at baseline from that at each subsequent visit (weeks 3, 6, 9, and 12). Subgroup analyses were conducted for individuals with SPPB scores ≤9 (low physical performance). All statistical analyses were conducted using SPSS statistical software (version 26.0; IBM Corp) and R software (version 4.2.0; R Foundation for Statistical Computing), with statistical significance set at $P<.05$.

Ethical Considerations

This study was approved by the institutional review board of Hallym University Sacred Heart Hospital (HALLYM 2022-10-020) and conducted in accordance with the tenets of the Declaration of Helsinki. The study was registered with the Clinical Research Information Service on February 23, 2023 (KCT0008230). All participants provided written informed consent after receiving a comprehensive explanation of the study objectives, procedures, and their right to withdraw at any time. To ensure confidentiality, all data were anonymized and restricted to authorized researchers. Participants received a transportation allowance of US $34.97 as compensation.

Results

Baseline Characteristics

Recruitment occurred from February to August 2023 until the target sample size was achieved. Overall, 30 participants were enrolled and randomly assigned to either the AT+EX or the AT-only group (Figure 1). The baseline characteristics of the study participants are presented in Table 1. The mean age of the participants was 74.0 (SD 6.4) years, and 77% (23/30) were female participants. A significant difference was observed in body weight, with participants in the AT+EX group (mean 55.1, SD 8.6 kg) having a significantly lower body weight compared to those in the AT-only group (mean 62.0, SD 9.1 kg; $P=.04$). No significant differences were observed in BMI, marital status, educational level, occupation, number of falls during the previous year, or comorbidities between the groups.

[c]*P* values represent the differences between the AT+EX group and the AT-only group. Independent 2-tailed *t* tests were used for continuous variables and chi-square tests for categorical variables.

Fall-Related Outcomes

The intention-to-treat analyses of the primary outcomes, physical function, and body composition are presented in Table 2. Changes in fear of falling, assessed using the ABC and FES-I scores, showed significant improvement in the AT+EX group (*P*=.002 and *P*=.01, respectively). The AT-only group also showed improvements in the FES-I score (*P*=.01); the increase in the ABC score was only marginally significant (*P*=.07). Depression levels, assessed using the SGDS, significantly improved in both the AT+EX (*P*=.006) and AT-only groups (*P*=.02). Cognitive function, as measured by the Montreal Cognitive Assessment, showed no significant change in both the AT+EX (*P*=.10) and AT-only groups (*P*=.49). No significant differences were detected between the groups in any of the fall-related outcomes.

Physical Function

Regarding physical function, grip strength showed no significant change in both groups (AT+EX: 1.5 kg; *P*=.14 and AT-only: 1.7 kg; *P*=.12). The SPPB total score showed significant improvement in the AT+EX group (1.1 points; *P*=.004) but was not significant in the AT-only group (0.8 points; *P*=.09). The AT+EX group also demonstrated significant improvements in both the TUG test (1.4 seconds; *P*=.008) and the 2MST (26.7 steps;, *P*=.001), while the AT-only group showed a significant improvement only in the TUG test (1.3 seconds; *P*=.002). No significant differences were observed between the groups in terms of changes in any physical functional variables.

Body Composition

Regarding body composition, the AT+EX group showed reductions, including a significant decrease in total lean mass by 0.4 kg (*P*=.04). In contrast, the AT-only group showed nonsignificant decreases in total lean mass and skeletal muscle index (*P*=.19 and *P*=.07, respectively). No significant differences between the groups were observed in the changes of any body composition variables.

Changes in Mean Daily Steps

Figures 2 and 3 present the mean daily steps, while Table 3 details changes in mean daily steps over 12 weeks for both the overall group and the subgroup with low physical performance. At baseline, the AT+EX group averaged 11,622 daily steps compared to 9514 steps in the AT-only group, showing a mean difference of 2108 steps (95% CI –691 to 4906; *P*=.14). Throughout the 12-week study period, both groups maintained high levels of daily steps, and differences between them were not statistically significant. Over the study period, the AT+EX group decreased by 1005 (from 11,622 to 10,617) steps, whereas the AT-only group increased by 98 (from 9514 to 9613) steps.

Figure 2. Mean daily steps with SE of the mean at baseline and over specific weeks (1, 3, 6, 9, and 12) for the total group. AT+EX group: activity tracker and exercise group; AT-only group: activity tracker alone group.

[a]AT+EX group: activity tracker and exercise group.

[b]AT-only group: activity tracker alone group.

[c]*P* value for comparisons between 2 groups calculated using a mixed model. Mean daily steps were calculated over specific weeks. Baseline steps were the average of the first week (days 1 - 7). Subsequent steps were averaged between exercise sessions (weeks 1, 3, 6, and 9), and from week 9 to the final visit.

[d]Not applicable

[e]SPPB: Short Physical Performance Battery.

In the subgroup with low physical performance (SPPB scores ≤9), the AT+EX group started with 9002 steps, lower than the AT-only group's 11,659 steps, with a mean difference of 2657 steps (95% CI –7457 to 2143; *P*=.31). By week 12, the AT+EX subgroup increased by 776 steps, while the AT-only subgroup decreased by 1221 steps. However, the difference between the groups remained nonsignificant (mean difference 1997 steps, 95% CI –553 to 4547; *P*=.11).

Discussion

Principal Findings

We investigated the effects of integrating activity trackers with a home-based multicomponent exercise intervention (AT+EX group) compared to using activity trackers alone (AT-only group) in older adults (≥60 years) with a history of falls and COVID-19. Our results showed that both groups exhibited significant improvements in fear of falling (FES-I score) and depression (SGDS) as well as enhanced physical function (TUG test). Notably, the AT+EX group showed improvements in the ABC score, SPPB score, and 2MST. However, no significant between-group differences were observed in any outcome

XSL•FO
RenderX

variables. Although there is no consensus on the cutoff value of the ABC score for predicting future falls, previous studies have suggested cutoff values of <58 - 67 [36,37]. In this study, the mean ABC score at baseline was 56.5 (SD 17.8) and 57.9 (SD 18.2) in the AT+EX group and AT-only group, respectively. After the intervention, the ABC score improved significantly in the AT+EX group (15.5 points; *P*=.002) but was not significant in the AT-only group (10.2 points; *P*=.07). An increase in the ABC score reflects a reduction in fear of falling and activity limitation as well as an improvement in the quality of life of the study participants [38]. We also showed that the SPPB score improved significantly in the AT+EX group (1.1 points; *P*=.004) but was not significant in the AT-only group (0.8 points; *P*=.09) after the intervention. Better physical performance reduces the risk of mobility-related disability [32]. Although no significant increase in daily steps was observed in either group, the participants maintained a high activity level of approximately 10,000 steps per day over the 12-week study period.

To date, few trials have evaluated the impact of activity trackers on fall-related outcomes, and the results have been inconsistent. Yamada et al [23] reported that a 6-month pedometer-based behavioral change program effectively improved fear of falling, physical activity, locomotive function, and leg muscle mass compared with the corresponding in the control group (*P*<.05). Another study by Oliveira et al [22] examined the effectiveness of a fall prevention intervention with a Fitbit (Google Inc). Although mobility goal attainment improved at 6 months compared to that in the control group, no between-group differences were noted in fall rates, fear of falling, physical activity, and mobility limitation at 6 or 12 months.

Our study showed significant improvements in fear of falling and depression in both the AT+EX and AT-only groups without significant between-group differences. However, we did not observe any improvements in cognitive function. This may be attributed to the fact that our study included participants with normal cognitive function, which may have underestimated the effect on cognitive function. Given the high prevalence of depression and cognitive impairment and the close interaction between 2 common disorders among older adults [39], it would be useful to conduct future large clinical trials to demonstrate the effectiveness of exercise in patients with these conditions.

Previous studies have compared groups using activity trackers to control groups with no intervention, whereas our study compared the AT+EX group to the AT-only group. Moreover, these studies did not include direct exercise training in their interventions. Although cognitive decline and mood disorders, such as depression and anxiety, are associated with fear of falling, research on how interventions affect these variables is lacking [40,41]. Considering the effectiveness of exercise in improving physical and cognitive functions, further research is needed to explore the impact of integrating activity trackers with home-based exercise interventions on cognitive and mood parameters as well as the fear of falling.

Comparison With Prior Work

Studies on the impact of wearable devices on physical function in older adults are limited and have shown mixed results [22,23,42-48]. A few studies using pedometers or Fitbit devices reported improvements in physical function [42,44,47,48]. For instance, 2 randomized controlled trials with pedometer-based walking programs have found significant improvements in walking speed and physical performance [47,48]. Another study using Fitbit-based interventions showed improvements in the 30-second chair stand test and physical endurance [42,44]. However, some studies using wearable devices have not shown improvements in physical function [43,45,46].

In our study, both groups showed overall improvements in physical function, although no statistically significant differences were observed between the groups. However, the AT+EX group showed significant improvements in the total SPPB score, exceeding the clinically significant threshold of a 1-point improvement [31]. Moreover, the AT+EX group showed significant improvements in mobility and endurance, as measured by the TUG test and 2MST. These findings suggest that a multicomponent exercise intervention may be more effective in enhancing physical function (ie, balance, gait, mobility, and endurance) in older adults than using activity trackers alone.

The improvement in fear of falls and physical function in both groups using activity trackers may be related to the amount of physical activity. Physical activity has been associated with a lower risk of falls and improved physical function in older adults [49]. A comprehensive analysis of systematic reviews showed that the use of activity trackers is effective in increasing physical activity levels across various age groups [50]. However, we did not observe any increase in daily step counts in either the AT+EX or AT-only group over the 12-week period. There are several potential reasons for this lack of increase. First, the participants' baseline activity level was already high, and the target step count was set at a maximum of 10,000 steps per day. Those who met this goal were encouraged to sustain their activity level rather than increase it further. Second, the reactivity effect may have influenced the results; participants may have initially increased their activity levels upon realizing that their physical activity was monitored [51].

Although no significant increases were observed in daily step counts, both groups maintained close to 10,000 steps per day throughout the 12 weeks. Notably, even the AT-only group, which did not receive additional feedback, showed a consistently high step count. This suggests that setting a specific step goal and synchronizing the activity tracker data with the app provided participants with daily visual feedback, allowing them to objectively monitor their physical activity levels and maintain their daily step counts. However, considering that this study was conducted over 12 weeks, further long-term studies are required to determine the sustained effectiveness of activity trackers without additional interventions. Moreover, a subgroup analysis revealed that participants with low physical performance (SPPB scores ≤9) exhibited increased daily step counts in the AT+EX group. This indicates that the effectiveness of activity tracker use may vary based on participants' physical performance. Further research is required to identify the subgroups that benefit the most from using activity trackers.

XSL•FO
RenderX

Regarding body composition, the AT+EX group showed an unexpected substantial decrease in lean body mass. This may be attributed to the lack of nutritional intervention in this study. Inadequate nutritional support for increased physical activity may result in reductions in both fat and muscle mass [52]. Moreover, the multicomponent exercise program focused on enhancing balance and physical function rather than increasing muscle mass. Considering the inadequate protein intake of older people in Korea [53], future research should include both physical activity and nutritional interventions including protein supplementation. Further studies are required to determine the most effective exercise regimens when combined with activity trackers.

Limitations

This study had several limitations. First, the study duration was only 12 weeks, which may not have been sufficient to observe the long-term effects of the intervention. Second, the sample size was relatively small, potentially limiting the generalizability of the results to individuals who are not motivated to increase their physical activity levels. Third, the participants were already relatively active at baseline, which could have constrained the observable benefits of increased physical activity. Fourth, the study lacked a control group with no intervention, which restricted the possibility of comparing intervention effects. Fifth, participants' nutritional intake and other lifestyle changes were not controlled.

Conclusions

Although no significant between-group differences were observed, both activity trackers with and without a home-based multicomponent exercise program effectively improved fall-related parameters (fear of falling and depression) and physical function in older adults compared to baseline. Our findings underscore the potential of digital health technologies to enhance fall prevention strategies.

Abstract

Background: The usage of consumer wearables (CWs; eg, fitness trackers and smartwatches) in the population has increased enormously within the last decade. This has resulted in a large amount of digital person-generated health data that could be used to answer vital research questions. However, little is currently known about the usage of CWs to collect health data from the population living in Germany.

Objective: This study aimed to describe the ownership of consumer wearables and their usage for the collection of health data from the adult population living in Germany, as well as the motives for the collection of health data and the average wear times. In addition, this study also aimed to investigate sociodemographic and health- and behavior-related differences between the group of CW users and the group of nonusers.

Methods: We used data from the nationally representative survey "German Health Update," which was conducted through telephone interviews in 2021 and 2022. The final sample comprised 4464 adults aged 18 years and older. We derived weighted prevalences for the usage of CWs, as well as adjusted odds ratios for the ownership and the usage of CWs and their association with sociodemographic and health- and behavior-related variables.

Results: Of the adult population, 19.3% (843/4459) owned a CW, of whom 77.8% (650/842) used their CW to collect health data (which corresponds to 650/4458, 15.0% of the adult population). Older people, people with a low income, and people with a lower level of physical activity (PA) were less likely to own a CW and were less likely to use it for the collection of health data. Of the CW users who collected health data, 47.2% (321/650) wore their CW during nocturnal sleep. The most frequently named motives for the collection of health data with a CW were "to observe my PA" (544/647, 85.0%), "for fun" (508/644, 79.0%), and "for support during exercising" (423/647, 66.3%). Women chose the motive "to observe my PA" and "to increase my PA" more often than men, whereas men chose the motive "to observe health issues" more often than women.

Conclusions: Adults living in Germany owning a CW are younger, have a higher income, and are more physically active than individuals who do not use a CW. This means that the population groups that would be in particular need of health care are not sufficiently represented in these health datasets. Researchers should consider the selectivity of CW users when planning to use CW health data to answer research questions.

health survey; fitness tracker; smartwatch; selectivity; physical activity; sleep

Introduction

Background

Individuals can nowadays collect certain health-related data with commercial wearable devices (also called "consumer wearables" [CWs]) like fitness trackers or smartwatches using integrated sensor technology (eg, accelerometers, pulse oximeters, and geolocation). Therefore, CWs can track vital parameters and behaviors, such as heart rate, physical activity (PA), or sleep [1].

The usage of CWs in the population has increased enormously within the last decade. In 2022, around 500 million of these devices were sold worldwide, which means that the sales increased by the factor 16 compared with 2014 [2]. In Germany, 7.2 million CWs were sold in 2022 [3]. However, for Germany, data from adults on the ownership of CWs and their actual use to collect health data are scarce.

CW Data as Part of Public Health Surveillance

The prevalent usage of CWs in the population results in a large amount of digital person-generated health data that could be used to answer vital research questions or to support individual

XSL•FO
RenderX

health care [4,5]. Within the public health context, these CW data could supplement the monitoring of important health behaviors, like PA and sleep, within the national public health surveillance [6,7]. Public health surveillance includes the ongoing systematic collection, analysis, and interpretation of data on the population level by, for example, using questionnaires and integrating secondary data. It aims not to give personal feedback to individuals but to identify the range and extent of population-related risk factors to facilitate goal-oriented public health responses and health policies [8].

CW data as part of public health surveillance could be used to describe the PA level of the population continuously and point out trends over time. For example, it is possible to investigate whether certain events, such as heat waves or an outbreak of a pandemic, have an effect on PA and sleep behavior.

The usage of CW data collected by individuals with their own CWs produces a variety of benefits for the research community, like no expenditures on devices and data collection as well as the availability of objective data, which are often superior to self-reports [7,9]. Furthermore, the data are collected continuously by the CW users, which enables researchers to perform retrospective analyses and to observe health behavior over a longer period of time [7]. In addition, the effort required of the participants is low, as they only have to share their data via a smartphone app.

At the same time, there are challenges in using such data for research, such as privacy and security issues, technical issues and a lack of access to the raw data [9]. The algorithms used by the companies of the CWs to convert the raw data into, for example, steps or the duration of PA at different intensities, are often not disclosed [9]. This limits the comparability of CW data over time, as the algorithm may have changed, and between different devices. In addition, a further challenge is the selectivity of the population providing CW data [10,11]. Selectivity of study samples already exists in questionnaire-based observational studies (eg, lower response rates of people with a low educational level) and may increase for data collection using respondents' own CW [12]. A national survey of the US population showed that adults using a CW to monitor their health are younger, healthier, wealthier, and more educated than the general adult population [10]. The low representativeness of older adults using CWs was confirmed by a study from the United Kingdom based on nationwide datasets [13]. In addition, the authors of the United Kingdom study showed that CW users had a higher PA level than the general population. To the best of our knowledge, no study has so far investigated the usage of CWs in the population of Germany and characterized the user group.

Uncritical usage of CW data might lead to biased results that cannot be generalized to the whole population. Within this context, Ibrahim and colleagues [14] used the term "health data poverty" to describe the underrepresentation of certain groups in health datasets, which can foster health inequalities and create a digital health divide.

The first step to counteract health data poverty is to raise awareness of the existing inequalities in health datasets [14]. Therefore, knowledge about the characteristics of the group of CW users is important to be able to make informed decisions about the possibilities and limitations of such datasets and the interpretation of the results. Furthermore, the rapid development of the CW market and the increasing number of cheaper CWs will constantly change the user group, requiring regular characterization of the group of CW users.

Objective

The aim of this study is to describe the CW ownership and usage among adults living in Germany based on data from a nationally representative survey. The intentions are (1) to identify CW owners and users who collect health data and their sociodemographic and health-related characteristics as compared with the population not owning and not using a CW and (2) to gain insights into the motivations of individuals to use their CW to collect health data and their user behavior (eg, the wear time of the CW per day).

Methods

Study Design

The assessment of CW usage was integrated into the representative population-wide survey "German Health Update" (GEDA) 2021 and 2022. GEDA is a regularly conducted cross-sectional survey with the aim of describing the respondents' health status and health behavior and their influencing factors [12].

GEDA 2021 was conducted from July to December 2021 (n=5030) and GEDA 2022 from February 2022 to mid-January 2023 (n=33,149). In both surveys, telephone interviews were carried out using a programmed, structured questionnaire (computer-assisted telephone interview). The sampling is based on a random sample of mobile and landline telephone numbers (dual-frame method) [15]. The population comprised the German-speaking population aged 16 and older (until December 2021; after February 2022: 18 y and older), living in private households, and having a usual place of residence at the time of data collection in Germany. Measures have been taken to increase the response rate of people who are less likely to participate (eg, people with a low educational level and older people), such as oversampling.

The present analysis is limited to persons aged 18 years and older. The topic "consumer wearable usage" was assessed in GEDA in the periods from the end of October to the end of December 2021 (n=1986) and the beginning of February to mid-June 2022 (n=2478; total sample n=4464).

Ethical Considerations

GEDA 2021 and 2022 are subject to strict compliance with the data protection provisions set out in the EU General Data Protection Regulation and the Federal Data Protection Act. The Ethics Committee of the Charité – Universitätsmedizin Berlin assessed the ethics of the study and approved its implementation (application number EA2/201/21). Participation in the study was voluntary. The participants were informed about the aims and contents of the study and about data protection. Informed consent was obtained verbally. Participant confidentiality was maintained by pseudonymizing data and presenting results in

XSL•FO
RenderX

an aggregated format. No compensation or incentives were given for participating in the telephone interview.

Measures

Consumer Wearable–Related Variables

The questions regarding the usage of CWs were prefaced by short definitions of the terms “wearable,” “fitness tracker” and “smartwatch.” The ownership and the usage of a CW were assessed with the questions “Do you own a wearable?” (answer categories: yes or no) and “Do you currently use your wearable to measure your PA, fitness or other health data such as blood pressure or pulse?” (answer categories: yes or no).

The usage of CWs was assessed via the questions “Do you measure your PA, fitness or other health data such as blood pressure or pulse with a fitness tracker and fitness bracelet?” (answer categories: yes or no), followed by the question “On how many days per week do you wear the fitness tracker or fitness bracelet for a total of at least 8 hours per day?” (answer options: the number of days from 1 to 7 and “no day per week”). The same questions were asked to obtain information about the usage of other types of devices (we used the terms “smartwatch” and “other device” instead of “fitness tracker or bracelet”).

The usage of a CW during nocturnal sleep was assessed with the question “Do you wear any of your devices while sleeping at night?” and the answer categories were “no,” “yes, fewer than 4 nights per week” and “yes, at least 4 nights per week.” The motives for CW usage were assessed via the question “Which of the following statements apply to you? I measure my PA, fitness or other health data with a wearable or app on my smartphone...,” and the following motives could be chosen (multiple responses were possible): “to observe how active or inactive I am,” “for support during sports activities or training,” “to motivate myself to be more physically active,” “to monitor a health problem, for example blood pressure, pulse,” “to lose weight,” “to exchange or compare myself with others,” “to eat and drink more healthily,” “because it’s fun for me,” and “for other reasons”

Explanatory Variables

Gender identity was used to describe gender differences. The participants were able to indicate the gender to which they felt they belonged [16]. In the current study sample, 53.8% (2395/4454) identified themselves as female (Table 1). In the analyses by gender, individuals with a different gender identity or no indication are not shown (n=10).

Participants’ age (in years) resulted from their date of birth and the date of the survey. For the analyses, age was categorized into 7 groups: 18 to 29 years, 30 to 39 years, 40 to 49 years, 50 to 59 years, 60 to 69 years, 70 to 79 years and 80 years and older.

Education was categorized into low International Standard Classification of Education (ISCED 1 - 2), medium (ISCED 3 - 4) and high (ISCED 5 - 8) groups based on the educational and vocational qualifications of the study participants according to the 2011 version of the (ISCED 2011) [17].

Based on the self-reported monthly net income of the study participants’ households, the net equivalent income was calculated using the equivalence scale of the Organization for Economic Cooperation and Development. Missing income information was imputed using regression analysis procedures. Income groups were categorized as low (quintile 1), medium (quintiles 2 - 4), and high (quintile 5) for analyses.

For the evaluation of the participants’ subjective health status, they were asked, “How would you describe your general health status?” The five response categories were summarized in the categories “very good or good” and “medium or poor” (including fair, poor and very poor).

The achievement of the endurance-related part of the World Health Organization (WHO) recommendation for PA (at least 150 min moderate to vigorous PA per week [18]) was assessed via the German version of the European Health Interview Survey – PA Questionnaire [19]. The indicator considers the weekly duration of leisure time PA and weekly cycling for transportation. The recommendation was achieved if the sum of the described activities was at least 150 minutes per week.

Statistical Analysis

All the analyses were performed using a weighting factor that corrects for deviations of the sample from the population structure. First, a design weighting was carried out for the different selection probabilities (mobile and fixed networks), and then an adjustment was made to the official population figures with regard to age, gender, federal state, and district type (as of December 31, 2020) and in relation to education (Microcensus 2018). The analyses were carried out with Stata 17.0 (StataCorp LLC) using the survey procedures. Prevalences are reported with the corresponding 95% CI to display the range in which the true value falls with 95% probability (95% CIs are reported directly in the text or in the corresponding tables or figures). In bivariate analyses, differences between groups were determined using Pearson χ^2 tests. In addition, multivariable adjusted odds ratios (ORs) with corresponding 95% CIs were calculated using logistic regression analyses to identify relevant associations between the sociodemographic and health-related variables and the CW-related outcome variables ("ownership of a CW" and "collection of health data"). In the regression analysis about the "ownership of a CW" 82 participants (82/4464, 1.8% of the total sample) had to be excluded due to missing values for the included variables, and 83 participants had to be excluded (83/4464, 1.9% of the total sample) from the regression analysis regarding the "collection of health data." Following the recommendations of Statistics Canada, estimations with a coefficient of variation of 16.5% to 33.5% were flagged as having a high degree of uncertainty (estimations with even higher coefficients of variations would not be released; this does not apply to any of our results) [20]. A statistically significant difference between groups was assumed if the corresponding *P* value was less than .05.

Results

Study Sample

The study sample comprises 4464 participants aged 18 years and older. The weighted and unweighted distributions of the sample across gender, age, educational, and income groups are presented in Table 1. Participants younger than 40 years of age and those with a low educational level are underrepresented within the study sample, which is corrected by the weighting factor used.

Ownership of a CW

Among the adult population, 19.3% (843/4459) owned a CW (Table 2). In the bivariate analyses, age, educational level, income, subjective health status and PA behavior were significantly associated with CW ownership (Table 2).

[a]CW: consumer wearable.

[b]Pearson χ^2 test

XSL•FO
RenderX

[c]Not applicable.

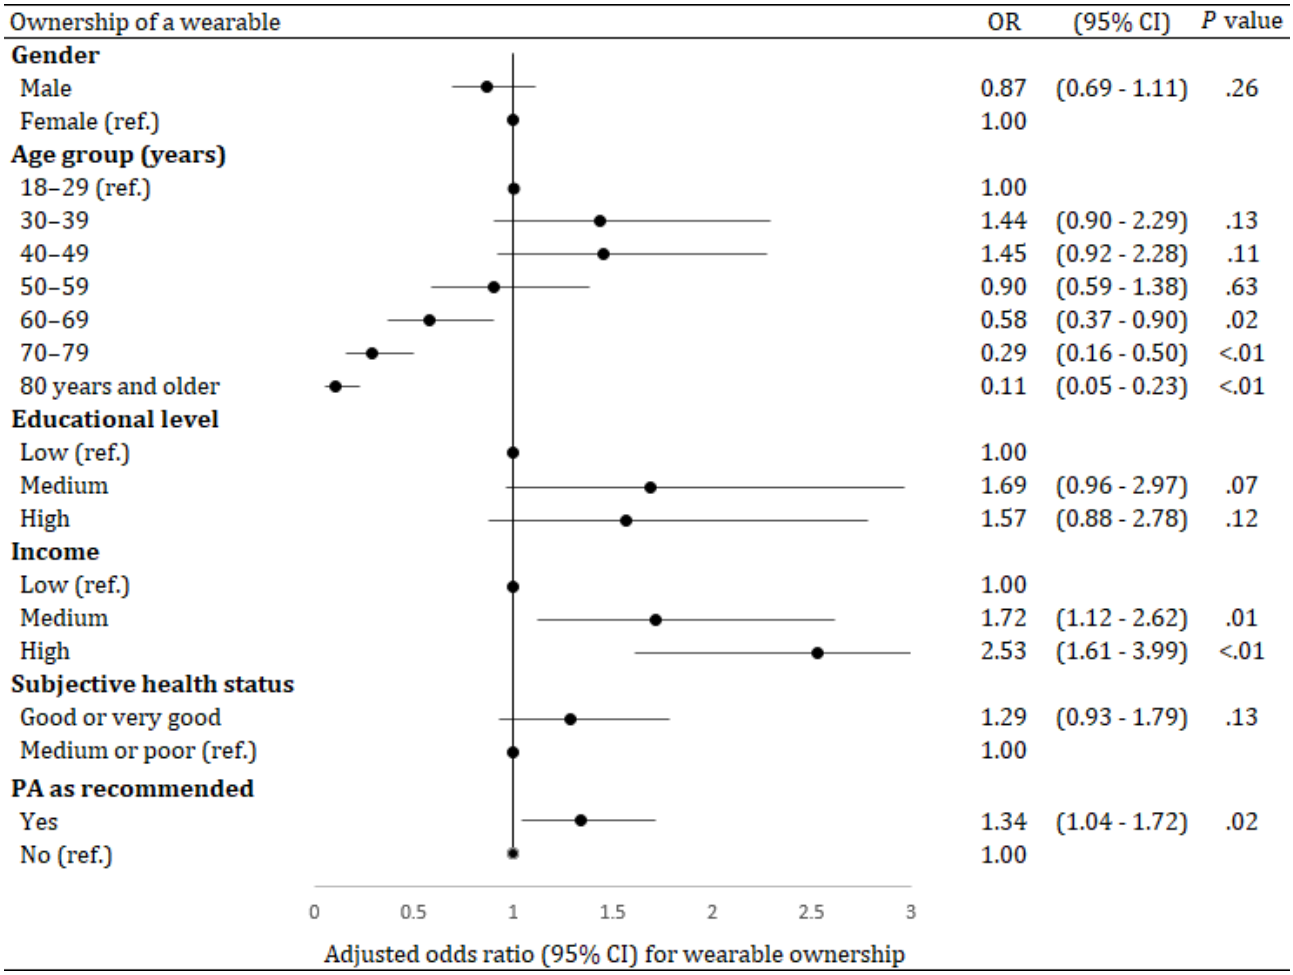
[d]Estimation with high uncertainty due to a small sample size.

[e]PA: physical activity.

[f]At least 150 min PA per week (WHO recommendation).

The multivariable regression analysis, including the dependent variables gender, age, education, income, subjective health status and PA level, revealed that the ownership of a CW was significantly associated with the age, income and PA level of the participants (Figure 1). Adults aged 60 years and older were less likely to own a CW than 18- to 29-year-olds: In 60- to 69-year-olds, the odds of owning a CW was 0.6 times lower than of those aged 18 to 29-year (P=.02), in 70- to 79-year-olds the odds was 0.3 times lower (P<.01), and of those aged 80 years and older the odds was 0.1 times lower (P<.01). Adults with a medium income had 1.7 greater odds to own a CW than adults with a low income (P=.01) and adults with a high income had 2.5 greater odds (P<.01). In addition, adults who achieved the WHO recommendation for PA had 1.3 greater odds to own a CW than adults not achieving the WHO recommendation (P=.02).

Figure 1. Results of a multivariable logistic regression analysis (dependent variable: "Ownership of a consumer wearable," categories: yes or no [reference], adjusted OR with 95% CI, n=4382). "PA as recommended" refers to at least 150 minutes of PA per week (WHO recommendation). OR: odds ratio; PA: physical activity; ref: reference category; WHO: World Health Organization.



Usage of a CW to Collect Health Data

Of the adult population, 15.0% (650/4458) used a CW to collect health data (Table 3). This corresponds to 77.8% (650/842) of the CW owners. In the bivariate analyses, we compared CW users with nonusers, and the respondents' age, education, income, subjective health status, and PA level were significantly associated with the collection of health data with their own CW (Table 3).

In the multivariable regression analysis, the variables age, income and PA level remained significant predictors for the collection of health data (Figure 2). The odds of adults aged 70 to 79 years to collect health data using a CW was 0.3 times lower than in 18- to 29-year-olds (P<.01). Participants aged 80 years and older had 0.1 lower odds to collect health data using a CW than the youngest age group (P<.01). In addition, participants who achieved the WHO recommendation for PA had 1.5 higher odds to collect health data than participants who did not achieve this recommendation (P=.01).

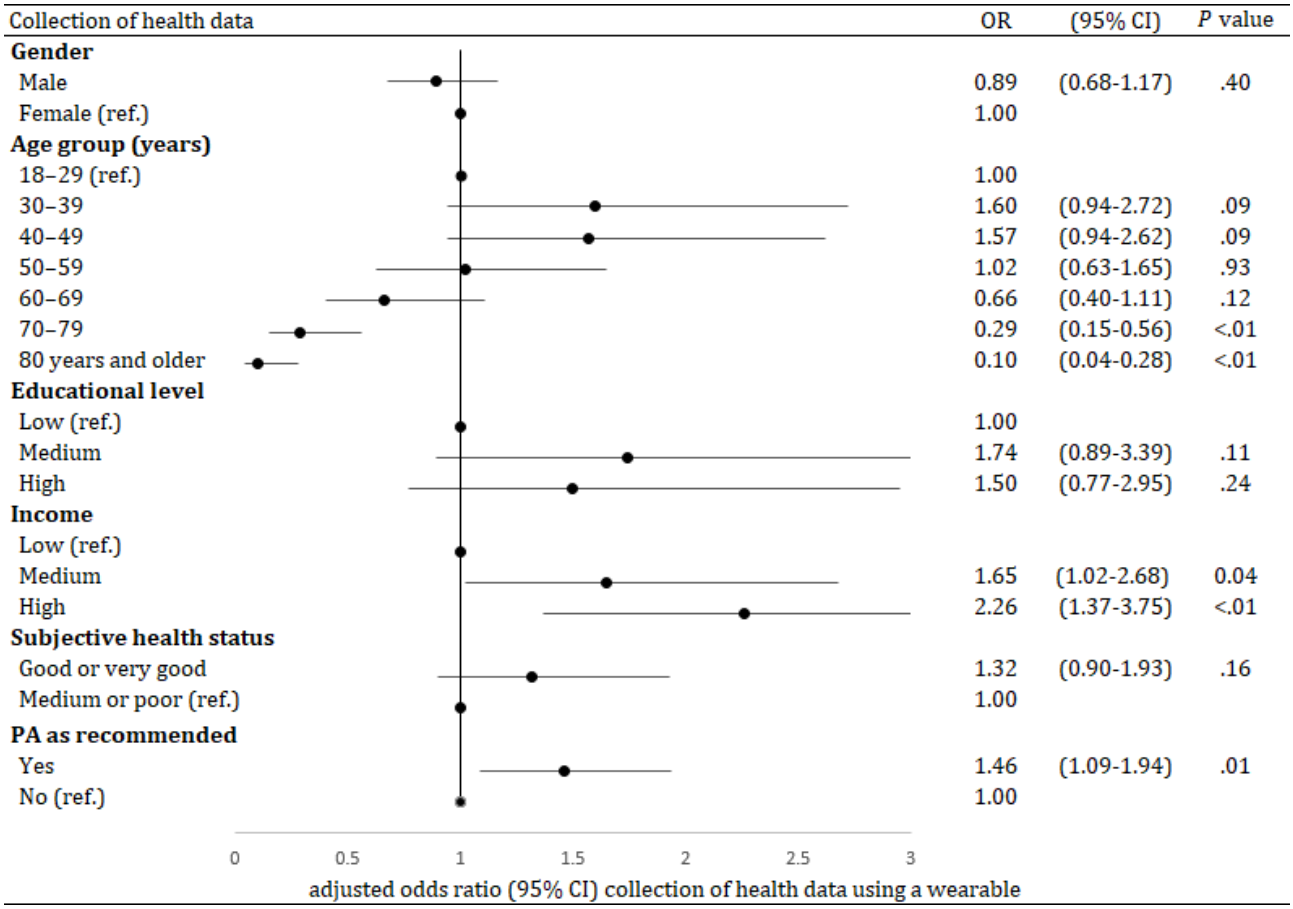
Figure 2. Results of a multivariable logistic regression analysis (dependent variable: "Collection of health data using a consumer wearable," categories: yes or no (reference), adjusted OR with 95% CI, n=4381). "PA as recommended" refers to at least 150 minutes of PA per week (WHO recommendation). OR: odds ratio; PA: physical activity; ref: reference category; WHO: World Health Organization.



User Behavior

The most commonly used CW to collect health data was a smartwatch. A total of 74.5% (456/648, 95% CI 69.1% - 79.3%) of the CW users who collected health data used a smartwatch, of whom 71.8% (341/456, 95% CI 65.0% - 77.8%) wore their smartwatch for at least 8 hours per day. Fitness trackers were used by 60.7% (414/650, 95% CI 54.7% - 66.4%), of whom 70.7% (310/413, 95% CI 63.0% - 77.3%) wore it for at least 8 hour per day. Furthermore, 26.8% (214/650, 95% CI 22.1% - 32.2%) used a CW other than a smartwatch or fitness tracker. The results show that some of the participants used more than one device.

Of the CW users who collected health data, 47.2% (321/650, 95% CI 41.4% - 53.2%) wore their CW during nocturnal sleep for at least 4 nights per week, and an additional 6% (42/650, 95% CI 4.0% - 9.1%) wore it for fewer than 4 nights per week. Consequently, 46.7% (287/650, 95% CI 40.8% - 52.7%) did not collect sleep data.

Motives for CW Usage

The most frequently chosen motives for the usage of a CW were "to observe my PA level" (544/647, 85.0%), "for fun" (508/644, 79.0%), "for support during exercise" (423/647, 66.3%), and "to increase my PA level" (386/647, 61.9%). Women named the motives "to observe my PA level" and "to increase my PA level" more often than men (287/321, 90.6% vs 257/326, 79.0%, *P*=.01; 211/321, 69.2% vs 175/326, 54.1%, *P*=.01, respectively), whereas men chose the motive "to observe health issues" more often than women (137/326, 41.6% vs 103/321, 29.5%, *P*=.04). The described differences between women and men remained statistically significant when the analyses were adjusted for age, educational level, income, subjective health status and PA level (results of multivariable logistic regression analyses, data not shown). The motives for the usage of a CW for the total sample and stratified by gender are shown in Figure 3.

XSL•FO
RenderX

Discussion

Principal Findings

To our knowledge, this is the first nationwide study to describe comprehensively the ownership of CWs and the usage of CWs for the collection of health data among the adult population living in Germany. In addition, the selectivity of the user group was investigated. We found that almost one-fifth of the adult population living in Germany owned a CW, 77.8% (650/842) of whom used their CW to collect health data (which corresponds to 650/4458, 15.0% of the adult population). Older people, people with a low income, and people with a lower PA level were less likely to own a CW and to use their own CW to collect health data. Of the 4 most frequently chosen motives for collecting health data using a CW, 3 were related to PA behavior, but using the CW for fun was also a common motive.

Comparison With Previous Work

Compared with our results, a nationwide survey from Canada conducted in 2017 showed a slightly higher prevalence of CW ownership, whereas the prevalence of using the device for the collection of health data in relation to the total population was almost the same: 25% of the Canadian population owned a CW (843/4459, 19% in this study) and 57% of the owners used the device to collect health data [21] (which corresponds to 14% of the population; 15% (650/4458) in our study). A nationwide study from the United Kingdom conducted in 2018 assessed the usage of a CW to collect health data and revealed similar prevalences to those of this study, with 14% using a smartwatch or fitness tracker [13], whereas a nationwide survey from the United States conducted in 2019 revealed a higher prevalence, with 30% using a CW in the past 12 months [10]. However, it should be borne in mind that the data collection for the studies described above took place 3 to 5 years before our study and that the prevalences of the ownership and usage of CWs may have increased in the meantime.

Our results concerning the selectivity of the group of CW owners and users confirm the findings of studies from the United States [10], the United Kingdom [13] and Canada [21] for the population living in Germany. Among CW users, people who are the most in need of health care and health promotion, such as older people and socio-economically disadvantaged people, are underrepresented. Older people (aged 60 y and older) may use CWs less frequently because they are less tech savvy, they may be more reluctant to use new technologies and they may have less fine motor skills or impaired vision, making it difficult to operate a CW or smartphone [22,23]. A study from the United States showed that seniors with higher technical self-efficacy were more likely to use a CW [22]. Thus, the improvement of technical skills in combination with the further tailoring of

XSL•FO
RenderX

devices to the needs of older people could increase the user behavior in this age group.

The lower likelihood of people with low income owning and using a CW in this study is consistent with the findings from the United States and Canada [10,21]. Furthermore, in the nationwide study from Canada, it was shown that costs are a common mentioned reason for not owning a CW [21]. However, due to the increasing proportion of low-cost CWs on the market, the economic aspect will probably become less important in the future. In addition, adults with a lower income often have a poorer state of health and lower PA levels, which might be accompanied by less interest in these behaviors and thus less interest in tracking health and PA indicators using a CW [24,25].

Our results revealed that adults with a higher PA level were more likely to own a CW and to use it for the collection of health data. A higher level of PA in CW users than in nonusers has also been shown in previous observational studies [26,27]. People with a higher level of PA may have a greater interest in their PA behavior and are thus more likely to track it using a CW than people with a lower level of PA [28]. This could also explain our findings on the motives for using a CW: 3 of the 4 most frequently named motives were related to PA behavior. Conversely, the use of CWs can influence the PA behavior of the users and increase their PA level. The authors of an umbrella review concluded that the usage of CWs is effective in increasing PA [29]. However, the positive effects are significantly smaller when the usage of a CW is the only measure compared with multifaceted interventions to promote PA [30]. In addition, little is known about the long-term effects of CW usage on PA behavior.

Health data collected by the population using their own CW can be used for different purposes. Our results indicate that almost 20% (843/4459) of the members of the adult population living in Germany who use a CW and collect health data wear the device regularly during daytime and thus provide data that reflect the general behavior of this group. However, only half of the CW users wear their device during nocturnal sleep, which restricts the possibilities for sleep analyses significantly.

Strengths and Limitations

A strength of our study is that we used a nationally representative survey to investigate the ownership and usage of CWs and the motives in the adult population living in Germany. In addition, we analyzed a variety of sociodemographic and health- and behavior-related predictors of CW ownership and usage. Our results can be used to inform researchers designing research projects including CW data, as well as practitioners. Nevertheless, the following limitations of our study must be considered. First, the analyses of the factors predicting the ownership and usage of CWs might miss predictors of CW ownership or usage because they were not assessed in our study. For example, further societal indicators, like cultural background, might have an impact on CW usage as well as the technical competence of a person. Second, our results provide some initial insights into the motives of using CWs, but we might have missed information about relevant motives because almost one-quarter of the sample used the answer category “other reasons.” Further research using open-ended questions or qualitative research approaches could help to better understand the motives for CW use. Third, small sample sizes of specific subgroups, such as younger adults and adults with a low educational level, resulted in estimations with higher measurement uncertainty. We have marked results with high measurement uncertainty to make this limitation transparent. In addition, we were not able to perform more in-depth analyses, such as further subgroup analyses, due to the small sample size in the subgroups. Fourth, the assessment of data using self-reports is a limitation because we cannot rule out the possibility of biased results due to recall bias or different interpretations of terms like “wearable,” “smartwatch,” or “fitness tracker.” However, we included short definitions of the aforementioned terms in the interviews to minimize the possibility of different interpretations. Finally, the cross-sectional design of the dataset does not allow us to clarify predictive directions. Future longitudinal study designs are needed to contribute to the understanding of the long-term effects of CW use on PA behavior.

Implications for Research and Practice

In our opinion, a major challenge when using health data collected by individuals through their own CW is that the sample is selective and does not represent the general population. Consequently, parts of the population who are particularly likely to need health care and the improvement of the health care system, such as older and socially disadvantaged people, would not benefit from these research approaches or might even be harmed. Thus, the use of data collected with respondents’ own device is, according to the current status, not suitable for the surveillance of health behavior on the populational level. A possibility to reduce the selectivity could be to supplement the sample with a randomly chosen sample of individuals who do not own a CW. This group could be sent a fitness tracker for the period of the study. Oversampling of difficult-to-reach groups of the population, like older people or people with low incomes, as well as a study design and study information adapted to difficult-to-reach target groups can further reduce selectivity.

However, health data collected by individuals using their own CW could be used to achieve other research aims than population-wide surveillance of health behavior. For example, they could be used to describe trends in PA and sleep behavior and to investigate whether certain events, like heat waves, have an impact on these behavior. In addition, these data could be used to describe individual trends in PA behavior in the form of longitudinal analyses to, for example, evaluate how the transition from employment to retirement affects PA and sleep behavior.

Researchers and practitioners should still consider carefully which parts of the population are underrepresented in their CW datasets and which conclusions can be drawn, and they should communicate the selectivity of the sample transparently. Eventually, it depends on the research question whether CW data collected by individuals with their own device are suitable for answering it. The results of our study might support the decision process that researchers should execute when planning a study using CW data.

XSL•FO
RenderX

Conclusion

Our results indicate that one-fifth of the adult population living in Germany owns a CW. Individuals owning a CW are younger, have higher incomes, and are more physically active than the general population. The usage of such data describing the health behavior at the population level will therefore overestimate health-promoting behaviors such as PA.

Abstract

Background: College students are vulnerable to setting long-term trajectories of low physical activity (PA) but are reachable via mobile health fitness tracking (eg, mobile health step counting) and interpersonal support tailored to the college community. However, no studies have statistically isolated the appeal and influence of these intra- and interpersonal components in college-based PA interventions.

XSL•FO
RenderX

Objective: This study retrospectively examined a college-based PA promotion program at a northeast US public university during the COVID-19 pandemic to (1) test the impact of student status on the use of intervention components and (2) determine whether such use was associated with successful retention and goal achievement in the program.

Methods: The university used a commercial platform for a 30-day PA promotion program during April 2021 with intrapersonal (step-tracker syncing, education, self-monitoring, and motivational messaging) and interpersonal (friend interactions and team games) components. App use was operationalized as intrapersonal (frequency of opening app, education, and self-monitoring) and interpersonal (friends made in-app and team affiliation and size).

Results: Campus-wide emails elicited sign-up by 156 undergraduate students, 57 graduate students, and 126 faculty and staff members. Objective 1 yielded the following results: undergraduates used the app less frequently (median 0.8, IQR 0.4-1.7 times per day) than other groups (graduate students: median 1.4, IQR 0.7-2.7 times per day; *P*=.01; faculty: median 1.3, IQR 0.7-2.7 times per day, H_2=14.5; *P*=.001) but made the same number of friends (median 1-2) and teammates (median 8-9; *P*=.77 for friends and *P*=.93 for teammates). Objective 2 yielded the following results: most participants (313/335, 93.4%; 95% CI 90%-96%) were retained for the first 7 days, but by 30 days, retention dropped, most notably for undergraduate students (82/154, 53.2%; 95% CI 45%-61%), followed by graduate students (39/56, 70%; 95% CI 56%-81%) and faculty and staff (93/125, 74.4%; 95% CI 66%-82%; χ^2_2=12.6; *P*<.001). Retention was associated with app engagement frequency (model hazard ratio 0.56, 95% CI 0.43-0.72; *P*<.001) and affiliation with a team having high median app engagement and a large size (intracluster correlation coefficient 0.064, 95% CI 0.001-0.164, *P*=.05). Meeting a daily step goal was associated with app engagement frequency (β=.72, SE=0.21; *P*=.001), number of friends (β=.40, SE 0.20; *P*=.04), and an initial motive of maintaining or increasing (rather than starting) PA (β=.99, SE=0.21; *P*<.001).

Conclusions: College students, compared with faculty and staff, used the app less frequently, used the app for a shorter duration before abandonment, and met the step goal on fewer days. Engagement with the program was associated with longer retention and better PA outcomes, which were critically modified by the interpersonal engagement. These findings suggest that college students using virtual PA support during times of physical isolation could benefit from more tailored implementation strategies (eg, timed prompts and team reassignments).

Introduction

Background

Physical activity (PA) levels are important determinants of long-term health outcomes. For instance, 6000 to 8000 steps per day is associated with a lower risk of health problems such as all-cause mortality, diabetes, and mental health concerns [1,2]. One critical life stage for PA support is during the college years for those who attend. For some people, college is a transition when great positive or negative change from adolescence is possible, and the lifestyle at the end of this transition is a predictor of the long-term health trajectory [3]. Studies have found that around half of college students have low PA levels [4], which further declined by 32% to 366% during the COVID-19 pandemic [5]. Thus, college is a critical window for interventions that maintain or increase PA to have a powerful and sustained impact on an individual's life.

College students are a prime population to reach through mobile health (mHealth; ie, medicine involving mobile devices) because most consider the internet a source of health information [6,7], almost all own a smartphone, and around half use a fitness tracker or other wearable device [8]. mHealth could be a viable strategy to help college students increase their PA because their use of wearable fitness trackers and mobile apps has been associated with higher PA levels.

This association in these studies was mediated by the social aspects of using such technology (eg, real-time sharing of step counts), making it critical to understand the social context in which students are functioning. Starting college presents students with a new set of social circumstances [9]. When they leave the outside world and enter the college community, often one with cultural and geographic differences from where they grew up, there is a desire to belong and feel accepted in this new community [9]. Such an innate want for interpersonal connections is a fundamental determinant of human cognition and health outcomes including PA [10-12]. Fortunately, this new community presents unique opportunities to make social connections. First, students are assigned class instructors with high education levels and experience mentoring young adults, a cross-demographic connection less likely to occur in the outside world [9,11]. Second, students share experiences and concerns with other students such as accessing unique or licensed educational content, feeling eustress or distress about academic performance, and concerns about loneliness because of the restricted size of the college community [9,11]. On the other hand, students often struggle to initially adapt to these aspects of college [9,12]. The COVID-19 pandemic further heightened students' unmet needs and desire for social connection [13,14]. However, when students are able to use the college environment opportunities to join peers in pursuing activities and exploring interests, these connections correlate with increased PA participation and engagement [11]. In fact, social support from friends effectively motivates PA among

XSL•FO
RenderX

college students, more so than family support [15]. Yet, despite these rewards of connecting to peers of like age and education level in college, it can also be overwhelming. For instance, while social support in college correlates with situational interest in PA,1 study found that the college students' environment was a barrier to PA because of feeling overwhelmed by the change in their first year of attendance [16]. For these reasons, college PA support must be considered and tailored to the college environment.

There are several frameworks for understanding determinants of human goal setting and accomplishment such as increasing PA. Goal-setting theory and the theory of planned behavior focus on intrapersonal determinants such as the specificity of the goal and beliefs about results from the goal. The self-determination theory also includes such intrapersonal competence but then extends to the inclusion of interpersonal relationships (ie, autonomy and relatedness) [17]. The social cognitive theory (SCT) extends beyond one-to-one and small-group interpersonal relationships to the broader sociocultural environment [18]. The SCT's intrapersonal determinants include self-efficacy (belief in oneself to perform a behavior) and outcome expectations (the expectation that a desired outcome will result from the behavior). Its interpersonal determinants include sociocultural factors (the influences from an individual's social and physical environment). Importantly, there is a reciprocal determinism (ie, feedback loops) between the intra and interpersonal determinants. For example, social persuasion and support from peers can boost a person's self-efficacy to become a successful athlete. Similarly, when peers see that heightened self-efficacy and athleticism, they are even more inclined to support that person. Therefore, it is critical to study both the intra and interpersonal aspects of PA support programs.

Wearables can support the aforementioned SCT constructs. They can support self-efficacy by conveyance of personal accomplishment (eg, tracking step counts in relation to previous days or a preset goal) and verbal persuasion (eg, encouragement messages to reach a goal), as well as by offering the opportunity to leverage this self-efficacy for goal setting. Self-efficacy has been shown to impact both engagement with wearable technology [19] and behavioral outcomes resulting from its use [20]. Wearables can also support outcome expectations because the metrics they collect and display such as step counts are associated with health benefits [1,2]. Finally, wearables can support sociocultural influences through methods such as group step challenges and social media postings of achievements [21,22]. Overall, this robust applicability to SCT shows that wearables should be explored to deliver both inter and intrapersonal intervention components among college students.

Health-related interventions often have low uptake among college students [23-25]. Some reasons are related to intrapersonal aspects such as students prioritizing more pressing needs and disbelief the information was valid and applicable to them. Other reasons related to interpersonal aspects such as lack of peer involvement in designing the intervention, and the interpersonal interactions occurring over a social media platform they were not accustomed to using. Students also noted the criticality of being able to conveniently select which intervention components to use. Thus, both the intra- and interpersonal components clearly represent areas for improvement. Some preliminary evidence suggests that social support could be incorporated into mHealth PA interventions for the college student population to promote PA adherence. Findings from a systematic review of 19 papers suggest a positive association between PA and social support for PA among college students [26]. A total of 14 primary studies leveraged social interactions in college community populations to promote PA through mobile apps, including social components [21-23,27-38]. Some of these mobile apps provided an "open forum" feature (eg, Facebook-style news feed and WeChat group chat) where participants could share PA performance, interact, and provide social (ie, interpersonal) support [21,23,27-32,35,36]. Some discussed an additional feature in the mobile app which allowed participants to form ongoing "team" relationships. These relationships included an ongoing comparison of step counts with other team members (ie, a social norm) [22,27-30,38], discussions fostering mutual support (eg, complimenting success and empathizing with barriers) [21,22,33-37], and discussing educational materials on PA [22]. These activities were rewarded with team success scores, thus leveraging the established gamification strategies of cooperation [39] and socially oriented persuasion [40]. These studies incorporated a mobile app with these interpersonal components, activity trackers, and standard solitarily (ie, intrapersonally) used behavior change techniques such as text message reminders to be active, health education, goal setting, self-monitoring, and extrinsic incentives (eg, prizes). The utility for tracking devices without support from a multimodal app tailored for college students has yielded mixed results (reviewed in the study by Sultoni et al [41]), thus, multimodal communication is considered best practice for mHealth interventions [42].

One challenge with current research is determining the use and effectiveness of each of the multiple intervention components; this information is crucial to the refinement and success of the intervention [43]. Edney et al [30] found self-monitoring and ongoing team relationships were rated highly by 50% to 70% of participants compared with individual incentives and open forum social interactions, which only 20% to 30% of participants rated highly. Tong et al [29] found the self-monitoring and ongoing team relationship features were used an average of approximately 2 times per week, while open forum use was less than weekly. When the app was subsequently refined to include more personalization of the individual self-monitoring, by tailoring it to participants' weekly progress and barriers, this approach was reported to be well-received [32]. Zhang et al [37] found participants randomly assigned to participate in an interpersonal team did not achieve greater PA increases than those randomly assigned to receive intrapersonal text messages. There is a need to build upon these mixed findings from clinical trials by statistically isolating which of the intrapersonal (ie, education, self-monitoring, and personalized advice) and interpersonal components (ie, open forum and team feature) are associated with successful engagement and PA promotion among college students in real-world settings.

XSL•FO
RenderX

Objectives

This study aimed to build upon prior findings from clinical trials by retrospective observation of an mHealth PA promotion program incorporating both intrapersonal and interpersonal components, which was delivered with campus-wide outreach to students and faculty and staff. The first research question was how the intervention components were used and whether this use was different between students and faculty and staff, and the second question was whether such use was associated with successful retention and goal achievement in the program. We hypothesized that undergraduate students would have lower use of intervention components than graduate students and faculty and staff and that such use would be associated with successful retention and goal achievement in the program. This statistical isolation of specific components builds upon prior studies by providing insight into specific facilitators and barriers of the program, which could inform future refinement of interventions aimed at increasing PA in situations of physical isolation from peers and PA spaces.

Methods

Intervention Design

The American College of Sports Medicine Exercise is Medicine On Campus initiative recognizes approximately 150 higher educational institutions per year for campus PA initiatives. One of their gold-level programs, the Southern Connecticut State University (SCSU) MoveSpring Steps Challenge, was suited to our study purpose because it used mHealth delivery with backend data capture. The university initiated the challenge in response to COVID-19 pandemic policies that restricted use of their fitness and recreational facilities. It operated from April 1 to 30, 2021, and was directed by the campus fitness center, incorporating input from the campus exercise physiology club and health center. It was digitally supported by the MoveSpring mobile app platform. This platform provides customizable fitness tracking and interaction features for individual companies and organizations. SCSU and MoveSpring collaborated to program the targeted intervention with both intra- and interpersonal components (Table 1). For the passive monitoring component, users could synchronize their own device such as a fitness watch or smartphone pedometer.

Table 1. Program components and content.

Type and component	Content
Intrapersonal	
Educational content on demand[a]	• Videos • Articles • Actionable health tips • Motivational quotes
Motivational content as push notifications	• Topic and mini challenge of the week (eg, benefits of nature walking or post a picture of your nature walk): 2-3 times per week • Campus events (eg, group walk): once per month • Prize reminders: 3 times per week • Achievement acknowledgment: once per week
Active monitoring (self-reported yes or no response)[b]	• Ate ≥3-4 servings of fruits and vegetables • Slept ≥7 hours • Drank ≥8 glasses of water
Passive monitoring (device)	• Steps (15,000 limit) in relation to both the personal goal[c] and tiered cutoffs for prize raffles[d] • Minutes of moderate to vigorous physical activity[e] • Distance
Interpersonal	
Community engagement and peer support	• Peer leaders and fitness center director • Chat box[f] • Friend activity (average daily steps of friends) • Team-specific challenges[g] • Team leaderboard (top 4 teams' avatar, name, and average daily steps per member)

[a]Content from MoveSpring proprietary collection and the Southern Connecticut State University student leaders related to physical activity, diet, sleep, hydration, and mindfulness.

[b]Completing ≥67% (20/30) of days ensured entry into a US $50 gift card raffle.

[c]Personal goal options were 6500, 10,000, or 12,500 steps per day.

[d]Average values of 7000, 10,000, or 12,500 steps per day ensured entry into a raffle for US $50, US $75, or US $100, respectively. One entry was awarded for days 1 to 15 and 2 entries were awarded for days 16 to 30.

[e]Meeting ≥20 min on 67% (20/30) of days ensured entry into a US $50 gift card raffle.

[f]Chat topics were wide ranging and sometimes unrelated to physical activity. This feature was only used by a few individuals, whereas the features in the subsequent 3 bullets were used by a majority of the 335 participants.

[g]The top 3 teams by average step count per member received T-shirts, grouped by the academic status of users who founded the team. Participants could actively form their own teams. Those not doing so were randomly assigned to a team in the first half of the first week of the challenge.

Recruitment and Enrollment

Nine days before the start of the challenge (March 22, 2021), the campus fitness center coordinator sent a single advertisement email to all SCSU students and employees with instructions guiding those interested to download the SCSU-customized MoveSpring SCSU app to their personal smartphone, create an account, and synchronize a watch or pedometer for passive monitoring. Upon registration, all participants were required to complete an intake survey of academic status, campus visit frequency, reason for enrolling, daily step goal, and device used for activity tracking (Multimedia Appendix 1). To minimize the onboarding burden, there was no query on sex or other demographics.

Data Capture

The SCSU Fitness Center and MoveSpring removed identifiers and donated the dataset to the Dataverse repository [44] and a research team based at Yale University (GIA, SSM, MA, BB, JL, SL, XX, SJ, LMF, MS-K, and MBG), who performed data cleaning, analysis, interpretation, and write-up. They liaised with several co-designers of the Steps Challenge program content (ADH, PB, and RSA) to summarize the intervention methodology for this manuscript.

Ethical Considerations

No researchers had contact with participants or access to identifiable information, so the Yale University Institutional Review Board determined that the project did not constitute human participants research, meaning the institution waived ethical approval (determination 2000033852). This manuscript follows STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines for cohort studies (Multimedia Appendix 2). Participant identifiers were removed before the transfer of the data to Dataverse and Yale.

Data Analysis

Overview

This study was a retrospective analysis of longitudinal observations on campus community members over the 30 days they were exposed to a steps challenge intervention app. Analyses used SPSS (version 26.0; IBM Corp; aim 1) and SAS (version 9.4; aim 2). Significance was set at .05. Study size was based on the available dataset.

Outcomes

The first objective was to determine how the app was used and whether app use differed by academic status. The outcomes for this first objective were app use metrics, operationalized as intrapersonal (average frequency of opening the app, education, and self-monitoring as continuous variables) and interpersonal features (friends made in-app, team affiliation, and team size as discrete variables). The second objective was to determine whether app use was associated with successful retention and goal achievement in the program. The outcomes for this second objective were (1) days of retention quantified as a time-to-event discrete variable censored at the end of the 30-day exposure (ie, the event being the discontinuation of app syncing) and (2) each day's success at meeting the step goal, quantified as a ternary categorical variable (tracking device not worn, tracking device worn but not reaching goal, tracking device worn, and reaching goal). The first objective analyzed outcomes at the person level (ie, daily averages), while the second objective analyzed outcomes at the day level adjusted for within-person correlations. These units were chosen based on the available granularity of the data from the app that both delivered the intervention and tracked its outcomes.

Research Question 1: How Was the App Used, and Did App Use Differ by Academic Status?

Participant characteristics (Table 2) were tabulated as frequencies and compared by academic status using chi-square tests (χ^2). The duration of app use before abandonment (Table 3) was compared by academic status using the Kaplan-Meier estimate of survival probability because it was right-censored at the 30-day length of the program. Most metrics of app use before abandonment (Table 3) were compared by academic status using Kruskal-Wallace (H) tests as they were interval scale variables with distributions that were bimodal (number of teammates) or right skewed (frequency of opening the app before abandonment, friends made in-app, and use of the self-monitoring and education features) and visually similar between the academic statuses. Two metrics of app use before abandonment were even more heavily right skewed—use of the self-monitoring and education features—so they were recoded as binary (<1 time weekly or ≥1 time weekly) and compared by academic status using chi-square tests. All variables with a significant main effect across the 3 academic groups were further tested by post hoc pairwise comparisons with *P* value multiplied by 3 to Bonferroni-adjust for multiple comparisons.

Research Question 2: Was App Use Associated With Successful Retention and Goal Achievement in the Program?

Independent variables were app use metrics (engagement frequency, number of friends made, and number of teammates made) and all available participant characteristics (academic status, campus visit frequency, motive for joining the program, and step count goal). Each of the following analyses tested each independent variable's bivariate association with the retention or goal achievement outcome; those meeting a *P*<.10 cutoff were tested in a multiple variable model, and those appearing to influence that model (*P*<.20) were retained in the final parsimonious model.

Retention (ie, duration until last time the app was opened before abandonment) was estimated using the Kaplan-Meier estimate, and effects of independent variables were examined using a Cox frailty proportional hazard model incorporating correlation

XSL•FO
RenderX

within teams. Besides accounting for the right censorship of the data, these methods can adjust for possible correlations within the dataset; in this case, the correlation between teammates. The lone influential independent variable was visualized using a survival curve (Figure 1), and correlation within teammates was visualized as a bubble plot (Figure 2).

Figure 1. Retention survival curve according to engagements per day, which was the only predictor of retention retained in the parsimonious final model.

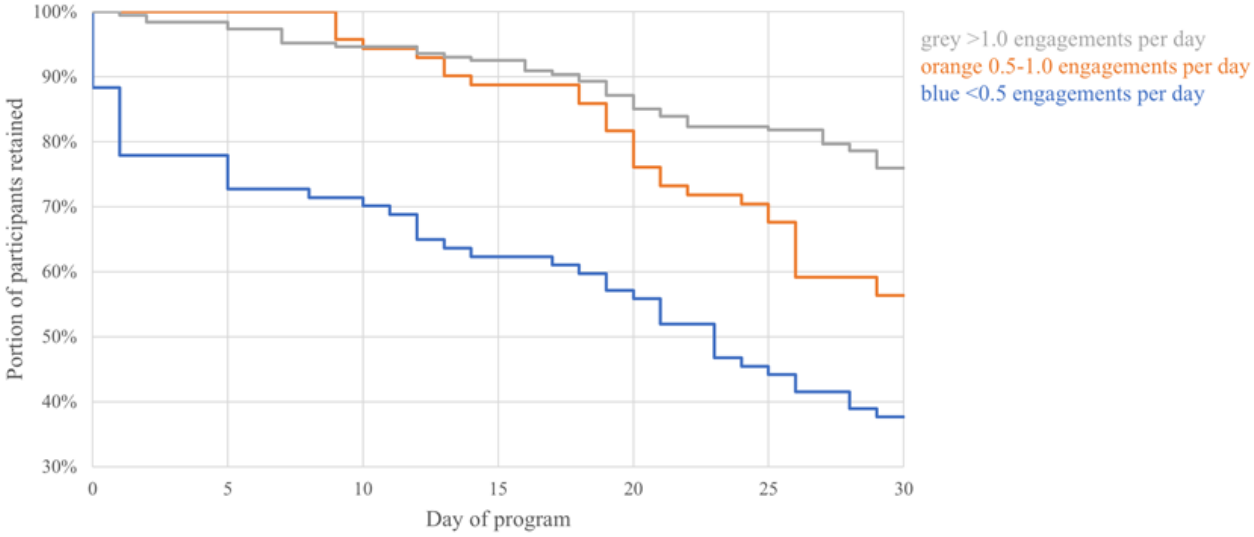

Figure 2. Retention (ie, duration of app use before abandonment) was clustered by team affiliation (intracluster correlation coefficient 0.064, 95% CI 0.001-0.164; *P*=.05). Therefore, we plotted average retention among team members in relation to team characteristics, including team size (bubble size) and median app engagements per day among team members (x-axis). It is visually apparent that the longer-retained individuals were those on teams with a larger size and higher median rate of app engagement. The dotted curve is for visual purposes and approximates retention days as 2.29 × ln(median engagement of team) + 24.29.

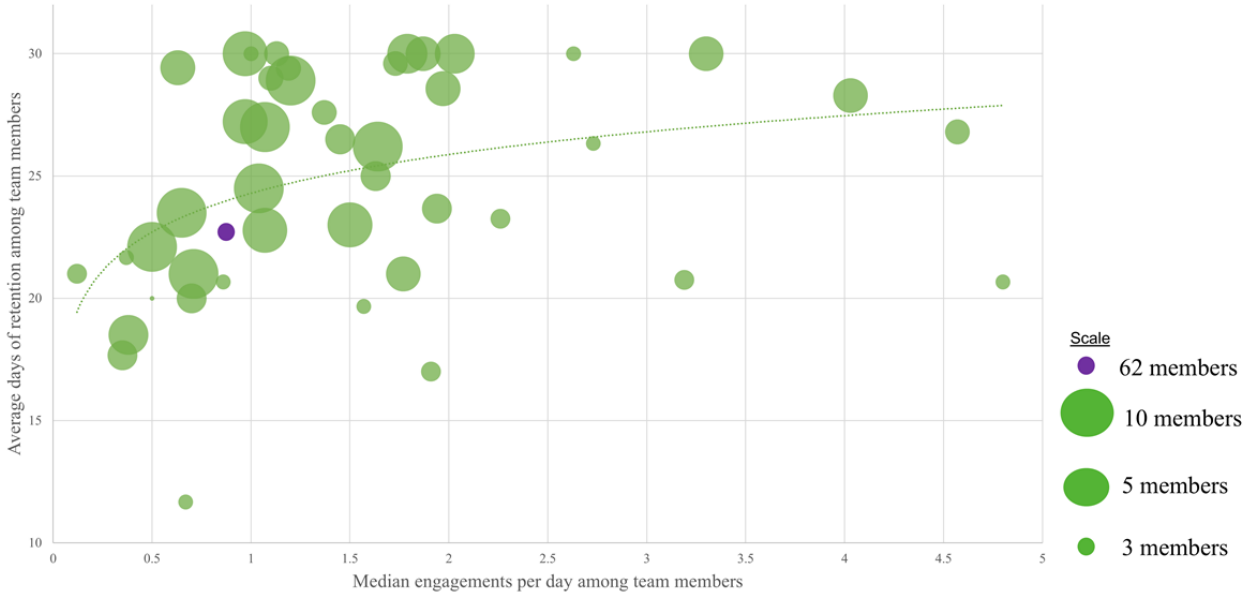

Goal achievement was labeled for each person-day as device nonwear (0 steps), wear-below-goal (steps nonzero but below goal), or goal (steps at or above goal). We tested independent variables associated with nonwear versus goal and wear-below-goal versus goal, using a generalized estimating equation that incorporated correlation within participants by a working correlation structure, a random intercept, and team affiliation as a random effect (Table 4). We also ran a supplemental analysis where the outcome variable was the total steps per day among participants meeting the standard minimum representative PA sampling of 4 days [45] (Multimedia Appendix 3).

Results

Enrollment

Overview

For the 2020 to 2021 school year, there were 11,055 individuals affiliated with SCSU (7047/11,055, 63.74% female, 6287/11,055, 56.87% non-Hispanic White) as either an undergraduate student (7440/11,055, 67.3%), graduate student (1891/11,055, 17.11%), or faculty and staff member (1724/11,055, 15.59%; Multimedia Appendix 4) [46]. Among these individuals, all of whom received a recruitment invitation email, 339 (3.1%) respondents registered for the steps challenge. A total of 156 (2.1%) undergraduate students, 57 (3%) graduate students, and 126 (7.3%) faculty and staff members enrolled in the program relative to the total SCSU population. All 339 enrolled individuals were included in the sample description (Table 2), although 4 were excluded from the subsequent analysis owing to missing data on the MoveSpring backend.

Campus Visit Frequency

Most undergraduate students (122/156, 78.2%) frequently visited campus, of whom about half reported also residing on campus.

XSL•FO
RenderX

Conversely, only 44% (25/57) of graduate students frequently visited campus, of whom the majority reported residing off campus. Nearly all faculty and staff (110/126, 87.3%) worked on campus but lived off campus as the university did not have faculty and staff housing.

Mechanism to Sync Step Count

Most participants (284/339, 83.8%) synchronized a device brand that most studies in a quantitative systematic review found to meet Consumer Technology Association validity standards (<10% mean absolute percent error; ie, Apple, Fitbit, or Garmin) [47]. Some (25/339, 7.5%) used a Google product (eg, Android phone step counter) to collect step count data, with faculty and staff members using this feature more than undergraduate and graduate students. In total, 6.2% (21/339) of participants manually entered step count, but it was unclear how the data were collected; 2.4% (8/339) of participants did not synchronize a device after sign-up and thus did not report any step count data.

Motives and Goals

Among possible motives for program enrollment, 20.1% (68/339) enrolled to initiate PA, 30.1% (102/339) to increase PA, and 49.8% (169/339) for PA maintenance. Among these 169 "maintainers," step goals were as follows: 75 (44.4%) chose 6500 steps, 76 (45%) chose 10,000 steps, and 18 (10.7%) chose 12,500 steps. These proportions were similar to the 102 "increasers:" (n=55, 53.9%, 6500 steps; n=39, 38.2%, 10,000 steps; and n=8, 8%, 12,500 steps; χ^2_2=2.4, *P*=.30) but higher than the 68 "starters" (n=46, 68%, 6500 steps; n=17, 25%, 10,000 steps; and n=5, 7%, 12,500 steps; χ^2_2=10.6; *P*=.005).

Research Question 1: Use of the App Overall and by Academic Status

Duration Before Abandonment

Most (313/335, 93.4%) participants stayed in the program for the first 7 days, and 63.9% (214/335) stayed for the full 30 days. At all time points beyond the first week, retention among undergraduate students tended to be lower than among graduate students and was lower than among faculty and staff (Table 3).

Frequency Before Abandonment

Most participants opened the app with some regular frequency—at least 0.5 times per day—but undergraduates did so less frequently than both faculty and staff and graduate students. Lower values of this metric were associated with both sooner abandonment and fewer step counts logged before abandonment.

Self-Monitoring and Education Features

In addition to regularly opening the app as described earlier, almost all participants (331/335, 98.8%) used at least one of the educational or self-monitoring features at least once to collect data about sleep, diet, and hydration. At the same time, the proportions using them at least weekly were much smaller: accessing education content (9/335, 2.7%), recording sleep data (54/335, 16.1%), recording diet (40/335, 11.9%), and recording hydration (62/335, 18.5%). Use of these features did not differ by academic status, although sleep logging had a nonsignificant tendency to be more common among graduate students than among undergraduates or faculty and staff.

Social Friends and Teams

Most participants made at least 1 friend in the app, and half made multiple friends. All participants were part of a team, which ranged in size from 2 to 62 members. Most teams comprised ≥6 individuals. Faculty and staff members were most often part of a team of 6 to 9 participants, and graduate students were most often part of a team of ≥10 participants. Most undergraduate participants were split between being in a team of 6 to 9 and a team of ≥10 participants. We did not detect statistically significant differences between the number of friends made or the number of teammates by academic status.

Research Question 2: Association of App Use With Successful Retention and Goal Achievement in the Program

Variables Associated With Retention

The final model of variables associated with retention (ie, duration of use before abandonment) included app engagement frequency (Figure 1) with adjustment for correlation within teams. Overall frailty model hazard ratios for abandonment were 0.56, 95% CI 0.43-0.72; *P*<.001 for those in the first and second quartile of engagement frequency (≥1.0/d), and 0.69, 95% CI 0.50-0.96; *P*=.03) for those in the third quartile of engagement frequency (0.5-1.0/d), compared with those in the fourth quartile of engagement frequency (<0.5/d). At 10 days, abandonment was highest among those in the fourth quartile compared with the 3 other quartiles (30% vs 5%). At 30 days, abandonment was again highest among those in the fourth quartile (62%), followed by those in the third quartile (44%) and those in the first and second quartiles (24%).

The intraclass correlation coefficient by teams was 0.064 (0.001-0.164); *P*=.05. Specifically, the longer-retained individuals were those on the teams with larger size and higher median rate of app engagement (Figure 2).

Variables Associated With Step-Goal Achievements

Among the 10,050 participant-days, 1763 occurred after app abandonment. Of the remaining 8287 participant-days, there were 3550 where steps meeting or exceeding goal amount were recorded, 4670 where steps exceeding a reasonable daily value (>250) but not meeting goal amount were recorded, and 80 days (among 28 participants) where no steps were recorded indicating nonwear of the device. On days the device was worn, the median step count was 6756 (IQR 4649-9793).

Both failing to meet the step goal and failing to wear the watch were less likely for individuals whose initial motive was maintaining or increasing PA, compared with those whose initial motive was to start PA (Table 4). Failing to meet the step goal was also less likely for individuals who engaged most frequently with the app and made a high number of friends. Finally, failing to meet the step goal was less likely for faculty and staff compared with students. When this analysis of meeting the step goal was repeated on average step counts, the associated

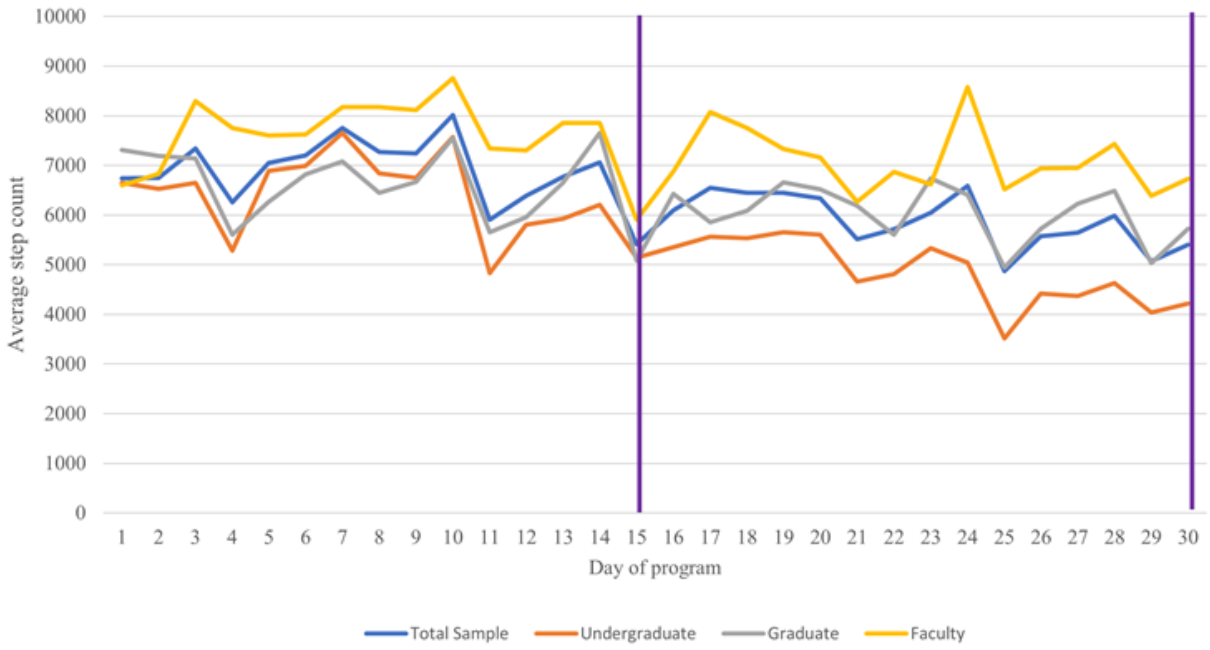
XSL•FO
RenderX

independent variables were the same (Multimedia Appendix 2).

Exploratory Analysis: Role of Gift Card Incentives as Possible Confounder

The escalation of incentive for extrinsic goals in the second half compared with the first half (ie, 2 raffle entries instead of 1) was not associated with a positive change in attaining these goals: among the 182 who did not meet the 7000 steps threshold in the first half, only 11 (6%) met it in the second half, whereas among the 157 who met the 7000 steps threshold in the first half, 36 (23%) did not meet it in the second half. A similar 4- to 10-fold smaller preponderance of upward versus downward transitioners was apparent at the step cutoffs of 10,000 (17/247, 6.9% vs 20/75, 27%) and 12,500 (8/304, 2.6% vs 8/27, 30%). In addition, visually, there was no indication that participants made a "sprint finish" as they approached day 15 or day 30 to qualify for the entries of that period (Figure 3).

Figure 3. Temporal trends in steps per day relative to the cutoffs for the prize drawings (purple).



The incentive of a drawing for completing self-reports on ≥67% (20/30) of days also appeared uninfluential as no participants met this goal. The incentive of a drawing for achieving 20 minutes of moderate to vigorous activity on ≥67% (20/30) of days could not be evaluated for influence because the database did not contain this metric on a day level. The incentive of receiving a T-shirt for being a top 3 team was not separable from the intrinsic motivation associated with being on a successful team.

Discussion

Principal Findings

We assessed intrapersonal and interpersonal factors to better understand facilitators and barriers to college community–based PA support at a northeast public university during the COVID-19 pandemic. For intrapersonal factors, most participants engaged solitarily with the app at least several times per week, and this frequency was positively associated with both retention and step-goal achievement while retained. College students, when compared with faculty and staff, (1) used the app less frequently; (2) used the app for a shorter duration before abandonment; and (3) were less successful in step count goal achievement. For interpersonal factors, students and faculty and staff equally used the open friends forum and the ongoing teams feature, which were positively associated with step-goal achievement and retention before abandonment, respectively. In fact, retention before abandonment clustered among teammates (Figure 2) with a similar intracluster correlation coefficient as various PA metrics cluster among high school classmates [48]. Overall, it is important to note this interaction between intrapersonal (ie, use of app) and interpersonal (ie, social support) characteristics.

College students are vulnerable to establishing a lifelong trajectory of low PA levels. Findings from our study suggest that expanding interventions beyond self-monitoring to a multimodal intervention including interpersonal components may help address engagement and retention. The multicomponent mHealth PA promotion program provided insight into enrollment, use of specific app features, retention, device wear, and achievement of step goals in a real-world setting of a public university during pandemic circumstances, which had presented barriers to PA. Furthermore, the sample was reflective of US 4-year public university averages with respect to the proportion of students living on campus (2.1 million/5.8 million, 37%) [49], studying remotely (2.1 million/9.1 million, 23%) [50], and choosing Apple tracking devices (567/768, 73.8%) [51]. This situation presented an opportunity to retrospectively observe the intervention in the

XSL•FO
RenderX

naturalistic college community environment with individuals having varying degrees and types of participation.

Comparison With Prior Work

Teams were included in this program because small-group team challenges within a fitness program improve individual challenge completion and the degree of participation [52]. Tong et al [29] and Edney et al [30] found that ongoing team relationships were a relatively popular aspect of such an intervention among college students, more so than open forum use. Similarly, we found that most of the social interaction on our app occurred in the "teams" rather than the "friends" feature. Our additional multiple variable and multilevel (person and team) analyses revealed that differential use of both intra- and interpersonal components critically modified outcomes in step counting and retention. This finding builds upon 2 previous studies that revealed correlations between intrapersonal component use (goal setting and content completion) and increased PA [53,54]. There is a need for further research with additional methodologies to provide further insight into how we could better deploy engagement strategies such as "teams" or "open forum friends" features to promote PA.

The SCSU-customized MoveSpring program was highly accessible to the college population because participants were able to participate from anywhere. Accessibility during this time was crucial due to COVID-19 pandemic restrictions creating a very inaccessible environment for PA. The steps challenge enabled participants to stay engaged within a social network, despite being physically isolated from their friends, family, and prior PA partners during the COVID-19 pandemic. Individuals were able to join teams with other individuals they may not have known previously. This virtual connection allowed individuals to immediately have at least one other individual on their campus also participating in the same activity.

However, because using an intensive recruitment and retention strategy would have been challenging during the pandemic, the program adopted a more pragmatic approach to implementation, which revealed a more true-to-life scenario. Naturalistic studies provide an opportunity to observe patterns in college students' PA patterns. In addition to examining participant results from an individual point of view, including teams in the intervention provided additional information about the potential of virtual teams in facilitating program engagement and retention, even in situations where participants are separated from each other and common PA spaces (eg, rural areas, satellite campuses, web-based degree programs). As college students can be a hard-to-engage population, having this knowledge, as well as understanding their PA habits can better inform future implementation and intervention efforts.

First, intervention planners should consider the added value of web-based interaction within an educational community and its ability to withstand barriers of geography and cost. The SCSU-customized MoveSpring program was accessible to those not physically on campus, incurred zero cost of devices (everyone used their own device), and had peer uptake and interactions that were mostly automatically facilitated by the app's team features. The minimal human facilitation required was achievable by student leaders and the fitness center director without extra staffing required in a minimal resource environment.

Second, these findings suggest that college students could benefit from a more tailored implementation strategy. For example, retention prompts could be targeted at those with the lowest overall engagement early in the program, and at those with medium engagement after 3 weeks of the program, in accord with when these respective groups fell below the highest engaged group in retention (Figure 2). Such anticipation of vulnerability to abandonment has been done elsewhere [55]. In addition, these prompts could include team reassignment to teams with high engagement to leverage the clustering of engagement by team affiliation. This strategy aligns with recent recommendations that interventions should be examined not only for their overall effects but also for the contribution of individual components to determine the active versus unnecessary ingredients and achieve tailoring to individuals and contexts [43]. Further tailoring could be attained by a machine learning prediction algorithm to trigger just-in-time adaptive intervention prompts.

Limitations and Strengths

This study had several limitations. First, although the program was offered campus-wide to recruit a representative sample, only 3.1% of the campus participated, which could lead to biased results. However, this representation is higher than the typical clinical trial enrollment of a population where often <3% even click the advertisement and <1% can commit to the logistical burdens of participation [56]. Nonetheless, future programs could make more extensive recruitment efforts to increase representation. Second, because it was a retrospective evaluation of a real-world program rather than a human subjects research study, we did not have survey assessments to test theoretical mechanisms (eg, self-efficacy and outcome expectations to test the SCT) nor participant demographics other than identification as undergraduate, graduate, or faculty and staff. Collecting more demographic and theoretical construct data would help target key program factors and their relationship with PA outcomes, accounting for theoretical mechanisms and diversity of participants. However, in young adulthood, the stage of independence or education is a more meaningful metric than biological age [57]. Third, also to reduce the burden of sign-up, participants used their own step-counting device. Almost all were previously validated up to consumer standards, but they nonetheless varied in brand and likely in model. However, the study outcome was behavioral goal achievement rather than a surrogate of the ground truth step [2]. Fourth, the program had a relatively short duration. Although, in our study and studies conducted by Lattie et al [14] and Adu et al [58] the first month of app use was critical regarding emergent differences between individuals in retention and degree of participation, so it was an appropriate timeframe for our research question. Finally, we isolated the inter- versus intrapersonal component comparison by controlling for within-person correlations statistically and within-environment correlations by using a single site, which held a gold-level designation. Nonetheless, it could also be useful to run a between-site design in which an alternate "control" site offered fewer of the components. It might also be useful to set up a design isolating intrinsic from extrinsic (ie,

prize incentives) motivation, but our brief analysis of the latter indicated a lack of influence.

While prior clinical trials evaluated interpersonal college community–based PA support [27-30,32], a unique strength of our study was addressing its real-world potential for retention, engagement, and association with step-goal achievement. Moreover, we ran this evaluation at the level of individual intervention components across the spectrum from intra to interpersonal. Doing so required detailed statistical analysis including survival curves and models including multiple variables and levels (person and team). This analysis was a critical advancement from prior studies that tested such associations only univariately and only for intrapersonal not interpersonal components [53,54]. Finally, the study was strengthened by its timing: it occurred during the COVID-19 pandemic before vaccine rollout to young adults, which was a time of extensive barriers to both PA and social interactions. Moreover, it was the month before the university's final examinations when college mHealth interventions were vulnerable to abandonment [24]. Thus, the results will inform guidance for coping with difficult times for PA and social interactions.

Future Directions

Clinical trials cannot address the real-world potential for retention and engagement by these applications. App disengagement and abandonment is prevalent in real-world settings according to survey data [59]. In direct assessments of interventions, while these metrics are challenging to standardize across studies, a recent systematic review found only 9% of 62 published studies considered their retention and engagement to be successful [60]. Retention was 10 times less likely if participants were not financially compensated and 4 times less likely if the app was for general lifestyle maintenance rather than for an existing clinical condition [60]. Although none of the included studies had an average age <30 years, other researchers have reported that college students are challenging to retain [23]. As such, despite the availability of pre-post outcomes on retained participants, there is a dearth of information regarding how to achieve retention and engagement, especially for preventive interventions for college students in real-world settings without financial compensation for participation. These retention issues also speak to concerns about the representativeness of the select group that is successfully recruited and retained. While concerns about representativeness apply to any research, the topic of social support approaches is particularly affected because it depends on the environment of these interactions; there is a need for open forums that represent the full university sociocultural environment rather than the subsample who met the criteria and commitment for research procedures.

We also considered that lack of goal achievement can result not only from lower-than-desired step counts but also from nonwear of the tracking device. In our analysis, these 2 occurrences were both associated with a motive for joining the program being the start rather than the increase or maintenance of PA. These findings suggest that the act of wearing and monitoring a fitness wearable has a motivational etiology, rather than simply being a methodological concern as it is usually treated in research contexts. Stricter study procedures with more controlled observation can sometimes cause participants to act differently than they would usually (ie, Hawthorne bias), potentially leading to different outcomes when implemented in a real-world setting. On the other hand, successful step-goal achievement on days the watch was worn was associated with variables that were not relevant to successful watch wear, including high engagement and a high number of friends. Thus, although having similar etiology, these 2 behaviors may require different interventions.

Finally, the intervention and analyses reported herein among several hundred participants from a single campus should be repeated at other campuses to test generalizability. Efforts should be made to engage campuses from the American College of Sports Medicine's Exercise is Medicine On Campus initiative lists and others for means that interventions can collect data and transfer it to research teams. The MoveSpring platform would be one excellent mechanism; many institutions offer it to faculty and staff but should consider offering it to students, as in this study.

Conclusions

Engagement with the program suggests longer retention and better PA outcomes, which were critically modified by the interpersonal aspects of this engagement. Adopting a pragmatic approach to implementation highlights opportunities for future trials and the need for specific strategies tailored to different groups to account for differences in demographics and baseline motives and goals.

Acknowledgments

The authors acknowledge support from the National Institute on Alcohol Abuse and Alcoholism of the National Institutes of Health (R01AA031959) and from the AL Williams Professorship funds. In addition, author GIA was supported by American Heart Association (grant 852679); Robert E Lee and Clara Guthrie Patterson Trust Mentored Research Award, Bank of America, NA, Trustee; and the National Institute of Diabetes, Digestive, and Kidney Diseases of the National Institutes of Health under a mentored research scientist development award (K01DK129441). These funders played no role in study design, data procurement, analysis and interpretation of data, or the writing of this manuscript.

The Southern Connecticut State University Fitness Center and the MoveSpring app supported the study by donating data from their previously conducted program. They played no role in analysis and interpretation of data or the writing of this manuscript.

Data Availability

All data analyzed in this study are publicly available on Dataverse [44].

Authors' Contributions

GIA, SSM, MS-K, and MBG conceptualized the research design, aims, and methodology with support from LMF, MA, BB, JJL, SL, and XX. MBG and GIA acquired funding. ADH, POB, and RSA summarized intervention methodology. GIA curated the data. SJ conducted formal analysis and data visualization with support from GIA, MS-K, and MBG. GIA validated the analysis. GIA and SSM wrote the first draft of the manuscript with support from ADH, MA, and SJ. MS-K reviewed and edited the first draft of the manuscript. MBG, LMF, SJ, ADH, MA, POB, RSA, BB, JJL, SL, SL, and XX reviewed and edited a subsequent draft of the manuscript, and all authors approved the final manuscript.

Conflicts of Interest

GIA receives professional service fees from Calm.com [61] (nominal fee), Labfront (full fee), and GlucoseZone (full fee). LMF and GIA have a provisional patent filed for a digital system for lifestyle medicine (047162-5346-P1US) outside the submitted work. SSM, ADH, MA, POB, RSA, BB, JJL, SL, XX, SJ, MS-K, and MBG declare no potential conflicts of interest. The authors attest that Calm.com [61], Labfront, GlucoseZone, and a digital system for lifestyle medicine had no influence on the design of this study or its outcomes.

Abstract

Background: Augmented reality (AR) superimposes virtual objects onto a real-world environment, allowing users to interact in real time. As AR has become widely used, its integration into smartphones or tablets has enabled mobile augmented reality (MAR) experiences. AR has been adopted in many industries, and the literature has highlighted its applications in academic and clinical settings, particularly in enhancing visualization, communication, and learning.

Objective: This study investigated the potential of MAR as a mobile health tool to enhance shared decision-making (SDM) in thoracic surgery by increasing patient understanding and engagement during medical consultations.

Methods: A randomized crossover clinical trial was conducted at the Tri-Service General Hospital in Taiwan. Participants scheduled for thoracic surgery were enrolled and randomized in a crossover design. The MAR intervention incorporated patient-specific 3D anatomical models that were reconstructed from computed tomography imaging to facilitate understanding and support SDM. The impact of each counseling approach on SDM was evaluated using postintervention questionnaires.

Results: A total of 47 participants were enrolled in this study. After analyzing the data, we found that patients in the MAR group showed significantly higher scores compared to those in the traditional counseling group (P<.001) during the SDM process. Moreover, patients reported higher satisfaction levels and found the visual objects helpful for understanding tumor location and surgical procedures.

Conclusions: This study demonstrated that MAR counseling significantly enhanced patients' comprehension of thoracic conditions and increased their active engagement in the SDM process (P<.001). The integration of patient-specific 3D anatomical models into MAR technology provided an intuitive method for critical medical information. This digital approach not only enhanced personalization in medical communication but also reinforced patient education about their health care conditions. These findings suggest that MAR counseling represents a promising approach for promoting patient-centered care in thoracic surgery and has potential applications across various clinical domains.

mobile augmented reality; shared decision-making; patient education; thoracic surgery; 3D models

Introduction

Role of Mobile Augmented Reality in Clinical Counseling and Mobile Health

Augmented reality (AR) allows the seamless integration of virtual elements with real-world environments, including the superimposition of digital files, such as 3D models, animations, and videos. This enhances interactive learning, visualization, and communication in medical contexts [1]. A more accessible and scalable evolution of AR is mobile AR (MAR), which operates via smartphones and tablets [2]. Unlike AR headsets or smart glasses, MAR leverages everyday mobile devices to deliver immersive experiences, making it a cost-effective and broadly deployable solution in both clinical and remote settings.

In the medical field, AR has been increasingly applied in thoracic surgery for training, preoperative planning, and intraoperative assistance [3]. However, a noticeable gap exists in the literature regarding the use of MAR as a patient-facing mobile health (mHealth) tool to improve communication and support shared decision-making (SDM). By enabling real-time 3D visualization of patient-specific anatomy through mobile devices, MAR represents a novel strategy within the mHealth paradigm to promote accessibility, patient engagement, and autonomy in surgical counseling.

Surgical Counseling Challenges in Thoracic Surgery

Lung cancer is a global health challenge, as reflected in the 2020 world statistics. The incidence of lung and bronchus cancer was reported at 31.5 cases per 100,000 population for men and 14.6 cases per 100,000 population for women. The widespread prevalence of lung cancer continues to affect a significant portion of the global population [4].

In Taiwan, the situation is even more concerning. According to the latest report by Taiwan's Ministry of Health and Welfare in 2021, the rate of new cases of lung and bronchus cancer was alarmingly high, at 77.39 per 100,000 population for men and 67.13 per 100,000 population for women. Among the 16,880 newly diagnosed cases, a considerable portion (40.4%) received surgical treatment [5], which is one of the essential treatment options and the standard approach for early-stage disease.

The surgical approaches for lung resection could be divided into open thoracotomy and minimally invasive thoracic surgery (ie, video-assisted and robot-assisted thoracoscopic surgery). The various modes of lung resection, including anatomical (pneumonectomy, lobectomy, and segmentectomy) and nonanatomical (wedge resection) [6], pose a significant challenge to patient understanding. Traditional methods of patient counseling, relying on oral explanations, 2D computed tomography scans, and schematic diagrams, often fail to provide a comprehensive understanding. Although informative, these methods do not fully convey the intricacies of each surgical option, leaving patients inadequately equipped to make informed decisions.

This gap in understanding is critical, as patients need to comprehend various aspects of their condition, such as tumor location, its proximity to vital structures, and the specifics of different surgical procedures, each with its unique risks and implications. The limitations of current counseling methods highlight the necessity for innovative approaches that can enhance physician-patient communication, provide better visual support, and enable patients to engage more effectively in their treatment planning.

Communication and SDM

Several factors contribute to the quality of patient counseling and decision-making. These include patient anxiety, cultural background, insufficient medical knowledge, and awareness, all of which can significantly influence clinical decision outcomes [7,8]. Patients tend to participate more actively in treatment planning when they clearly understand their medical information [9]. Ineffective communication, especially when lacking meaningful patient engagement [10], may result in misunderstandings, dissatisfaction, disputes, and even violence against health care providers [11]. SDM has been increasingly promoted to emphasize patient preferences, values, and autonomy in the medical decision-making process [12]. It is now widely endorsed by academic and professional societies as a means to improve decision quality [13]. In addition, assistive tools—especially visual and interactive aids—have also been shown to support this process [14].

Study Objective

To address this unmet need, we developed a MAR-based counseling system that integrates patient-specific 3D visualization into the SDM process for thoracic surgery. This study introduces a novel application of mHealth aimed at bridging the gap between complex surgical information and patient understanding.

Methods

Study Design

This study was a single-center, 2-arm, randomized crossover clinical trial conducted at Tri-Service General Hospital, Taipei, Taiwan, between July 2022 and June 2023. The study compared traditional image-based counseling with MAR-enhanced counseling for patients undergoing thoracic surgery. Participants were randomized to 1 of 2 counseling sequences: traditional followed by MAR (group A) or MAR followed by traditional (group B). Each participant received both formats of counseling during a single encounter. To evaluate the impact of each method, participants completed self-administered questionnaires after each session to assess SDM and counseling preferences. No formal washout period was implemented due to the educational and noninterventional nature of the study.

XSL•FO
RenderX

Patient and Public Involvement

Patients or the public were not involved in the design, conduct, reporting, or dissemination of this study, as the research focused on the technical development and initial validation of a mobile-based counseling tool. Future iterations may incorporate patient feedback to optimize usability and relevance.

Sample Size Calculation

Sample size was calculated using G*Power (version 3.1.9.7; Heinrich Heine University Düsseldorf) to detect a significant difference between 2 independent groups using nonparametric analysis. The calculation was based on unpublished pilot data from our research team, involving 10 patients who received both MAR and traditional counseling. A large effect size (Cohen d=0.9) was observed in SDM score differences. Based on a two-tailed test with an alpha level of .05 and statistical power of 0.80, the required sample size was calculated to be 44 participants (22 per group). To accommodate for potential dropouts, 47 patients were ultimately enrolled.

Recruitment

Participants were recruited through outpatient and inpatient referrals from thoracic surgery clinics. Inclusion criteria were as follows: (1) scheduled for thoracic surgery (eg, lobectomy, segmentectomy, or wedge resection); (2) aged 20 to 65 years; (3) capable of using a smart device; (4) able to communicate in Mandarin or Taiwanese; (5) willing and able to provide informed consent; and (6) capable of completing questionnaires independently or with minimal assistance. Exclusion criteria were as follows: (1) emergency surgery, (2) severe cognitive impairment or psychiatric illness interfering with participation, (3) visual or hearing impairments interfering with mobile device interaction, (4) prior participation in similar counseling studies, and (5) inability to complete follow-up.

Randomization

Consenting participants were randomly allocated to either group A (traditional counseling first) or group B (MAR counseling first) using a basic random number generator by a research assistant without allocation concealment or stratification. Due to the nature of the interventions, blinding was not feasible in this study.

Interventions

A standardized counseling protocol was developed to ensure consistency across both groups and was delivered by the same thoracic surgeon to minimize interoperator variability. During crossover sessions, surgeons maintained neutrality and avoided providing additional interpretation. Surgeons adhered to the protocol and followed a structured sequence to explain the tumor location, surgical options, and associated risks.

In group A, participants received traditional counseling first, which involved an explanation of their health condition using verbal explanations supported by axial, coronal, and sagittal CT images and a 10 to 15-minute discussion. They were asked to complete a questionnaire related to SDM (questionnaire 1), followed by MAR counseling with interactive, patient-specific 3D anatomical models presented through mobile devices, and then to fill out a second questionnaire (questionnaire 2). In contrast, participants in group B began with MAR counseling. This part included a 5-minute app introduction followed by a 10-to-15-minute personalized anatomical visualization and discussion using the MAR application. After participants (specifically to participants who are in group B) completed the questionnaire 1, they received traditional counseling and proceeded to complete questionnaire 2. All participants experienced both counseling approaches, and their overall preferences and perceptions were evaluated through a questionnaire 3. In Multimedia Appendix 1, demonstration of both traditional and mobile augmented reality (MAR) counseling methods is shown in MP4 format.

Patient-Specific 3D Models via MAR Application

CT images of 47 patients scheduled for thoracic surgery at the Tri-Service General Hospital were collected. Digital images in Digital Imaging and Communications in Medicine format were acquired and imported into Materialise Mimics software (version 22; Materialise NV) for anatomical segmentation and 3D reconstruction of the lung and tumor regions (Figure 1A). Subsequently, we meticulously crafted standard tessellation language 3D models and transformed these Standard Tessellation Language models into GLB format models in Blender software (version 3.6, Blender Foundation) to ensure accurate color representation. The finalized GLB files were then uploaded into the MAR Editor platform (version 3.4.2, Mifly). In the process of editing, we enhanced the visualization by assigning realistic colors, transparency settings, and interactive marks (Figure 1B). The editing platform allowed real-time interaction with the model on tablets or smartphones. Each model was fully interactive, allowing rotation, zooming, and exploration of the anatomical structures from multiple angles (Figure 1C). During counseling sessions, surgeons used these personalized models to explain the disease, treatment options, and the anticipated surgical procedures. (Figure 1D). For standardization, all participants interacted with the same mobile device, an iPad Pro (12.9 inch; fourth generation; Apple Inc), during MAR counseling sessions. In Multimedia Appendix 2, step-by-step demonstration of the mobile augmented reality (MAR) 3D model creation and deployment is shown in MP4 format.

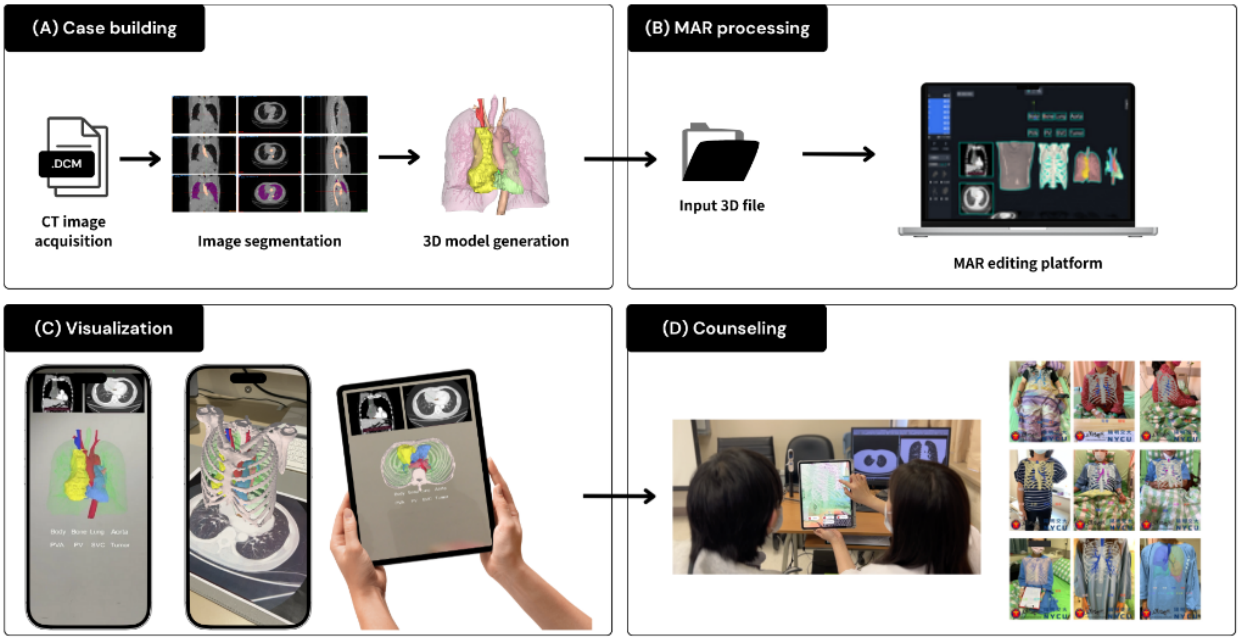
(B) Models are optimized and uploaded to the editing platform to adjust settings. (C) Models are embedded into the application's interface, enabling interactive manipulation (zoom, rotation). (D) The finalized interactive model is deployed to the mobile device for physician-patient counseling.



Measurement of Satisfaction Outcomes

To assess the impact of the different counseling methods on SDM and user preference, we designed the self-reported questionnaires for this study. Questionnaire 1 focused on SDM outcomes following the counseling session and included 10 items. Questionnaire 2 was the same as questionnaire 1, allowing the acquired preferences to be determined by comparing the results of questionnaire 2 with those of questionnaire 1. Questionnaire 3 specifically evaluated participants' overall preference for a traditional or an MAR counseling approach. All questionnaire items were rated on a 5-point Likert-type scale, ranging from 1 ("strongly disagree") to 5 ("strongly agree"). A higher score indicated a stronger impact of patient counseling on SDM. To ensure content validity, the questionnaires were reviewed and refined with input from an expert panel.

The primary outcome was the level of SDM assessed in each counseling session (questionnaire 1 and questionnaire 2). The secondary outcome was participant preference (questionnaire 3).

Data Collection and Statistical Analysis

All 47 participants completed the questionnaires, and no one was excluded from the analysis. After the questionnaires were collected and anonymized in Microsoft Excel, relevant statistical analyses were performed using SPSS (version 24.0; IBM Corp). Descriptive statistics were used to summarize the baseline characteristics, demographic data, and outcome variables. Group differences were assessed using Fisher exact and the chi-square tests for categorical variables. To evaluate group comparisons and relationships among variables, independent 2-tailed *t* tests, paired 2-tailed *t* tests, Pearson correlation analyses, and multiple linear regression models were conducted. We recognized that in a crossover study, participants receiving the experimental variable in the first period might continue to be affected in the second period. To minimize carryover effects, we applied a linear mixed model analysis, considering sequence and period effects to adjust the influencing factors. $P<.05$ was considered statistically significant.

Given the noninterventional and educational nature of this study, no interim analyses or stopping guidelines were planned.

Ethical Considerations

The study was reviewed and approved by the institutional review board of Tri-Service General Hospital (A202205082) and was retrospectively registered on ClinicalTrials.gov (NCT07062393). Written informed consent was obtained from all participants before enrollment after being informed of the study purpose, procedures, and voluntary nature of participation. The study posed minimal risk, involved no invasive procedures, and used patients' own clinical data for educational counseling purposes. No additional imaging was required. No concomitant care or cointerventions were provided during the trial period. Participation was voluntary, with the right to withdraw at any time. All data were securely stored and anonymized before the analysis to ensure participant confidentiality. Access to identifiable information was restricted to authorized research personnel. No financial or material incentives were provided to participants.

RenderX

Results

Participant Characteristics

A total of 47 participants fully completed questionnaires and were included in the final analysis, with 25 from counseling group A and 22 from counseling group B. A visual summary of the study flow is provided in Figure 2. No adverse events or unintended effects were reported in either group during or after the counseling sessions. The interventions involved no physical or psychological risks, and all participants completed the study without incident. Most participants in both groups were older than 30 years, held a university degree or higher, had been using smartphones for 10 to 20 years, and had no experience with AR or virtual reality (VR) technologies. No significant differences were observed in participant characteristics between the two groups, as summarized in Table 1.

SDM Scores

Table 2 presents the results of the questionnaire related to SDM. Before grouping, the overall mean score for traditional counseling was 37.40 (SD 5.83), and the overall mean score for MAR counseling was 47.98 (SD 2.92). The results related to patient SDM scores showed a significant difference ($P \leq .001$). This finding indicates that MAR counseling was more effective in supporting patients' engagement in the decision-making process. In traditional counseling, the lowest-scoring topics were encouraging participation (mean 3.66, SD 0.70) and enhancing communication (mean 3.66, SD 0.67). In contrast, MAR counseling achieved significantly higher scores in these 2 topics (mean 4.83, SD 0.38 and mean 4.87, SD 0.34; $P < .001$), including thought organization (mean 4.83, SD 0.38) and trusting health care providers' treatment methods (mean 4.83, SD 0.38). MAR counseling also supported participants in understanding medical options (mean 4.74, SD 0.44) and provided more opportunities to ask questions to health care providers (mean 4.77, SD 0.43), thereby supporting decision-making (mean 4.79, SD 0.41).

XSL•FO
RenderX

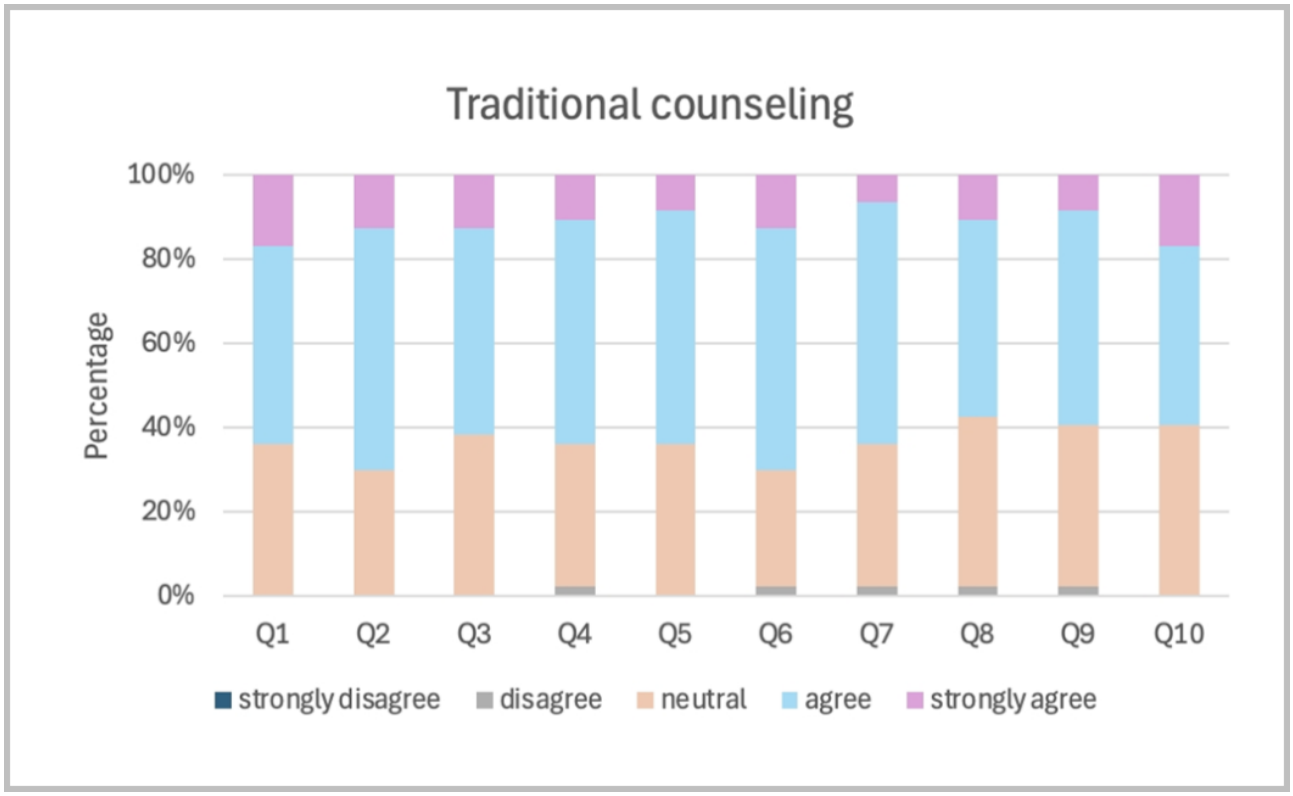
Table 2. Results from the 10-item questionnaire assessing patients' perspectives on shared decision-making (SDM) after traditional versus mobile augmented reality (MAR) counseling.

Questions	Traditional counseling, mean (SD)	MAR counseling, mean (SD)	*P* value[a]
1. Helps me feel more prepared to make decisions.	3.81(0.71)	4.79 (0.41)	≤.001
2. Helps me organize my thoughts about these decisions.	3.83 (0.64)	4.83 (0.38)	≤.001
3. Helps me consider the pros and cons of each option.	3.74 (0.68)	4.77 (0.48)	≤.001
4. Helps me compile the questions I want to ask.	3.69 (0.67)	4.77 (0.43)	≤.001
5. Clarifies and communicates what matters most to me.	3.72 (0.62)	4.79 (0.41)	≤.001
6. Helps me understand the available medical options.	3.81 (0.68)	4.74 (0.44)	≤.001
7. Provides me with the opportunity to ask questions.	3.68 (0.63)	4.77 (0.43)	≤.001
8. Encourages my participation in the health care process.	3.66 (0.70)	4.83 (0.38)	≤.001
9. Enhances communication between me and health care providers	3.66 (0.67)	4.87 (0.34)	≤.001
10. Helps me trust health care providers' treatment methods	3.77 (0.73)	4.83 (0.38)	≤.001

[a]*P* values were obtained using the Wilcoxon rank-sum test. Higher scores indicate greater agreement with each statement (1-5 Likert scale).

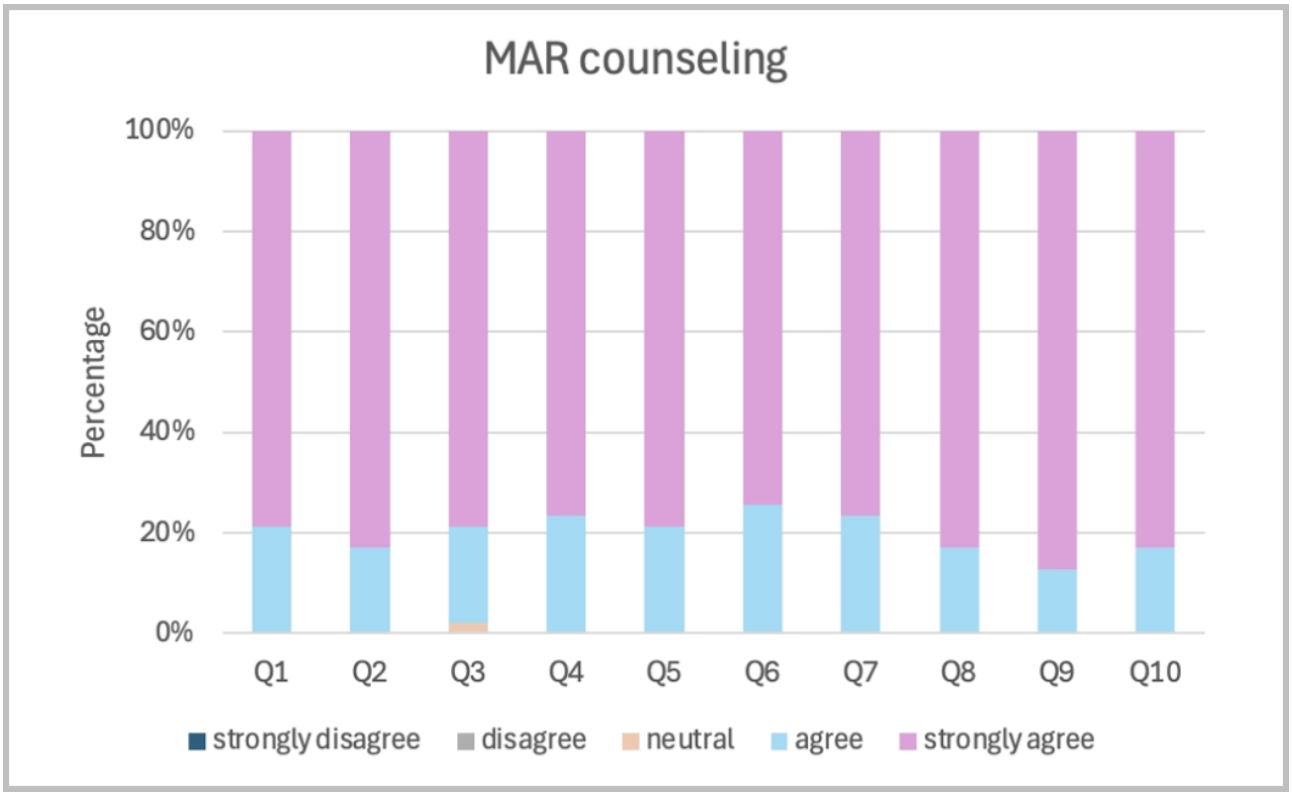
Figures 3 and 4 illustrate the distribution of participant responses for each of the 10 questionnaire items following traditional and MAR counseling. In traditional counseling, most participants rated between "agree" and "neutral," with a few selecting "strongly agree." By contrast, the MAR counseling demonstrated higher agreement across all topics, with nearly all participants selecting "agree or strongly agree." The lowest-scoring item, considering the pros and cons of each treatment option (question 3), was rated at 95.46%. For all other topics, 100% of participants rated either agree or strongly agree, with virtually no neutral or negative responses.

Figure 3. Distribution of participant responses to each item of the 10-item Shared Decision-Making Questionnaire (SDM-Q-10) following traditional counseling. Responses were measured on a 5-point Likert scale ranging from "strongly disagree" to "strongly agree." Item wording is provided in Table 2.



XSL•FO
RenderX

Figure 4. Distribution of participant responses to each item of the 10-item Shared Decision-Making Questionnaire (SDM-Q-10) following mobile augmented reality (MAR) counseling. Responses were measured on a 5-point Likert scale ranging from "strongly disagree" to "strongly agree." Item wording is provided in Table 2.



Interventions in Crossover Design

To evaluate the effect of counseling sequence on participant satisfaction, an independent sample *t* test was conducted to compare the differences between group A and group B in this crossover design. Participants were randomly assigned to either group A, which received traditional counseling followed by MAR counseling, or group B, which received MAR counseling first, followed by traditional counseling. The results showed no significant differences between the 2 sequences. The mean satisfaction score for traditional counseling was 36.92 (SD 6.07) in group A and 37.95 (SD 5.64) in group B (t=−0.60, P=.55), whereas MAR counseling scored 47.72 (SD 2.94) and 48.27 (SD 2.95) in group A and B, respectively (t=−0.64, P=.52) These findings indicated that the order in which traditional and MAR counseling methods were administered did not influence satisfaction outcomes.

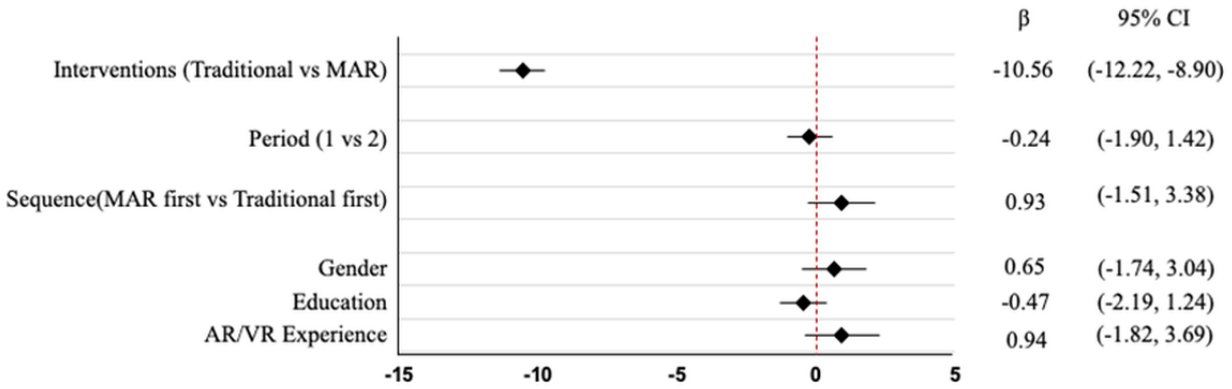
Further within-group analyses revealed that MAR counseling was consistently rated higher than traditional counseling across both sequences. In group A, the mean difference between traditional and MAR counseling was −10.80 (SD 5.65, P<.001, Cohen d=−1.91), and in group B, the difference between MAR and traditional counseling was 10.32 (SD 5.61, P<.001, Cohen d=1.84).

Adjusted Comparison Using Linear Mixed Model

Although the paired samples *t* test provided preliminary evidence that MAR counseling was rated higher than traditional counseling, additional analyses using a linear mixed model were conducted to examine any potential carryover effect. Considering both the sequence (traditional first or MAR first) and the period (first or second), neither the period nor the sequence effect reached statistical significance (P>.05). Demographic variables, including gender, education level, and AR and VR experience, also did not significantly affect the outcomes. However, the analysis showed that the different interventions demonstrated a significant difference; MAR counseling scored 10.55 points higher than traditional counseling, reaching statistical significance (P≤.001). These findings indicate that the type of intervention was the primary factor influencing participants' perceptions; whereas period and sequence effects did not significantly impact counseling outcomes. The fixed-effect estimates are presented in Figure 5.

XSL•FO
RenderX

Figure 5. Fixed effects estimated from linear mixed model assessing the impact of treatment sequence, period, and demographic variables on shared decision-making (SDM) scores. AR: augmented reality; VR: virtual reality; MAR: mobile augmented reality.



Participant Preferences

The participants' overall preferences were assessed with questionnaire 3 (I am willing to use this counseling method to communicate with health care providers; 1=traditional; 2=MAR). The analysis revealed that participants had a strong preference for the MAR counseling method. The mean score for MAR counseling (4.96, SD 0.20) was significantly higher than that for traditional counseling (mean 3.77, SD 0.70; $P \leq .001$). Furthermore, 45 of 47 (96%) participants indicated a strong willingness to use MAR counseling as a communication method in the SDM process.

Influence of Demographic Variables

To further investigate whether the participants' preferences were influenced by demographic variables, a multiple linear regression analysis was conducted (Table 3). The results showed that none of the demographic variables, including gender, education level, duration of mobile phone use, average daily internet use, and AR and VR experience, reached statistical significance ($P > .05$) in the MAR counseling group. Similarly, most of the demographic variables did not demonstrate a significant result in traditional counseling. However, without AR and VR experience showed a positive effect (B=0.583, β=.357; $P=.03$), indicating that the participants without AR and VR experience reported a higher preference for the traditional counseling approaches compared to those who had the experience in AR and VR technology. The adjusted R^2 values for both models were low (MAR=0.12; traditional=0.19), indicating that demographic factors explained a small proportion of the results.

Table 3. Multiple linear regression predicting shared decision-making scores from demographic variables.

Discussion

Principal Findings

The study results indicated that participants preferred MAR counseling more than traditional counseling approaches during SDM, particularly regarding trust and participant engagement. This effect may be attributed to participants gaining more disease-specific knowledge from MAR, which, in turn, led to increased engagement [9]. Paired samples *t* tests revealed significantly higher scores for MAR counseling, demonstrating that the digital approach had a positive impact in helping participants comprehend the risks and benefits associated with their treatment options. Furthermore, the findings were strengthened by the linear mixed model analysis, which considered sequence and period effects to adjust the impact factors. Neither the sequence nor the period effects reached statistical significance.

These findings are consistent with those of a previous study that used 3D models in patient counseling for renal masses [15]. Although it is possible that the visually rich nature of MAR contributed to patient engagement, the structured questionnaires assessed more than just visual appeal. Notably, items such as question 3 (“Helps me consider the pros and cons of each option”) and question 6 (“Helps me understand the available medical options”), which evaluated the understanding of pros and cons and treatment options, showed significant improvement in the MAR counseling. This suggests that MAR facilitated greater engagement and deeper cognitive processing of medical information. These findings indicate that the observed improvements in SDM were not limited to increased engagement or visual novelty but included measurable enhancement in understanding treatment risks and options. This supports the value of MAR not only as a communication aid but also as a decision-support tool grounded in cognitive comprehension that strengthens SDM processes in clinical practice.

Implementation Considerations

However, several considerations should be noted. MAR counseling demanded more time and a more complex preparation process compared with traditional counseling. The cost-effectiveness of adopting this new counseling method should be explored thoroughly before full implementation.

MAR offers a powerful solution to enhance telemedicine and improve technological literacy. One key advantage is its ability to address the challenge of interpreting complex medical data, such as 2D DICOM images, which can be difficult for patients without specialized anatomical knowledge to understand. MAR overlays 3D visualizations onto the physical world, making it easier for patients and health care providers to comprehend medical images by offering an interactive, spatial representation of anatomy. This interactive experience enhances the clarity of diagnostic information, allowing for more informed SDM.

Moreover, unlike the use of AR smart glasses, which can sometimes cause discomfort such as dizziness or visual fatigue, patients using MAR on mobile devices did not report such issues. The display on a mobile device offers flexibility in positioning and control, reduces strain on the eyes, and prevents the sensory overload that can occur with head-mounted displays. As a result, patients were more comfortable engaging with the technology for extended periods, facilitating a more seamless integration of MAR into telemedicine and clinical workflows. This ease of use further promotes patient empowerment, enabling them to take an active role in understanding their own health data.

Prior literature has reported that 3D models have made telemedicine visits as effective as in-person visits [15]. This finding could be applied to MAR counseling, as the counseling process can be conducted through smartphones or tablet devices. The integration of MAR into telemedicine can potentially enhance the quality of counseling in the future.

Limitations

However, the implementation of MAR consultation also has hidden challenges. Compared with traditional methods, MAR counseling demands a longer preparation time, additional training for clinical staff, and reliance on stable hardware and network infrastructure. Although MAR technology offers the advantage of accessing virtual resources anytime and anywhere, whether in medical education or clinical settings, its effectiveness and usability remain closely tied to technical settings. When users operate MAR systems in environments with limited bandwidth or outdated hardware, they may experience delays, failed file loading, or degraded 3D rendering performance. These limitations may result in reduced acceptance or satisfaction, regardless of the perceived educational or clinical value of the MAR content.

Additionally, the questionnaires used in this study were developed to reflect the unique attributes of MAR, which may limit direct comparison with SDM outcome measures (eg, the 9-item Shared Decision Making Questionnaire or the OPTION [Observing Patient Involvement] scale). Future studies should incorporate validated tools alongside MAR-specific items to improve generalizability and construct validity. Finally, the study was conducted at a single institution with a modest sample size, which may limit the broader applicability of our findings. Although the sample size was statistically adequate based on pilot data, larger multicenter trials are warranted to improve generalizability and explore subgroup effects. Future multicenter studies with larger and more diverse populations, time-matched conditions, and validated instruments are warranted to confirm the impact and feasibility of MAR counseling in thoracic surgery and beyond.

Conclusions

MAR counseling demonstrated a significantly higher impact on SDM compared with traditional counseling for patients undergoing thoracic surgery. This indicates that MAR consultation is effective in supporting patients’ engagement in the decision-making process and enhancing their understanding, participation, and trust. Importantly, MAR counseling demonstrated statistically significant improvements in participants’ perceptions compared to traditional counseling. In contrast, under traditional counseling, patients often find it difficult to effectively organize their questions. Insufficient interaction with physicians may limit patients’ active

XSL•FO
RenderX

participation in the SDM process. MAR consultation scored significantly higher in the same topics, better supported patients, and promoted communication between physicians and patients. However, we recommend conducting a multicenter study with a usability score assessment to validate the generalizability and feasibility of MAR counseling in future research. This will help ensure the widespread applicability and practicality of this approach in a broader context.

Acknowledgments

The authors wish to thank Mifly Company (Taipei, Taiwan) for their technical assistance in integrating and deploying the mobile augmented reality platform used in this study. No financial support or sponsorship was received from the company. This research was supported by the Tri-Service General Hospital Medical Research Project (TSGH-E-112239). No external commercial or nonprofit funding was received for this study. OpenAI's ChatGPT (GPT-4) was used to assist in language refinement, formatting, and drafting of reviewer response letters during manuscript preparation. Abstract

Background: The adoption of high-quality health apps has been slow, despite the myriad benefits associated with their use. This is partly due to concerns regarding the effectiveness, safety, and data privacy of such apps. Quality assessments with robust and transparent criteria can address these concerns and, thereby, encourage the use of high-quality apps. However, a major challenge for such assessments is reaching a scale at which a substantial proportion of the more than 350,000 available health apps can be evaluated.

Objective: To support the scaling of health app quality assessments, this study aimed to examine the preferences and willingness to pay for assessments with different value propositions among potential customers.

Methods: We conducted 2 discrete choice experiments: one with 41 health app developers and another with 46 health system representatives (from health care institutions, authorities, and insurers) from across Europe. Mixed logit models were applied to examine the impact of assessment attributes on participants' choices as well as to calculate marginal willingness to pay and predicted assessment uptake.

Results: Among health app developers, the attributes with the largest impact on assessment choices were the associated clinical care uptake (integration into clinical guidelines and reimbursement or procurement) and cost (purchase price). Increased willingness to use assessed apps and app store integration of assessment results had a moderate impact on choices, while required developer time investment and time until assessment results become available made the smallest contribution. Among health system representatives, increased willingness of clinicians and patients to use evaluated apps had the greatest impact on assessment choices, followed by cost. Time until assessment result availability and the percentage of peers recommending the assessment made a moderate contribution, while reassessment frequency had the smallest impact on choices. On average, health app developers were willing to pay an additional €9020 (95% CI €4968-€13,072) if an assessment facilitates guideline integration and procurement or reimbursement (at the time of data collection, €1=US $1.11), while health system representatives were, on average, willing to

XSL•FO
RenderX

pay €7037 (95% CI €4267-€9806) more if an assessment results in a large, rather than a small, increase in willingness to use the evaluated app. The predicted uptake of assessments that offer the preferred values for all attributes was 88.6% among app developers and 91.1% among health system representatives.

Conclusions: These findings indicate that, to maximize uptake and willingness to pay among health app developers, it is advisable for assessments to facilitate or enable clinical guideline integration and reimbursement or procurement for high-scoring apps. Assessment scaling thus requires close collaboration with health authorities, health care institutions, and insurers. Furthermore, if health system organizations are targeted as customers, it is essential to provide evidence for the assessment's impact on patients' and clinicians' willingness to use health apps.

Introduction

Background

There is increasing recognition that digital health technologies, including health apps that support health system services, disease prevention, self-management, and treatment, should play a greater role in health care [1]. Health apps complement in-person care and could ease the strain on clinicians and health systems, which is partly due to a shortage of health care professionals [2,3].

A number of recent studies have demonstrated the beneficial effects of health apps on health outcomes and quality of life [4], including in condition areas such as mental health [5,6], diabetes [7-9], hypertension [7], cancer [10,11], and asthma [12]. Moreover, health apps can contribute to cost savings and more efficient use of health system resources that are facing an increasing demand [13,14]. Indeed, past estimates suggest that using health apps to their full potential could have resulted in vast savings across the European Union in 2017 [15].

To attain these benefits, the widespread use of health apps is necessary, yet adoption has been slow [16], with concerns related to the effectiveness, safety, usability, and data privacy of such apps reported as a major barrier to their use among both patients and clinicians [17,18].

Importantly, these apprehensions are justified in some cases [19], and current European regulations are arguably not sufficient to fully alleviate such concerns [20,21]. First, the Medical Device Regulation (MDR) only covers apps that are *specifically intended by the developer ("manufacturer") to be used for medical purposes*. This creates a "loophole" related to the phrasing of an app's intended purpose, incentivizes development of apps with nonmedical purposes, and leaves a substantial number of health apps unregulated by the MDR [22]. For instance, in a sample of 271 health apps examined for the Dutch Ministry of Health, 215 apps (79.3%) did not fall under the MDR [23]. Such apps, as well as apps falling under MDR risk class I, are not required to undergo conformity assessment by a notified body [23]. Second, although the General Data Protection Regulation applies to health apps available in Europe that process personal data, compliance with this regulation is usually not independently evaluated. Indeed, it has been found that a large proportion of health apps on the market do not meet relevant data protection requirements [24,25]. Third, concerns have been raised regarding the quality and appropriateness of the studies that are deemed acceptable under the MDR to demonstrate a product's safety and effectiveness [26,27]. Finally, the only user-facing output of the MDR assessment is a Conformité Européenne (CE; European Conformity) mark, which consists of the letters "CE" being affixed to medical devices, including health apps, if they have been found to comply with the MDR (through self-assessment for class I apps or through evaluation by a notified body for apps with a higher risk classification). This CE mark only aims to indicate conformity with the MDR, without seeking to provide transparency to users unfamiliar with regulatory requirements regarding the domains that have been assessed and how apps compare across them.

Partly as a result of the aforementioned considerations, a number of third-party health app assessment frameworks have been established by organizations such as health authorities, health care institutions, medical professional associations, and for-profit companies to promote the use of high-quality apps across Europe and beyond [28,29]. However, a major challenge for such assessment initiatives is reaching a scale at which they can evaluate a large proportion of the more than 350,000 health apps available on the global market [30] or even of the approximately 100,000 health apps available in Europe [29,31,32]. Such scaling can only be achieved if, alongside an efficient assessment process and a sufficient number of assessors, an appropriate customer group is targeted and customers' expectations regarding assessment costs and benefits are met.

Objectives

To facilitate the scaling of health app quality assessments, this study aimed to gather insights into the preferences and willingness to pay for health app assessments with different value propositions among potential assessment customers across Europe. For this purpose, employees of health app development companies and health system representatives (from health care institutions, health authorities, health technology assessment bodies, and health insurers) were invited to take part in a discrete choice experiment (DCE).

The study was conducted as part of the European Union–funded Label2Enable project, which aims to support the adoption and operation of the CEN ISO/TS 82304-2 health app quality assessment as a trusted standard across Europe [33,34].

XSL•FO
RenderX

However, the study's findings are not specific to the CEN ISO/TS 82304-2 assessment and provide valuable information for the scaling of health app quality evaluation initiatives more generally.

Methods

Overview

DCEs are commonly used in health care contexts to examine stakeholders' preferences [35]. In such experiments, participants are presented with several choice sets consisting of 2 or more alternatives (eg, 2 treatment options) that differ across a range of attributes (eg, cost, effectiveness, and side effects). Participants repeatedly choose between alternatives with different attribute values, allowing researchers to determine participants' preferences as well as the trade-offs that participants are willing to make across attributes.

As part of this study, the DCE methodology was applied to elicit preferences for health app quality assessments with different value propositions from potential customers of third-party assessments. The study was designed and conducted in line with best practices developed by the International Society for Pharmacoeconomics and Outcomes Research Conjoint Analysis Working Group [36].

Selection of Attributes and Levels

To identify relevant assessment attributes for the DCE as well as realistic values for these attributes, interviews were conducted with representatives of digital health assessment organizations from 7 European countries (for details, refer to Table S1 in Multimedia Appendix 1). The interviews, which also served to inform other aspects of the Label2Enable project, covered topics such as assessment scope, assessment trigger, time requirements, costs and funding, benefits of the assessment for health care stakeholders, progress to date, and barriers to scaling.

Subsequently, a video conference discussion was held with representatives of the stakeholder groups targeted by this study to determine the attributes they regarded as most important. Each representative was called on individually to comment on the attributes identified during the interviews and to suggest additional aspects to consider. All attributes that were indicated as being important by any of the representatives were shortlisted. More specifically, 2 shortlists were created (with some overlapping attributes): one for health app developers and another for health system representatives (from health care institutions, health authorities, health technology assessment bodies, and health insurers). Creating 2 attribute lists for use in 2 separate DCEs was deemed necessary due to the differing priorities and objectives of these stakeholder groups. For instance, an important attribute for health app developers was the amount of time they would need to invest to prepare the necessary documentation for the assessment. By contrast, this attribute was not relevant for health system representatives because they are not involved in gathering documentation as part of the assessment process.

The attribute shortlists were further refined through email correspondence with the stakeholder representatives until a consensus agreement on 5 to 6 attributes was reached. This number of attributes was chosen to limit the cognitive load of the choice task with full profiles. The levels for the selected attributes were based on the range of values reported by the assessment organizations during the interviews as well as the values observed during pilot testing of the CEN ISO/TS 82304-2 assessment. In line with recommendations [36], no more than 3 levels were chosen for each attribute. The final lists of attributes and levels for the 2 DCEs, as presented to participants, are shown in Figures 1 and 2.

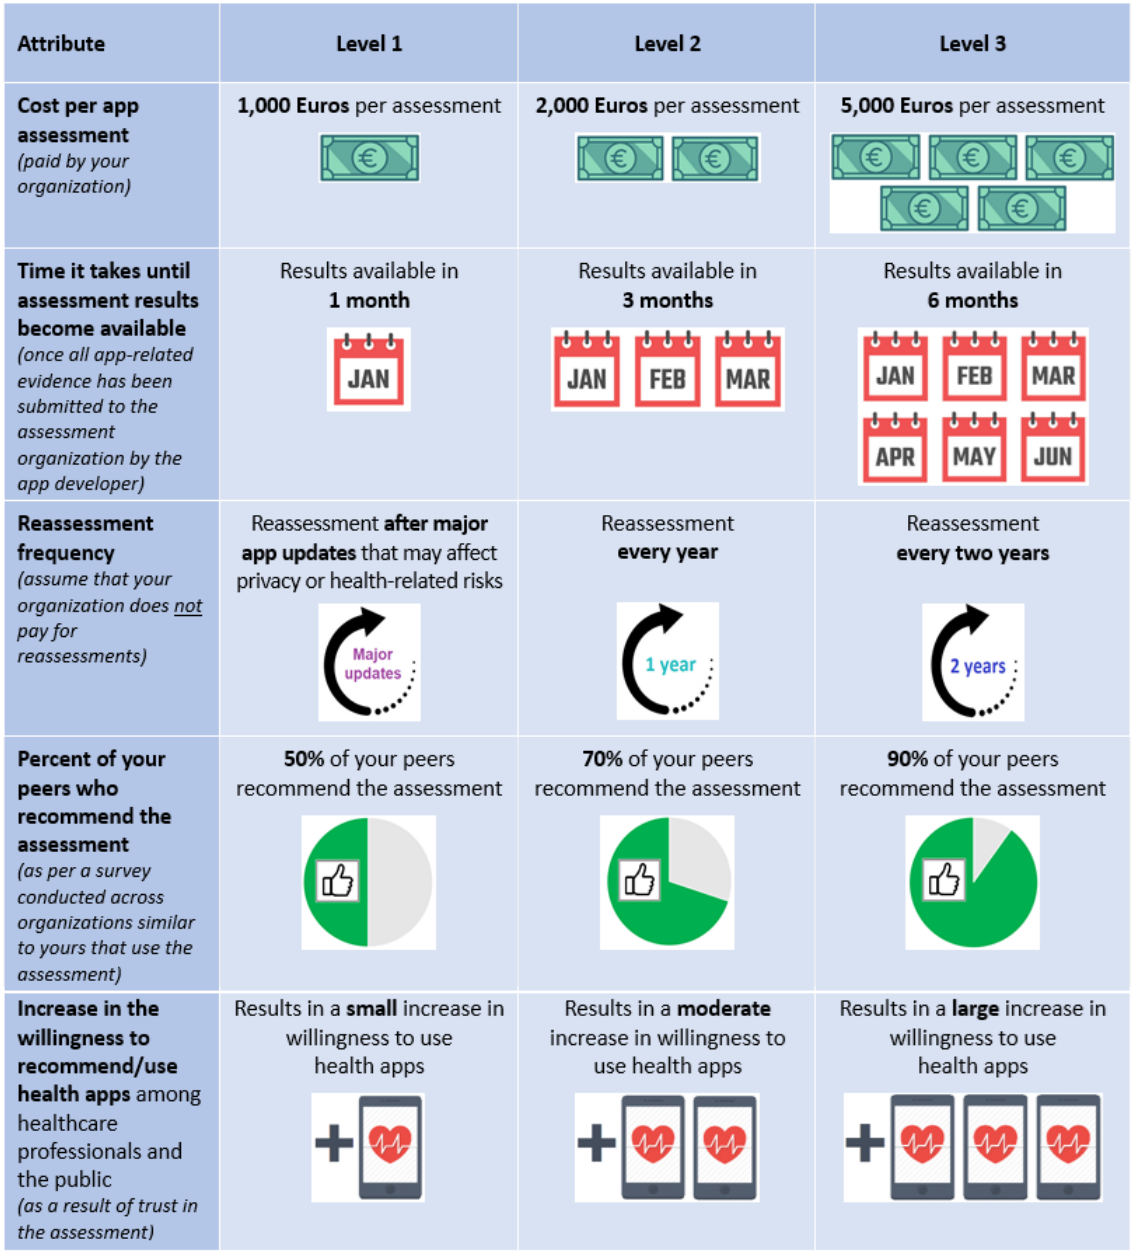
Figure 1. Attributes and levels presented to health app developers during the discrete choice experiment.

Attribute	Level 1	Level 2	Level 3
Cost per app assessment *(paid by your organization)*	**1,000 Euros** per assessment	**2,000 Euros** per assessment	**5,000 Euros** per assessment
Time investment made by your organization *(to collate app-related evidence for the assessment)*	**10 hours** invested by your organization	**20 hours** invested by your organization	**40 hours** invested by your organization
Time it takes until assessment results become available *(once your organization has submitted all app-related evidence to the assessor)*	Results available in **1 month**	Results available in **3 months**	Results available in **6 months**
Impact of the assessment **on clinical care uptake** of your app *(if the results meet stakeholder requirements)*	Does **not** result in either app integration into care **pathway guidelines or** app reimbursement/ **procurement**	Results in app integration into care **pathway guidelines** but **not** in app reimbursement/ **procurement**	Results in app integration into care **pathway guidelines and** app reimbursement/ **procurement**
Integration of assessment results into Google Play and Apple **App stores**	**No** option to prominently **display** assessment **results** in app stores and **no impact on** app search result **rankings**	Option to prominently **display** assessment **results** in app stores **without impact on** app search result **rankings**	Option to prominently **display** assessment **results** in app stores **and prioritisation in** app search result **rankings**
Increase in willingness to use your health app(s) among potential customers *(as a result of trust in the assessment)*	Results in a **small** increase in willingness to use your health app(s)	Results in a **moderate** increase in willingness to use your health app(s)	Results in a **large** increase in willingness to use your health app(s)

XSL•FO
RenderX

Figure 2. Attributes and levels presented to health system representatives during the discrete choice experiment.



Choice Task

For the choice task, a forced-choice elicitation format with 2 alternatives was selected. Specifically, for each choice set, participants were presented with 2 assessments and asked to select the option that they would recommend to their organization. Other approaches, such as presenting >2 alternatives or requiring the ranking of a larger number of options, were deemed to be too cognitively demanding due to the number of included attributes.

After participants had made a selection for a given choice set, they were asked to choose between the assessment they had just selected and an opt-out option (ie, recommending that their organization does not make use of any assessment). Including an opt-out option is beneficial for determining demand [36]. However, if opt-outs are offered as a third option as part of the main choice set, the results can be difficult to interpret. This is because participants may select the opt-out option for reasons unrelated to a true preference, such as to minimize effort and avoid difficult choices [37,38]. The dual response design used in this study has been suggested as a way to address this issue because it requires participants to choose between the offered alternatives on each trial before being given the option to opt out [38].

To ensure that participants could reasonably evaluate choice sets that contained all selected attributes (ie, full profiles), a pilot test was conducted with 15 participants for both DCE versions. The pilot feedback indicated that participants did not find the choice task too complex; thus, full profiles were used.

Experimental Design

The experimental design was generated using Ngene software (version 1.2; ChoiceMetrics Pty Ltd) [39]. For each of the 2 DCEs, a model was specified (refer to the Data Analysis subsection for details) and, through various iterations, the fractional factorial design with the lowest D-error value, and

XSL•FO
RenderX

thus the highest statistical efficiency, was selected [39]. As recommended by the Ngene manual when no previous results are available [39], we used small priors, which indicated the expected sign of the parameters. Specifically, priors for cost, developer time investment, and assessment completion time were assigned a negative sign (−0.00001), and priors for the remaining benefit-related attributes were assigned a positive sign (0.00001).

Each DCE included 18 choice sets generated by Ngene, which, based on the pilot testing, was deemed to yield a suitable survey length without causing fatigue or dropout. In addition, a "rationality test" was incorporated, in which 1 assessment contained presumably preferable values for all attributes compared to the alternative option (ie, a lower level for the first 3 attributes and a higher level for the remaining attributes shown in Figures 1 and 2). The inclusion of such a test is recommended practice to determine whether participants demonstrate rational choice behavior, which is an assumption of the DCE methodology.

Elicitation Method and Data Collection Instrument

The DCEs were presented to participants within a web-based Google Forms survey. At the start of the survey, the following background information was collected: the type, size, and country of the participants' organization; the participants' role in digital health–related decision-making; their previous experience with health app assessment; their views on whether making use of health app assessment would be beneficial for their organization; and their opinion on whether displaying assessment information should be mandatory or voluntary for health app developers.

Health system representatives were additionally asked to rank their preferences for different ways of engaging with health app assessments. Specifically, they ranked the following options from 1 (most preferred) to 5 (least preferred): paying for third-party assessment, paying for access to a library of assessed apps, performing assessments in-house, relying on self-assessments from health app developers, and not making use of assessments. The order in which these options appeared during the ranking task was randomized across participants.

After the background questions, DCE instructions, including a detailed description of each attribute level and an example choice set of 2 assessments, were presented. The DCE was framed by asking participants to imagine that their organization had selected a health app for potential submission to a third-party quality assessment and that they had been asked to make a recommendation regarding which assessment, if any, their organization should purchase. Choice sets were presented in table format, as shown in Figures 1 and 2 but with 2 alternatives.

Participants

The study sample consisted of 41 employees of health app development companies (from hereon referred to as "health app developers" for short) and 46 health system representatives from across Europe. On the basis of power calculations, using the formula recommended by Johnson and Orme [40], which incorporates the number of attribute levels, choice sets, and alternative options, a sample size of 40 participants was required for each group.

The survey was promoted through newsletters of relevant professional organizations, such as the Healthcare Information and Management Systems Society, as well as through social media, professional networking sites, and contacts of the Label2Enable project team.

Data Analysis

Responses to the background questions were summarized using descriptive statistics. For the rankings of assessment options provided by health system representatives, chi-square values were calculated as described by Finch [41]. Owing to a technical issue, information for 1 (2%) of the 41 health app developers was missing regarding their role in decision-making as well as their organization's size and country.

Data from the 2 DCEs were analyzed using 2 separate mixed logit models, with observed assessment choices as the dependent variable and attribute levels of the presented assessments as predictors. In both models, cost (purchase price) and assessment completion time were entered as fixed, continuous variables to allow for the calculation of marginal rates of substitution without complications related to determining mean values [42]. All other attribute levels were entered as random, categorical variables, thus accounting for preference heterogeneity across participants. The categorical variables were dummy coded using level 1 (as indicated in Figures 1 and 2) as the reference category (refer to the paper by Daly et al [43] for a discussion of effects coding vs dummy coding for choice models).

The opt-out decisions, collected after the initial choice between assessments A and B, were incorporated into the analysis as recommended by Diener et al [44]. Specifically, trials on which participants selected the same assessment (A or B) for both the initial question (A vs B) and for the opt-out question (previously selected assessment [A or B] vs no assessment) were treated as 1 choice set with 3 options (A, B, and no assessment). By contrast, trials on which participants selected "no assessment" after initially choosing assessment A or B were treated as 2 choice sets with 2 (A and B) and 3 (A, B, and no assessment) options, respectively. In addition, an alternative specific constant (coded as 1 for "no assessment" and 0 for assessments A and B) was added to the model as a random effect.

Parameter estimation was conducted in Stata (version 18; StataCorp LLC) [45] using 2000 Halton draws to achieve stable coefficients. A sensitivity analysis was performed in which participants who did not select the expected option in the rationality test (health app developers: 3/41, 7%; health system representatives: 5/46, 11%) were excluded. The estimated coefficients for this analysis are presented in Multimedia Appendix 1. In the Results section, the estimates across all participants are reported. This is recommended practice, given that the deletion of *potentially* "irrational" responses may lead to the introduction of biases and the reduction of statistical efficiency and power [46].

Moreover, relative attribute importance was calculated by first subtracting the coefficient of the least preferred level from the coefficient of the most preferred level for each attribute and

XSL•FO
RenderX

then dividing this range for a given attribute by the sum of these ranges across all attributes.

Mean marginal willingness to pay and marginal rates of substitution for assessment completion time were calculated by dividing the estimated model coefficients of the other attributes by the negative coefficients of cost and assessment completion time, respectively. SEs for these values were calculated using the delta method, as instantiated by the *nlcom* function in Stata.

In addition, predicted choice probabilities were examined for the best-, middle-, and worst-case scenarios, with all attributes set to the most preferred, middle, and least preferred levels, respectively, using the methodology and Stata code described by Lancsar et al [42].

Finally, a linear regression analysis was conducted to examine whether responses to the background questions predicted the percentage of times participants opted for "no assessment" during the DCE (refer to Multimedia Appendix 1 for the details and results of this analysis).

Ethical Considerations

The study was reviewed and approved by the Biomedical and Scientific Research Ethics Committee of the University of Warwick (BSREC 82/22-23).

All participants provided informed consent at the start of the survey, after being presented with an information sheet outlining the purpose, methodology, and data-handling arrangements of the study. Participants could withdraw from the study at any point before submitting their responses, in which case none of the survey data were saved. All collected data were fully anonymous. No personally identifiable information was collected at any stage of the survey. Participants were not offered any compensation for completing the survey. This was made clear in the information sheet.

Results

Health App Developer Survey

Participant Characteristics

Health app developers were located across 18 European countries, including France (8/40, 20%), Germany (4/40, 10%), the Netherlands (4/40, 10%), the United Kingdom (4/40, 10%), Denmark (3/40, 8%), and Portugal (3/40, 8%; refer to Table S2 in Multimedia Appendix 1 for the full list of countries).

Most health app developers were based in micro (<10 employees; 11/40, 28%) or small (10-49 employees; 18/40, 45%) companies, rather than medium (50-249 employees; 6/40, 15%), large (250-999 employees; 2/40, 5%), or very large (≥1000 employees; 3/40, 8%) organizations.

Of the apps developed by the participants' companies, 37% (15/41) provided operational support (eg, enabling web-based consultation with health care professionals or offering administrative services), 46% (19/41) supported disease prevention (eg, promoting a healthy lifestyle), 61% (25/41) facilitated self-management (eg, providing disease-specific information or symptom management aid), 66% (27/41) supported health care delivery (eg, assisting with diagnosis, clinical decision-making, treatment, or remote follow-up), 24% (10/41) offered health research support (eg, gathering patient-reported outcomes for clinical trials), and 5% (2/41) had other core functionalities not captured by the aforementioned categories.

With regard to digital health–related decisions, 18% (7/40) of the health app developers reported being the sole or final decision maker, 45% (18/40) indicated being part of a group of decision makers, and 35% (14/40) stated that they provided advice to inform decisions, while 2% (1/40) indicated having no influence on decision-making.

The majority of health app developers (32/41, 78%) had prior experience with health app assessment, which was indicated to include regulatory certification. Of these developers, 47% (15/32) reported that this experience had been mostly positive, while 34% (11/32) and 19% (6/32) stated that their experience had been neutral or mostly negative, respectively.

In addition, across all health app developers, 49% (20/41) strongly agreed and 44% (18/41) agreed that it would be advisable and beneficial for their organization to submit their health apps to a third-party quality assessment in the next 2 years, while 5% (2/41) and 2% (1/41) disagreed and strongly disagreed with this statement, respectively.

Finally, 59% (24/41) of the health app developers stated that, in their opinion, it would be preferable if it was *mandatory* for health app developers to display their app's quality assessment results or a statement that their app has *not* been assessed in app stores and marketing materials, while the remaining 41% (17/41) thought such reporting should be *voluntary*.

Model Estimation Results and Relative Attribute Importance

The mixed logit model estimation results for the health app developer DCE are presented in Table 1. All attributes made a significant contribution to assessment choices, with coefficients associated with levels 2 and 3 differing significantly from those associated with the reference level 1 in all cases, except for the levels of "20 hours developer time investment" and "moderate increase in willingness to use assessed apps."

The estimated coefficients for the sensitivity analysis, excluding participants who did not select the expected option in the rationality test, are presented in Table S3 in Multimedia Appendix 1.

All attribute levels had the expected sign and order, with health app developers, on average, preferring assessments that have a lower cost (purchase price), involve less developer time investment, make results available more quickly (ie, have a shorter assessment completion time), facilitate broader clinical care uptake via clinical guideline integration and procurement or reimbursement, offer full app store integration (ie, display of assessment scores and impact on search result rankings), and lead to a larger increase in willingness to use assessed apps.

Relative attribute importance values indicated that the largest contribution to health app developers' choices was made by the clinical care uptake attribute (40.3%), followed by cost (17.9%).

XSL•FO
RenderX

Increased willingness to use assessed apps (13.8%) and app store integration (13.6%) had a moderate impact on choices, while assessment completion time (9.5%) and developer time investment (4.8%) made the smallest contribution (refer to Figure S1 in Multimedia Appendix 1).

[a]Details for the SD (SE and *P* value) are not applicable to fixed effects.

[b]N/A: not applicable (SD, SE, and *P* values are not applicable to reference levels).

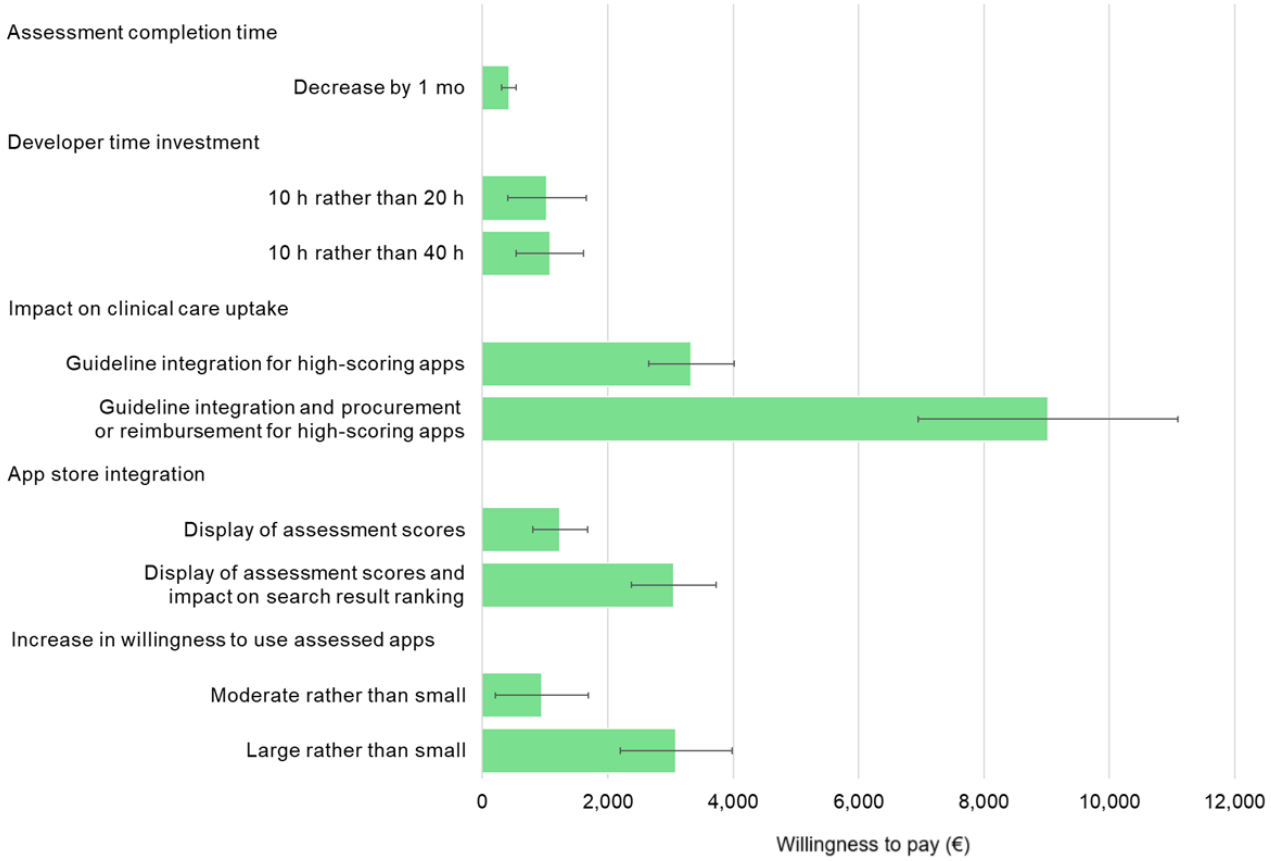
Marginal Willingness to Pay and Marginal Rates of Substitution for Assessment Completion Time

On average, health app developers were willing to pay an additional €9020 (95% CI €4968-€13,072) if an assessment facilitates guideline integration and procurement or reimbursement for high-scoring apps (ie, for apps that meet the requirements of stakeholders involved in clinical care uptake decisions). The marginal willingness to pay was only approximately a third of this amount if an assessment offers full app store integration (€3052, 95% CI €1722-€4381); or leads to a large, rather than a small, increase in willingness to use assessed apps (€3090, 95% CI €1341-€4840). Marginal willingness to pay for receiving the assessment results 1 month sooner was €425 (95% CI €196-€654; refer to Figure 3 and Table S4 in Multimedia Appendix 1 for the full results).

Moreover, health app developers were willing to wait an additional 21 months (95% CI 8-34 mo) for the evaluation results if the assessment facilitates clinical guideline integration and procurement or reimbursement for high-scoring apps. Furthermore, they were willing to wait approximately 7 months longer for assessment results if full app store integration (95% CI 3-11 mo) or a large, rather than small, increase in willingness to use assessed apps (95% CI 2-12 mo) is offered. For a cost reduction of €100, they were willing to wait an extra week (0.2 mo, 95% CI 0.1-0.4 mo) for the assessment results (refer to Table S5 in Multimedia Appendix 1 for all findings).

XSL•FO
RenderX

Figure 3. Health app developers' marginal willingness to pay for different assessment attribute levels (error bars represent SEs). Note that the currency exchange rate at the time of data collection was approximately €1=US $1.11.



Predicted Assessment Uptake

Predicted assessment uptake was examined for the best-, middle-, and worst-case scenarios, with all attribute levels set to the most preferred, middle, and least preferred levels, respectively.

For the best-case scenario, the predicted assessment uptake among health app developers was 88.6% (95% CI 77.9%-96.5%) while for the middle- and worst-case scenarios, the predicted uptake was 49.2% (95% CI 38.9%-62.8%) and 12.4% (95% CI 4.8%-22.1%), respectively.

Health System Representative Survey

Participant Characteristics

Health system representatives worked at the following types of organizations: public health care institutions (18/46, 39%), private health care institutions (10/46, 22%), health authorities (8/46, 17%), health technology assessment bodies (6/46, 13%), private health insurance companies (3/46, 7%), and public health insurance companies (1/46, 2%). These organizations were distributed across 13 European countries, including Spain (14/46, 30%), Belgium (5/46, 11%), the Netherlands (5/46, 11%), the United Kingdom (5/46, 11%), Croatia (4/46, 9%), and Lithuania (3/46, 7%; refer to Table S6 in Multimedia Appendix 1 for the full list of countries).

The organizations' size ranged from very large (≥1000 employees; 15/46, 33%) and large (250-999 employees; 6/46, 13%) to medium (50-249 employees; 12/46, 26%), small (10-49 employees; 10/46, 22%), and micro (<10 employees; 3/46, 7%). The vast majority of organizations (41/46, 89%) were currently using, promoting, reimbursing, or otherwise interacting with digital health technologies.

Most health system representatives reported being part of a group of individuals making digital health–related decisions (25/46, 54%) or providing advice to inform such decisions (14/46, 30%), while 2% (1/46) indicated being the sole or final decision maker related to digital health, and 11% (6/46) stated that they did not contribute to digital health–related decisions at their organization.

The majority of health system representatives (34/46, 74%) had previous experience with health app assessment. Of these, 76% (26/34) reported that this experience had been mostly positive, while 21% (7/34) and 3% (1/34) indicated that their experience had been neutral or mostly negative, respectively.

Furthermore, of all health system representatives, 35% (16/46) strongly agreed and 59% (27/46) agreed that it would be advisable and beneficial for their organization to make use of third-party health app quality assessments in the next 2 years, while 7% (3/46) strongly disagreed with this statement.

Finally, 80% (37/46) of the health system representatives indicated that, in their opinion, it would be preferable if it was *mandatory* for health app developers to display their app's quality assessment results, or a statement that their app has *not* been assessed, in app stores and marketing materials, while the

XSL•FO
RenderX

remaining 20% (9/46) thought that such reporting should be *voluntary*.

Separate response summaries for health care institution employees and representatives of other organization types can be found in Table S7 in Multimedia Appendix 1.

Ranking of Assessment Options

Examining the mean rankings (from 1=most preferred to 5=least preferred) of different ways to engage with health app quality assessments revealed that, on average, health system representatives' most preferred option was to have assessments conducted in-house (mean 2.04, SD 1.10), followed by paying for third-party assessment (mean 2.39, SD 0.98) or access to a library with assessed apps (mean 2.70, SD 1.38). Relying on developer self-assessments (mean 3.35, SD 1.06) or not making use of assessment at all (mean 4.52, SD 1.07) were, on average, the least preferred options. The same pattern of preferences was observed for both health care institution employees and other representatives when the rankings of these groups were considered separately. A chi-square test across all health system representatives indicated that the rankings were not random (χ^2_4=70.2; P<.001). The number of times each option received a given rank is displayed in Table 2.

Table 2. Indication of the frequency with which assessment options were given each rank by health system representatives, with rank 1 indicating the most preferred option and rank 5 the least preferred option (N=46).

Assessment options	Ranks, n (%)				
	1	2	3	4	5
Paid third-party assessment	9 (20)	16 (35)[a]	16 (35)[a]	4 (9)	1 (2)
Paid access to a library with assessed apps	11 (24)	13 (28)[a]	7 (15)	9 (20)	6 (13)
In-house assessment	20 (43)[a]	10 (22)	10 (22)	6 (13)	0 (0)
Developer self-assessment	4 (9)	5 (11)	11 (24)	23 (50)[a]	3 (7)
Not making use of assessment	2 (4)	2 (4)	2 (4)	4 (9)	36 (78)[a]

Model Estimation Results and Relative Attribute Importance

The mixed logit model estimation results for the health system representative DCE are shown in Table 3. All attributes made a significant contribution to health system representatives' choices, with coefficients associated with levels 2 and 3 differing significantly from those associated with the reference level 1 in all cases. All attribute levels had the expected sign and order, with health system representatives, on average, preferring assessments that have a lower cost (purchase price); make results available more quickly (ie, have a shorter assessment completion time); offer reassessment after substantial updates, rather than every year or every 2 years; are recommended by a higher proportion of peers; and lead to a larger increase in willingness to use assessed apps.

[a]Details for the SD (SE and *P* value) are not applicable to fixed effects.

[b]N/A: not applicable (SD, SE, and *P* values are not applicable to reference levels).

The estimated coefficients for the sensitivity analysis, excluding participants who did not select the expected option in the rationality test, are presented in Table S8 in Multimedia Appendix 1.

Relative attribute importance values indicated that increased willingness to use assessed apps had the largest impact on health system representatives’ choices (39.3%), followed by cost (22.3%). Assessment completion time (15.1%) and the percentage of peers recommending the assessment (15.1%) made a moderate contribution to choices, while reassessment frequency had the smallest impact (8.1%; refer to Figure S2 in Multimedia Appendix 1).

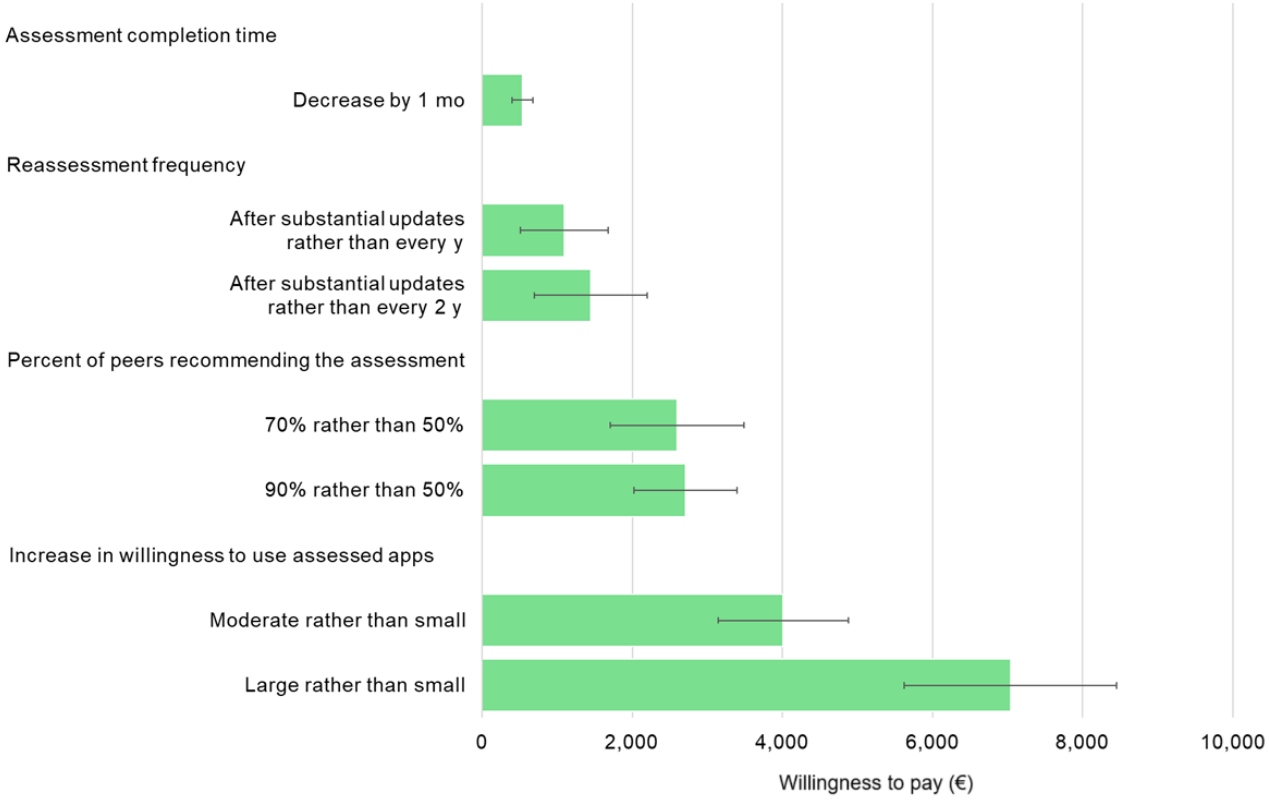
Marginal Willingness to Pay and Marginal Rates of Substitution for Assessment Completion Time

On average, health system representatives were willing to pay an additional €7037 (95% CI €4267-€9806) if an assessment yields a large, rather than a small, increase in willingness to use assessed apps; and €2709 more (95% CI €1355-€4063) if the assessment is recommended by 90%, rather than 50%, of peers. Marginal willingness to pay for app reassessment after substantial updates, rather than every 2 years, was €1448 (95% CI −€25 to €2921); and a decrease in assessment completion time of 1 month was, on average, worth €542 (95% CI €269-€816) to health system representatives (refer to Figure 4 and Table S9 in Multimedia Appendix 1 for the full results).

Furthermore, health system representatives were willing to wait an additional 13 months (95% CI 7-19 mo) for the assessment results if the assessment is associated with a large, rather than a small, increase in willingness to use assessed apps; and a further 5 months (95% CI 2-8 mo) if the assessment is recommended by 90%, rather than 50%, of peers. For a cost reduction of €100, health system representatives were willing to wait an additional week (0.2 mo; 95% CI 0.1-0.3 mo; refer to Table S10 in Multimedia Appendix 1 for the full results).

XSL•FO
RenderX

Figure 4. Health system representatives' marginal willingness to pay for different assessment attribute levels (error bars represent SEs). Note that the currency exchange rate at the time of data collection was approximately €1=US $1.11.



Predicted Assessment Uptake

The predicted assessment uptake was examined for the best-, middle-, and worst-case scenarios, with all attribute levels set to the most preferred, middle, and least preferred levels, respectively.

For the best-case scenario, the predicted assessment uptake among health system representatives was 91.1% (95% CI 68%-99.2%), while for the middle- and worst-case scenarios, the predicted uptake was 78.7% (95% CI 48.7%-94.2%) and 35% (95% CI 11.8%-65.8%), respectively.

Discussion

Principal Findings

The aim of this study was to examine preferences and willingness to pay for health app assessments with different value propositions among potential customers of such assessments, namely health app developers and health system representatives.

The DCEs revealed that, among health app developers, the attributes with the largest impact on assessment choices were clinical care uptake (guideline integration and reimbursement or procurement) and cost (purchase price). Increased willingness to use assessed apps and app store integration had a moderate impact on choices, and assessment completion time and developer time investment made the smallest contribution. Among health system representatives, increased willingness to use assessed apps had the largest impact on participants' choices, followed by cost. Assessment completion time and the percentage of peers recommending the assessment made a moderate contribution to choices, and reassessment frequency had the smallest impact.

On average, health app developers were willing to pay an additional €9020 (95% CI €4968-€13,072) if an assessment facilitates guideline integration and procurement or reimbursement. The marginal willingness to pay was only approximately a third of this amount if an assessment offers full app store integration (assessment score display and impact on app search result rankings; €3052, 95% CI €1722-€4381); or leads to a large, rather than a small, increase in willingness to use assessed apps (€3090; 95% CI €1341-€4840). Health system representatives were, on average, willing to pay €7037 (95% CI €4267-€9806) more if an assessment results in a large, rather than a small, increase in willingness to use assessed apps; and an additional €2709 (95% CI €1355-€4063) if the assessment is recommended by 90%, rather than 50%, of peers.

Attitudes and Preferences Regarding Health App Assessment Attributes

The interest in, and predicted uptake of, health app assessments was high among both health app developers and health system representatives. In both groups, a majority of the participants (health app developers: 38/41, 93%; health system representatives: 43/46, 93%) agreed that it would be advisable and beneficial for their organization to make use of third-party app assessments in the next 2 years. The predicted uptake of assessments that offered the preferred values for all attributes was 88.6% among app developers and 91.1% among health system representatives. This indicates that both groups are viable

XSL•FO
RenderX

target customers for health app assessments if their expectations regarding cost and benefits are met.

In this context, it is worth noting that health system representatives' most preferred option for engaging with app assessments was to have apps evaluated in-house. This may partly be the case because approximately half of the participants (21/46, 46%) in this group worked at large or very large organizations that may have their own product evaluation processes in place. For instance, large health care institutions may contain procurement or IT departments that routinely evaluate products, including digital health technologies. Where such a trusted evaluation process is available in-house, this may be the routine approach for assessing health care products in general and, as such, also the preferred approach for ensuring the quality of used health apps. Nevertheless, making use of third-party assessment was, on average, the second most favored option. Together with the DCE results, this suggests a solid interest in app assessments from health system organizations, as long as a suitable cost-benefit balance is offered.

Specifically, the DCE results indicate that, to maximize uptake among health system organizations, it is important to demonstrate that an assessment substantially increases the public's and health care professionals' willingness to use health apps. This impact could, for instance, be demonstrated by conducting a controlled study in which participants are presented with hypothetical apps that either carry or do not carry a quality assessment label and are asked whether they would use or recommend these apps. A recent study using this approach showed that health care professionals' willingness to recommend health apps was significantly higher for apps that carried a quality label than for those that did not [47]. Besides this direct effect of a quality label, there may also be a more indirect impact of assessment on health care professionals' willingness to use evaluated apps *if* the assessment enables the integration of health apps into clinical guidelines. This may further encourage health app use and recommendation, given that health care professionals rely on clinical guidelines to inform their practice [48,49].

Similarly, assessment may also increase the use of health apps among the public. Yet-to-be-published research from the Label2Enable project shows that nearly 9 in 10 surveyed European citizens think that the government should review and rate apps or pay another organization to do so to help them choose a health app. This indicates a high demand for guidance regarding health app choices among the public. In the future, this research could be extended to further quantify the increase in willingness to use health apps as a result of trust in and visibility, transparency, and clarity of different quality assessments.

Our findings further show that enabling or facilitating the clinical guideline integration and reimbursement or procurement of assessed apps is an important factor for maximizing assessment uptake among health app developers. This requires the close collaboration of assessment providers with health authorities, health care institutions, and health insurers. While reimbursement of health apps is arguably still in its early stages, reimbursement mechanisms have started to emerge across Europe, including through the German digital health app assessment [50], the Belgian National Institute for Health and Disability Insurance assessment [51], and the French "early access to reimbursement for digital devices" program [52]. Our findings underscore that, as expected, such reimbursement programs provide a substantial incentive for developers to submit their apps for associated quality assessments. However, even if reimbursement is offered, assessment scaling can be a challenge [48,53]. Therefore, it is important to also optimize other assessment characteristics, such as cost, developer time investment, and assessment completion time, as well as the visibility of and trust in the assessment. In addition, further efforts are needed to encourage professional medical societies and other relevant bodies to include health apps in clinical recommendations and guidelines [48,49].

Another attribute with a moderate impact on developers' assessment choices was app store integration. Notably, such integration has substantial benefits beyond being an incentive for app developers to opt for quality assessment. Currently, search result rankings in major app stores are influenced by download numbers and user ratings, among other factors [54]. However, research has shown that these metrics are not significantly correlated with health app quality, as determined by in-depth assessment [55]. Given that users rarely consider more than the first 5 to 10 apps listed in the search results before making a choice [56], the current ranking system may indirectly encourage the use of potentially ineffective or unsafe health apps. This could be partially counteracted by incorporating trusted third-party quality assessment scores into search result ranking algorithms, ideally placing a higher weight on such scores than on download numbers and user ratings.

A further attribute that warrants consideration beyond its influence on assessment choices is reassessment frequency. Perhaps somewhat surprisingly, this attribute had the smallest relative impact on health system representatives' assessment choices. A potential contributing factor to this finding may have been uncertainty regarding how frequently reassessment would take place if it was contingent on substantial app updates that affect privacy or health-related risks, which was the reference category for the DCE analysis. It was not possible to specify the reassessment frequency for this scenario because this likely varies widely across apps. Recent data show that the median time since the last update among the highest-ranking health and fitness apps in the Google Play Store is just 14 days [57]. However, updates that impact evaluated components to an extent that warrants reassessment are likely to be substantially less frequent. Nevertheless, due to the fast pace of app development, reassessment at regular intervals or after substantial app changes is important to ensure that key quality information is applicable to the most recent version of the app. If no reassessment takes place or if it is too infrequent or poorly timed, the result could be reliance on outdated information. This, in turn, could potentially lead to the recommendation of health apps that no longer meet quality standards, which could undermine trust in the assessment. Future quantitative and qualitative research could further examine how frequently health apps, on average, provide updates that affect privacy and health risks and to what extent the frequency of such updates may affect preferences for

XSL•FO
RenderX

reassessment, as well as trust in assessment results, among health system representatives and app users.

Willingness to Pay for Health App Assessments

The findings of this study provide useful insights regarding the willingness to pay for health app assessments with varying characteristics across potential customer groups. For instance, the DCE results indicate that health app developers would be willing to pay €6843 more for an assessment with the middle attribute values *compared to an assessment with the least preferred* values, that is, for an assessment requiring 20, rather than 40, hours of time investment (€1076-€1028 = €48); providing assessment results in 3, rather than 6, months (€425 × 3 = €1275); facilitating clinical guideline integration for high-scoring apps (without reimbursement; €3332); displaying assessment results in app stores (without impact on search result ranking; €1240); and resulting in a moderate, rather than a small, increase in willingness to use assessed apps (€948). Similarly, health system representatives would be willing to pay €8587 more for a "middle case" assessment *compared to one with the least preferred attribute values*, that is, for an assessment that provides results in 3, rather than 6, months (€542 × 3 = €1626); is recommended by 70%, rather than 50%, of their peers (€2600); offers reassessment every year, rather than every 2 years (€1448-€1098 = €350); and leads to a moderate, rather than a small, increase in willingness to use assessed apps (€4011).

In this context, it should be noted that the DCEs used in this study only investigated willingness to pay for one-off assessments to avoid dependencies between attributes, such as between cost, time investment, and reassessment frequency. For this reason, the health system DCE instructed participants to assume that reassessment costs would not be covered by their organization. Therefore, a further examination of how reassessment frequency affects willingness to pay is warranted. This is especially important given the fast pace of digital health development, as mentioned previously, and considering the additional cost and resource requirements for assessment organizations that are implementing frequent reassessment.

Moreover, it should be taken into account that the willingness to pay estimates for app developers may not fully capture the necessary trade-offs in resource allocation, especially when it comes to meeting mandatory versus voluntary requirements. Specifically, ensuring that a health app meets regulatory requirements, such as those outlined by the General Data Protection Regulation and MDR, necessitates resource investment; and the more time and money have already been spent on aligning a given app to these mandatory requirements, the less willing or able developers may be to invest additional resources in voluntary quality assessment. This point was raised by several participants in a free-text comment section at the end of the current survey (eg, "We have already spent upwards of 200,000 Euros obtaining our MDR certification - why should we spend more?"). To address these concerns, it is advisable to not only emphasize the additional benefits offered by a given voluntary assessment but also allow for the reuse of documentation from mandatory certifications, where appropriate. This helps to minimize resource requirements and avoid duplicating the MDR related evaluation performed by notified bodies.

Relatedly, it should also be considered how resource requirements, including for covering assessment fees, affect smaller versus larger organizations. As part of this study, both assessment organization interviewees and survey participants voiced concerns that assessment costs or extensive time requirements for app developers could disadvantage smaller companies that do not have the necessary resources to pay for or invest time in the assessment process. This could negatively impact innovation by creating additional barriers for the scaling of start-ups, especially if assessment outcomes, or the lack thereof, have a substantial impact on users' health app choices. Some interviewees suggested that adjusting assessment fees based on company size or charging health system organizations instead of app developers may partially address this issue.

Next Steps

As mentioned in the Introduction section, a major challenge for current health app assessment initiatives, including national programs, is reaching a scale at which they can evaluate a substantial proportion of the large number of health apps on the market [29,31,32]. Such scaling requires both an efficient assessment process with a sufficient number of assessors and a value proposition and pricing that make the assessment attractive to a substantial number of customers, such as health app developers or health system organizations.

This study is part of a larger initiative that aims to establish such a scalable assessment program across Europe, using the quality requirements of CEN ISO/TS 82304-2. In terms of the organizational implementation of this program, it is envisioned that there will be a central governing body, alongside a distributed network of assessment organizations located across Europe, that will carry out the health app evaluations. The intention is to rely, in the first instance, on organizations that already provide digital health assessment services (using various evaluation frameworks) and, therefore, have the necessary resources and structures in place. A pilot study was recently carried out with 5 such organizations to examine their interrater reliability for a draft version of the CEN ISO/TS 82304-2 assessment, which yielded promising results [58].

To enhance the efficiency, quality, affordability, and scalability of CEN ISO/TS 82304-2 assessments and reassessments as well as to avoid a duplication of assessment efforts, automated evaluation will be used, where feasible, and the results from trusted existing assessments will be accepted as evidence for subsets of CEN ISO/TS 82304-2 quality requirements. It is expected that the CEN ISO/TS 82304-2 assessment will be comprehensive enough to provide health care decision makers with the vast majority of the information they require, reducing their assessment efforts to merely examining a small number of context-specific requirements. This expectation is supported by a recent, comparative analysis by the Catalan government body responsible for health app evaluations, which showed that the CEN ISO/TS 82304-2 app assessment handbook covers 93% of the evaluation criteria considered important by the Catalan assessment body [59].

XSL•FO
RenderX

The findings of this study will be used to inform decisions regarding the pricing and value proposition of the CEN ISO/TS 82304-2 assessment. The study showed that both health app developers and health system representatives widely agree that their organizations would benefit from health app assessments and that both groups demonstrate a sufficient willingness to pay for such assessments if their preferences are met. Therefore, both health app companies and health system organizations will likely be targeted as customers of the CEN ISO/TS 82304-2 assessment. In addition, it will be explored how the preferences expressed by these stakeholders as part of this study can be realized to ensure optimal assessment uptake.

The hope is that through the efficient, distributed implementation of the app evaluation and the alignment to customer preferences, the CEN ISO/TS 82304-2 assessment program will eventually be able to provide evaluation results for a substantial proportion of health apps available on the market while using a thorough and consistent assessment approach.

Limitations

A few limitations of this study should be noted. First, participants who took the time to complete the DCE survey were likely already interested in or well informed about the topic of health app assessment. Indeed, this study's results indicate that the majority of participants had previous experience with, and a positive attitude toward, health app assessment. Therefore, the recruited sample may not be entirely representative of all health app developers or health system representatives across Europe. It is possible that willingness to pay and assessment uptake may, in reality, be lower than indicated by these findings (eg, due to a greater negative effect of assessment cost or more opt-out decisions in the larger population compared to this study's sample). Moreover, it is possible that other attributes that were not included in this study may be of importance to some stakeholders, the inclusion of which could result in differing preferences and willingness to pay values. Future research could examine this further by actively recruiting participants with less awareness of, and less positive attitudes toward, digital health and quality assessments.

Second, due to the limited sample size, we were not able to perform subgroup analyses for participants with different characteristics (eg, those with previous positive, negative, or no assessment experience) or for different organization types (eg, for health care institutions, authorities, insurers, or health technology assessment bodies; or for health app developers with varying business models). Future research is warranted to examine whether preferences and willingness to pay for health app assessments differ across these subgroups.

Finally, when interpreting the study findings, it should be kept in mind that the estimates for health app developers and health system representatives cannot be directly compared. This is partly due to the use of different attributes within the DCEs, which was necessary to account for the varying relevance of different attributes across the 2 groups (refer to the Methods section for details).

Conclusions

This study aimed to examine preferences and willingness to pay for health app assessments with different value propositions among potential customers of such assessments. Among both app developers and health system representatives, interest in, and the predicted uptake of, health app assessments was high if the most preferred assessment attribute values were offered. Moreover, for health app developers and health system representatives, the attributes with the largest impact on assessment choices were facilitation of clinical care uptake (guideline integration and reimbursement or procurement) and increased willingness to use assessed apps, respectively. The study's findings provide valuable information, including marginal willingness to pay estimates, that can be used to inform decision-making and support the scaling of health app assessments.

Acknowledgments

The authors are grateful to the following individuals who provided input to the discrete choice experiment design as part of the assessment organization interviews: Vidar Eltoft, Lauren Harkins, Jari Haverinen, Rhodri Joyce, Søren Lange Nielsen, Arve Paulsen, Danny Van Roijen, and Monique Westerlaken. In addition, the authors would like to thank everyone who participated in the study or supported the promotion of the survey. This study was funded by the European Union (grant 101057522). The views and opinions expressed are those of the authors and do not necessarily reflect those of the European Union or the European Health and Digital Executive Agency. Neither the European Union nor the granting authority can be held responsible for them.

Data Availability

The datasets generated and analyzed during this study are available from the corresponding author on reasonable request.

Conflicts of Interest

All authors are involved in the Label2Enable project, which supports the implementation of the CEN ISO/TS 82304-2 health app quality assessment framework and related label across Europe. In addition, at the time of this study, ALF and SL were employed by the Organisation for the Review of Care and Health Apps, which provides health app assessments.

Abstract

Background: To bridge the gap between clinical guidelines and suboptimal stroke management in rural settings, we conducted an implementation trial using evidence-based, mobile health–enabled strategies to empower primary care providers in rural China. The system-integrated and digital technology–enabled model of care (SINEMA) model was shown to significantly reduce blood pressure and mortality among people with stroke in rural China.

Objective: This study aimed to evaluate the cost-effectiveness of the SINEMA intervention within both the active trial and the post-trial observational periods and its budget impact for potential nationwide scalability.

Methods: In the cluster-randomized implementation trial (the SINEMA trial), 50 villages were randomized to either a 1-year intervention (2017-2018) or usual care, with 1299 patients with stroke followed up until 2022-2023—6 years after the trial baseline. The incremental cost-effectiveness ratios (ICER) for systolic blood pressure reduction and quality-adjusted life year gains were estimated from a health sector perspective. Both probabilistic and deterministic sensitivity analyses were conducted to assess the robustness of the findings. Additionally, a budget impact analysis was performed from a public payer perspective to estimate the per-capita and total costs of national scale-up under 2 scenarios: a standalone intervention and integration into the existing basic public health service system.

XSL•FO
RenderX

Results: The ICER per 1 mmHg systolic blood pressure reduction was $8.4 for the within-trial estimation. The ICER per quality-adjusted life year gained was $837.9 within-trial and $727.9 post-trial, both highly cost-effective relative to any commonly adopted thresholds and robust in sensitivity analyses. The first-year budget impact ranged from $115.6 million to $197.7 million in the 2 scenarios, reducing to $46.6 million to $78.7 million by year 5, with a per-capita cost of $0.03-$0.06.

Conclusions: Our findings demonstrate that the SINEMA intervention was cost-effective during the trial period and remained so throughout the 6-year sustainability observation period. These results highlight the potential of adopting similar health system–integrated, mobile health–enabled strategies to enhance the management of stroke and other chronic diseases in resource-limited settings.

economic evaluation; stroke secondary prevention; budget impact analysis; mHealth; cluster-randomized trial

Introduction

Stroke is a leading cause of mortality and disability, representing a major global health burden with approximately 4.4 million deaths annually [1]. Beyond mortality, stroke survivors incur substantial direct and indirect economic costs, which impose a significant financial burden on individuals, families, and health care systems [2,3]. In rural China, the number of stroke survivors is higher than in urban areas, with a stroke prevalence of approximately 1291.1 cases per 100,000 individuals, and this number continues to rise, encompassing around 5 million survivors [4]. To address this issue, significant evidence exists regarding management and intervention guidelines for stroke survivors in China [5-7]. However, there is a lack of practical implementation to test the effectiveness of these strategies in preventing stroke recurrence and providing essential care, particularly in resource-constrained settings [8]. To address such unmet health gaps, we developed the system-integrated and technology-enabled model of care (SINEMA), a primary care–based intervention with digital health components, to empower primary health care providers for secondary stroke prevention [9]. Through a cluster-randomized implementation trial, we have shown that the SINEMA intervention significantly reduced systolic blood pressure (SBP), stroke recurrence, hospitalization, and disability at 12 months postbaseline [10]. Follow-up data collected in October 2022 and May 2023 highlighted the sustained effectiveness of the intervention, showing significant SBP reductions and a mortality risk reduction of over 20% [11].

Although the effectiveness of the SINEMA model has been demonstrated through a cluster-randomized implementation trial and long-term follow-up [10,11], guidelines emphasize the importance of recording on-site costs to validate the cost-effectiveness of such intervention trials [12]. For example, 2 studies on poststroke management interventions have not only proven their effectiveness but also demonstrated their cost-effectiveness—although both used different telehealth strategies [13,14]. In resource-limited settings, researchers have applied community-based workforce strategies, similar to the SINEMA model, to manage other chronic diseases such as hypertension [15-17]. While these strategies have shown both effectiveness and cost-effectiveness, they did not integrate mobile health (mHealth) technology, and only 2 studies have conducted long-term post-trial follow-up. Previous studies have demonstrated the increasing use of mHealth interventions in primary care settings for managing chronic diseases in low- and middle-income countries (LMICs) with modest evidence of effectiveness in behavioral and clinical outcomes [18], while the evidence regarding how best to manage individuals with stroke history and the cost-effectiveness of mHealth interventions remains limited [19]. Such gaps raise questions about the cost-effectiveness of integrating mHealth technology into the primary care model and the sustainability of such intervention strategies [20-22].

By leveraging comprehensive data from both the within-trial and long-term post-trial follow-up of the SINEMA trial, this study addresses the evidence gap regarding the cost-effectiveness of an mHealth technology–based primary care model for stroke secondary prevention and its sustained outcomes in resource-limited settings. Additionally, we incorporate budget impact analyses to evaluate the feasibility of scaling up similar approaches that integrate mHealth and community-based workforce strategies. Our findings provide valuable insights and practical support for implementing evidence-based chronic disease management strategies in China and other LMICs facing similar challenges.

Methods

SINEMA Trial Design and Participants

This study presents an economic evaluation based on the SINEMA trial, a cluster-randomized implementation trial conducted in a rural region of Hebei Province, China. We conducted both within-trial and post-trial economic evaluations from the health sector perspective, using data from the 1-year trial (ClinicalTrials.gov NCT03185858) and a 6-year observational follow-up postbaseline (ClinicalTrials.gov NCT05792618). Additionally, we performed a budget impact analysis from the public payer perspective.

Detailed information on trial design [9], mHealth intervention design and evaluation [23,24], within-trial results on health

XSL•FO
RenderX

outcomes [10], and long-term follow-up health outcomes [11,25] have been published [9,24]. In brief, 50 villages from 5 townships were randomly assigned in a 1:1 ratio to either the intervention or control arm, with stratification by the township. A total of 1299 participants who had been diagnosed with stroke but were in a clinically stable condition were recruited between June 23 and July 21, 2017, and followed up at 12 months. Village doctors underwent training, were equipped with the SINEMA app, and performed monthly follow-up visits for patients with stroke with support from township physicians and financial incentives. Patients with stroke received these visits either at village clinics or at home and were delivered with daily voice messages containing health education on medication adherence and physical activities. In the control arm, village doctors continued their standard practices as usual, involving general clinical care and the delivery of the basic public health services, which included quarterly follow-up visits for some patients with hypertension or diabetes at no out-of-pocket cost [26].

After concluding the 1-year intervention phase, we proceeded with follow-up data collection to assess the long-term effectiveness of the intervention in October 2022 and May 2023 – approximately 5 and 6 years after the trial baseline. The same methodologies were applied with blinded data collectors.

Study Design of Cost Effectiveness and Budget Impact Analysis

To ensure transparency, we published the study protocol for within-trial economic evaluation [27]. We adhered to the Consolidated Health Economic Evaluation Reporting Standards 2022 guidelines (Table S1 in Multimedia Appendix 2). We describe the previously published within-trial economic evaluation protocol briefly below as well as the post-trial cost-effectiveness analyses and national budget impact analyses in more detail. A CONSORT (Consolidated Standards of Reporting Trails) 2025 checklist is provided in Multimedia Appendix 3.

Assessment of Costs

Costs were categorized and calculated from the use of health care resources and program delivery costs. Discounting was only applied to post-trial economic analysis, where an annual discount rate of 5% was applied. We adjusted all costs to reflect the 2023 US dollar, using the rural consumer price index for conversion [28].

Costs associated with health care resource use include inpatient care, outpatient care, and medication expenses. For the within-trial period, inpatient costs were retrospectively collected from the admission systems of 4 major hospitals at our study sites, which captured about 98% of inpatient care in the region and were verified against patients' self-reported history of inpatient care. These records were categorized into 3 groups: stroke-related inpatient care, cardiovascular disease–related inpatient care (excluding stroke), and other causes of inpatient care (Table S2 in Multimedia Appendix 2). For the base case analysis, all-cause inpatient care costs were included in the analysis. As the data on outpatient costs from medical insurance scheme records was not available, we estimated outpatient costs by using the average cost of outpatient visits excluding the medication costs based on existing literature [29].

Medication costs were valued by multiplying the amount of medication used and the unit price for each type of medication. The questionnaires contained questions regarding the specific subtypes of medication used and the duration and adherence of medication use for 3 major types of medications including antiplatelet, statins and antihypertensive drugs (Multimedia Appendix 1). The unit cost of medication was estimated from the municipal government procurement website [30]. Prices for each specific medication were cross-referenced with local village doctors, and the median values for each category of medications were used to ensure balance at baseline. Outpatient costs, excluding medication costs, were estimated based on existing official Chinese statistics [29]. Resources supporting the SINEMA program—including the development of the SINEMA app, compensation for human resources, and voice message delivery fees—were estimated based on detailed project financial records.

The post-trial analysis relied on patients' self-reported data collected during the 6-year sustainability observation period. Hospitalization costs were estimated using the number of hospital visits recorded in the post-trial period and the average costs associated with different causes of inpatient visits, as determined during the within-trial period. Variables collected during follow-up and the detailed assumptions underlying these estimations are presented in Tables S3 and S4 in Multimedia Appendix 2.

Assessment of Effectiveness and Utility Outcomes

The within-trial measure of effectiveness is the mean reduction in mmHg in SBP from baseline to the end of follow-up at 1 year after randomization in the SINEMA trial. The health state utilities for the SINEMA study participants were estimated from the EQ-5D-5L using the Chinese EQ-5D-5L value set [31]. The quality-adjusted life years (QALYs) gained for both the within-trial period and post-trial period were calculated using the area under the curve approach [32]. For participants who died during this timeframe, their status and date of death were confirmed using the death registry system. A utility score of 0 was then assigned from the date of death onward. For the post-trial period, we similarly calculated the intervening missing utility values by using a linear imputation method and then summed the QALYs on an annual basis (Table S4 in Multimedia Appendix 2).

Economic Evaluation and Statistical Analysis

The incremental cost-effectiveness ratios (ICERs) were computed by dividing the mean difference in costs by the mean difference in effectiveness outcomes. ICERs were represented as additional cost per 1 mmHg reduction in SBP and per QALY gained between the SINEMA intervention and usual care.

We used a mixed multilevel effect model to evaluate effectiveness, with a random intercept for the cluster (village) and a fixed effect for townships to account for the stratified design, baseline SBP or baseline utility value, age, and sex based on the intention-to-treat principle. We used bootstrapping techniques to investigate the uncertainty around the ICERs by

XSL•FO
RenderX

generating 5000 replications to estimate the combined uncertainty of both cost and health outcomes and plotted on the cost-effectiveness plane to represent the uncertainty from 5000 estimates. To understand the cost-effectiveness of the SINEMA intervention across a spectrum of willingness-to-pay (WTP) thresholds, we used cost-effectiveness acceptability curves [33]. The WTP threshold was set as $18,766, equivalent to 1.5 times China's gross domestic product per capita in 2023 [34-36].

We performed both probabilistic sensitivity analysis by implementing nonparametric bootstrapping with 5000 replications and deterministic sensitivity analyses by assessing the impact of varying key input parameters individually. This involved evaluating the implications of adapting the 95% CI for health state utilities, considering 50% cost scenarios in both within-trial and post-trial economic evaluations. Additionally, we considered changes in hospitalization costs and each component of intervention to gauge the robustness of our findings. All statistical analyses were conducted using Stata version 17.

Budget Impact Analysis

We conducted the base-case budget impact analysis from a public payer perspective, quantifying all costs associated with the SINEMA program. These costs include the following: (1) compensation for township physicians, (2) compensation for the local project manager, (3) compensation for village doctors, (4) training costs, (5) voice messaging costs, (6) annual system maintenance and management costs, and (7) intervention development costs. The budget impact analysis assumes that the SINEMA program would be scaled up using existing village doctors and reach all rural households within the first year of implementation.

To quantify total costs, we estimated both unit costs and the number of people expected to receive SINEMA. We first assumed SINEMA as a standalone project as scenario A. Since a large proportion of patients with stroke already receive nationwide services under the national basic public health services, which involves quarterly visits by village doctors to monitor blood pressure, we integrated the SINEMA program into the current public health services for scenario B analysis. The estimation method for costs and the eligible population are detailed in Table S5 in Multimedia Appendix 2. The health service utilization analysis showed that SINEMA led to a significant and consistent increase in the use of antihypertensive and antiplatelet medications compared to usual care. Therefore, these medication costs are included (Table S6 in Multimedia Appendix 2). We assumed that supervision and system coordination costs would decline after the first year, reflecting typical scale-up patterns observed in similar community-based interventions [37,38], where oversight and training expenses declined substantially as programs became integrated into routine service delivery (Table S5 in Multimedia Appendix 2).

Ethical Considerations

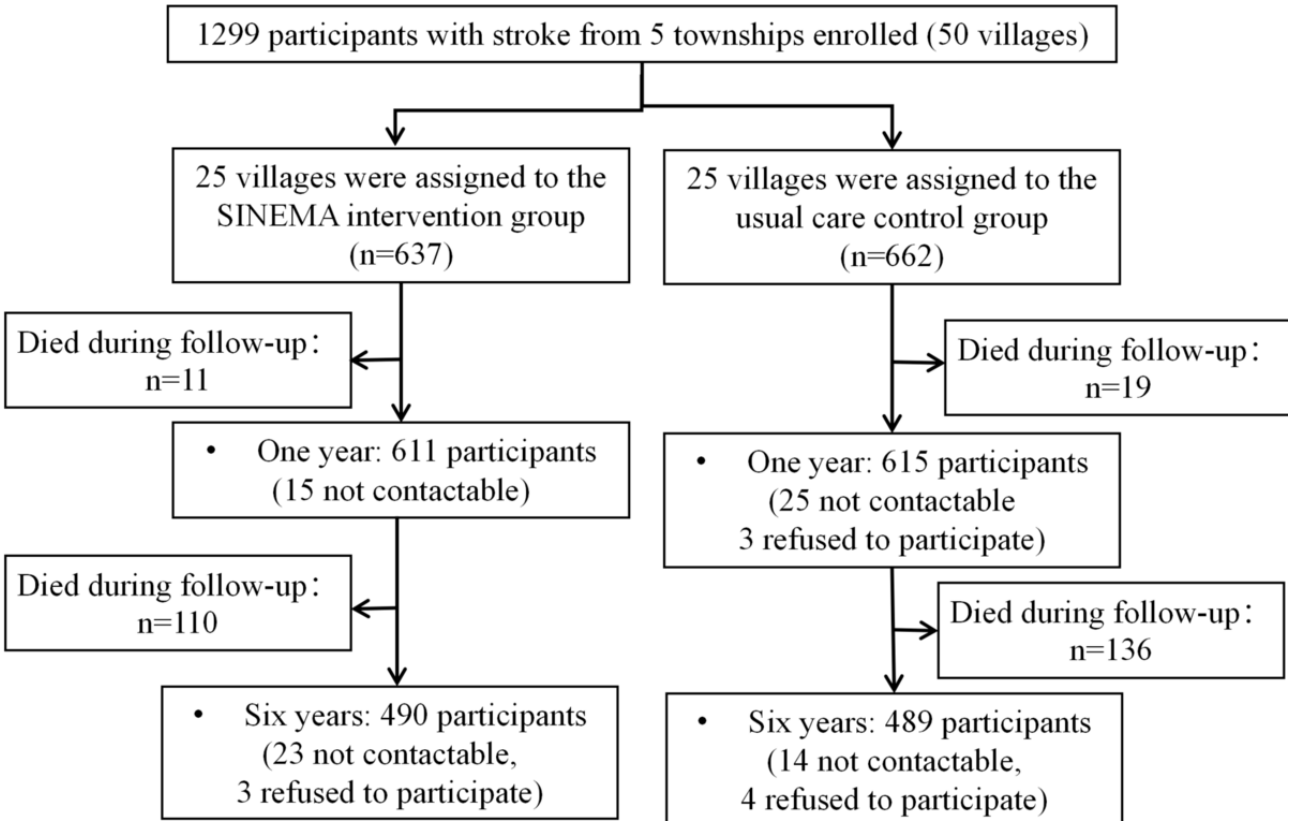
The study protocol was approved by the Institutional Review Boards of Duke University (Pro00082130), Beijing Tiantan Hospital (2015MRC0012), and Duke Kunshan University (China). All participants, including health care providers and patients, provided written informed consent after being informed of the study's purpose, procedures, potential benefits and risks, and data confidentiality safeguards. In addition, cluster-level consent was obtained from township and village opinion leaders. This post-trial follow-up study was approved by the ethical boards of the Chinese Academy of Medical Sciences (CAMS&PUMC-IEC-2022-062 and CAMS&PUMC-IEC-2024-047) and Duke University (Pro00082130-AMD-9.1).

Results

Both groups had comparable baseline characteristics (Table S7 in Multimedia Appendix 2). Participants' average age was 65.6 years (SD 8.2), with 71.2% (n=925) having no or only primary education. Their average SBP was 145.9 mm Hg (SD 22.4), and the mean health state utility score was 0.80 (SD 0.20). By the 1-year follow-up, 30 out of 1299 participants (2%) died, and 43 out of 1299 participants (3%) were lost to follow-up, leaving 611 and 615 participants in the intervention and control groups, respectively, who completed the survey (Figure 1 and Table S8 in Multimedia Appendix 2).

XSL•FO
RenderX

Figure 1. CONSORT (Consolidated Standards of Reporting Trails) flowchart of the SINEMA trial and the post-trial follow-up.



Within-Trial Cost-Effectiveness Analysis

The total program implementation costs were $32,389.2, averaging $50.8 per participant in the intervention group. During the trial period, the average total cost per person for inpatient visits was slightly higher in the control arm, though the difference was not statistically significant (mean difference: –$32.4, 95% CI –$107.3 to $172.1). The costs for antiplatelets and antihypertensives were significantly higher in the intervention arm, with mean differences of $2.11 (95% CI $1.27-$2.98) and $2.99 (95% CI $0.71-$5.27), respectively, suggesting an increased use of these medications. The total costs, including both intervention-related costs and health service use, were $236.5 per participant in the intervention arm and $213.1 in the control arm, resulting in a mean cost difference of $23.3 (95% CI: –$115.5 to $162.0). The bootstrapped analysis showed a mean difference of –2.8 mmHg (95% CI –4.7 to –1.0) in SBP and a 0.03 (95% CI 0.02-0.04) difference in QALYs between the 2 arms (Tables 1 and 2).

Table 1. Intervention costs during the within-trial period.

Intervention costs	Unit cost ($)	Quantity	Total costs ($)	Total cost per participant ($)
Compensation for township physicians	228.9	5	1144.7	1.8
Compensation for village doctors	414.8	25	10369.9	16.3
Compensation for local project manager	740.7	1	740.7	1.2
Compensation for county specialists	134.7	2	269.3	0.4
Voice messages	0.02	97,000	1548.8	2.4
Printing materials	0.5	700	336.7	0.5
System maintenance and management costs per year	1481.4	1	1481.4	2.3
Intervention development fee	16,497.6	1	16,497.6	25.9
Total	N/A[a]	N/A	32,389.2	50.8

[a]Not applicable.

Table 2. Health service utilization costs and effectiveness during the within-trial period.

Category	Intervention, mean (SD)[a]	Control, mean(SD)[a]	Mean difference (95% CI)
Health service utilization costs ($)[b]			
Outpatient visit (excluding medication costs, per participant)	45.5	45.5	0
All causes of inpatient visit (per participant)[c]	218.3	254.5	–2.4 (–107.3 to 172.1)
Medication costs (individual adherence discounted)[d]			
Antiplatelet	11.0	8.9	2.11 (1.27 to 2.98)
Statin	3.2	3.1	0.09 (–0.67 to 0.50)
Antihypertensive medicines	23.1	20.3	2.99 (0.71 to 5.27)
Average total costs[e]	236.5	213.1	23.3 (–115.5 to 162.0)
Effectiveness			
Change in systolic blood pressure (mmHg)[f]	–7.1 (0.6)	–4.3 (0.7)	–2.8 (–4.7 to –1.0)
Change in health-related quality of life score[f]	0.01 (0.01)	–0.06 (0.01)	0.06 (0.04 to 0.08)
Average quality-adjusted life years gained	0.81 (0.19)	0.79 (0.20)	0.03 (0.02 to 0.04)

[a]Cost values represent mean costs per participant calculated from aggregated data, not individual-level distributions; therefore, SDs are not reported.

[b]Health service utilization costs are reported as total costs per participant.

[c]Inpatient costs represent the mean total costs among participants who had at least one hospitalization.

[d]Medication costs represent the mean total costs among participants who used medication.

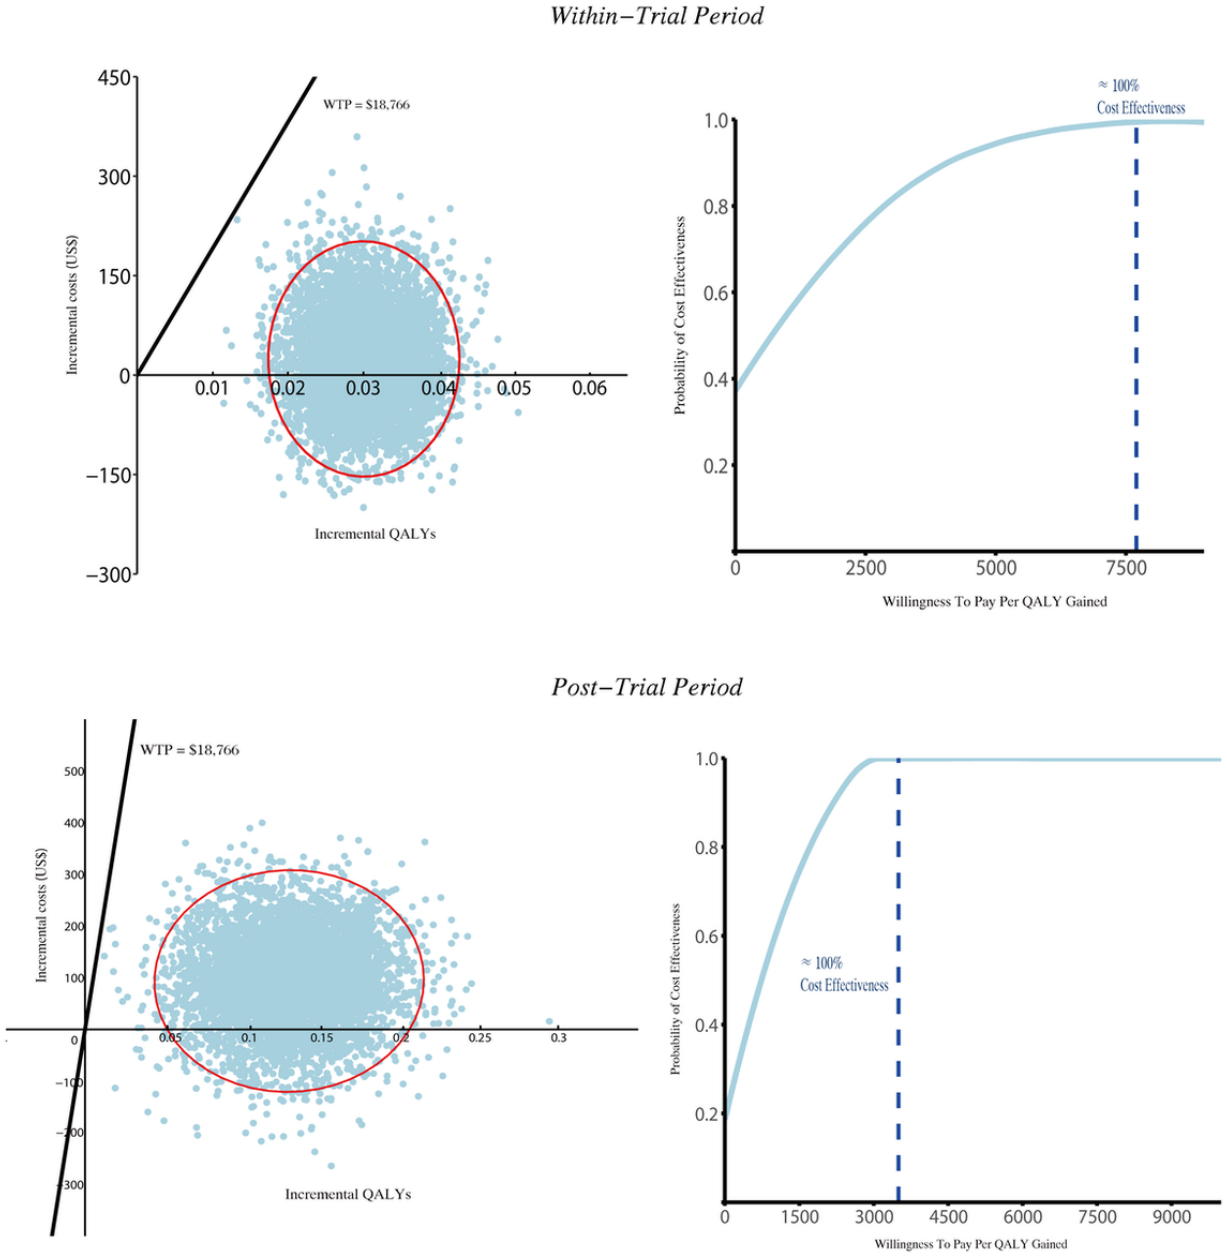
[e]The total cost reflects the mean cost per participant across the entire study population, including those without any hospitalization or medication use.

[f]Change represents the difference from baseline to 1-year follow-up within the trial period.

The ICER was $8.4 per mmHg reduction in SBP (95% CI 4.3-12.6) and $837.9 per QALY gained (95% CI $766.9-$908.9). The bootstrapped estimates of the mean differences in costs and effects were concentrated in the northeast quadrant of the cost-effectiveness plane (Figure 2, top left panel), indicating that the SINEMA intervention had a 100% probability (5000/5000 replications) of being cost-effective based on the predefined WTP threshold of $18,766. The cost-effectiveness acceptability curves for QALYs demonstrated that the probability of SINEMA being cost-effective was 100% at a WTP of approximately $7700 (Figure 2, top right panel).

XSL•FO
RenderX

Figure 2. All currency values are in 2023 US$. ICER: incremental cost-effectiveness ratio. “Within-trial period” refers to the intervention phase (2017–2018). “Post-trial period” refers to the time after the intervention concluded (from 2018 onward). Each blue dot represents an outcome from one of 5,000 iterations. The red circle indicates the 95% confidence interval (CI) of these outcomes. The dashed vertical line marks the probability of cost-effectiveness across willingness-to-pay thresholds, including the estimated threshold at which cost-effectiveness reaches 100%.



The scenario analysis of the ICER to changes in key parameters is presented in Table 3. The base case analysis estimated an ICER of $8.4 (95% CI $4.3-$12.6) per unit reduction in SBP and $837.9 (95% CI $766.9-$908.9) per QALY gained during the trial. Scenario analyses revealed that the ICER ranged from $3.8 to $23.0 per mmHg reduction in SBP and from $298.7 to $1363.9 per QALY gained across different adjustment models. Among intervention-related cost components, variations in the compensation for village doctors had the largest influence on the ICER. Regarding health service utilization costs, changes in annual hospitalization costs contributed the most to variations in the ICER.

Incremental annual medication cost	2.6-7.8	7.5	12.9	692.6	975.1
Incremental annual hospitalization cost	–48.6 to 16.2	4.8	16.7	298.7	1363.9

[a]The range was defined as a 50% decrease or increase from the base case for key parameters, except for systolic blood pressure reduction and difference in QALYs between 2 groups.

[b]SBP: systolic blood pressure.

[c]Calculated based on the 5000 bootstrapping and adjusted for baseline outcome, township, sex, and age.

[d]QALY: quality-adjusted life year.

[e]Range values are the bounds of the 95% CIs from the primary outcome analysis in the SINEMA trial.

[f]Not applicable.

[g]Presented as the average cost for township physicians and village doctors including performance-based incentives.

Post-Trial Cost-Effectiveness Analyses

During the 6-year sustainability observation period, 246 deaths were observed (intervention group: 110/626, 17.3%; control group: 136/643, 20.4%). Of the 1023 surviving participants, 979 (95.7%) completed the survey and 44 (4.3%) were lost to follow-up (Figure 1 and Table S8 in Multimedia Appendix 2).

The total post-trial costs were higher in the intervention group, with a mean difference of $91.5 (95% CI –$67.9 to $250.1). The mean difference in QALYs between the groups was 0.13 (0.06-0.20). This led to a lower ICER of $727.9 (95% CI $626.4-$829.4) in the post-trial period compared to the within-trial period (Table 4). The bootstrapped estimates demonstrated that the probability of the SINEMA intervention being cost-effective remained at 100% (Figure 2, bottom left panel). The cost-effectiveness acceptability curve indicates that the willingness-to-pay threshold for 100% cost-effectiveness is approximately $3,000 (Figure 2, bottom right panel). Scenario analysis revealed that the ICER varied the most when hospitalization costs were adjusted at the second follow-up, but no parameter changes affected the overall cost-effectiveness conclusions (Table 5).

Table 4. Costs and effectiveness during the post-trial period.

Category	Intervention, mean (SD)[a]	Control, mean (SD)[a]	Mean difference (95% CI)
Costs ($)			
Outpatient visit (excluding medication costs, per participant)	124.2	122.7	1.74 (–0.68 to 3.63)
All cause of inpatient visit (per episode)	639.8	564.9	74.80 (–97.96 to 247.49)
Medication costs (individual adherence discounted)			
Antiplatelet	52.7	44.3	8.41 (3.56 to 13.25)
Statin	12.0	11.4	0.53 (–1.25 to 2.31)
Antihypertensive medicines	56.7	48.0	8.69 (1.87 to 15.50)
Average total costs	889.9	798.4	91.50 (–67.87 to 250.80)
Effectiveness			
Change in health-related quality of life score[b]	–0.24 (0.01)	–0.23 (0.01)	–0.02 (–0.06 to 0.02)
Average Quality Adjusted Life Years Gained	2.51 (0.03)	2.41 (0.03)	0.13 (0.06 to 0.20)

[a]Cost values represent mean costs per participant calculated from aggregated data, not individual-level distributions; therefore, SDs are not reported.

[b]Change represents the difference from 1-year to 4.5-year follow-up in the post-trial period.

Table 5. Sensitivity analyses for calculating incremental cost-effectiveness ratios during the post-trial period.

Additional scenario analysis	Range of values[a]	Cost per QALY[b] gained[c] ($)	
		Low	High
Changes in cost-related parameters			
Medication cost at the second follow-up ($)	82.7-160.2	717.6	843.1
Hospitalization cost at the second follow-up ($)	391-994.5	219.2	1328.8
Discount (%)	3-8	511	860.5
Changes in effectiveness-related parameters			
Difference in QALYs between 2 groups[d]	0.07-0.19	488.8	1325.8
Incremental mean medication adherence[d]	0.47-1.41	660.5	839.7

[a]The value range was defined as ±50% of the base case for key parameters, except for the difference in QALYs between the 2 groups and the incremental mean medication adherence.

[b]QALY: quality-adjusted life year.

[c]Calculated based on the 5000 bootstrapping and adjusted for baseline outcome, township, sex, and age.

[d]Low and high values are the bounds of the 95% CIs from the primary outcome analysis in the SINEMA trial.

Budget Impact Analysis

Based on a stroke prevalence of 2.58% [39] and a rural proportion of patients with stroke of 52.9% [29], the eligible population for scaling up the SINEMA intervention to rural China was estimated to be 11,676,010 people. For subsequent years, we estimated the eligible population based on an annual stroke incidence rate of 8.26% [39], assuming a 1% annual national population growth and a 0.16% death rate [29]. This broader reach enabled the amortization of fixed costs such as system development and oversight across a much larger population, resulting in a reduced per capita cost. In scenario A, the program cost was estimated at $16.93 per participant, leading to a total budget impact of $197.72 million in the first year. Since intervention costs were only incurred in the first year, expenditure decreased in subsequent years. By the fifth year, with 4 visits from village doctors per year maintained, the expenditure decreased slightly by 3.2%, reaching $78.07 million (Table 6).

Table 6. Budget impact analysis of the system-integrated and digital technology–enabled model of care (SINEMA) intervention in year 1 and year 5.

Item	Scenario A: stand-alone project		Scenario B: integrated with NBPH[a]	
	Year 1	Year 5	Year 1	Year 5
Eligible population, n	11,676,010	11,695,170	11,676,010	11,695,170
Eligible participants receiving NBPH[b]	N/A[c]	N/A	7,125,158	7,136,851
Eligible participants excluded from NBPH[b]	N/A	N/A	4,550,852	4,558,319
Cost per participant ($)	16.93	6.68	9.90	3.98
Total budget impact[d] ($)	197,726,357	78,067,406	115,585,636	46,592,046
Total population, n	1,411,750,000	1,459,785,833	1,411,750,000	1,459,785,833
Cost per capita[e] ($)	0.14	0.06	0.08	0.03

[a]NBPH: national basic public health.

[b]Eligible participants receiving NBPH are individuals with stroke and hypertension or diabetes living in rural communities. Eligible participants excluded from NBPH are individuals with stroke who do not have hypertension or diabetes.

[c]Not applicable.

[d]Total budget impact is rounded to the nearest $10.

[e]Calculated as the total budget impact divided by the total population.

In scenario B, where the SINEMA intervention was integrated into the existing national basic public health services, we identified that 7,125,158 participants—approximately 61% of the eligible population—had already received these services [39]. The cost per participant in this scenario was reduced to $9.90, which resulted in a total budget impact of $115.59 million in the first year, only slightly over half of the costs in scenario A (Table 6). Results for all years and specific components are shown in Table S9 in Multimedia Appendix 2. Compensation for village doctor visits accounted for the largest portion of the total budget in both scenarios.

Discussion

Principal Results

With a mean follow-up of 6 years of the SINEMA trial, we conducted within-trial and post-trial cost-effectiveness analyses and budget impact analyses for the SINEMA model—an integrated mHealth primary care model for stroke management. The hybrid, type 2, effectiveness-implementation SINEMA trial has previously demonstrated not only the effectiveness of evidence-based strategies but also the feasibility of their implementation strategies [10,40]. Building on these findings, this study further showed that the SINEMA model was cost-effective for controlling blood pressure and improving QALYs compared to usual care, both within the 12-month trial period and during the 5-year post-trial follow-up. The base case analysis estimated an ICER of $8.4 per unit reduction in SBP, $837.9 per QALY gained during the trial, and $727.9 per QALY gained in the post-trial period, much lower than the WTP thresholds. Sensitivity analyses across various scenarios consistently supported these findings, reinforcing the robustness of the results. The budget impact analysis further supported the potential of the SINEMA intervention as a sustainable solution that incorporates both system-level consideration and mHealth empowerment, suitable for national scale-up in managing stroke and potentially for other chronic diseases.

Comparison With Prior Work

Our results demonstrating the high cost-effectiveness of the SINEMA model highlighted the importance of investing in primary health care and mHealth technology for stroke management and improving patient outcomes. To our knowledge, no cost-effectiveness studies on stroke interventions using similar mHealth technology have been conducted in LMICs, aside from one study from the United States and another from India, both of which used telemedicine-based approaches [13,14]. In a US-based study, the ACCESS teleneurology program for acute stroke care reduced unnecessary patient transfers and improved early treatment, resulting in a cost saving of $4241 and a QALY gain of 0.20 per patient over a 90-day horizon, demonstrating economic dominance over standard care [14]. In the Indian study involving 1200 postneurosurgery patients, telemedicine follow-up care was more effective and less costly than routine in-person care, with a cost per utility unit of $40.5 versus $105.4 and an ICER of –$537 [13]. However, the large differences in intervention design and context preclude direct comparison with our results. Moreover, telemedicine adoption in rural China has faced significant barriers, particularly related to digital literacy [41]. The SINEMA model, which includes voice message–based health communication, may help improve digital health acceptance among rural populations. Its cost-effectiveness has been clearly demonstrated, with a cost of $837.9 per QALY gained during the within-trial period—well below the internal cost-effectiveness threshold in China (eg, 1.5 times the 2023 gross domestic product per capita of $18,766).

We also compared our results with other community-based blood pressure–lowering trials in LMICs in rural Asia. For example, the COBRA trial in Pakistan reported an ICER of $23 per mmHg reduction in SBP [42]. The COBIN intervention in

XSL•FO
RenderX

Nepal, though initially cost-effective [37], saw a puzzling reversal of its benefits over time from a 5-mmHg reduction at 1 year to a 5-mmHg increase by 5 years [21]. In contrast, our 5-year post-trial results demonstrated sustained effectiveness of the intervention over time [11]. The ICER in our study was $10.5 per mmHg reduction in SBP, which was lower than that in the COBRA trial. One possible explanation for the higher and sustained long-term cost-effectiveness observed in our study, which was not accounted for in their analyses, could be the integration of mHealth technology, including a provider-facing Android app and patient-oriented voice messages.

Based on our budget impact analysis, scaling up the SINEMA model nationwide is both affordable and impactful. In China, while per capita health expenditure surged from RMB 1090 to RMB 4700 (US $164.9 to US $710.3) [43], spending on specialized public health organizations increased in absolute terms but dropped as a share of total health expenditure, from 8.58% to 5.47% [44]. In our study, the required investment for scaling up the SINEMA intervention represents about 0.15% of the basic national health services expenditure and could reduce hospitalization costs, underscoring the importance of investing in primary care and the value of task-shifting strategies from specialists to primary care providers [45,46]. Our study also explored the scenario of integrating the SINEMA app into the national basic public health service, adding intervention components of voice messaging and frequent SBP electronic records, which is estimated at nearly half the costs of the standard intervention. This finding highlighted the potential for saving costs when leveraging mHealth technology within the existing system. However, potential barriers and challenges, such as regional disparities in health care infrastructure, workforce capacity, and digital literacy, may be raised when considering large-scale implementation, which may lead to additional intervention components and additional costs. Furthermore, given that incentives for village doctors consistently accounted for the largest proportion of overall costs, future studies could further explore the strategies of a risk-based, adaptive delivery model that tailors follow-up intensity based on patients' clinical stability.

Limitations

Unlike most within-trial or modelling studies, this economic evaluation study based on the SINEMA trial has 3 parts—within-trial and post-trial cost-effectiveness analyses and budget impact analyses. We used extensive data on costs and effectiveness at the individual level collected mainly from our trial data, including mortality for both periods, alleviating the need to rely on blood pressure–based parameter estimates from literature and risk prediction models. Our study has some limitations. First, data on outpatient care were unavailable from the trial, requiring us to use external sources. Nonetheless, outpatient costs constitute only a small proportion of total medical costs. Second, while we collected patient-level data for the past year at the end of the active trial in 2018 and in the 5-year post-trial survey (2022-2023), data during the intermediate years (2019-2021) were missing. We extrapolated data for these years from available data. Extensive sensitivity analyses, varying each parameter by ±50%, found that the results were robust, mitigating concerns about missing data. Third, this trial was conducted in a single city in rural China, which may limit its generalizability. Nonetheless, our budget impact analysis explored the potential for national scale-up and highlighted that this intervention aligns well with the existing health system. The mHealth-enabled system, aligned with the current basic public health services framework, has the potential to enhance the management of stroke and other chronic diseases on a larger scale. Lastly, in the budget impact analyses, we lacked cost data from rural areas beyond the trial site and therefore assumed that intervention costs in other rural settings would be comparable to those observed in the trial, which was conducted in a single rural location. Additionally, we projected potential cost reductions in subsequent scale-up years, particularly related to human resources and the mHealth system. While such assumptions are commonly used in similar budget impact analyses, they remain strong and are inherently difficult to validate. Nonetheless, the analyses offer concrete estimates of potential financial implications and serve as a valuable tool for informing policy decisions and guiding resource allocation.

Conclusions

In summary, our findings on the cost-effectiveness of the SINEMA model highlight the value of investing in primary care services and mHealth technology for stroke care in rural China. The budget impact analyses provide evidence for sound policymaking and reveal their significant potential for nationwide scaling up in China. While this study was conducted among patients with stroke in a resource-limited region of China, its high cost-effectiveness highlights the need for future research to explore whether and how similar models—integrating mHealth technologies with the primary care workforce—can be adapted for other chronic conditions and comparable settings in LMICs.

Acknowledgments

We would like to thank the independent International Steering Committee Chair (Yangfeng Wu) and members (Eric Peterson and Craig Anderson) and advisory group members (Alba AmayaBurns, Allan Burns, Ninghua Wang, Xie Bin, Jesse Hao, Jixiang Ma, Jixin Sun, Jianxin Zhang, Jianmin Yao, Jinmei Liu, Qian Long, and Cheng Sun) who have provided great advice in designing and implementing the study. We also thank the Xingtai City Center for Disease Prevention and Control, Nanhe County Center for Disease Prevention and Control, Ren County Center for Disease Prevention and Control, all staff members from township health care centers and village clinics, and all patients who participated in or supported the project. Lei Si can be contacted as a co-corresponding author at l.si@westernsydney.edu.au.

This letter is regarding the recent publication "Efficacy of a WeChat-Based, Multidisciplinary, Full-Course Nutritional Management Program on the Nutritional Status of Patients With Ovarian Cancer Undergoing Chemotherapy: Randomized Controlled Trial" [1]. The authors reported a novel approach to managing the nutrition status of patients with ovarian cancer who underwent chemotherapy. With supportive results, it might be a potentially beneficial program for this patient cohort. However, there might be a problem in the description of Figure 7.

The authors described the changes in leukocytes, lymphocytes, neutrophils, and platelets as "inflammation-related blood indices." It might be appropriate for most patients with normal immune status but is not applicable for those undergoing chemotherapy with bone marrow suppression (BMS) [2]. BMS is one of the most common adverse effects in patients undergoing chemotherapy and can be divided into chemotherapy-induced leukopenia, neutropenia, thrombocytopenia, and anemia [3]. The changes in the blood cells above are not only an indication of inflammatory status but also critical to monitor the BMS in patients. It is important to discuss BMS in treatment using chemotherapy separately or combined with others. Additionally, the authors have reported a systematic inflammatory index, which is more accurate, to evaluate the inflammatory status of patients [4]. As for Figure 7, we noticed a significant decrease in leukocytes, dropping almost to the diagnostic criteria of leukopenia [5] in the control group, which suggests more severe BMS in the control group. So we suggest it might be more accurate to describe Figure 7 simply as "the changes in blood cells," and the potential benefit for improving BMS should also be described in this section.

The findings of this study are meaningful and interesting. The authors provided a potential approach to improve the clinical outcomes of patients with ovarian cancer undergoing chemotherapy, especially in China. Additionally, we noticed the intervention could improve BMS for these patients, although it should be described and addressed more accurately in the publication.

We agreed with the authors of the letter to the editor [1] that Figure 7 simply describes "the changes in blood cells." Our study [2] only focused on the effect of nutritional status on the inflammatory response of the patients but neglected an important point: the changes in blood cells such as "leukocytes, lymphocytes, neutrophils, and platelets" were also closely related to the occurrence of bone marrow suppression (BMS) in the patients [3]. Figure 7 illustrates that the nutritional intervention program in this study can reduce the occurrence of BMS in patients to a certain extent.

We couldn't agree more with the letter's suggestion. We would like to include the benefits of improved BMS in the Discussion section of our study, which would primarily include the following:

- Improvement in BMS can contribute to the patient's quality of life during chemotherapy [4].
- Reversal of the hematocrit condition corresponds to a reduction in the number or degree of the patient's chemotherapy symptoms: elevated neutrophils lead to lower levels of fatigue, fewer persistent or chronic infections, and less nausea/vomiting [5].
- An increase in hemoglobin improved the patient's appetite and reduced vertigo [6].
- An increase in the number of platelets reduced the incidence of hemorrhage [7].

Methodological Considerations in Evaluating Mental Health Apps: Ensuring Reliability and Patient Safety

Harikrishnan Balakrishna, MBBS, MBA

We read with great interest and appreciate Mehrotra et al [1] for their systematic review of mental health apps accessible to Indian users. Their assessment of 350 apps provides valuable insight into the current digital mental health landscape in India. Still, several methodological and reporting considerations require clarification. This letter addresses 3 key areas: interrater reliability, sampling scope, and patient safety considerations.

To establish interrater reliability, the Mobile Application Rating Scale (MARS) was developed and validated with independent dual ratings and calculation of intraclass correlation coefficients (ICCs) [2]. Mehrotra et al [1] describe efforts like joint training and expert validation of a small subsample but divide the remaining apps among 4 reviewers for independent evaluation. ICC values for the main ratings were not reported, an approach that deviates from the established MARS methodology [2]. A past study demonstrated that when MARS is applied without strict dual-rater methodology, interrater agreement can be low (Krippendorff α=0.29), indicating high variability among reviewers [3]. Without ICC data, it is difficult to determine whether differences in app quality scores reflect their true variation or rater inconsistency. Reporting ICCs for a random subsample or acknowledging this limitation would improve interpretability for clinical application.

Regarding sampling scope, World Health Organization (WHO) guidance emphasizes transparent reporting and clear description of inclusion criteria for digital health interventions to support accurate interpretation and generalizability [4]. The study assessed only free apps and freely accessible portions of paid apps, yet its conclusions are framed as applying to all “mental health apps available to Indian users.” Premium apps often differ from free ones in professional input, empirical validation, and privacy safeguards. The finding that 65% of apps lacked professional input and only 11% cited empirical research [1] may therefore not represent the entire app ecosystem. This approach limits its generalizability and could mislead policymakers and clinicians relying on evidence-based recommendations. Hence, conclusions should be categorically limited to the free or freemium app marketplace or, in future work, expanded to include paid apps.

Regarding patient safety considerations, WHO guidance emphasizes that systematic evaluations of digital health interventions should transparently identify and report potential harms to support safe implementation and evidence-based decision-making [4]. The authors identified apps with potentially harmful features, such as misleading claims or alarming feedback without crisis support, but did not indicate whether these concerns were addressed or reported in any way. Vulnerable patients experiencing mental health crises could have worsened outcomes when exposed to such inadequately designed assessment tools [5]. Empirical evidence shows that adverse events in consumer-facing mental health apps are underreported and may pose significant risks to users [5]. Highlighting such risks ensures that clinicians, policymakers, and end users are aware of potential harms when translating review findings into practice, without implying that reviewers are responsible for regulatory action.

Clarifying interrater reliability, explicitly defining app sampling scope, and transparently reporting safety-relevant issues strengthen the interpretability and applicability of systematic reviews in digital mental health. Methodological limitations, such as inconsistent rating procedures or selective sampling, reduce confidence in app quality scores and limit generalizability. While patient safety considerations are primarily reporting issues, systematically highlighting potentially harmful apps enhances the practical utility of reviews and supports safe evidence-based decisions.

mental health apps; mHealth; review of apps; smartphone apps; MHapps for indian users; India

We thank Balakrishna [1] for the letter to the editor in response to our article [2] on the systematic review of mental health apps accessible to Indian users and appreciate both their interest and the critical points raised.

As described in our paper, we adopted a multiphased approach to interrater reliability. This included initial training of reviewers; independent rating of 3 apps by 4 primary reviewers, followed by joint discussions with mentors; joint review of 3 additional apps, leading to the creation of an internal guide; independent review of 6 more apps and further mentor discussions; detailed independent review of the remaining apps; and mentor review of a subset of 7 reviewed apps, along with joint rating of all apps flagged as doubtful [2]. We acknowledge the concern regarding the absence of intraclass correlation coefficients due to the lack of dual ratings across all apps. It is a limitation noted in our paper. Given the broad search strategy, with use of 15 mental health–related terms, we had a large set of apps to review even after initial screening (n=792). Moreover, our review extended beyond the Mobile Application Rating Scale to include additional predefined parameters, requiring substantial time and effort. The dynamic nature of app store content further constrained the timeline, limiting the feasibility of dual independent ratings for all apps. Nonetheless, we believe our sequential, collaborative approach helped mitigate rating inconsistencies to a reasonable extent. We appreciate the suggestion to report intraclass correlation coefficients for a random subset, and this exercise is already underway.

Regarding sampling scope, as noted in the Limitations section of our paper, we evaluated only free apps, apps offering free trials, and the freely accessible portions of paid apps. This may have led to an incomplete basis for rating certain apps, and we agree that our findings may not fully represent the broader app ecosystem. However, information regarding involvement of mental health professionals and empirical research was drawn from app store descriptions and "about the app" sections, which were accessible even for paid apps. Our focus on free and partially free apps reflects what is most accessible to users and our findings align with patterns observed in other reviews [3-5]. That said, we acknowledge that ratings on some parameters would have benefited from access to full app content. This review is part of a planned recurring exercise, and in the next phase we will conduct detailed assessments of a random sample of fully paid apps, along with newer entries in this dynamic and evolving space.

Lastly, we concur with the observation that adverse events in clinical trials of mental health apps remain underreported. Ours was a review study, and we hope that our identification of certain instances of unscientific or potentially misleading content will prompt further research into these aspects. Looking ahead, we are developing a web-based platform to guide users and professionals on key cautionary indicators—contextually relevant cues to assess app quality and support informed decision-making.

KEYWORDS

mobile phone; mHealth; eHealth; telemedicine; telehealth; spinal cord injury; self-management; internet-based intervention; World Wide Web; systematic review; caregiver

I read, with great interest, the recent article by the team from Swiss Paraplegic Research, Nottwil, Switzerland, titled *Self-Management Support Apps for Spinal Cord Injury: Results of a Systematic Search in App Stores and Mobile App Rating Scale Evaluation* [1].

The authors conducted a comprehensive review of available mobile apps aimed at supporting self-management for individuals with spinal cord injury (SCI). Their work provides valuable insights into the current landscape of digital tools in this domain.

As a rehabilitation nurse specializing in SCI at the North Rehabilitation Centre of Portugal, having worked in this field since 2017, I have dedicated my career to researching the rehabilitation process of patients with SCI, particularly the training and empowerment of caregivers [2]. This experience, coupled with my research and app development background, informs my perspective on the study by Bernard et al [1].

I commend the authors for their rigorous systematic search of mobile apps designed to support self-management for individuals with SCI. However, I would like to highlight a critical aspect that may warrant further consideration: the exclusion of caregiver-centered apps. Many patients with SCI, particularly those with cervical injuries, experience severe functional limitations that hinder their ability to independently use self-management apps. As emphasized by Armstrong-Wood et al [3], individuals with high-level SCI may struggle with smartphone accessibility, which underscores the importance of caregiver involvement in the creation of these apps and caregivers' presence during app usage.

A crucial point raised in the study is the role of technological companies in developing self-management apps without direct involvement from SCI specialists or end users. While collaborations with researchers are mentioned, it is essential that these partnerships are more structured and systematic, ensuring that apps meet the real needs of patients with SCI and their caregivers. Without this validation process, there is a risk of developing tools that do not effectively address the complexities of SCI self-management, which calls for a more standardized and research-driven approach to app development.

Furthermore, the study's focus on English-language apps presents a potential limitation. While the authors acknowledge this constraint, restricting searches to English-language apps may exclude valuable resources tailored to non–English-speaking populations, limiting the generalizability of findings.

The integration of validation studies and collaborative research is fundamental to enhancing the effectiveness, usability, and real-world applicability of digital tools in SCI rehabilitation. Expanding this approach will ensure that these tools are not only evidence-based but also practical and adaptable to diverse patient needs.

The study identifies the absence of gamification elements in most reviewed apps, presenting an opportunity for innovation, as interactive learning approaches have demonstrated efficacy in enhancing engagement and knowledge retention [4].

I appreciate the authors' valuable contribution to this evolving field and encourage future research to expand the scope of app evaluations to include caregiver-focused tools, multilingual resources, and usability considerations for individuals with functional impairments. These additions would provide a more comprehensive understanding of digital health solutions in SCI rehabilitation.

Correction of: https://mhealth.jmir.org/2025/1/e65668

(JMIR Mhealth Uhealth 2025;13:e79507) doi:10.2196/79507

In "Participant Adherence in Repeated-Dose Clinical Studies Using Video-Based Observation: Retrospective Data Analysis" (JMIR JMIR Mhealth Uhealth 2025;13:e65668), the authors noted three errors.

- The order of authors was incorrectly listed in the originally published article. This has been changed from:

  Seunghoon Han, MD, PhD; Jihong Song, BSN; Sungpil Han, MD, PhD; Suein Choi, MD, PhD; Jonghyuk Lim, BE; Byeong Yeob Oh, BBA; Dongoh Shin, MEng

To:

  Jihong Song, BSN; Sungpil Han, MD, PhD; Suein Choi, MD, PhD; Jonghyuk Lim, BE; Byeong Yeob Oh, BBA; Dongoh Shin, MEng; Seunghoon Han, MD, PhD

- In the subsection of "Methods" titled "The System Overview," casing type was changed from:

  (2) Verified Deviated Dosing, (3) Unverified Dosing, (4) Missed Dosing

To:

  (2) Verified deviated dosing, (3) Unverified dosing, (4) Missed dosing

- The values in the final column of Table 2, "Allowed time window for SAI (min)," were adjusted to more accurately represent the intended time windows. These values have now been provided in a range rather than a single negative value, and the table will appear as follows:

XSL•FO
RenderX

Table 2. Self-administration of the investigational medicinal product-specific characteristics by cohort.

Cohort	SAI[a] schedule				Dosing notification (min before the planned dosing time)	Dosing reminder (min after the planned dosing time)	Allowed time window for SAI (min)
	SAI day	Number of total SAI days	Number of SAIs per day	Planned dosing time[b]			
1	2-4, 6-8, 10-12, 14-16, 18, 19	14	1	9 AM	–60, –30, 0	15, 30, and 45	–60 to 60
2	1, 2, 6, 7, 9-11	7	1	9 AM	N/A[c]	N/A	–60 to 60
3	1, 2, 4-6, 10, 11	7	1	9 AM	N/A	N/A	–60 to 60
4	1, 2, 12-15, 17-20, 24, 25	12	1	9 AM	N/A	N/A	–60 to 60
5	1-4, 13-17, 21-23	12	1	9 AM	–60, –30, 0	15, 30, and 45	–60 to 60
6	1-32	32	2	Variable[d]	–60, –15, 0	60 and 110	–120 to 120
7	3, 5, 7, 9, 10, 12-14, 16-21, 23-30, 32-45, 47-60, 62-75, 77-90	78	1	9 AM	–30, –5, 0	10, 20, 165, and 665	–180 to 180
8	1-28	28	2	Variable[d]	–60, –10, 0	60, 180, and 350	–120 to 360
9	3-7	5	2[e], 3	8 AM, 2 PM, and 8 PM	–30, 0	N/A	–120 to 120
10	4-8, 11	6	2[e], 3	8 AM, 2 PM, and 8 PM	–30, 0	N/A	–120 to 120
11	5-9, 12	6	2[e], 3	8 AM, 2 PM, and 8 PM	–30, 0	N/A	–120 to 120
12	2-4, 8-96	92	1[e], 2[e], 4	1 AM, 9 AM, 9:10 AM, 5 PM	–10, 0	10	N/A
13	1-89, 92-96	94	2[e], 3	1 AM, 9 AM, 5 PM	–10, 0	10	N/A
14	2, 3, 5, 6, 8, 9, 11	7	1	9 AM	–30, 0	30	–60 to 60

[a]SAI: self-administration of the investigational medicinal product.

[b]The presented data refer to the reference point for the planned dosing time (eg, 9 AM) in each cohort, with minor variability across participants (eg, 9:02 AM, 9:04 AM, 9:06 AM, etc).

[c]N/A: not applicable.

[d]The planned dosing times vary across participants, and no common reference point can be provided.

[e]SAI event and dosing by the investigator on the same day.

The correction will appear in the online version of the paper on the JMIR Publications website, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Submitted 29.06.25; this is a non–peer-reviewed article;accepted 02.07.25; published 30.07.25.

Abstract

Background: Digital phenotyping provides insights into an individual's digital behaviors and has potential clinical utility.

Objective: In this observational study, we explored digital biomarkers collected from wrist-wearable devices and smartphones and their associations with clinical symptoms and functioning in patients with schizophrenia.

Methods: We recruited 100 outpatients with schizophrenia spectrum disorder, and we collected various digital data from commercially available wrist wearables and smartphones over a 6-month period. In this report, we analyzed the first week of digital data on heart rate, sleep, and physical activity from the wrist wearables and travel distance, sociability, touchscreen tapping speed, and screen time from the smartphones. We analyzed the relationships between these digital measures and patient baseline measurements of clinical symptoms assessed with the Positive and Negative Syndrome Scale, Brief Negative Symptoms Scale, and Calgary Depression Scale for Schizophrenia, as well as functioning as assessed with the Social and Occupational Functioning Assessment Scale. Linear regression was performed for each digital and clinical measure independently, with the digital measures being treated as predictors.

Results: Digital data were successfully collected from both the wearables and smartphones throughout the study, with 91% of the total possible data successfully collected from the wearables and 82% from the smartphones during the first week of the trial—the period under analysis in this report. Among the clinical outcomes, negative symptoms were associated with the greatest number of digital measures (10 of the 12 studied here), followed by overall measures of psychopathology symptoms, functioning, and positive symptoms, which were each associated with at least 3 digital measures. Cognition and cognitive/disorganization symptoms were each associated with 1 or 2 digital measures.

Conclusions: We found significant associations between nearly all digital measures and a wide range of symptoms and functioning in a community sample of individuals with schizophrenia. These findings provide insights into the digital behaviors of individuals with schizophrenia and highlight the potential of using commercially available wrist wearables and smartphones for passive monitoring in schizophrenia.

Introduction

Schizophrenia is a debilitating condition affecting at least 20 million individuals worldwide [1]. This lifelong condition [2] is frequently associated with impairments in personal, social, occupational, and other important areas of daily function [3]. Despite advancements in pharmacology and psychosocial interventions, recovery rates among patients have not improved

XSL•FO
RenderX

[4], and the high rate of relapse places a heavy burden on patients and their caregivers [5].

In present-day psychiatric care, the clinical status of patients is determined at periodic consultations via clinician interviews and self-reported questionnaires. The episodic nature of these visits and the removal of patients from their natural environment result in limited assessments that do not always reflect the state of patients in different environments and over varying periods of time [6]. Moreover, there is a risk of unreliable self-reporting in patients with schizophrenia, influenced by cognitive impairments, biases, and self-reporting confounders [7].

Digital phenotyping may allow care teams to circumvent these limitations. Digital phenotyping is defined as the moment-by-moment quantification of the individual-level human phenotype in situ using data from smartphones and other personal digital devices [8,9]. Through personal digital devices, insightful and objective longitudinal data, such as on sleep and mobility, can be unobtrusively and continuously collected from patients [10].

There has been growing interest in digital phenotyping in psychiatry [11,12]. People with schizophrenia have shown willingness to use smartphones to monitor their condition [13]. Furthermore, preliminary trials have shown that the long-term use of wearable technology is feasible and acceptable by people with schizophrenia and that paranoia toward devices was not a significant barrier [14-16].

There is also some evidence that wearable and mobile devices can deliver clinically relevant information in real-world contexts. Movement data estimated from a 3-axis accelerometer were negatively correlated with negative symptoms assessed with the Positive and Negative Syndrome Scale (PANSS) in patients with schizophrenia [17]. The number of steps was negatively correlated with PANSS positive-factor, negative-factor, general subscales, and total score, in patients with schizophrenia in an inpatient setting [18]. Sleep duration estimated from mobile phone–based accelerometer data was moderately correlated with subject self-assessment of sleep duration [19]. Geolocation and motor activity inferred from gyroscopes and data from the ambient light sensor, accelerometer, and other sensors in smartphones were used as indices of negative symptoms [20,21]. Data from anonymized call and text message logs may be potential markers for social functioning, and data on screen touches, such as typing speed, may provide novel clinical data about a user's cognitive functioning [9].

Despite this evidence, past studies have noteworthy limitations, such as small sample sizes [17,22], nonclinical samples [23,24], being conducted in closed-ward settings [18], and having used made-for-research wearable devices [22], which would affect the generalizability of the research findings or scaling up to larger populations. To date, few studies have reported digital phenotyping measures collected with both low-cost, commercially available digital wearable devices and smartphones among patients with schizophrenia in a community setting.

The aim of this study was to provide an initial examination of the associations between multimodal digital markers and clinical outcomes in patients with schizophrenia.

Methods

Setting and Participants

The Health Outcomes via Positive Engagement in Schizophrenia (HOPE-S) study is a prospective observational study conducted at the Institute of Mental Health, Singapore, with recently discharged individuals with schizophrenia spectrum disorders. Details of the study have been previously reported [25]. In brief, participants were followed up for up to 6 months.Clinical, cognitive, and functioning data were collected at intervals of every 6 weeks, and digital data from smartphones and wrist wearables were collected continuously over the follow-up period. The clinical, cognitive, and functioning data collected at baseline and the digital data collected in the first week after study enrollment were used for this study. The study aimed to examine the associations between clinical, cognitive, functioning, and digital data to develop prediction algorithms that might detect clinically significant outcomes. We recruited 100 English-speaking patients aged 21 - 65 years between November 2019 and January 2023. One participant requested to be withdrawn from the study after completing the baseline assessment due to objections from family members. Of the remaining participants (n=99), 63 were diagnosed with schizophrenia, 12 with brief psychotic disorder, 11 with schizophreniform disorder, 5 with schizoaffective disorder, 5 with delusional disorder, and 3 with other specified psychotic disorder.

Ethical Considerations

Ethics approval was obtained from the National Healthcare Group's Domain Specific Review Board, Singapore (2019/00720). Written informed consent was obtained from all participants after the study was fully explained. Data were anonymized and encrypted to protect patient privacy. Participants were reimbursed SGD 50 (US $37.19) on completion of the baseline visit for their time, inconvenience, and transportation costs.

Clinical Symptom Severity Measures and Scales

Assessment data from baseline were used for the present analyses. Symptom severity was assessed on the PANSS [26]. The PANSS is a 30-item clinical scale measuring positive symptoms, negative symptoms, and general psychopathology. PANSS factor scores, including positive (PANSS_Pos), negative (PANSS_Neg), cognitive/disorganization (PANSS_Cog/Dis), depression/anxiety (PANSS_Dep/Anx), and hostility (PANSS_Hos), were calculated in accordance with a previously validated factor structure [27].

Negative symptoms were measured with the Brief Negative Symptom Scale (BNSS) [28], a well-established 13-item instrument designed to measure 5 negative symptom domains, including asociality, anhedonia, avolition, blunted affect, and alogia [29].

XSL•FO
RenderX

Depressive symptoms were assessed on the Calgary Depression Scale for Schizophrenia (CDSS) [30], a 9-item scale widely used for assessing depression in schizophrenia that differentiates between depression symptoms and the negative and positive symptoms in schizophrenia.

Neurocognition was assessed with the Brief Assessment of Cognition in Schizophrenia (BACS) [31], a cognitive battery that assesses attention, verbal and working memory, motor and processing speed, verbal fluency, and executive function. A composite *z* score was obtained and used for analysis [31]. The Social and Occupational Functioning Assessment Scale (SOFAS) [32] was used to evaluate the patients' social and occupational functioning.

Digital Data Collection and Preprocessing

Digital data were collected from both wrist wearables and smartphones. Each participant was issued a Fitbit Charge 3 or 4 (Fitbit Inc) at the beginning of the study. Participants were required to wear the Fitbit every day during the study period, including when asleep. The Health Outcomes through Positive Engagement and Self-Empowerment (HOPES) app [33] was installed on a participant's smartphone if the device used the Android operating system. In the circumstance that a participant's phone was not compatible with the HOPES app, we provided a phone for use during the study period. In this case, study coordinators aided in the patient's migration to the study phone, and the patient was instructed to use only the study phone as their primary mobile device during the study. Data collected from the wrist wearables and smartphones were automatically synchronized with the HOPES app and subsequently sent to the research premises for storage and further analysis. Data collected by the Fitbit included data from the heart rate monitor, pedometer (step counts), and sleep sensor, including sleep stages. Data collected from the smartphone included locational mobility features (through GPS), touchscreen tapping speed, and sociability indices from texts and calls (via both the mobile service provider and WhatsApp). Significant steps were taken to ensure data privacy, validate data quality, and engineer better features, which are covered in detail in a publication by Wang et al [33]. The subset of data analyzed in this paper is described in Multimedia Appendix 1. Table 1 summarizes the resulting digital measures used in our analyses.

Table . Digital measures collected by Fitbit wearables and smartphones.

Daily digital measures	Data source	Description
total_sleep_hrs	Wearable	Total hours of sleep, including naps but not including the "wake" stage (see below).
sleep_hrs_wake	Wearable	Total hours of sleep classified as the "wake" sleep stage by the Fitbit, estimated to be the time in bed not sleeping (ie, falling asleep, after waking up, and awaking during the night).
sleep_hrs_light	Wearable	Total hours of sleep classified as the "light" sleep stage by the Fitbit.
sleep_hrs_deep	Wearable	Total hours of sleep classified as the "deep" sleep stage by the Fitbit.
sleep_hrs_REM	Wearable	Total hours of sleep classified as the "REM" (rapid eye movement) sleep stage by the Fitbit.
sleep efficiency	Wearable	Sleep efficiency score from the Fitbit for the main sleep segment.
HR_asleep	Wearable	Average of heart rate samples while asleep, as measured by the Fitbit heart and sleep monitors.
total steps	Wearable	Total steps taken, as measured by the Fitbit.
dist_travelled	Smartphone	Total distance traveled, as computed by GPS processing routines.
mode_intertap_dist	Smartphone	Mode of a rolling 7-day distribution of intertap durations, excluding taps in games (a higher value indicates a slower tapping speed).
total_msg_sent	Smartphone	Total messages (texts and images) sent via mobile service provider and WhatsApp.
screen_time	Smartphone	Total time of smartphone use as represented by the power state logs.

For each daily digital measure, data collected during the 7 days following the baseline visit (not including the data on the day of the baseline visit) were used. The 1-week duration should account for any day-of-week effects in the digital measures. Digital markers were taken as the average of the observations for each digital measure over the week of interest, except for the *mode_intertap_dist* measure, for which the last valid (ie, nonmissing) value was taken since this is already a 7-day rolling window statistic. We required at least 4 valid observations in the week-long observation window to produce a nonnull marker.

XSL•FO
RenderX

Successful data collection rates for the wearables as the fraction of hour-long windows with at least 1 successfully collected heart rate sample in the window of study (ie, the 7 days [168 hours] following the baseline visit) were calculated. A successful data collection rate for the smartphones was calculated similarly using the ambient light sensor. Note that these 2 data sources were continually sampled by each device regardless of user action, so long as the participant was compliant, that is, the wearable was correctly worn, and the phone was powered on with the app running in the background.

Statistical Analysis

Descriptive statistics on clinical measures, digital data measures, and successful data collection rates were analyzed. The successful data collection rates were compared between groups of participants who used study phones and their own phones with the Mann-Whitney *U* test. As an exploratory analysis to discover possible digital markers as factors associated with different clinical measures, a multiple linear regression was performed independently for each pair of digital markers (independent variable) and clinical measure (dependent variable). In each regression model, age was included as a covariate along with an interaction term with the digital measure, which has been reported as a significant factor in relapse behavior, psychosocial functioning, and psychotic symptoms [34,35]. Because a significant difference in digital data collection rates was noticed between participants using a study-provided phone and those using their own phone, we also included a variable indicating whether the participant was using a study-provided phone (along with its interaction with the digital measure) in all models regressing onto a digital measure from the smartphone. To easily compare the relative effect sizes between different measures, both the digital markers and clinical scales were standardized across the population; an intercept term was therefore not included in the models. Due to the particularly skewed distributions of the *distance_travelled* and *total_msg_sent* features, a log(1+x) transform was applied to these features before standardization. As this was an exploratory analysis attempting to uncover trends in the digital markers, multiple testing corrections were not used. A heat map was used to show effect sizes and visualize trends across digital markers and clinical scales.

Results

Sample Characteristics

The demographic and clinical characteristics of the study sample are summarized in Table 2.

Table . Demographic and clinical characteristics of the study sample (n=99).

Characteristics	Values
Sex, n (%)	
Female	57 (57.6)
Male	42 (42.4)
Marital status, n (%)	
Single	85 (85.9)
Married	7 (7.1)
Separated or divorced	7 (7.1)
Ethnicity, n (%)	
Chinese	73 (73.7)
Malay	17 (17.2)
Indian	6 (6.1)
Other	3 (3.0)
Currently on antipsychotics, n (%)	
Yes	97 (98.0)
No	2 (2.0)
Age (years), mean (SD)	29.88 (6.72)
Years of education, mean (SD)	14.07 (2.27)
Duration of illness (years), mean (SD)	2.61 (4.00)
Antipsychotic dose[a] (mg), mean (SD)	484.37 (375.55)
PANSS [b] score, mean (SD)	
Total	51.11 (9.97)
Positive	8.49 (3.82)
Negative	13.20 (4.08)
Cognitive/disorganization	10.55 (2.50)
Depression/anxiety	8.85 (3.43)
Hostility	5.40 (1.89)
BNSS [c] score, mean (SD)	
Total	20.90 (9.30)
Anhedonia	5.51 (2.76)
Asociality	3.34 (1.55)
Avolition	3.30 (1.89)
Blunted	5.77 (3.89)
Alogia	2.82 (2.61)
CDSS[d] total score, mean (SD)	12.31 (3.55)
SOFAS[e] score, mean (SD)	53.96 (11.85)
BACS[f] score, mean (SD)	−1.31 (1.36)

[a]Antipsychotic dose was computed as total daily chlorpromazine equivalent (n=91).

[b]PANSS: Positive and Negative Syndrome Scale.

[c]BNSS: Brief Negative Symptom Scale.

[d]CDSS: Calgary Depression Scale for Schizophrenia.

Digital Data Collection Rate and Digital Data Profile

In total, 41 and 58 participants were issued a Fitbit Charge 3 and Charge 4, respectively. Thirty-nine participants used a smartphone provided by the study at the baseline visit, while the rest used their own phone. The successful data collection rate in the week following the baseline visit was 91% (SD 22%) for the Fitbit and 82% (SD 32%) for the smartphone. Those using a study-provided phone had a significantly higher successful data completion rate than those using their own phone (mean 91% vs 77%; Mann-Whitney *U* test: $P<.001$). Sensor-specific successful data collection rates are also provided in Multimedia Appendix 2. The sample size of valid digital measures (n=99), along with the means and SDs, are presented in Table 3.

Table . Summary of digital markers.

Visit-level digital markers	Values, mean (SD)
Total_sleep_hrs (n=92)	8.76 (2.13)
Sleep hrs-wake (n=91)	0.83 (0.30)
Sleep hrs-light (n=91)	5.32 (1.71)
Sleep hrs-REM (n=91)	1.68 (0.51)
Sleep hrs-deep (n=91)	1.23 (0.39)
Sleep_efficiency (n=91)	0.93 (0.03)
Total_steps (n=96)	9186.91 (5413.21)
Distance_travelled (km) (n=87)	27.64 (34.59)
HR_asleep (bpm) (n=74)	69.94 (10.06)
Mode_intertap_dist (ms) (n=96)	596.06 (389.08)
Total_msg_sent (n=92)	38.02 (65.16)
Screen_time (hrs) (n=92)	4.74 (3.64)

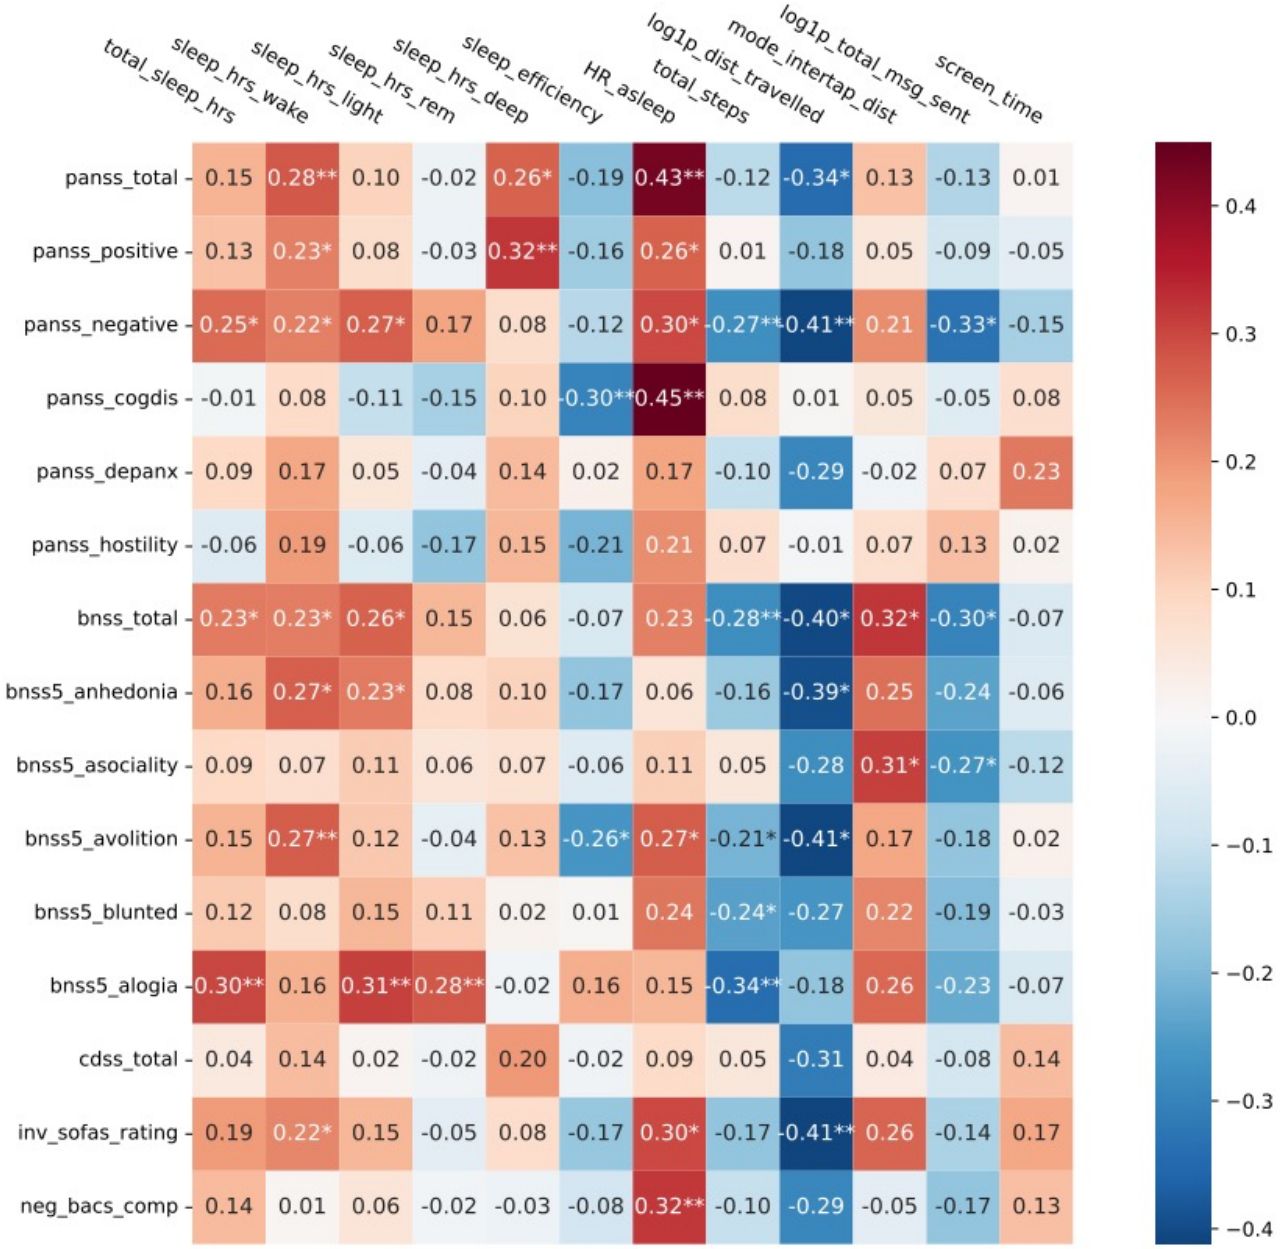
As expected, several digital measures were correlated with one another (such as sleep stage measures). The correlation coefficients between digital measures are provided in Multimedia Appendix 3.

Association Between Clinical Scales and Digital Markers

The linear regression coefficients of the digital measures are visualized for the different clinical measures as a heat map (Figure 1) at the mean age level (29.88 years) and for participants using their own phone. The numbers in the cells are the value of the regression coefficient, which also determines the cell color and intensity.

XSL•FO
RenderX

Figure 1. Regression coefficients between clinical scales and digital markers. Notes: A log(1+x) transformation was applied to *distance_travelled* and *total_msg_sent*. All clinical scales and digital markers were standardized prior to the regression. The Social and Occupational Functioning Assessment Scale (SOFAS) score was inverted (denoted as *inv_soafs_rating*, calculated as 100 minus the SOFAS rating) in the analyses to maintain a consistent direction among the scales and the digital markers, which aids visualization and interpretation. Analogously, the Brief Assessment of Cognition in Schizophrenia composite score was inverted (denoted as *neg_bacs_comp*) by taking the negative of its value. Ordinary least squares: *P_{OLS}<.05, **P_{OLS}<.01.



Starting with the symptoms and their associated digital biomarkers, first, we found that negative symptoms as assessed by both the BNSS and PANSS-negative were associated with the most digital measures (8 of the 12 being studied). Experiential deficits, that is, anhedonia and avolition, tended to be associated with less distance traveled and more hours spent awake in bed; fewer messages sent, a digital marker of sociability, tended to be associated with asociality. Expressive deficits, that is, affect blunting and alogia, tended to be negatively associated with steps taken. Alogia was additionally associated with sleep features such as total sleep hours and hours in light and rapid eye movement (REM) sleep. Second, PANSS-positive and SOFAS scores were associated with at least 3 different digital measures. Third, cognition and cognitive/disorganization symptoms were associated with 1 or 2 digital measures.

Among the digital measures, heart rate measured when asleep was associated with the most clinical measures. Specifically, a higher heart rate was associated with greater severity scores on PANSS-total and its factors (ie, positive, negative, and cognitive/disorganization) and BNSS avolition and asociality, as well as poorer functioning and cognitive performance. Time awake in bed and distance traveled were associated with mostly similar clinical measures, that is, negative symptoms, in particular anhedonia, avolition, and functioning. The only digital

XSL•FO
RenderX

measure not significantly associated with a clinical measure was screen time.

Discussion

Principal Findings

In this study, we examined the associations between digital markers (collected via commercially available wrist-wearable devices and smartphones) and a comprehensive range of clinical assessments in a sample of 99 recently discharged patients with schizophrenia spectrum disorders. Notable patterns of associations for digital measures were observed with psychiatric symptoms, specifically negative symptoms, functioning, and cognitive performance.

Longer total sleep time was positively associated with negative symptom domains; sleep efficiency was negatively associated with BNSS avolition and the PANSS cognitive/disorganization score. These results are in line with previous studies that reported associations between negative symptom severity and sleep disturbances (such as hypersomnia and sleep satisfaction) collected through self-reporting [36,37] and as measured by actigraphy [22,38]. One study also found no correlation between sleep markers collected via actigraphy and negative symptoms assessed via the PANSS-negative symptom subscale [39]. In addition, whether and how each sleep stage is associated with symptoms in schizophrenia remains inconclusive. A previous study reported that REM sleep duration was correlated with the Brief Psychiatric Rating Scale (BPRS) total score but not with the constituent negative symptom score [40]; in contrast, this study found no association between REM sleep duration and PANSS-total score but found a positive association with alogia. Use of nonspecific negative symptom assessment scales such as PANSS and BPRS, variations in sleep instruments, and other clinical factors, such as duration of illness and medication status [41], likely contributed to the mixed results in the literature.

Several types of passive digital phenotyping measures are associated with negative symptoms, such as phone use data (call/text logs, screen time), GPS data (distance traveled), sleep data (total sleep duration), and physical activity (step count). These findings support the use of passively collected digital phenotyping data as objective measures of negative symptoms and functional outcomes. These measures also provide longitudinal data that are usually not available directly to clinicians. Our study found a negative association between physical activity (as measured by step count) and negative symptom severity, particularly BNSS avolition, blunted affect, and alogia. This is in line with previous research that showed associations between decreased activity or sedentary behavior and negative symptoms in schizophrenia [17,18,22,42-44].

Distance traveled, messages sent and touchscreen tapping speed yielded the strongest signals associated with negative symptoms, specifically experiential deficits such as avolition, anhedonia and asociality. These results are consistent with previous studies that reported greater GPS mobility was associated with lower negative symptom severity and better community functioning [20,45]. Social behaviors (such as duration of outgoing calls and number of text messages) have been found to be predictive of psychotic symptoms and relapse in schizophrenia [46,47]. Typing-related data have been reported to be associated with mood symptoms and cognition in people without psychosis [48-50], but no such association was found in our study. The current study appears to be the first to report significant associations between negative symptoms, specifically asociality, and a messaging log feature (ie, the number of messages sent out) as well as touchscreen tapping speed.

We found that increased heart rate while asleep was associated with increases in positive psychopathology and worse cognitive performance. The relationship between increased heart rate and a greater severity of positive symptoms has often been documented [51-53], but only one previous study reported this relationship for heart rate during sleep, supporting our findings [54]. These associations likely indicate altered autonomic functioning, as indexed by increased heart rate, in response to stressors such as manifestations of psychotic symptoms [51,55]. Similarly, altered autonomic functioning may affect cognition. While no studies have reported the association of increased heart rate during sleep with worsening cognition, reduced heart rate variability has been linked to worse cognitive scores in schizophrenia [56].

The successful data collection rates in this study were high—about 91% for the Fitbit devices and 82% for the smartphones, which is comparable to the compliance rates in previous studies [15,19]. The good data collection rates support the potential of wrist wearables and smartphones as longitudinal passive monitoring devices in people with schizophrenia. It should be noted that the enrolled sample was relatively young, with a mean age of 30 years, and this group of people may be more accepting of digital devices. The digital data collection rate from the smartphones was impacted by both the compliance of participants and technical factors, such as proper device functioning and syncing with the mobile app. Some smartphone models automatically suppress all app activity during the night to save battery power, preventing complete data collection from the phone. In addition, some participants were provided with a phone for the study because their personal phone was incompatible with the HOPES app, and it was often the case that the participant's phone was too old. The above 2 points could explain why the data collection rate was higher with study-provided phones, as these (newer) phones could have exhibited better functioning.

Although there is a considerable amount of literature reporting associations between digital markers and clinical symptoms in populations of outpatients with schizophrenia, the majority collected digital data via only smartphones or actigraphy devices. Despite the expanding interest in using commercially available wearables in health care [57], studies using these devices in the medical field are still few. This study contributes such an investigation with a large clinical sample. Notably, the data reported in this study were not affected by Singapore's COVID-19 movement control measures: none of the 1-week digital data collection periods under study overlapped with the movement control period.

XSL•FO
RenderX

Limitations

There are some limitations to this study to be considered. The participants were relatively young (mean age: 30 years) and mildly ill (PANSS-total score: 51) [58] with a short duration of illness (2.6 years), which limits the generalizability of the results. Associations in older, chronic, and more severely ill patients might differ and should be further investigated. Due to the nature of this cross-sectional study, no causal relationships could be inferred. In addition, all participants included in this study were taking psychotropic medications with varying types and dosages, which may have had differential effects on cardiac function [59] and sleep [60], warranting further examination. Participants received financial incentives at timed intervals in the study, which might have positively affected adherence and data acquisition. Similar studies, however, noted that the majority of participants expressed a desire to continue using the wrist wearable without incentive after the study [19]. The longer-term use of wearable devices by individuals with schizophrenia should be further studied. Finally, because the regression analyses were exploratory in nature, and we aimed to detect all potential indicators of symptoms and functioning that could be useful in future studies, corrections for multiple testing were not applied before reporting significant associations.

Despite the limitations of the study, the patterns highlighted in the findings may guide future directions for research. The reported associations suggest that unobtrusively and passively collected digital phenotyping markers hold promise for continuous monitoring of clinical symptoms in people with schizophrenia between clinical visits. Digital phenotyping–enhanced care can improve the identification of patients in need of attention and may allow health care providers to delivery timely interventions [61].

Conclusion

Our study found notable patterns of associations between a range of digital biomarkers and clinically important outcome measures in a community sample of individuals with schizophrenia spectrum disorders. These results support the use of commercial wrist wearables and smartphones in continuous but passive monitoring of the health status of individuals with schizophrenia. Future studies should explore longer-term digital phenotyping observations in naturalistic settings and their utility in predicting clinical events.

Acknowledgments

The authors would like to express their sincere gratitude to the participants for their valuable contributions and to the clinicians who helped in study recruitment and assessments. We would like to thank Dr Gurpreet Rekhi, who trained and supervised the research psychologists in conducting the clinical assessments. The study was supported by the Ministry of Health Office for Healthcare Transformation and the Ministry of Health National Medical Research Council Centre Grant (NMRC/CG/M002/2017_IMH). JL is supported by the Ministry of Health National Medical Research Council Clinician Scientist Award (NMRC/CSAINV17nov005). The funders played no role in study design, data collection, analysis and interpretation of data, or the writing of this manuscript.

Data Availability

The datasets generated and/or analyzed during the current study are not publicly available, because the participants in this study did not give written consent for their data to be shared publicly.

Authors' Contributions

JL, RJTM, ZY, and CH designed the study. RJTM and JL obtained the funding. ZY, NAAR, and TB managed the study. ZY, AS, NAAR, SZ, YFQ, SB, KWL, CT, SV, and JL supported recruitment and data collection. CH, ZY, and XW analyzed the data. CH, ZY, JL, and RJTM interpreted the results. ZY and CH drafted the manuscript. All authors revised and approved the final version of the manuscript.

Abstract

Background: Intensive measures of well-being and behaviors in large epidemiologic cohorts have the potential to enhance health research in these areas. Yet, little is known regarding the feasibility of using mobile technology to collect intensive data in the "natural" environment in the context of ongoing large cohort studies.

Objective: We examined the feasibility of using smartphone digital phenotyping to collect highly resolved psychological and behavioral data from participants in a pilot study with participants in Nurses' Health Study II, a nationwide prospective cohort of women.

Methods: In this pilot study, an 8-day intensive smartphone protocol was implemented using the "Beiwe" smartphone app. Participants (n=181) completed a baseline survey on day 1 and answered ecological momentary assessment (EMA) surveys twice daily (days 2-8; early afternoon and evening) using their smartphone and provided minute-level accelerometer and GPS data. A feedback survey at the end of Substudy queried participants' experience with the app and data collection process. We assessed adherence to the protocol by examining completion on EMA surveys and completeness of accelerometer and GPS data at the participant, participant day, and prompt levels.

Results: Our pilot study demonstrated modest overall compliance with smartphone-based surveys: the baseline survey completion rate was high (156/181, 86.2%), but average daily EMA response rates during the 7-day period were lower with 55.6% (SD 3.9%) for early afternoon and 54.7% (SD 3.2%) for evening. We also observed good average daily completeness of smartphone accelerometer (mean 62.0%, SD 4.5%) data and GPS data (mean 57.7%, SD 3.1%). The feedback survey revealed that the participants found "the app easy to use" (median 85.0 on a scale of 1 - 100) and were "willing to repeat similar studies" (median 85.0 on a scale of 1 - 100). Although participants reported feeling their participation was a positive experience (median 64.0 on a scale of 1 - 100), they also identified some important issues, including user fatigue due to repetitive daily surveys.

Conclusions: We observed modest compliance with smartphone surveys and completeness of smartphone passive sensing data in this pilot study compared with similar studies in the past. However, this was not unexpected, given our participants were older (aged 57 - 75 years, with more than 3 decades of follow-up at the time of the substudy) and may encounter more technological

RenderX

barriers, not to mention that the indication of willingness to participate in such studies again was fairly high. Our findings also highlight that the success and data quality of efforts to obtain daily measures may vary depending on data type and emphasize the need to improve the design of the EMA survey to improve or sustain participant engagement over the study period. Overall, our findings suggest smartphone-based digital phenotyping as a promising technology when embedding in large epidemiological cohorts to collect intensive longitudinal observation data.

Introduction

Background

Many dimensions of psychological well-being—both stable traits (eg, optimism) and time-varying states (eg, happiness)—are linked to positive physical health outcomes such as a lower risk of chronic disease and mortality [1-3]. Health behaviors, including diet, physical activity, and sleep, are risk factors for many chronic diseases and may also be influenced by psychological well-being, thus acting as pathways by which psychological well-being affects physical health [4-9]. However, most studies have collected psychological and behavioral data annually or at longer intervals, limiting the ability to examine dynamic relationships between the two, which may be critical for elucidating the mechanisms linking psychological well-being to chronic disease. To better understand the relationships between psychological well-being and health behaviors, it is necessary to collect granular data on both factors on a daily or diurnal basis [9,10].

To address this limitation, emerging research has focused on the use of smartphone-based digital phenotyping, defined as the moment-by-moment quantification of individual human phenotypes via personal smartphone data, to collect temporally intensive longitudinal (eg, minute-by-minute) data [11]. In particular, ecological momentary assessment (EMA) can be combined with accelerometer-enabled smartphones to measure participants' behaviors and experiences repeatedly in real time. This approach facilitates efficient and cost-effective digital phenotyping of psychological well-being and specific health behaviors in a naturalistic setting [12-16]. Consequently, EMA conducted with personal smartphones may facilitate large-scale data collection to study psychological well-being and behavioral health with finer temporal resolution than is possible with standard survey research. Recruiting samples for such research can be difficult and time-consuming, whereas drawing on existing cohorts with participants who have a history of compliance with and commitment to the overall study may provide a more efficient means for conducting such studies. However, embedding smartphone digital phenotyping in large epidemiological cohorts has not yet been sufficiently explored [17], nor has the acceptability and effectiveness of this strategy among populations that have generally agreed to participate in survey research been tested.

Objectives

This study describes the methodology for integrating the Beiwe smartphone digital phenotyping platform into the Nurses' Health Study II (NHSII), a large and long-running US-based cohort of middle-aged and older women (aged 55 - 77 years). We collected data on psychological well-being, physical activity, and geolocation from 181 NHSII participants during an 8-day intensive measurement burst that included daily EMA surveys and minute-level accelerometer and GPS sensing. Our aim was to assess the feasibility of using smartphone digital phenotyping to collect highly resolved psychological, behavioral, and environmental data by examining compliance with the survey schedule, completeness of passive sensing data, and participant responses to the end-of-study feedback survey.

Methods

Beiwe Smartphone Substudy Embedded Within the NHSII

NHSII is an ongoing prospective cohort study involving 116,429 female registered nurses aged 25 - 42 years at enrollment in 1989. The participants currently reside in all states of the United States. Participants completed a mailed questionnaire asking detailed questions about demographic characteristics, lifestyles, and history of chronic diseases at the time of enrollment. Participants are invited to complete biennial questionnaires to update their medical status and lifestyle factors [18]. The Beiwe Smartphone Substudy of NHSII is a pilot study designed to examine the feasibility of using smartphone apps to collect psychological well-being, physical activity, and geolocation data at a granular level (eg, daily and minute-by-minute) among participants in this ongoing cohort study. The substudy targeted those who have most frequently engaged with the larger NHSII through biennial survey completion and provision of biological specimens [12]. For this pilot study, participants took part in an 8-day intensive measurement burst via the Beiwe app, completing psychological well-being surveys twice daily while the app collected smartphone accelerometer and GPS data at the minute level. At the beginning of the study, the participants were instructed to download the Beiwe app on their smartphones and log on via provided credentials. During the 8-day data collection period, participants were asked to keep their smartphone on them during waking hours, charge it regularly, and connect to Wi-Fi at least once a week to synchronize their data. Trained research assistants provided technical support throughout the study by phone or email. Upon completion of the study, participants were instructed to delete the app, and

XSL•FO
RenderX

their user accounts were deactivated. The pilot study ran from July 21, 2021, to November 21, 2021 (the last day the last participant provided data within 8-day period).

Our goal was to recruit 200 participants for the substudy. To be eligible for an invitation to the pilot study, participants must have been active NHSII participants and not participating in other NHSII substudies. From this pool, we randomly selected 600 individuals to whom we emailed invitations to complete an eligibility screener. The screener included the following additional eligibility criteria: (1) owns an Apple or Android smartphone, (2) lives in the contiguous United States (excluding Hawaii, Alaska, or Puerto Rico), and (3) has access to Wi-Fi at least once a week. Upon confirmation of eligibility, there was an informed consent process; after consenting, they were instructed to download the Beiwe app from the iOS or Android app stores.

Data Collection—Beiwe App

The Beiwe app guided participants through onboarding, during which they gave their consent for the app to assess location data and to send notifications (see Multimedia Appendix 1, eg, screenshots of the app as viewed by the participant). Upon first opening the app (day 1), participants completed a baseline survey and then received 14 EMA surveys over the next 7 days (days 2-8), with 2 surveys administered daily during the same time windows each day. The shorter early afternoon survey (21 questions, including some branched yes or no questions) was sent out randomly between 12 PM and 3 PM; the longer evening survey (63 questions, including some branched yes or no questions) was sent out at 6 PM. The app notified participants when a survey was available for completion and marked it as incomplete if it was not completed before the next survey was sent. For each completed survey, the app recorded the start and end time and computed the duration. Meanwhile, the Beiwe app was programmed to collect raw GPS data every 15 minutes for 90 consecutive seconds and raw accelerometer data at 10 Hz every 30 seconds for 10 consecutive seconds. This approach was intended to minimize battery consumption while maintaining the ability to determine participant movement patterns and behavior throughout the day [19]. Technical support was available throughout the duration of the substudy for participants who encountered issues downloading or using the app. At the conclusion of our study, we downloaded the study data via the "Mano" algorithm in the "Forest" Python library (Python, version 3.9.2; Python Software Foundation).

Smartphone-Based Measures

We assessed our key variables of interest and others that could be relevant when studying linkages between psychological well-being and behavior. We used a standard set of self-report items included on the baseline and EMA surveys administered twice daily (Multimedia Appendix 2), as well as passive sensing of smartphone accelerometer and GPS data.

Psychological Well-Being

In the baseline survey, we assessed *dispositional optimism*, a stable attribute positively associated with higher psychological well-being using the validated Life Orientation Test—Revised [20]. Participants rated their agreement with 3 positive and 3 negative statements on a 5-point Likert scale ranging from "Strongly disagree" (0) to "Strongly agree" (4). The positive statements included the following: (1) In uncertain times, I usually expect the best. (2) I'm always optimistic about my future. (3) Overall, I expect more good things to happen to me than bad. The negative statements included the following: (1) If something can go wrong for me, it will. (2) I hardly ever expect things to go my way. (3) I rarely count on good things happening to me. An overall optimism score was calculated by summing the positive and reverse scores of the negative statements [20].

We assessed time-varying psychological states contemporaneously (in the early afternoon EMA survey) and retrospectively (in the evening EMA survey) using the modified version of the Positive and Negative Affect Schedule—Expanded Form (PANAS-X) [21]. The 10 PANAS-X items designed to capture momentary affect included in the early afternoon EMA surveys were queried using the stem "Right now, I feel…." with response options yes or no scored as 1 or 0, respectively. Four items (happy, determined, enthusiastic, and curious) were summed to derive a *positive affect* scale, and 6 items (sad, afraid, angry, lonely, nervous, and worried) were summed to derive a *negative affect* scale.

A modified PANAS-X designed to capture affect experienced over the course of the day was administered in evening EMA survey and included 11 items queried using the stem "Today; did you feel…." with response options yes (score = 1) or no (score = 0). Five items are summed to derive a scale capturing *positive affect in the day* (happy, determined, enthusiastic, curious, and grateful) and 6 items are summed to derive a scale capturing *negative affect in the day* (sad, afraid, angry, lonely, nervous, and worried). In addition, participants were asked to report when they experienced these feelings (midnight: 5:59 AM; 6-11:59 AM; noon: 5:59 PM; 6-11:59 PM). The evening EMA also included a question on *life satisfaction*: "How satisfied are you with your life at this moment?" (queried on a scale of 1 [very unsatisfied] to 5 [very satisfied]) [22].

Health Behaviors

We obtained participants' *physical activity* (ie, walking steps and walking time) by processing raw accelerometer data with the "Oak" walking recognition method in the "Forest" Python library (Python, version 3.9.2), which estimates gait cadence per second. We have focused on walking because it is the most common form of physical activity performed daily by middle-aged and older-aged women and has been associated with cognitive function and disease outcomes such as cardiovascular disease and cancer [23,24]. Our walking recognition method has been validated against 20 publicly available annotated datasets on walking activity data collected at various body locations (thigh, waist, chest, arm, and wrist). It estimates walking periods with high sensitivity and specificity and is able to account for missing data due to noncontinuous sampling to conserve smartphone battery [25]. Due to the large volume of raw accelerometer data, we implemented an "on-the-cloud" processing approach. Specifically, we fetched hourly level raw data, processed them in temporary cloud computing memory by applying the "Oak" algorithm, and stored

XSL•FO
RenderX

the processed results (minute-level step counts) locally without downloading raw data. This approach substantially reduced the processing time. Details of the validated walking detection algorithm for Beiwe are available in a previous study [25] and through the GitHub link [26]. After identifying the walking periods, we aggregated the second-level data to the minute level, calculating the total number of seconds walked and step counts per minute.

Participants also reported their previous night's sleep and wake times in the evening EMA survey, which we used to determine their *daily sleep duration*. Additionally, they reported their *sleep quality* during the previous night. Multimedia Appendix 2 lists the answer choices for the sleep survey.

Additional Measures

We assessed a number of key covariates relevant to the association between psychological well-being and health behaviors. First, since psychological distress can influence behaviors [13,27] and is related to facets of psychological well-being, we measured depressive symptoms using the Center for Epidemiologic Studies Depression Scale [28] in the baseline survey. Second, we included items to assess strategies participants may use to regulate their affective states (ie, emotion regulation and coping strategies) in the context of stressful events or positive experiences since these may also be related to behaviors [29-32]. These were included on both daily EMA surveys. In the early afternoon EMA survey, we queried the use of strategies to regulate emotions in the context of stressful events occurring in the past hour [33]. Items assessed the nature of the stressful event (eg, argument, financial issues, and traffic) and stress levels ("not at all" or "a little" or "somewhat" or "very"). Participants then rated their levels of agreement on a 5-point Likert scale (strongly disagree to strongly agree) with a list of strategies they might have used to cope with such events (eg, "I controlled my emotions by not showing them" and "I made a plan to make the situation better"). In the evening EMA survey, we presented participants with a list of stressful events and positive experiences and asked whether any had occurred in the past 24 hours (yes or no) and also queried levels of stressful or positive experience on a 4-point Likert scale of 1 (not at all), 2 (a little), 3 (somewhat), and 4 (very) in relation to each event (Multimedia Appendix 2). Additionally, in the evening survey, participants reported which positive and negative emotion they experienced most intensely that day (eg, happy and sad). They were then asked to indicate on a 5-point Likert scale (strongly disagree to strongly agree; Multimedia Appendix 2) the extent to which they used each strategy to cope with such events from a list of strategies presented (eg, "I reveled in the moment and concentrated on how good I felt" and "I made a plan to make the situation better") [33]. They were also asked whether they changed their diet in response to the indicated emotion (ie, increased/decreased/did not change how much I ate) and whether this change was a way to comfort themselves with response options of yes or no. Finally, we inquired about psychotropic medication use in our evening EMA survey, asking whether participants had taken any of the following medications in the prior day: antidepressant medication (for any reason), antianxiety medication, and sleep medication.

Considering that individual daily mobility and environmental contexts may also be important [34], we obtained participants' geolocation every minute by processing raw smartphone GPS data using a Python-based method called "Jasmine" in the "Forest" library (Python, version 3.9.2). This algorithm imputes minute-level geolocation and also calculates daily summary statistics measuring participants' mobility, such as time spent at home and on trips and the number of places visited. Details of the validated GPS data-processing algorithm for Beiwe are available in a previous study [35] and through the GitHub link [26].

End-of-Study Feedback Survey

We invited participants to complete a feedback survey at the conclusion of the study to evaluate their overall experience in participating in the pilot study and their willingness to engage in any future smartphone-based data collection. This survey included items querying their overall experience, any difficulties using the app, and their likelihood of participating in similar future studies and offered the opportunity to provide open-ended feedback on app design and study experience. Feedback survey questions are shown in Multimedia Appendix 2.

Sociodemographic, Lifestyle, and Health Characteristics

To evaluate potential differences between study participants and those in the parent study who did not participate, we also extracted key sociodemographic and health characteristics from the baseline NHSII surveys. These included factors that are not time-varying (race) and time-varying ones from the 2019‐2021 NHSII biennial questionnaire, closest in time to the start of the pilot study in August 2021. These include participants' age at the time of the substudy, race (White/Black/Other; non–time-varying), husband's level of educational attainment (high school or less/more than high school, reported in 1999), percentages married or in a relationship, smoking status (current/former/never), BMI (calculated as weight in kilograms divided by height in meters squared), Alternative Healthy Eating Index (AHEI) diet score (continuous scores 0‐100) [36], and region of residence (Northeast/Midwest/South/West) based on 2010 Census data [37]. The AHEI assigns ratings to foods and nutrients predictive of chronic disease [36]. The AHEI is created by a group of researchers at Harvard TH Chan School of Public Health as an alternative to the US Department of Agriculture's Healthy Eating Index, which measures adherence to the federal Dietary Guidelines for Americans.

Statistical Analysis

Our examination of adherence to the smartphone digital phenotyping data collection protocol had 2 components. For the smartphone EMA surveys, we assessed compliance at the time of receiving each EMA prompt at participant day and participant levels. At the *participant level*, we calculated separate response rates for the baseline survey (day 1) and for the daily early afternoon and evening EMA surveys (days 2-8 only), each defined as the total number of surveys submitted by all participants out of all possible EMA prompts. We also calculated the proportions of participants with 25% (at least 2 out of 7 surveys), 50% (at least 4 out of 7 surveys), and 75% (at least 6 out of 7 surveys) response rates for the early afternoon

XSL•FO
RenderX

and evening EMA surveys separately. At the *participant day* level, we examined the daily response rates for early afternoon and evening EMA surveys separately from days 2 to 8 (defined as the total number of surveys submitted by all participants in days 2, 3, …, 8 divided by total number of participants). In addition, we summarized the length of time it took to complete a given survey (ie, completion duration) in minutes for the baseline survey and for each daily EMA assessment.

To assess the completeness of passive sensing data (accelerometer and GPS), we identified days with high-quality data (ie, valid days) as those with at least 600 valid minutes (10 valid hours) per day, following the established criteria in GPS-based physical activity studies [34]. We also define noncollection days as days without data. In this study, the primary reason for noncollection was attrition (ie, the app was deleted from a participant's phone before the 7-day study period because the participant herself unenrolled from the substudy). Another reason was sensor noncollection, which could be due to a participant forgetting to charge their phone or disabling the GPS or a major update from the operating system causing the Beiwe app to malfunction temporarily, among other reasons. A valid minute was defined as one with at least 1 second of observation time, following guidelines provided by previous Beiwe data studies [25]. We then calculated data completeness at both the *participant day* and *participant* levels. At the *participant day* level, we summarized the valid hours per day for all participants and days and calculated the percentages of valid, nonvalid, and noncollection days, respectively. At the *participant* level, data completeness was defined as the percentage of valid days out of 7 possible days (days 2-8), with proportions calculated for participants with 25% (minimum of 2 valid days), 50% (minimum of 4 valid days), and 75% (minimum of 6 valid days) completeness of accelerometer and GPS data. To test the sensitivity of this measure of completeness to an alternative threshold, we applied a stricter criterion defining a valid day as one with at least 960 valid minutes (16 valid hours), accounting for typical 8-hour sleep periods. Some participants did not delete the app at the conclusion of the study (ie, after day 8) and left the app running for up to 150 days, resulting in the collection of additional EMA surveys and passive sensing data. Their data beyond the study period were not included in the "Smartphone Data Characteristics" section. All statistical analyses were conducted using R (version 4.3.3; R Core Team).

Ethical Considerations

All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional review boards of the Brigham and Women's Hospital (protocol numbers 1999P003389). All participants provided informed consent for data collection at the beginning of the pilot study. Participants were not compensated. We encrypted raw data collected by the Beiwe app before sending them to the Amazon Web Services production server. Subsequently, we either securely transferred data to the analytical server (for GPS and survey data) or deleted those data from the temporary storage on the analytics server after processing (for accelerometer data). We protected Amazon Web Services production and analytics servers by 2-factor authentication and Secure Shell Protocol keys. To protect participant identity, we did not enter personal or health-related information through Beiwe.

Results

Participant Characteristics

We invited 600 NHSII participants (600/116,429, 0.52% of the larger NHSII cohort) to complete the eligibility screener. Of these 600 participants, 333 (55.5%) completed the screener, 326 (54.3%) were eligible to participate, 238 (39.7%) consented, 200 (33.3%) downloaded and registered the app, and 181 (30.2%) transmitted data. A CONSORT (Consolidated Standards of Reporting Trials) diagram of the participants at different recruitment stages is shown in Figure 1. Table 1 compares the demographics of the Beiwe pilot study participants who transmitted data against those who consented, who were invited, and the active NHSII participants at the beginning of the pilot study (late July 2021). Overall, our sample had a mean age of 67.8 (SD 3.9) years, were all female, and predominantly White (178/181, 98.3%). Most participants (148/181, 81.8%) were married and 58.6% (106/181) were never smokers. Breaking down by Census regions, 11.6% (21/181) of the participants lived in the Northeast, 17.7% (32/181) lived in the West, 26.0% (47/181) lived in the South, and 44.8% (81/181) lived in the Midwest. Most participants (84.5%, 153/181) were iOS users. Across the variables we considered, there were no major differences among the invited, consented, and enrolled participants. Additionally, no major demographic differences were observed between iOS and Android users (Multimedia Appendix 3).

Table . Characteristics of active Nurses' Health Study II participants at the beginning of the Beiwe smartphone pilot study (August 2021) who were invited, consented, and participated in the study.

Variable	Beiwe Substudy participants—invited (n=600)	Beiwe Substudy participants—consented (n=238)	Beiwe Substudy participants—registered and downloaded the app (n=181)
Age (years), mean (SD)	68.2 (4.1)	68.0 (4.0)	67.8 (3.9)
Race, n (%)			
White	590 (98.3)	235 (98.7)	178 (98.3)
Black	0 (0.0)	0 (0.0)	0 (0.0)
Other/more than 1 race	10 (1.7)	3 (1.3)	3 (1.7)
Husband's highest level of education, n (%)			
High school or less	160 (26.7)	70 (29.4)	51 (28.2)
More than high school	440 (73.3)	168 (70.6)	130 (71.8)
Marital or in a relationship, n (%)			
Married or in a relationship	491 (81.8)	190 (79.8)	148 (81.8)
Smoking status, n (%)			
Current	13 (2.2)	5 (2.1)	5 (2.8)
Former	195 (32.5)	91 (38.2)	70 (38.7)
Never	392 (65.3)	142 (59.7)	106 (58.6)
BMI (kg/m^2), mean (SD)	26.8 (6.2)	27.0 (6.0)	27.0 (6.4)
AHEI score[a], mean (SD)	69.0 (12.7)	70.2 (12.7)	70.0 (12.4)
Region of residence, n (%)			
Northeast	55 (9.2)	29 (12.2)	21 (11.6)
Midwest	259 (43.2)	103 (43.3)	81 (44.8)
South	175 (29.2)	66 (27.7)	47 (26.0)
West	111 (18.5)	40 (16.8)	32 (17.7)

[a]AHEI: Alternative Health Eating Index (ranging from 0 to 110, where a higher score reflects a healthier diet). The AHEI assigns ratings to foods and nutrients predictive of chronic disease (McCullough and Willett [36]). AHEI is created by a group of researchers at Harvard TH Chan School of Public Health as an alternative to the US Department of Agriculture's Healthy Eating Index, which measures adherence to the federal Dietary Guidelines for Americans.

Smartphone Data Characteristics

Data collection was completed in November 2021. In total, we received 40.0 GB of data from 181 participants, including 19.2 GB of accelerometer data, 0.6 GB of GPS data, and 0.01 GB of survey data. Each participant contributed data (at least 1 byte of data within the enrollment period) for an average of 7 out of 8 possible days (SD 2; median 8).

Smartphone-Based Survey Compliance

Each afternoon and evening assessment was sent once a day for 181 participants for 7 days. A total of 181 participants completed 156 baseline surveys (86.2% response) at day 1. From days 2 - 8, they responded to 705 early afternoon EMA prompts out of 1267 prompts sent (181 participants for 7 days; 55.6% response across all participant-days) and 693 evening EMA prompts out of 1267 prompts sent (181 participants for 7 days; 54.7% response across all participant-days). On average, the shorter surveys given with the early afternoon prompts took 1.5 minutes to complete (SD 8.3; median 0.8), while the longer surveys given with the evening prompts took 5.2 minutes (SD 5.3; median 4.3). The response rates to nonbranching items (ie, did not depend upon the answer of "Yes or No" in the previous question) within a submitted survey were 99% for early afternoon EMA (13 nonbranching items out of 21) and 96% for evening EMA surveys (30 nonbranching items out of 63). The daily response rates for the early afternoon and evening EMA surveys fluctuated between 50% and 60% across days 2-8 (mean 55.6%, SD 3.9% for early afternoon; mean 54.7%, SD 3.2% for evening; Figure 2). Each participant completed an average of 4 early afternoon prompts (SD 2; median 4) and 4 evening prompts (SD 2; median 4). Among the 181 participants, 136 (75.1%) completed >25%, 118 (65.2%) completed >50%, and 71 (39.2%) completed >75% of the early afternoon prompts. For evening prompts, 138 (76.2%), 116 (64.1%), and 69 (38.1%) participants completed >25%, >50%, and >75%, respectively (Table 2).

XSL•FO
RenderX

Figure 2. Daily completion with the EMA survey in the early afternoon (A) and evening (B) over the period of the study period (1 week) for the Beiwe Smartphone pilot study in the Nurses' Health Study II (181 surveys sent each day per each EMA survey type). EMA: ecological momentary assessment.

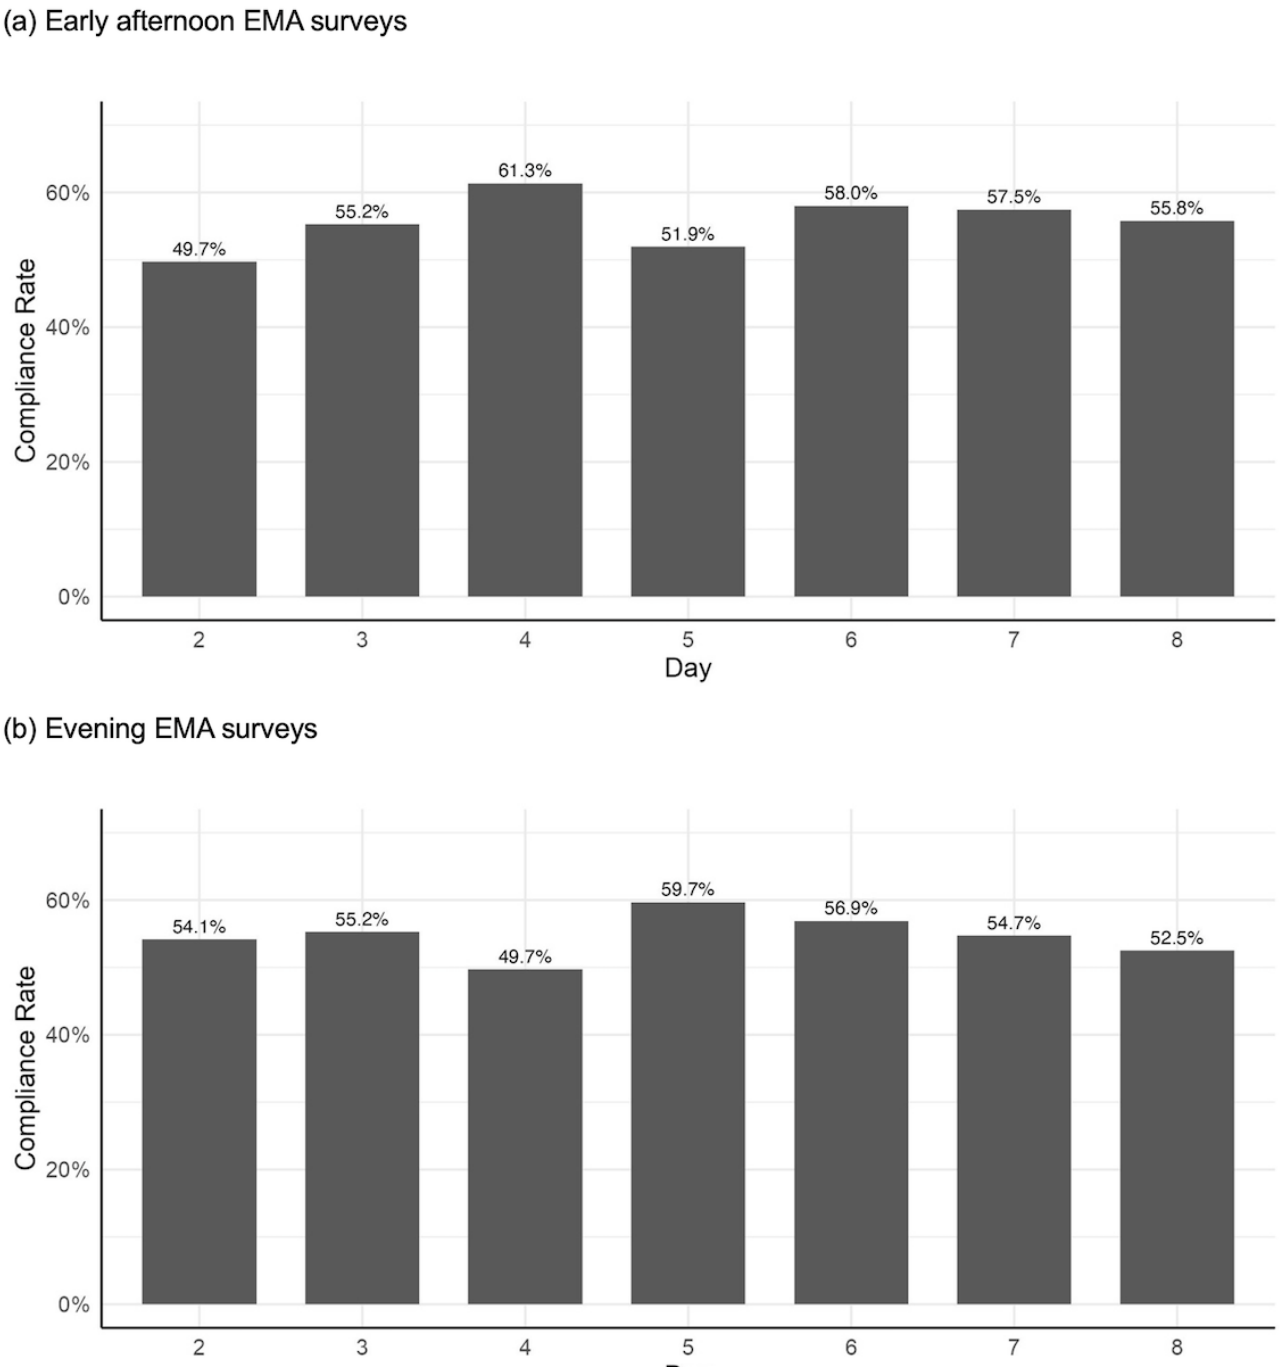

Table . Participant-level compliance of early afternoon and evening ecological momentary assessment surveys over the pilot study period (1 week) (N=181).

Variable	Overall, n (%)	
	Early afternoon survey	Evening survey
Participants completed >25% of prompts sent	136 (75.1)	138 (76.2)
Participants completed >50% of prompts sent	118 (65.2)	116 (64.1)
Participants completed >75% of prompts sent	71 (39.2)	69 (38.1)

Accelerometer and GPS Data Completeness

From 174 out of 181 participants, we collected an average of 11.8 valid hours (SD 5.6, median 12.9) of accelerometer data and 15.2 valid hours (SD 7.0, median 18.0) of GPS data per participant-day in days when any data were collected. Using the criterion of ≥10 valid hours for valid days (Table 3), we obtained 786 valid days (62.04% completeness) of accelerometer

XSL•FO
RenderX

data and 731 valid days (57.70% completeness) of GPS data from 1267 potential data collection days (181 participants on days 2-8).

Table . Completeness of accelerometer and GPS data at the participant-day level over the pilot study period (N=1276[a] total potential data collection days).

Participant day-level data completeness	Overall, n (%)	
	Accelerometer	GPS
Valid days	786 (62.04)	731 (57.70)
Invalid days	293 (23.13)	142 (11,21)
Noncollection days[b]	188 (14.84)	394 (31.10)

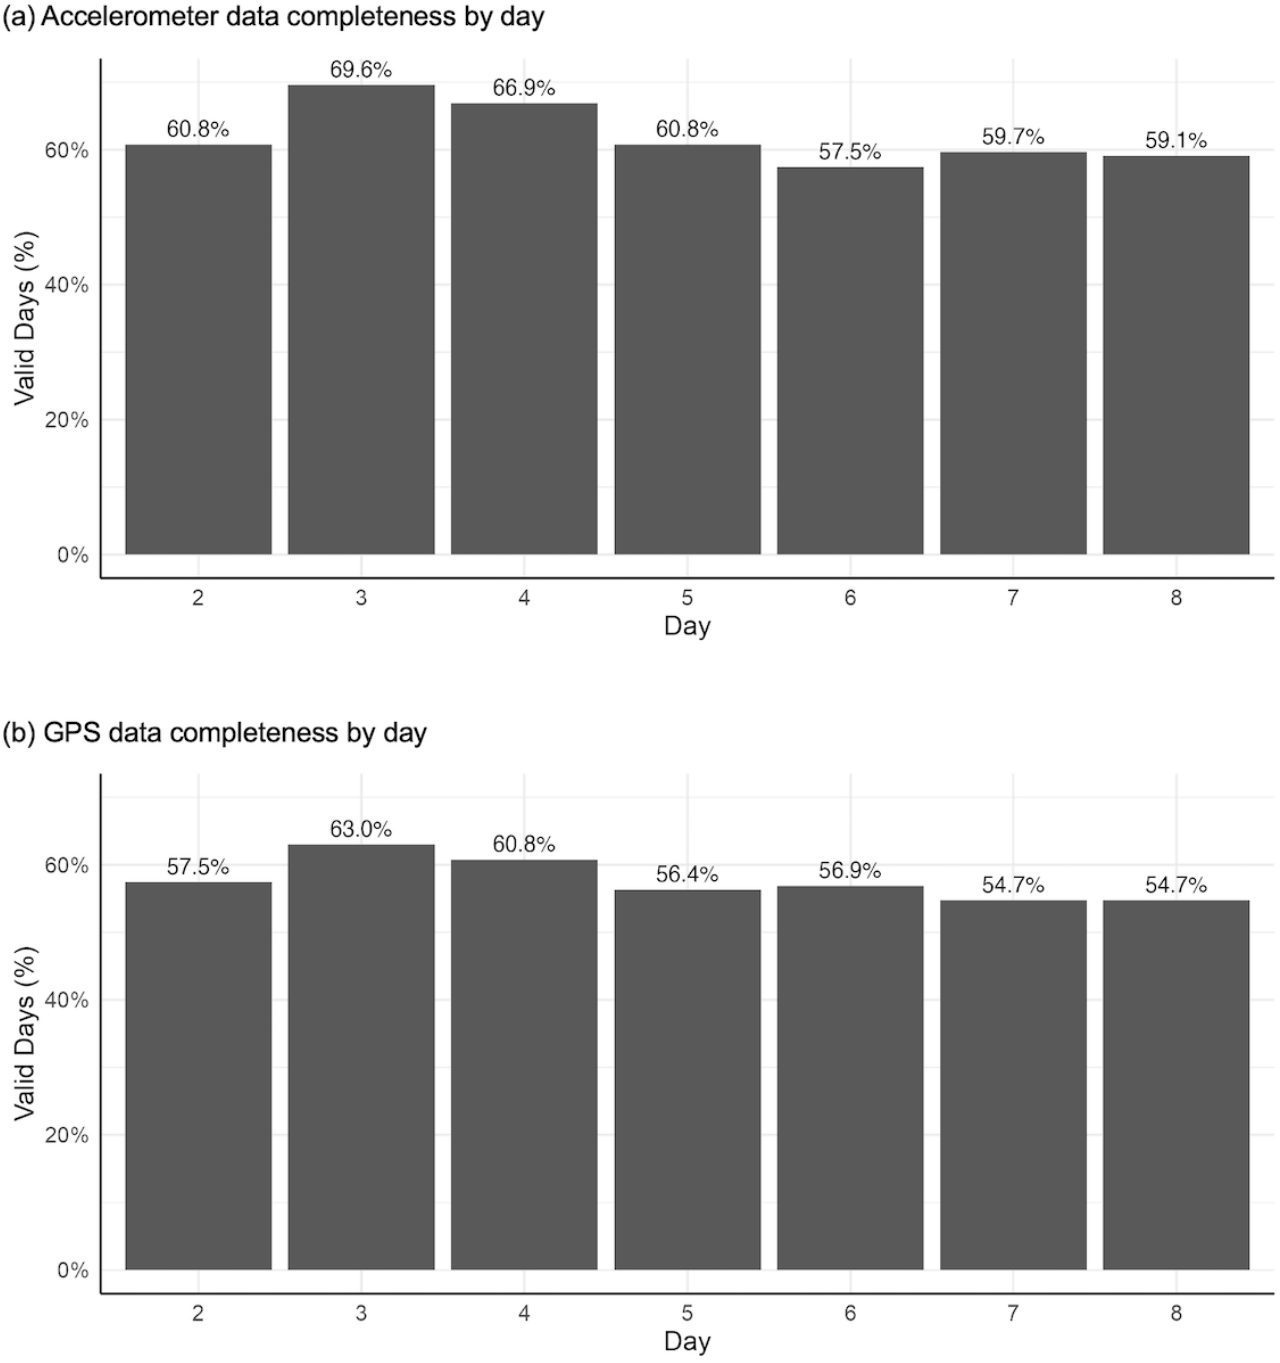
[a]Data included 7 participants who did not contribute any data.

[b]Noncollection days were defined as days without data. In this study, the primary reason for noncollection was attrition (ie, the app was deleted from a participant's phone before the 7-day study period because the participant unenrolled from the substudy). Another reason was sensor noncollection, which could be due to a participant forgetting to charge their phone or disabling the GPS or a major update from the operating system causing the Beiwe app to malfunction temporarily, among other reasons.

Over time, completeness of the accelerometer and GPS data fluctuated between 54.7% and 69.6%, with accelerometer data having slightly higher percentages than GPS data (mean 62.0%, SD 4.5% for accelerometer; mean 57.7%, SD 3.1% for GPS; Figure 3).

XSL•FO
RenderX

Figure 3. Daily completeness of accelerometer (A) and GPS (B) data over the pilot study period (N=1276 total potential data collection days). The statistics for day 1 were not included because the participants started at different times of the day, which meant that the validity criteria were not comparable.



For participant-level completeness, the average valid days for accelerometer and GPS data per participant were 4 for each parameter (SD 3; median 5). Among 181 participants, 145 (80.1%) had 25% valid days of accelerometer data, 112 (61.9%) had 50%, and 79 (43.6%) had 75%, while 125 (69.1%) had 25% valid days of GPS data, 105 (58.0%) had 50%, and 90 (49.7%) had 75% (Table 4).

XSL•FO
RenderX

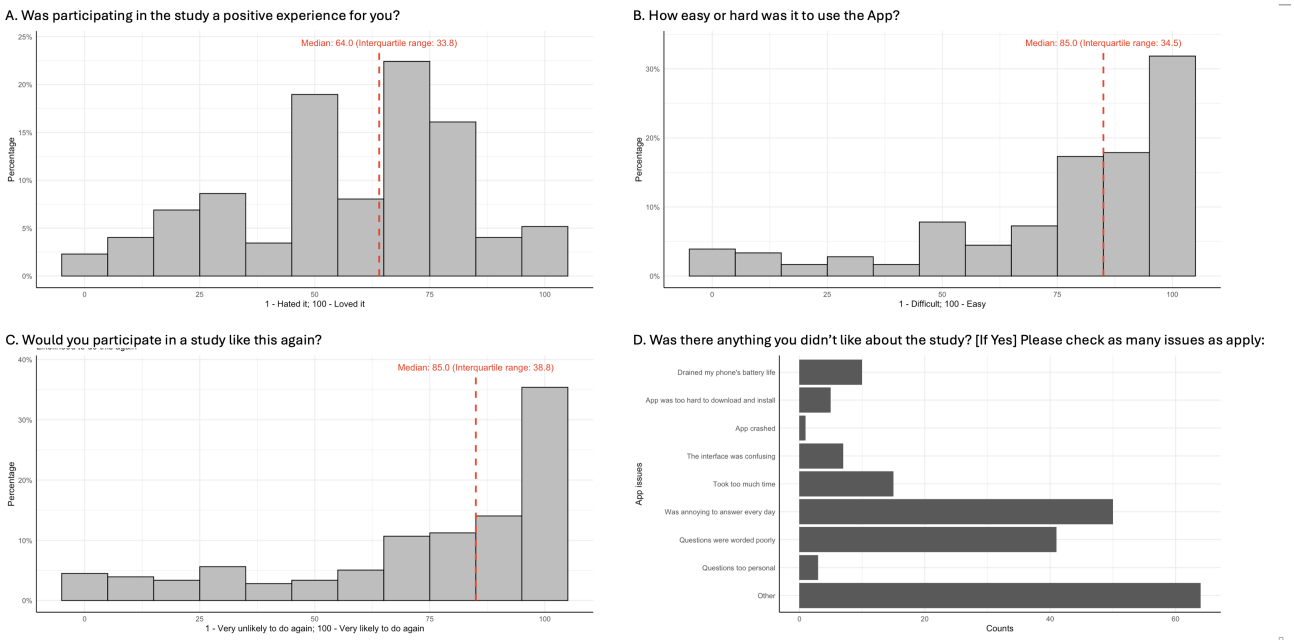
Table . Participant-level data completeness of accelerometer and GPS data over the pilot study period (N=181).

Variable	Overall, n (%)	
	Accelerometer	GPS
Participants (N) who had:		
≥25% data days were valid days	145 (80.1)	125 (69.1)
≥50% data days were valid days	112 (61.9)	105 (58.0)
≥75% data days were valid days	79 (43.6)	90 (49.7)

Feedback Survey

Participants reported an overall relatively "positive experience" (Figure 4A) with data collection (median 64.0 among 174 out of 181 participants, where 1="I hated it" and 100="I loved it") and generally found the Beiwe app easy to use (median 85.0 among 179 out of 181 participants, where 1="difficult" and 100="easy"; Figure 4B). They also indicated a high likelihood of participating again (median 85.0 among 178 out of 181 participants, where 1="Very unlikely" and 100="Very likely"; Figure 4C). Despite this, across a list of potential concerns we provided, 2 main issues were selected with higher frequency (Figure 4D): the Substudy EMA prompt was "annoying to answer every day," and the "questions were worded poorly." Users also reported several major issues of the app, including "App was too hard to download and install" and "The interface was confusing." Additional issues mentioned in the open-ended responses after selecting the "Other" answer included repetitive questions, unclear wording, the need for better notifications such as sound alerts, and lengthy completion times for some tasks (summarized in Multimedia Appendix 4). Users were also asked for open-ended feedback on problems faced during the study (Multimedia Appendix 5 summarized some commonly reported ones). Notably, we found the participants (19/181, 10.5%) who completed the feedback survey but not the baseline surveys mainly had issues including technical difficulties during app installation and registration, inability to reach the study staff for support, and lack of reminders.

Figure 4. An overview of the distribution of answers to the questions in the feedback survey. (A) Whether the study was a positive experience. (B) The ease of use of the app. (C) Likelihood to participate again. (D) Things not liked about the study.



Discussion

Principal Findings

This study examined adherence to a smartphone-based digital phenotyping protocol as part of a pilot study examining willingness to participate in an 8-day intensive measurement protocol to capture psychological well-being, health behaviors, and geolocation data among participants in the NHSII, a nationwide prospective cohort of women in the United States. Our findings indicated high compliance (86%) with the baseline survey and modest compliance (approximately 55% on average) with the daily EMA surveys, with no major differences evident based on the time at which the prompt was delivered (afternoon vs evening) or survey length (evening survey was longer). We also observed good levels of daily completeness (fluctuating between 55% and 70%) of passive sensing data (accelerometer and GPS) using the criterion of 10 valid hours per day. Even with overall modest survey compliance, feedback survey results indicated that participants found the app user-friendly and were willing to engage in similar future studies. However, they also highlighted issues, such as the need for improved survey question wording and user fatigue from repetitive daily surveys. Overall, our evaluation provides valuable insights and lessons

XSL•FO
RenderX

for future studies aimed at incorporating smartphone-based digital phenotyping in large prospective cohorts with participants who more often engage in surveys and periodic assessments than in intensive measurement bursts.

Compared with previous smartphone-based EMA studies that collected data on psychological well-being, our day-level compliance statistics were lower overall. For example, a 2021 systematic review of smartphone-based EMA studies that focused on psychological well-being [38] reported an average compliance rate of 71.6% based on all EMA prompts in each study across 53 studies with a median duration of 7 days. However, these studies often recruited convenience samples and provided compensation to participants. In addition, their participants were often younger (mean 30.8, SD 10.5 years) than our participants (mean 67.8, SD 3.9 years), who may encounter less technological barriers. Furthermore, these studies also represented more of a general population, likely more flexible in survey schedules than our population who were nurses and nursing professionals at baseline. Interestingly, in our study, compliance for the early afternoon and evening EMA surveys varied between 50% and 60% and showed no signs of user fatigue (ie, compliance rates decreased over time). In addition, we found no substantial differences in compliance rates for individual questions in either early afternoon or evening EMA surveys. This is somewhat surprising given that the most common complaint in the feedback survey was that the EMA survey was "boring to answer every day." This may be due in part to conducting this study among a cohort of participants who have been engaged and active in the study for many years.

When we examined survey compliance at the participant level, we found that 32 out of 181 participants were noncompliant (did not submit any early afternoon or evening survey). We therefore speculate that the lower than average compliance with the daily EMA survey may be due to the initial technical difficulties (another common complaint found in the feedback survey) that users encountered in registering and setting up the Beiwe app, which led to early dropout. Therefore, we suggest that future studies ensure timely and adequate technical support during app installation, registration, and throughout the study. This is particularly crucial when the study contains a population that may face higher usability barriers for smartphone apps, such as the older adults in our pilot who may have varying levels of digital literacy [39].

Moreover, according to the feedback survey, participants suggested smartphone EMA survey design ideas to potentially improve their compliance with the schedule, such as daily reminders and notification enhancements with visual or sensory triggers such as icons or sounds, as well as simplifying the layout of the app. We suggest incorporating these functionalities in future studies, particularly in occupational populations with busy work schedules, such as nurses and nursing professionals in our cohort.

Additionally, another 2021 systematic review and meta-analysis [40] found a negative association between the number of items per prompt and EMA compliance in nonclinical studies assessing self-reported health behaviors and psychological constructs in adults. Consequently, our surveys might impose a higher user burden and result in quicker user fatigue than those with fewer questions (eg, asking "how is your current well-being" 3 times a day through established constructs such as Life Orientation Test—Revised and PANAS-X, while most studies previously inquired this through 1 or 2 questions) [41]. Future research should explore strategies to mitigate survey fatigue, such as alternating between truncated and full versions of the EMA survey daily or adopting an intensive longitudinal approach (ie, space out multiple week-long surveys within a year or over several years) [40].

The completeness of our accelerometer and GPS data is slightly lower than that of previous smartphone-based studies that collected similar types of data [17,38,42]. However, this was not unexpected given few studies have simultaneously collected smartphone-based psychological well-being and health behavior data [43-45], which may place higher user burden. From our observations, one of the main reasons for data incompleteness in the passive sensing data was attrition (ie, the app was deleted from a participant's phone before the 7-day study completion date because the participant was unenrolled from the substudy). Besides, to minimize failures in the collection of smartphone passive sensing data, we instructed participants at the start of the data collection period to always carry their smartphones with them. Nonetheless, data noncollection or device noncompliance may still be higher than in similar studies due to the older age of our participants, who may be less likely to carry their smartphones everywhere or keep smartphones on them and charged, compared with the younger populations in these studies [43,44]. This issue was further compounded by our noncontinuous sampling strategy for passive sensing data and the tendency of phone operating systems to disable sensor access when the phone is inactive for extended periods, such as during sleep.

In addition, data collection may also be disrupted by major updates of phone operating system, which may cause the Beiwe app to malfunction temporarily. We recommend that future studies experiment with more advanced passive sensing schemes, such as turning sensors on and off based on the participants' movement status (ie, moving or staying sedentary) rather than a fixed frequency [46], to further conserve batteries while improving the data quality of geolocations and activity tracking.

Furthermore, we found that the completeness of the passive sensing data over the study period was overall higher than EMA survey compliance rate. This indicates that passive sensing data collection may impose a lower burden than smartphone-based surveys and can be extended longer, which is desirable as a 1-week period may not be sufficient for capturing the usual activity patterns of study participants [17,47]. Future studies should consider varying the data collection duration for each data stream instead of maintaining a fixed period for all or reducing the frequency of smartphone surveys (eg, from daily to every other day).

Collecting highly resolved smartphone-based data on psychological well-being and physical activity will facilitate novel investigations of their relationships at finer temporal resolutions, such as daily or diurnal levels. For instance, we can

XSL•FO
RenderX

examine whether a stressful event and strategies used to regulate one's affective states in this context, as reported by the EMA in the last hour, are associated with physical activity levels in the subsequent (or prior) hours. Additionally, we can analyze whether daily positive or negative affect correlates with physical activity on the same or the following day. Furthermore, linking location-based behavior data to environmental factors allows examining the relationship between psychological well-being, health behaviors, and momentary environmental exposures. For example, one could examine whether GPS-based greenspace exposure in the previous hour impacts EMA-reported positive affect. In another example, one can explore momentary associations between GPS-based temperature or $PM_{2.5}$ exposure and smartphone-assessed physical activity [9,48-52].

Strengths and Limitations

Our study has certain limitations. Although our walking recognition algorithm accounts for missing data due to noncontinuous sampling, we may still miss some forms of physical activity due to participants not carrying their smartphones while engaging in these types of activities, which could impact the representativeness of the collected data. Our GPS data may have additional missing data due to environmental conditions (eg, being indoors and heavy tree coverage that can interfere with GPS satellite signals). Additionally, the 1-week data collection period may not capture variability in physical activity and mobility over longer durations, such as seasonal changes [17,53]. The EMA-prompting scheme, administered twice daily, may also fail to capture within-day variations in some experiences, such as positive and negative affect [54]. Furthermore, the NHSII study's homogeneous population—predominantly White, middle-aged and older women who were nurses at the 1989 baseline and have maintained high engagement rates with the cohort over long follow-up periods [18]—may limit the generalizability of our findings regarding device compliance and feasibility of embedding an EMA study within a larger cohort study with participants who generally engage in periodic surveys. Nonetheless, all epidemiologic cohorts focus on compliant participants, and thus our results are informative, especially for other cohorts that may seek to embed smartphone data collection into existing studies.

This study has several strengths. This is one of the first studies to comprehensively examine adherence to an intensive smartphone measurement burst protocol in a large, nationwide prospective cohort of middle-aged and older women. Unlike previous studies, we used multiple metrics to assess compliance with daily EMA surveys over an 8-day period and the completeness of passive sensing data during the same time frame. Our findings offer crucial, detailed insights into the feasibility of and participation in an embedded smartphone-based digital phenotyping protocol into epidemiological cohorts, amidst growing interest in this area [55]. Additionally, the study incorporated feedback survey data, providing subjective and individualized insights that complement objective metrics and help explain trends observed in adherence. This feedback also highlights potential improvements in future study designs and app functionalities.

Conclusions

This pilot study investigated adherence to a smartphone-based data collection protocol embedded within an ongoing cohort study, assessing willingness to participate in an 8-day intensive measurement burst to collect data on psychological well-being, physical activity, and mobility. Our findings suggest modest compliance with smartphone EMA surveys and good completeness of passive sensing data is possible. Adherence remained stable over the 1-week period. Notably, participants expressed a strong interest in participating in similar future studies, according to the feedback survey. These findings have major implications for future research aimed at intensively measuring psychological well-being and physical activity over short periods via smartphones. Smartphone-based digital phenotyping allows researchers to use devices that participants already have and are familiar with for data collection, rather than mailing out wearables, which could be particularly important when seeking to recruit large numbers of participants from established epidemiological cohorts. Overall, these methodologies appear promising for advancing epidemiological research on the psychological and behavioral determinants of health.

Acknowledgments

The authors would like to thank the participants and staff of the Nurses' Health Study II for their valuable contributions. The authors assume full responsibility for analyses and interpretation of these data. This work was supported by the National Institutes of Health (grants R01 HL150119, U01 CA176726, U01 HL145386, and R01 AG85375), Harvard T.H. Chan School of Public Health Dean's Fund for Scientific Advancement Acceleration Award, and the Thomas O. Pyle Fellowship from the Department of Population Medicine, Harvard Medical School and Harvard Pilgrim Health Care Institute.

Data Availability

The datasets generated and analyzed during this study are available in the controlled-access repositories, except for personal identifying data such as names, addresses, smartphone location data, and contact information.

Conflicts of Interest

None declared.

Abstract

Background: Keystroke dynamics on smartphones have emerged as a promising form of passive digital biomarker. While previous studies have explored their utility in several diseases and disorders, relatively few have examined how these dynamics change systematically with chronological age in the general population.

Objective: This study aimed to investigate age-related patterns in mobile keystroke dynamics, with a particular focus on temporal variations throughout the day. By identifying behavioral signatures associated with different age groups, we further assess whether artificial intelligence–based models can accurately estimate chronological age using passively collected keystroke data.

Methods: We conducted a field study involving 177 healthy adults in the Republic of Korea, collecting free-living smartphone typing logs over multiple weeks through a custom Android keyboard app (CodeRed Corp). For each keystroke, the app recorded press and release timestamps and key type, from which 43 behavioral features were extracted across categories of speed, frequency, and temporal variability. Weekly feature vectors were constructed at 3 temporal resolutions (6-hour intervals, daily, and weekly). In total, 8 artificial intelligence models, including random forest, TabNet, transformer, and long short-term memory, were trained with participant-wise 10-fold cross-validation. A custom loss function was introduced to reduce intraparticipant prediction variability. Descriptive statistics and ablation studies were conducted to assess behavioral trends and feature contributions.

Results: The study included 177 participants (female: n=115; male: n=62) with a mean age of 28.8 (SD 11.1) years, all residing in the Republic of Korea. On average, data were collected for 25 weeks per participant, resulting in a dataset of more than 2.5 million typing sessions. Descriptive analysis revealed clear age-related differences. Younger participants typed faster and more frequently, while older participants showed slower and more variable typing. The long short-term memory model using the 6-hour interval median features achieved the best age estimation performance (mean absolute error 3.69 years, R^2=0.71). When the customized loss function was applied, the model's performance further improved to a mean absolute error of 3.60, with a reduction in intraparticipant variability in estimated ages by 7.8%. Notably, feature importance analysis suggested that the early morning (midnight to 6 AM) and late evening (6 PM to midnight) periods may carry more age-discriminative keystroke patterns.

Conclusions: Our findings demonstrated that smartphone keystroke dynamics reflect age-sensitive behavioral patterns, particularly when analyzed with fine-grained temporal resolution. While the primary goal was not age estimation per se, the ability to model

XSL•FO
RenderX

these patterns highlights the potential of keystroke dynamics as a passive, unobtrusive behavioral marker for age-related functional characteristics. These insights may inform future applications in digital health, such as age-sensitive personalization or early detection of age-related decline without requiring any active user input.

Introduction

The rapid expansion of mobile health apps has enabled individuals to monitor and manage their health conveniently and continuously. However, these services often rely on users' active engagement, such as logging symptoms or responding to surveys. This dependence on manual input can present a barrier to long-term use. Passive sensing techniques can offer a promising alternative in digital health care, as they enable unobtrusive and continuous health monitoring without requiring explicit user participation [1-4].

Among various passive sensing modalities, digital biomarkers derived from everyday interactions with smartphones have received increasing attention, such as GPS [5,6], biosignals [7,8], and motion sensor data [9,10]. One promising approach involves analyzing mobile keystroke dynamics—patterns such as typing speed, interkey delay, and error frequency during smartphone keyboard usage. These subtle signals are unobtrusively collected and can reflect changes in cognitive and motor function [11-13], offering a valuable source of information for health-related inference.

Keystroke dynamics have been explored in previous work for various health domains like mild cognitive impairment [14], multiple sclerosis [15,16], loneliness [17], bipolar disorder [18], and mental health [13,19]. Specifically, Vesel et al [13] examined how mood, age, and diurnal patterns affect mobile keystroke dynamics using hierarchical mixed-effects models. However, their primary focus was on mood symptomatology—treating keystroke features, such as typing speed and variability, as outcomes influenced by depression severity, age, and time of day. Similarly, Zulueta et al [18] estimated brain age from smartphone typing kinematics and analyzed prediction error in relation to bipolar disorder risk. However, their focus was on diagnostic group differences rather than exploring how keystroke patterns change with age in the general population.

In contrast, our study aimed to conduct an in-depth investigation of age-related variations in keystroke dynamics, with particular attention to temporal keystroke patterns across different age groups. Given that aging is often accompanied by gradual changes in motor and cognitive function, these shifts may be subtly reflected in how individuals type on their smartphones. Importantly, such functional changes are not exclusive to aging—they may also result from sudden health deterioration. For instance, in patients at risk of cognitive impairment, subtle slowing and increasing variability in keystroke patterns may serve as early indicators of decline. Beyond health care, the ability to continuously and passively detect such functional changes could also contribute to security-related monitoring purposes. For instance, keystroke dynamics could reveal anomalous behavior when a compromised account is accessed by someone whose typing rhythm deviates markedly from the legitimate user, thereby serving as a continuous authentication layer.

Methods

Data Collection

We conducted a field study with a total of 177 healthy adults in the Republic of Korea from September 2022 to September 2023. Participants were recruited through online university communities and campus bulletin boards. Inclusion criteria were male and female individuals between 14 and 69 years of age without any mental or physical disabilities, who were Android smartphone users. Exclusion criteria were (1) inability or unwillingness to follow the investigator's instructions; (2) difficulty in communication or lack of cooperation with the study procedures; (3) explicit refusal to participate in the study; (4) previous diagnosis of any psychiatric or physical illness; and (5) for minors (aged 14-19 years), lack of consent from a parent or legal guardian, or cases where parental consent was provided but the participant did not assent to participate. Those interested submitted an online application form that included their age, sex, smartphone operating system, preferred keyboard layout, and contact information. Eligible individuals were contacted to schedule an online meeting, during which they received a detailed explanation of the study and provided informed consent electronically. Following consent, participants were guided through the installation process and instructed to use our custom keyboard app as their default keyboard in daily life. The study was conducted exclusively in smartphone environments, and other platforms, such as desktop keyboards, were not included. Our custom keyboard app, developed for the Android operating system (CodeRed Corp), supported QWERTY layouts for Korean, English, numbers, and special characters. It recorded timestamps for each key-pressing and key-releasing event, along with the type of key (eg, Korean, English, delete, and special character). Per participant, a log file was generated, in which each row contained the timestamp of key press, the timestamp of key release, and the type of the pressed key. These files were automatically and securely transmitted to our research server on a daily basis. Data were collected during participants' natural smartphone usage over a multiple-week period, without task-specific constraints, to ensure ecological validity.

XSL•FO
RenderX

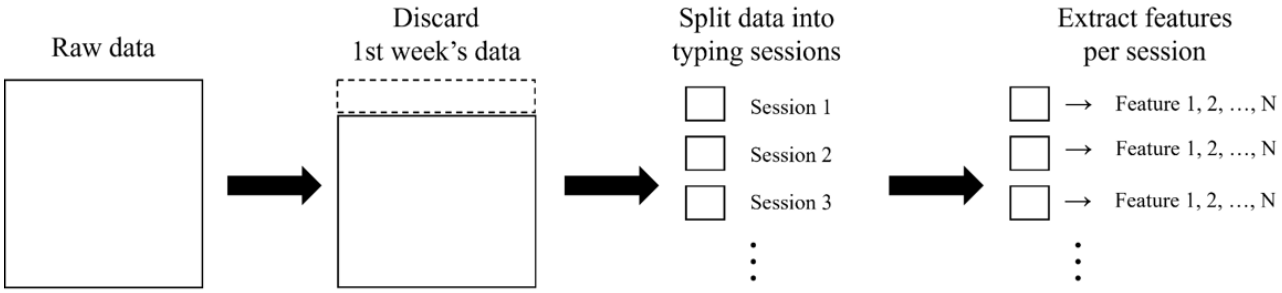
Ethical Considerations

The study was approved by the Institutional Review Board of Hanyang University (HYUIRB-202207-003-04). All participants were provided with detailed information about the study, including its objectives, the procedures for data collection, the devices and mobile apps to be used, the types of data to be collected, and the subsequent processing of these data. They were clearly informed that participation was entirely voluntary and that they could withdraw from the study at any time without penalty. Written informed consent was obtained from all participants before enrollment. A modest financial incentive was offered as compensation for their time and effort. The entire collected dataset was deidentified.

Data Preprocessing and Feature Extraction

As illustrated in Figure 1, we first discarded the data collected from each participant during the first week, since most participants spent the first week as an adaptation week to practice the provided keyboard app. For the remaining data, we excluded the key-press logs whose duration between press and release is longer than 5 seconds. Then, we processed the remaining logs in units of typing sessions. The typing session was determined by referring to the work by Vesel et al [13]: (1) duration between the keyboard activation and deactivation, or (2) if there was no press for more than 8 seconds after the last key release. We excluded the data of the typing sessions where key-pressing activities occurred more than or equal to 10 times per second (ie, interkey intervals ≤100 ms). This conservative threshold was chosen to eliminate abnormal or artifact-prone events, with reference to a large-scale study by Dhakal et al [20]. They analyzed 136,857,600 keystrokes from 168,960 participants who were asked to transcribe 15 English sentences using desktop keyboards. Their results showed that the average interkey interval across all participants was 239 milliseconds, whereas even the fastest typists exhibited an average of 122 milliseconds. Although their study was based on desktop keyboards, these findings provide a reasonable reference point for identifying abnormal keystrokes.

Figure 1. Flow of data preprocessing and feature extraction for each participant's data.



Within each typing session, we calculated speed and frequency-related features (speed and frequency, respectively, in Table 1), based on the existing studies [13,15-18]. The speed feature includes hold time (HT; a duration of each key press), flight time (a duration between release of the previous key and press of the current key), press-to-press latency (PPL), and release-to-release latency. Additionally, we calculated the correction, the HT for the delete key, and pre- and postcorrection, the flight times before and after pressing the delete key, respectively. The frequency features are the number of times any key is pressed and pressing the delete key, respectively (AllKey and DEL). In addition, we calculated various features in order to represent keystroke dynamics in terms of speed and frequency in a more delicate manner. First, we added the features regarding the keyboard layout shift (eg, from Korean QWERTY to English QWERTY): duration of layout shift (dur_shift) and the number of layout shifts (num_shift). Second, we counted the number of pressing any keys and the delete key per second, respectively (AllKeyRate and DELRate). Third, we added 2 features, that is, the duration of typing session (dur_session) and the number of typing sessions (num_session).

Table 1. Keystroke dynamics features (n=43) categorized into speed-related, frequency-related, and temporal variability-related features, which were used as input variables for the analyses in our study.

Category	Value, n	Features
Speed	11	HT[a], FT[b], PPL[c], RRL[d], precorrection, correction, postcorrection, AllKeyRate, DELRate, dur_shift, dur_session
Frequency	4	AllKey, DEL, num_shift, num_session
Speed variability	22	HT_MaxGap, FT_MaxGap, PPL_MaxGap, RRL_MaxGap, precorrection_MaxGap, correction_MaxGap, postcorrection_MaxGap, AllKeyRate_MaxGap, DELRate_MaxGap, dur_shift_MaxGap, dur_session_MaxGap, HT_STD, FT_STD, PPL_STD, RRL_STD, precorrection_STD, correction_STD, postcorrection_STD, AllKeyRate_STD, DELRate_STD, dur_shift_STD, dur_session_STD
Frequency variability	6	AllKey_MaxGap, DEL_MaxGap, num_shift_MaxGap, AllKey_STD, DEL_STD, num_shift_STD

[a]HT: hold time.

[b]FT: flight time.

[c]PPL: press-to-press latency.

[d]RRL: release-to-release latency.

Finally, we designed additional features to capture the temporal variability of speed and frequency features, respectively (speed variability and frequency variability in Table 1). We hypothesized that keystroke dynamics would fluctuate across different times of the day (eg, morning, afternoon, and night), analogous to the diurnal variations observed in physiological indicators [21]. We defined 2 types of variability features. The first, denoted as {Feature_Name}_MaxGap, represents the maximum fluctuation within a given time window (eg, day). It is calculated as the difference between the 95th and 5th percentiles of the feature's values. The other is the SD of each feature's values within a time window ({Feature_Name}_STD).

Analysis Through Descriptive and Artificial Intelligence–Based Methods

We analyzed the extracted 43 features, as described in Table 1, across different chronological age groups (younger-than-30-years, 30s, 40s, and 50s). Considering potential options for the analysis time window, such as an hour, a day, and a week, we empirically determined to conduct an analysis on a weekly basis. We believed that a larger window, such as a month, might fail to capture the temporary change in health status, while a smaller window, such as a day, would lead to unnecessarily frequent analyses, introducing redundancy without improving interpretability. For visualization, we followed a three-step aggregation process. First, for each participant, multiple values of each feature were extracted within every 1-hour window. Second, the median value of each feature was computed per participant for each hour. Finally, the average of these per-participant medians was calculated across all participants within the same age group for each hour.

In addition to the descriptive analysis, we investigated the feasibility of artificial intelligence (AI)–based age estimation. We organized the extracted features as weekly feature vectors to serve as inputs for nonsequential and sequential AI models, introduced in the Age Estimation Model Development section. To construct the weekly feature vectors for nonsequential models, we used 3 temporal resolutions: weekly median, daily median, and 6-hour interval median (Figure 2). In the weekly median case, we built a feature vector using the median values of all features for each week. In the daily median case, we organized a feature vector by arranging the median value of each feature per day within each week. Considering the diurnal rhythm mentioned above, we split a day-resolution into hour levels. In the 6-hour interval median case, we constructed a feature vector by arranging the median value of each feature in 6-hour intervals (midnight-6 AM, 6 AM-noon, noon-6 PM, and 6 PM-midnight) for each week. For sequential models, such as a transformer-based and the long short-term memory (LSTM)–based models, the same features were organized as a temporal sequence across days and 6-hour periods, allowing the model to learn temporal dependencies. Accordingly, we used the daily median and 6-hour interval median resolutions only for sequential models, since the sequential information was already abstracted as a median value in the case of the weekly median. Thus, for sequential models, the feature vector using the daily median has a sequence length of 7, while the feature vector using the 6-hour interval median has a sequence length of 28. Given the importance of data order in sequential models, we further adjusted the organized feature vectors to begin with Monday's data and end with Sunday's data.

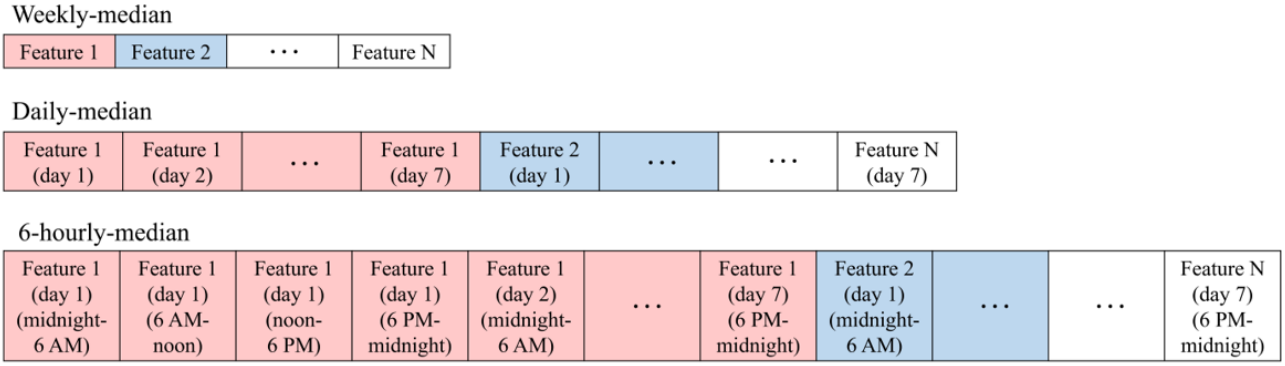
Figure 2. Examples of weekly feature vectors according to different temporal resolutions.



Age Estimation Model Development

To train and evaluate AI models, we constructed 7 datasets from the original dataset to ensure balanced representation across different age groups. Specifically, we divided the data of participants younger than 30 years into 7 participant-wise subsets (17×1+18×6). This division was based on the average number of participants in the other 3 age groups (30s, 40s, and 50s), which was approximately 17.3. Thus, we used 17 and 18 as the subset sizes for the younger-than-30-years group. Each subset of the younger-than-30-years group was then combined with the full data from the other age groups to form 7 age-balanced datasets. The resulting datasets had mean ages ranging from 38.5 to 38.9 (SD 0.1) years. Sex distribution was also comparable across the datasets, with the number of female participants ranging from 41 to 48 and male participants from 22 to 29. Within each dataset, missing values were imputed using the values from the nearest week. Minimum-maximum normalization was applied within each constructed dataset.

For the age estimation in this study, we used 8 AI models: logistic regression, random forest regressor, extreme gradient boosting (XGBoost) regressor, CatBoost regressor, multilayer perceptron (MLP), and TabNet [22], as well as sequential models based on a transformer and LSTM. Using Python version 3.11.4, we implemented the 8 AI models, which take the constructed weekly feature vectors and then output the estimated age.

For each of the 7 age-balanced datasets, we conducted 10-fold cross-validation while exploring the hyperparameter space to maximize the regression performance. We divided the individual dataset into 10 folds in a participant-wise manner, ensuring that the same participant's data did not appear in both training and test sets. The fold construction was based solely on participant separation without rebalancing age distribution across folds. For logistic regression, we opted for a consistent hyperparameter set, choosing "liblinear" as the solver and "L2" for regularization. For the random forest regressor, XGBoost regressor, and CatBoost regressor, we adjusted the number of estimators and the depth of each estimator, additionally changing the learning rate only for the XGBoost regressor and CatBoost regressor. For MLP, we stacked BatchNorm1d, Linear, ReLU, and Dropout layers using the torch package. Within the architecture, we adjusted the number of layers, the number of nodes in each layer, the number of epochs, and the batch size. We used a dropout rate of 0.3, a weight decay of 0.001, and the ReduceLROnPlateau scheduler for the learning rate. For TabNet, a deep learning model designed for tabular data, we used the pytorch_tabnet package. We adjusted the dimension of decision prediction layers, the dimension of the attentive transformer, the number of decision steps, the number of epochs, and batch size, while using the Adam optimizer and the ReduceLROnPlateau scheduler, from the torch package, for the learning rate. For the transformer-based model, we examined various options for the number of layers, the number of attention heads, the hidden dimension, the learning rate, and the batch size. For the LSTM-based model, we regulated values of the number of layers, the number of nodes in each layer, the learning rate, and the batch size. For the deep learning models, in each fold, we stored the model from the epoch that achieved the best performance on the validation set and used it for evaluation, rather than simply reporting the last epoch.

We hypothesized that if an individual is in good health, the estimated age would remain relatively stable across different weeks. Given that our participants were from a healthy population, we customized the loss function of the AI model to minimize deviations in estimated age within the same participant. The training process was divided into 2 phases. In the first phase, we constructed mini-batches such that each batch contained multiple weekly samples from the same participant. For each batch, we calculated the average L1 loss between the real and estimated ages across the participant's weekly samples. If this average L1 loss exceeded an empirically defined threshold, a penalty term—computed as the average L1 loss multiplied by a weight—was added to the original loss. We experimented with threshold values of 1, 2, and 3, and weight values of 0.2, 0.4, 0.6, 0.8, and 1.0. In the second phase, training continued using the standard L1 loss without the additional penalty. We tuned the number of epochs for each phase to achieve optimal age estimation performance.

Upon completion of model training, we assessed age estimation performance based on mean absolute error (MAE) and R^2. Each metric was then averaged across the results from the 7 age-balanced datasets to obtain the final evaluation scores.

Results

Participant Data Overview

Table 2 shows the characteristics of the dataset of the entire 177 participants, including a sex distribution of 115 females and 62

XSL•FO
RenderX

males. All of them were residents of the Republic of Korea. The participants had a mean age of 28.8 (SD 11.1) years, with a minimum of 19 years and a maximum of 58 years. The majority (n=125) were younger than 30 years old, while the remaining participants were distributed across the following age groups: 30-39 years (n=16), 40-49 years (n=19), and 50-59 years (n=17). On average, data were collected over a 25-week period per participant, ranging from a minimum of 4 weeks to a maximum of 41 weeks. In total, 2,597,692 typing sessions were collected, of which 89,219 (3.4%) were discarded because they contained at least 1 instance of ≥10 consecutive keystrokes occurring within 1 second.

Table 2. Demographic distribution of participants and the duration of keystroke data collection across all participants in our study.

Item	Value
Participants, n	177
Age (y), mean (SD)	28.8 (11.1)
Total group age range (y), n	
<30	125
30-39	16
40-49	19
50-59	17
Sex (female:male), n	115:62
Data collection weeks, mean (SD; minimum-maximum)	25.0 (13.3; 4-41)

Descriptive Analysis Results for Different Age Groups

Figure 3 illustrates the hourly patterns of 4 features—number of pressed keys, number of typing sessions, HT, and PPL—across different age groups (younger than 30 years, 30s, 40s, and 50s). As illustrated in Figure 3, the younger groups (younger than 30 years in black, and 30s in red) consistently exhibited a higher number of pressed keys throughout the day compared with the older groups (40s in blue, and 50s in green). Notably, the younger than 30 years group peaked at 11 PM, whereas the older groups showed a slight decline approaching that hour. The number of typing sessions showed a similar pattern. PPL remained low (approximately 0.2 seconds) for the younger groups, while it was higher for the older groups. HT followed a similar trend to PPL.

Figure 3. Visualization of keystroke dynamics across age groups, showing the hourly distribution of the number of key presses, the number of typing sessions, press-to-press latency, and hold time, highlighting age-related differences over the course of a day. HT: hold time; PPL: press-to-press latency.

Age Estimation Results Using Keystroke Dynamics

Table 3 presents the age estimation results obtained from the 8 AI models used in our study, based on speed and frequency features. These results were produced without applying the customized loss function, as our goal was to first report baseline performance from conventional AI models. Among the nonsequential models, MLP and TabNet demonstrated competitive performance, with MAEs of 3.85 and 4.01, respectively, under the weekly median resolution. These 2 deep learning–based models consistently outperformed traditional machine learning models across all temporal resolutions. Overall, the sequential model LSTM showed improved performance as the temporal resolution became finer. With the 6-hour interval median resolution, LSTM achieved an MAE of 3.69 and an R^2 of 0.71, which is the optimal performance in this experiment. R^2 generally increased with finer temporal resolutions across most of the 8 AI models. Although we also tested the 3-hour interval median resolution, it did not lead to further performance improvement (MAE remained at 3.69).

Table 3. Age estimation results of 8 artificial intelligence models using speed and frequency features and 3 different temporal resolutions (weekly median, daily median, and 6-hour interval median).

	Weekly median		Daily median		6-hour interval median	
AI[a] model	MAE[b]	R^2	MAE	R^2	MAE	R^2
Nonsequential models						
Logistic regression	6.43	0.01	6.77	–0.09	6.81	0.13
Random forest regressor	5.49	0.44	5.34	0.48	5.13	0.53
XGBoost[c] regressor	5.54	0.47	5.38	0.49	5.07	0.55
CatBoost regressor	5.26	0.50	5.28	0.50	5.04	0.55

[d]MLP: multilayer perceptron.

[e]Not applicable.

[f]LSTM: long short-term memory.

Impact of Different Combinations of Feature Sets

Using the LSTM model with the 6-hour interval median resolution, which achieved the optimal MAE of 3.69 (Table 3), we conducted an ablation study to examine the effectiveness of different feature set combinations in our age estimation task. For each experiment in Table 4, we regulated hyperparameters of the LSTM model to find the optimal MAE. Overall, the speed feature appeared more influential for age estimation than the frequency feature. Using only the speed feature yielded a comparable MAE of 3.70, in which both speed and frequency features were used (MAE=3.69). In contrast, the inclusion of speed and frequency variability features did not result in noticeable improvements, suggesting their limited effectiveness in this context. When used in isolation, the frequency feature and its variability yielded limited but marginal improvements.

[a]MAE: mean absolute error.

Impact of Different Combinations of 6-Hour Periods

Using the LSTM model with the 6-hour interval median resolution, we conducted an additional ablation study to examine the impact of using different 6-hour periods within a single day. For this experiment, we fixed the hyperparameters to those of the optimal case presented in Table 3. As illustrated in Table 5, we conducted experiments using all possible combinations of the four 6-hour periods. Overall, the MAE increased as the total number of hours used for age estimation decreased. When using only one 6-hour period, the MAE ranged from 4.34 to 4.61, indicating relatively poor performance. With 12-hour combinations, the optimal performance (MAE=3.95) was achieved when using data from midnight-6 AM and 6 PM-midnight. A similar trend was observed for the 18-hour combinations, where the lowest MAE (3.87) occurred in 2 combinations that included these time intervals.

Table 5. Results of the ablation analysis examining the impact of using different combinations of 6-hour periods within a day on age estimation performance.

Total duration	Midnight-6 AM	6 AM-noon	Noon-6 PM	6 PM-midnight	MAE[a]

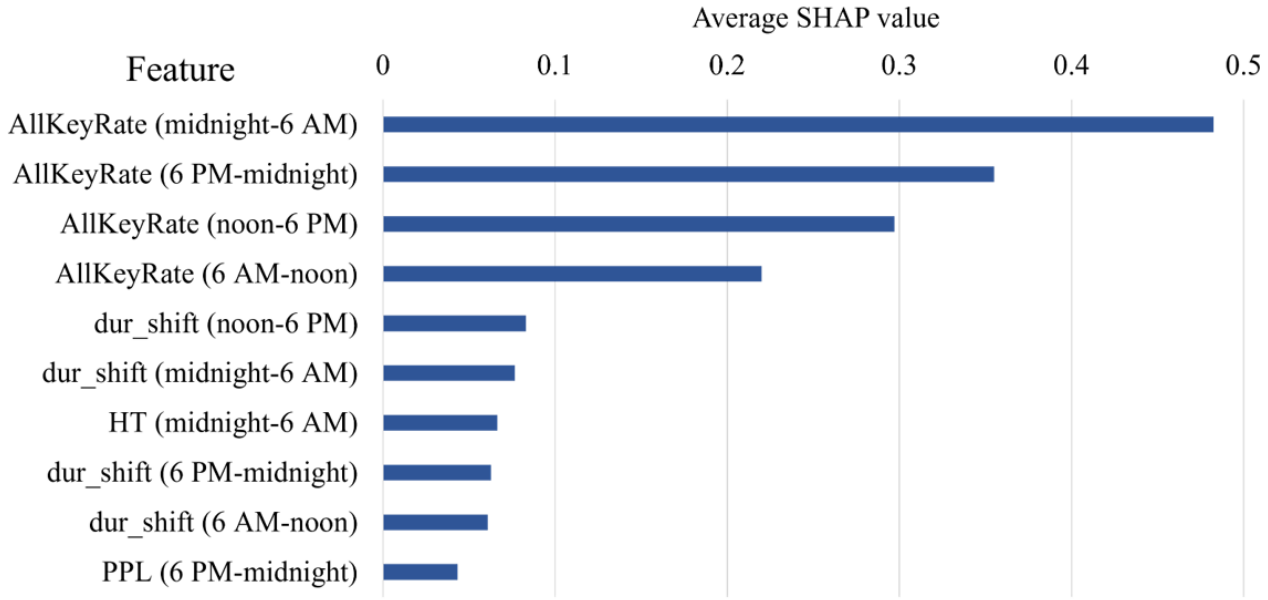
Feature Selection and Optimized Estimation

We applied the previously introduced customized loss function to the LSTM model with the 6-hour interval median resolution to reduce intraparticipant deviation in estimated age. The model was trained from scratch and achieved an MAE of 3.60. To evaluate the effectiveness of the customized loss function, we computed the SD of estimated ages across weeks for each participant and then averaged these values across all participants. The average SD decreased from 1.28 (SD 0.22; without the loss function) to 1.18 (SD 0.14; with the loss function), indicating a 7.8% reduction in intraparticipant variability.

We also applied Shapley Additive Explanations [23] to assess feature importance in the model trained with the customized loss function. As illustrated in Figure 4, the top 10 most influential features out of 60 were predominantly related to keystroke speed and rhythm, such as AllKeyRate, dur_shift, and HT, measured across various 6-hour time periods.

Figure 4. Top 10 most influential features for age estimation, identified via SHAP analysis of the long short-term memory model trained with the customized loss function and 6-hourly-median resolution. HT: hold time; PPL: press-to-press latency; SHAP: Shapley Additive Explanations.



Discussion

Principal Results

This study aimed to investigate whether age-related differences manifest in everyday smartphone keystroke dynamics. Through both descriptive and AI-based analyses, we demonstrated that typing behavior—such as speed, latency, and session frequency—systematically varies across age groups. For instance, younger participants exhibited consistently faster and more frequent typing patterns, particularly during late evening hours, while older individuals showed slower and less variable patterns throughout the day.

Building on these observations, we explored whether such behavioral signals could support accurate AI-driven age estimation. Among the 8 models tested, the LSTM model with the 6-hour interval median resolution achieved the best performance (MAE=3.69, R^2=0.71), highlighting that fine-grained temporal patterns carry meaningful age-related information. While predicted ages that differ from actual ages by only a small margin (eg, within ±5 y) may reflect normal variability, sudden large deviations (eg, 10-20 y) could arise from short-term factors, such as stress, fatigue, or sleep deprivation, as well as from long-term or chronic factors, such as disease onset or persistent cognitive or motor decline. Previous studies have shown that short-term conditions like fatigue or stress can alter keystroke dynamics, increasing interkey latencies and error rates [24,25]. Similarly, chronic neurological or cognitive disorders, including Parkinson disease and mild cognitive impairment, have been associated with measurable changes in typing patterns [26,27]. The magnitude of fluctuation in age predictions is therefore likely to depend on both the timescale and the underlying cause of behavioral change. Future work should not only disentangle short- and long-term contributors but also investigate how the scale of predicted age deviation corresponds to these different contributors. Such insights could enable adaptive age-prediction strategies that dynamically adjust to the likely source of variability, improving both robustness and interpretability in real-world conditions.

Ablation studies further revealed that typing speed features contributed most strongly to model performance, aligning with the behavioral differences observed in the descriptive analysis. Notably, our time-of-day ablation study (Table 5) revealed that the early morning (midnight-6 AM) and late evening (6 PM-midnight) periods contained more informative signals for age prediction. These findings suggest that age-related behavioral differences may be more pronounced during off-peak hours, potentially due to variations in daily routine structures, fatigue, or circadian rhythms.

Taken together, our results indicate that keystroke dynamics encode subtle, age-sensitive behavioral patterns that can be

XSL•FO
RenderX

leveraged for passive, AI-based age estimation—without requiring any explicit input from users.

Comparison With Previous Work

In total, 2 studies are particularly relevant for contextualizing our contributions, that is, studies by Vesel et al [13] and Zulueta et al [18].

Vesel et al [13] applied hierarchical mixed-effects models to examine how mood, age, and diurnal patterns influence keystroke behavior. They found that younger users (20 y) typed substantially faster, less variably, and paused less frequently compared with older users (≥70 y), with effect sizes ranging from 57% to 62%. Importantly, they also identified a significant interaction with diurnal patterns, such that older adults displayed greater slowing and variability in the later hours of the day. Consistent with these findings, our study also observed similar age-related differences in typing speed (Figure 3). However, Vesel et al [13] did not focus on prediction but rather on identifying how typing behavior varies as a function of demographic and clinical factors. They treated age as an independent variable affecting keystroke features, whereas in our study, age was the target variable to be predicted. Moreover, while Vesel et al [13] identified diurnal trends in typing speed and variability, our model leveraged this information to improve prediction through time-resolved feature representation and ablation experiments across 6-hour periods. In this sense, our study operationalizes the temporal behavioral patterns identified by Vesel et al [13] into an actionable, AI-driven predictive framework.

Zulueta et al [18], on the other hand, estimated "brain age" from mobile keystroke kinematics and examined the deviation between predicted and actual age in relation to bipolar disorder risk. They tokenized free-living iOS (BiAffect) typed logs into sessions and then summarized kinematic features per participant. To estimate chronological age, they trained random forest regressors on a 75:25 train-validation split using 10-fold cross-validation with 3 repeats. On the held-out validation set, they reported root mean square errors of 9.5-9.7 years, Breiman pseudo R^2 of 0.42-0.44, and MAEs of 5.5-5.9 years. While they also performed age prediction using smartphone metadata, their goal was to assess brain age as a digital biomarker of psychiatric risk, particularly differentiating prediction error patterns across diagnostic groups (positive vs negative Mood Disorders Questionnaire screens). Their models were evaluated primarily using participant-level aggregates, whereas our study preserved temporal granularity by modeling week-by-week patterns within participants. We also proposed a novel loss function to explicitly reduce intraparticipant variability, which was not addressed in their work. Finally, our best-performing model achieved an MAE of 3.60, substantially lower than the 5.5-5.9 years reported by Zulueta et al [18], possibly indicating the advancement of our method.

In summary, while previous works have laid important theoretical foundations, our study offers a methodological advancement by combining fine-grained temporal feature engineering, intraparticipant variance penalization, and deep learning architectures for high-resolution, week-level age estimation.

Limitations

Despite promising findings, our study has several limitations. First, our dataset was heavily skewed toward younger participants who were younger than 30 years of age. Although we constructed age-balanced subsets to partially mitigate this imbalance, the initial sampling bias may still have influenced model training and evaluation. In particular, residual imbalance across the cross-validation folds could not be fully eliminated, which may have led to performance estimates biased toward younger age groups. Future studies should validate our findings on larger and more demographically diverse populations, including a broader distribution of age groups.

Second, all participants in this study were healthy individuals without known motor or cognitive impairments. While this design choice helped isolate age as a primary factor, it limits the generalizability of our findings to clinical populations. Since keystroke dynamics are known to be affected by neurological and psychiatric conditions, future work should explore how such models perform across varying health statuses.

Third, our study population consisted exclusively of Korean Android users, which may limit the generalizability of our findings. Cultural factors (eg, language-specific typing conventions), linguistic aspects (such as Korean vs alphabet-based input), and operating system–specific characteristics (eg, Android vs iOS) could all affect keystroke dynamics. Furthermore, our study did not consider keystroke dynamics on desktop or other mobile devices (eg, tablet), which may also limit generalizability. To strengthen external validity, future studies should validate the model across multiple platforms and operating systems by including both Android and iOS users, expand recruitment to participants from different countries and linguistic backgrounds, and incorporate broader age groups, including younger adolescents and older adults. Such efforts would allow more comprehensive evaluation of the robustness and applicability of keystroke-based age prediction models.

Fourth, another limitation is that individual and device-specific factors, such as the dominant hand or screen size, were not considered in this study. These factors may systematically influence typing speed, rhythm, and error patterns, thereby introducing variability that is independent of age-related effects. For instance, larger screens may allow for more stable keystrokes, while different input languages and keyboard layouts could alter interkey intervals. Although such factors may add noise to the prediction, they are unlikely to fully explain the observed associations, yet future work should explicitly account for them to improve model validity and generalizability.

Fifth, our study did not evaluate the long-term temporal stability of the proposed models. Although we used multiweek data for training and testing, we did not assess whether age predictions remain consistent over several months. This is especially important for real-world applications where behavioral patterns may shift gradually due to lifestyle changes, seasonality, or device replacement.

XSL•FO
RenderX

Sixth, although our dataset volume was large, deeper statistical analysis revealed that the keystroke features did not follow Gaussian distributions. Specifically, we conducted Shapiro-Wilk normality tests across all features, and none satisfied the assumption of normality (all P values <.001). As a result, Gaussian-based methods, such as linear or quadratic discriminant analysis, would not have been appropriate for this dataset. This supports our choice of nonlinear AI-based approaches, which are better suited to capture the inherently non-Gaussian nature of keystroke dynamics.

Finally, while our analysis of temporal variance features (speed variability and frequency variability) did not lead to meaningful performance gains, we believe this area holds potential. The human body follows natural diurnal rhythms that affect motor and cognitive function across the day. With more refined feature engineering, temporal variability may better capture such rhythms and contribute to improved age estimation in future models.

Conclusions

This study demonstrates that everyday smartphone keystroke dynamics contain measurable behavioral patterns that vary systematically across age groups. By analyzing typing speed, rhythm, and frequency features across different time windows, we showed that younger and older individuals exhibit distinct temporal keystroke signatures—with our results suggesting that early morning and late evening periods may carry more predictive information for age estimation. These findings suggest that keystroke dynamics may serve as meaningful digital behavioral markers of age-related functional differences.

Building on these behavioral insights, we developed AI models to estimate age using passive keystroke data, with the LSTM model and the 6-hour interval median resolution achieving the best performance (MAE=3.69, R^2=0.71). We further introduced a customized loss function that reduced intraparticipant variability, and used Shapley Additive Explanations analysis to identify key typing features contributing to model predictions.

Importantly, this work is not merely an age estimation exercise. Rather, it illustrates how fine-grained, temporally structured passive behavioral data can be used to detect subtle functional differences across individuals. These results suggest potential future applications of mobile keystroke dynamics in digital health, such as aiding the early detection of cognitive or motor decline and supporting age-sensitive personalization of interventions. However, given that our study included only healthy participants, the clinical applicability of these approaches requires further validation in clinical populations.

Acknowledgments

The authors sincerely thank all study participants for their valuable time and commitment to this research.

Abstract

Background: Questionnaire-based symptom assessment may introduce recall bias and lacks bidirectional exploration. This is particularly relevant, given the unclear direction of the associations between physical activity (PA), sedentary time (ST), and symptoms in patients with chronic obstructive pulmonary disease (COPD). Understanding these associations could inform symptom management strategies and improve patient quality of life.

Objective: This study aimed to investigate the direction of the association between PA, ST, and symptoms in patients with COPD using accelerometry and ecological momentary assessment (EMA).

Methods: A subsample from the FAntasTIGUE study answered 8 randomly timed EMA questionnaires daily for 5 days. Ten symptoms were rated on a 7-point Likert scale: “I feel relaxed, short of breath, energetic, cheerful, insecure, irritated, satisfied, anxious, tired, and mentally fit.” Concurrently, step count and ST were measured using the ActiGraph GT9X Link placed on the right hip. Step count and ST 15 and 30 minutes pre- and post-EMA were used in multilevel models, controlled for pre-EMA steps and ST, and the previous EMA score. Significant confounders were used as covariates, and patient ID was used as random intercept.

Results: Thirty-four patients (19/34, 56% men, mean age 66, SD 7 years; forced expiratory volume in 1 second 52±20% predicted; 1035 EMA responses) were included. Feeling more relaxed was associated with a higher step count 15 minutes post-EMA (β=5.1; 95% CI 0.9 to 10.1; *P*=.046). Conversely, higher step count 15 and 30 minutes pre-EMA was associated with feeling less relaxed (β=-5.2×10^{-4}; 95% CI -9.7×10^{-4} to -7.0×10^{-5}; *P*=.02; and β=-3.2×10^{-4}; 95% CI -5.6×10^{-4} to -7.9×10^{-5}; *P*=.009), more short of breath (β=8.5×10^{-4}; 95% CI 4.7×10^{-4} to 1.2×10^{-3}; *P*<.001; and β=4.6×10^{-4}; 95% CI 2.6×10^{-4} to 6.6×10^{-4};

XSL•FO
RenderX

P<.001), and tired (β=5.1×10^{-4}; 95% CI 7.2×10^{-5} to 9.4×10^{-4}; P=.02; and β=2.9×10^{-4}; 95% CI 5.3×10^{-5} to 5.2×10^{-4}; P=.02). Higher ST 15 and 30 minutes pre-EMA was associated with feeling more anxious (β=1.7×10^{-4}; 95% CI 1.7×10^{-5} to 3.2×10^{-4}; P=.03; and β=8.5×10^{-5}; 95% CI 2.5×10^{-6} to 1.7×10^{-4}; P=.04).

Conclusions: A bidirectional association of feeling relaxed with PA was found in patients with COPD. Higher step count was related to feeling more short of breath and tired, whereas higher ST was associated with heightened anxiety.

KEYWORDS

COPD; chronic obstructive pulmonary disease; ecological momentary assessment; accelerometry; physical activity; sedentary behavior; symptom assessment

Introduction

Chronic obstructive pulmonary disease (COPD) is a heterogeneous chronic lung condition characterized by shortness of breath, cough, and/or sputum production. This is, at least partly, due to abnormalities of the airways or alveoli that cause persistent airflow obstruction [1]. The heterogeneity of COPD manifests in variations in disease progression, symptom burden, and response to interventions, requiring personalized care [2]. In addition to respiratory symptoms, patients with COPD frequently experience physical symptoms such as fatigue, alongside psychological symptoms such as depressed mood and anxiety [3,4]. Moreover, they are physically less active and spend more time sitting and lying down compared to healthy controls, contributing to disease progression and poorer health outcomes [5-9].

Both the number of steps per day and sedentary time (ST) are linked to the transient exacerbation of symptoms in patients with COPD [7,10,11]. However, the direction of these associations is unclear [10-13]. For example, while physical activity (PA) may enhance feeling short of breath immediately, during, or after PA, it is also possible that worsening symptoms lead to a decline in PA and increased ST. This short-term bidirectional relationship suggests a potential vicious cycle of physical inactivity and symptom exacerbation. A deeper understanding of these associations is essential for developing targeted interventions aimed at interrupting this cycle and improving symptom management [7,8,14]. Increasing PA and reducing ST have been shown to improve symptoms and health-related quality of life in patients with COPD and may even improve survival [7,8,13,14].

Traditional symptom assessment methods typically involve clinical interviews and questionnaires asking about symptom burden 1 to 2 weeks retrospectively, which can be subject to recall bias [15,16]. This creates a challenge, considering that patients with COPD experience variability in PA, ST, and symptoms within the day and from day to day [17-19]. To address this limitation, ecological momentary assessment (EMA) emerges as a feasible method to assess symptom experience over time. EMA is defined as ‘repeated sampling of people’s current thoughts, emotions, behavior, physiological states, and context, in their natural environment, typically (but not necessarily) via electronic wearable devices’ [15,16,20]. Compared to traditional assessment methods, EMA minimizes recall bias, and ecological validity is maximized because events are monitored as close in time to their occurrence as possible [20-24]. EMA has been validated across multiple study populations, but the use of EMA for capturing symptoms in patients with COPD is still limited, and further examination of its psychometric properties is needed [25-28]. It offers a less cumbersome and cost-effective alternative for assessing multiple symptoms, making it suitable for COPD research [21,22,29]. Combining information collected with EMA and from continuous PA tracking such as accelerometry may reveal the complex bidirectional relationship between PA, ST, and symptoms. The ActiGraph accelerometer (ActiGraph Corp, Pensacola, FL, USA) has been validated for measuring PA and ST in patients with COPD, demonstrating good reliability. Its use in COPD research has been supported because of its sensitivity in detecting variations in PA and ST, making it suitable for real-world monitoring of activity patterns. Limited research is available where the temporal associations between PA, ST, and symptoms in patients with COPD are explored using real-time assessment [29].

Therefore, the main objective of this study was to investigate the direction of the association between PA and ST measured with accelerometry and physical and psychological symptoms measured with EMA in patients with COPD. It is hypothesized that PA would be associated with subsequent increases in symptoms such as breathlessness and fatigue in the short term, while worsening symptoms would predict subsequent reductions in PA and increasing ST. In addition, we aimed to explore whether the strength of these associations differed across the 10 symptoms assessed in this study. By addressing these gaps in knowledge, this study contributes to a more nuanced understanding of how daily activity patterns and symptom fluctuations interact in COPD, with potential implications for personalized intervention strategies.

Methods

Design

These analyses were a part of a multicenter, longitudinal, observational study in patients with COPD investigating physical, systemic, psychological, and behavioral factors associated with precipitation and/or perpetuation of fatigue (FAntasTIGUE study) [30]. The prevalence of fatigue and its associated factors in patients with COPD participating in the FAntasTIGUE study has been published before [3,31].

RenderX

Ethical Considerations

The study was approved by the Medical Research Ethics Committee United, Nieuwegein, The Netherlands (R17.036/NL60484.100.17) and was registered in the Dutch Trial Register (NTR6933). Written informed consent was obtained from all study participants. Participation was entirely voluntary, and participants could withdraw at any time without consequence. Participants did not receive any financial compensation. Data were deidentified before analysis.

Participants

Patients were recruited between 2018 and 2021 via the pulmonary consultation at the outpatient clinics of the Department of Respiratory Medicine in Maastricht and the Department of Pulmonary Diseases of the Radboud University Medical Center in Nijmegen and via general practitioners (Research Network Family Medicine Maastricht [32] and the Academic General Practitioner Network in the Nijmegen region). In addition, patients with COPD who attended a meeting for patients with chronic lung diseases (cfr. *longpunt*) in Maastricht or Nijmegen and patients recruited from primary and secondary care that previously participated in the Chance Study (NTR3416) and had indicated on the informed consent form that they agreed to be approached for follow-up research were invited to participate in the FAntasTIGUE study. Patients had to meet the following criteria for inclusion: (1) a diagnosis of COPD according to the Global Strategy for the Diagnosis, Management and Prevention of COPD (Global Initiative for Chronic Obstructive Lung Disease [GOLD], grade 1A–4D), (2) no exacerbation-related hospitalization less than 4 weeks preceding enrollment, (3) no use of oral corticosteroids and/or antibiotics less than 4 weeks preceding enrollment, and (4) provided written informed consent.

A subsample of the first 60 patients who were interested in participating in the EMA study had to meet these extra inclusion criteria: (1) access to the internet at home (Wi-Fi) and (2) able to operate an iPod.

Patients lacking sufficient understanding of the Dutch language and/or participating in concurrent intervention studies were excluded.

Measurements

During the baseline assessment, sociodemographic, physical, psychological, and behavioral characteristics (eg, age, sex, BMI, smoking status, marital status, working status, level of education [The Netherlands; low: primary school only and lower vocational education, medium: secondary vocational education, and high: higher vocational education and academic education], Charlson Comorbidity Index [CCI], forced expiratory volume in 1 second [FEV_1] as percentage from the predicted volume, the forced expiratory volume in 1 second to forced vital capacity ratio, GOLD stage based on forced expiratory volume in 1 second % predicted [score of 1-4], occurrence of an exacerbation and exacerbation-related hospitalization in the previous 12 months [33], and the Modified Medical Research Council [mMRC dyspnea scale]) were assessed as described elsewhere [34]. The mMRC dyspnea scale assesses the current severity of dyspnea on a scale of 5 grades (0-4), each describing a level of activity that induces dyspnea, ranging from 0 (“only gets breathless with strenuous exercise”) to 4 (“too breathless to leave the house or breathless when dressing”) [34]. An mMRC score of ≥2 indicates severe dyspnea [1]. The Checklist Individual Strength—subscale subjective fatigue (CIS-Fatigue) was used in which a score of ≥36 points denoted severe fatigue [35]. Anxiety and depression symptoms were assessed using the Hospital Anxiety and Depression Scale (HADS), where a score of >11 points indicates probable symptoms of anxiety/depression [36].

EMA Symptom Assessment

Electronic EMA questionnaires were completed for 5 consecutive days through an iPod Touch (Apple) with a custom-installed app called PsyMate (version 1.1b). During the baseline assessment, patients received oral instructions on how to use the iPod Touch and were given a printed instruction to take home. Patients were told to carry the iPod Touch with them at all times and keep to their usual day/night routine. Patients had to answer the questions immediately after the beep but no longer than 15 minutes after the beep; otherwise, the questionnaire would be skipped. PsyMate was programmed to beep at 8 random time points between 7:30 AM and 10:30 PM. When receiving the beep, patients had to rate 10 symptoms with a 7-point Likert scale, ranging from 1 (“barely”) to 7 (“very”). A score of 1 - to 2 is classified as ‘not’, 3 - to 5 is classified as ‘somewhat’, and 6 - 7 is classified as ‘very’. These symptoms included ‘I feel: relaxed; short of breath; energetic; cheerful; insecure; irritated; satisfied; anxious; tired; and mentally fit.’ On the second day, patients were called to ensure everything was going well and to discuss if any problems occurred.

Physical Activity

During the EMA home monitoring period, patients were asked to wear the ActiGraph GT9X Link 3-axis activity monitor with a sample frequency of 30 Hz for 7 consecutive days. Patients were instructed to wear the ActiGraph on the right hip from the moment they woke up until the moment they went to sleep, keep a normal day/night routine, and remove the ActiGraph if they had to shower or went swimming. During the baseline assessment, the ActiGraph was demonstrated, and printed instructions were provided for patients to take home. Data were recorded in 10-second epochs, and patients’ steps were used to indicate the amount of PA because this is a simple metric and captures the most relevant and problematic daily activity for the majority of patients with COPD [37].

Sedentary Time

Freedson Adult (1998) activity counts were used to categorize ST. ST was tracked during waking hours and was defined as a period in minutes where the activity counts fell into the sedentary range (0-99) with no interruption [38]. For valid PA data, the wear time per day needed to be a minimum of 8 hours with a minimum of 4 days. These 4 days needed to include at least one weekend day and 3 weekdays [37,39].

Data Cleaning

If patients completed less than one-third of the total beeps (ie, 13 of 40 beeps), these patients were excluded using R statistical software [40]. If the time between the first and last answer on

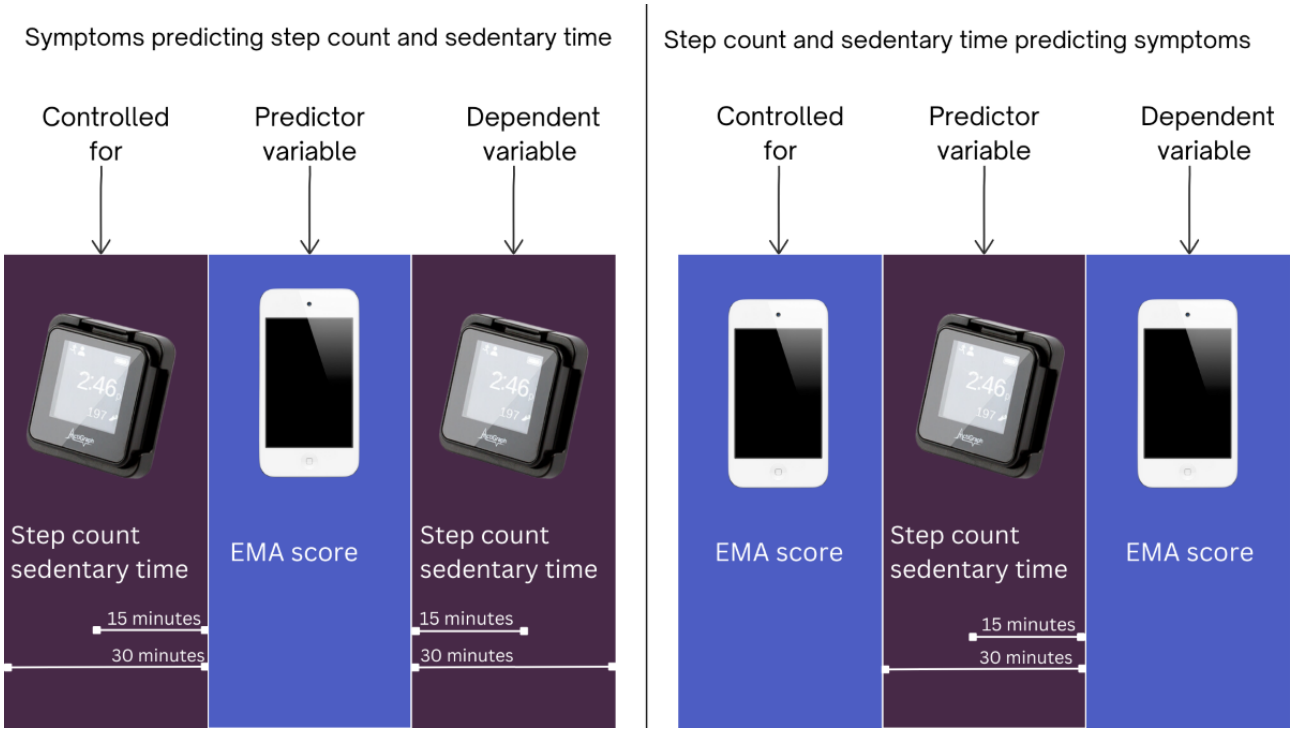
XSL•FO
RenderX

the EMA questionnaire was longer than 10 minutes, this was considered invalid, and the EMA datapoints were excluded. ActiLife6 software was used to check whether PA and ST data of the same 5 EMA home monitoring days were valid, and this was manually aligned [41]. For all the patients from Nijmegen, the ActiGraph started measuring at 9 AM on the first day because of incorrect initialization, but these patients still have the minimum of 8 hours of wear time on this day. To ensure data validity, ActiGraph wear time was verified 15 and 30 minutes before and after each EMA prompt. The EMA datapoint was excluded using MATLAB if the ActiGraph was not worn during the relevant time windows.

Data Analysis

All analyses were performed using SPSS (IBM SPSS Statistics for Windows, version 28.0.1.1; IBM Corp, Armonk, NY, USA). The distribution of data was tested using the Shapiro-Wilk test with a 2-tailed significance of <.05. Descriptive statistics were reported as means and SDs, median and quartiles 1 and 3 (Q1-Q3), percentages, and numbers as appropriate. To examine the direction of the association between steps, ST, and symptoms assessed with EMA, 15- and 30-minute time windows were created before giving the first answer on the EMA questionnaire (pre-EMA) and after giving the last answer (post-EMA), which is in line with previous research [26-28]. The total number of steps and ST within each time window was captured. Data from 11 patients were collected during the COVID-19 pandemic, and patients were measured during all 4 seasons throughout the year, which could potentially influence mood and alter PA and ST patterns. Therefore, based on normality, an independent samples *t* test or Mann-Whitney *U* test was done to compare the average amount of steps and ST during the 5 days between patients measured during COVID-19 and not during COVID-19. Furthermore, as appropriate, a one-way ANOVA or an independent Kruskal-Wallis test was done to compare the average number of steps and ST during the 5 days between the 4 seasons. A priori, a Spearman correlation analysis was run to screen for potential confounders. This was done to determine the relationship between the total number of steps and total ST of the 5 days and between EMA symptom scores and several characteristics, including age, sex, BMI, smoking status, marital status, working status, CCI, GOLD stage, exacerbation history, and exacerbation-related hospitalization in the previous 12 months [8,9,42]. The correlation between time of day with steps, ST, and EMA symptom scores was also tested because previous research showed associations between PA, ST, and time of day [18,43]. Confounders that had a significant correlation (P<.05) were used as covariates in the multilevel models. Patient ID was included as a random intercept, specifying that all observations by the same patient would be correlated with each other. Multilevel linear mixed models were performed using the ‘mixed’ command and restricted maximum likelihood estimations with a significance of <.05. While we hypothesized associations specifically for dyspnea and fatigue based on prior literature and clinical relevance, analyses involving the remaining symptoms were exploratory in nature. These additional analyses aimed to identify potential patterns in the data and generate hypotheses for future research. In multilevel model 1, step count 15 and 30 minutes post-EMA was used as the dependent variable, and the EMA score was used as the predictor (Figure 1). This was controlled for the step count 15 and 30 minutes pre-EMA.

Figure 1. Illustration of the multilevel model methodology. EMA: ecological momentary assessment.



In multilevel model 2, the EMA score was used as the dependent variable, and the step count 15 and 30 minutes pre-EMA was used as predictor. This was controlled for the previous EMA score on the same day, so the first EMA score of a day was not corrected for a previous EMA score. In multilevel model 3, ST 15 and 30 minutes post-EMA was used as the dependent

XSL•FO
RenderX

variable, and the EMA score was used as the predictor. This was controlled for ST 15 and 30 minutes pre-EMA. In multilevel model 4, the EMA score was used as the dependent variable, and the ST 15 and 30 minutes pre-EMA was used as predictor. This was controlled for the previous EMA score. All 10 symptoms were tested in separate multilevel models.

Results

Overview

A total of 60 patients were assessed for eligibility. However, 26 (43%) patients were excluded because of the absence of valid ActiGraph data (n=23) or valid EMA data (n=3). Specifically, a technical error and incorrect initialization of the ActiGraph resulted in 10 (43%) patients lacking any ActiGraph data. In addition, another 10 (43%) patients had ActiGraph data, but they were not valid since seven of these patients had only 1 day of PA measurement, and 3 patients had just 1 day of PA measurement but with less than 4 hours of valid recording. In addition, 3 (13%) patients had a mismatch between the PA and EMA measurement days. Two (67%) patients did not have any EMA data available, and 1 (33%) patient had less than one-third of answered EMA responses. Consequently, 34 patients were included for this analysis.

Participants

As a lot of patients were excluded, the sociodemographic, physical, psychological, and behavioral characteristics of the included and excluded patients were compared. There were no significant differences in any of these characteristics between the included and excluded patients (Table 1). Of the 34 included patients, 19 were men (56%), 32 (94%) had moderate-to-severe COPD, and almost half had at least one exacerbation in the previous 12 months. Severe dyspnea was reported by 13 of 33 patients (39%), and 15 of 34 patients (44%) experienced severe fatigue. Among the patients, 3 of 33 (9%) and 5 of 33 (15%) had probable symptoms of anxiety and depression, respectively. No statistically significant impact of the COVID-19 pandemic or seasonality on both steps and ST was found (all $P>.05$).

EMA Symptom Assessment

Of the 1054 EMA datapoints, 5 were excluded because the time between the first and last answer of the EMA questionnaire was longer than 10 minutes, and 1 was excluded because it was sent after 10:30 PM. In addition, 13 EMA datapoints were excluded because patients received the first EMA prompt before 9 AM, whereas the ActiGraph started measuring at 9 AM on the first day, so no ActiGraph data were available. Consequently, 1035 EMA responses were analyzed, resulting in a response rate of 76.1% (1035 completed EMA responses of the 1360 possible EMA responses). The mean response rates of the 34 patients per day were 196 of 272 (72.1%), 221 of 272 (81.3%), 213 of 272 (78.3%), 198 of 272 (72.8%), and 207 of 272 (76.1%). The lowest number of total responses during the 5 days was 18 of 40 (n=1), and the highest number of total responses was 38 of 40 (n=3; Table 2;).

The median (Q1-Q3) time of completing the EMA was 1 minute and 1 second (00:48-01:22). During the 5 days, patients generally rated feeling very relaxed, cheerful, and satisfied, while not feeling insecure, irritated, and anxious (Figure 2).

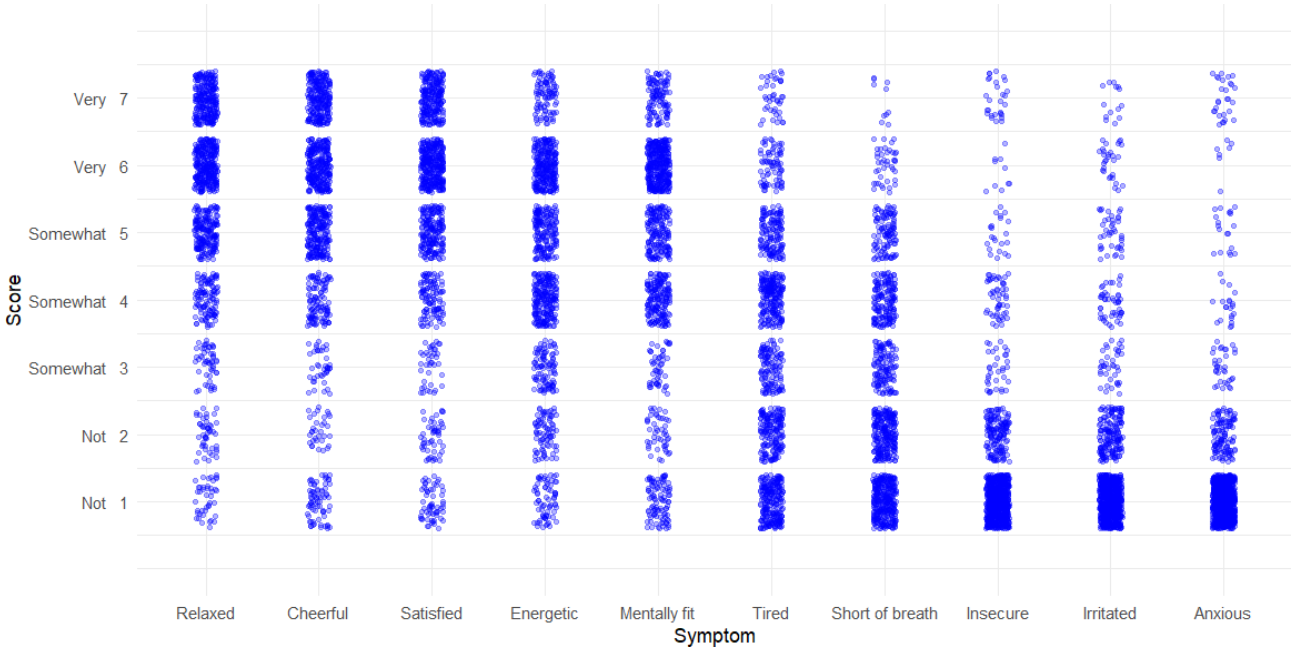
[a]EMA: Ecological Momentary Assessment.

XSL•FO
RenderX

Figure 2. Jittered scatterplot of the EMA-based symptoms scored on a 7-point Likert scale for 5 consecutive days.



Physical Activity

During the 5 days, patients had a median (Q1-Q3) of 19 (3-74) steps pre-EMA and 20 (3-67) steps post-EMA in the 15-minute time windows. During the 30-minute time windows, patients had a median (Q1-Q3) of 55 (10-148) steps pre-EMA and 52 (11-139) steps post-EMA.

In the unadjusted models 1, it was found that when patients reported feeling more energetic and more mentally fit, step count was statistically significantly higher 15 minutes post-EMA, and when patients reported feeling more tired, step count was lower 15 and 30 minutes post-EMA (Table 3).

Table . Associations between symptoms and step count 15 and 30 minutes post–ecological momentary assessment.

[a]Adjusted for time of day, working status, GOLD stage, exacerbation history, and exacerbation-related hospitalization in the previous 12 months.

The total number of steps taken during the 5 days was positively correlated with being currently employed (r=0.38; P=.03) and negatively correlated with GOLD stage (r=−0.53; P<.001), exacerbation history (r=−0.41; P=.02), and exacerbation-related

XSL•FO
RenderX

hospitalization in the previous 12 months (r=−0.36; P=.04). Furthermore, steps were negatively correlated with time of day (r=−0.12; P<.001). When adjusting for these significant confounders, no significant associations were found in models 1 between symptoms and step count 30 minutes post-EMA. Only feeling relaxed had a positive relationship with step count 15 minutes post-EMA. That is, for a 1-unit increase in feeling relaxed, the expected value of step count 15 minutes post-EMA increases by 5.1 steps.

Feeling short of breath was positively correlated with GOLD stage (r=0.44; P=.009), whereas feeling energetic was negatively correlated with GOLD stage (r=−0.35; P=.046). Feeling cheerful and satisfied was both negatively correlated with being a current smoker (r=−0.38; P=.03; and r=−0.41; P=.02), and feeling irritated was negatively correlated with CCI points (r=−0.34; P=.049). Furthermore, feeling relaxed was positively correlated with time of day (r=0.12; P<.001), whereas feeling irritated was negatively correlated with time of day (r=−0.07; P=.04).

In both the unadjusted and adjusted models 2, it was found that a higher step count during a 15- and 30-minute time window pre-EMA was associated with feeling less relaxed and feeling more short of breath and tired (Table 4).

Table . Associations between step count 15 and 30 minutes pre–ecological momentary assessment and symptoms.

Sedentary Time

Patients, on average (SD), spent 314 (116) minutes sedentary per patient per day during waking hours. During the 5 days, patients had a median (Q1-Q3) of 9 (3-13) minutes ST pre-EMA and 9 (4-13) minutes post-EMA in the 15-minute time windows. During the 30-minute time windows, patients had a median (Q1-Q3) of 18 (7-24) minutes ST pre-EMA and 18 (9-24) minutes post-EMA.

The total ST during the 5 days was positively correlated with BMI (r=0.36; P=.04) and negatively correlated with being currently employed (r=−0.39; P=.03). In addition, ST was positively correlated with time of day (r=0.24; P<.001). In both the unadjusted and adjusted models 3, no significant associations were found between symptoms and 15 or 30 minutes post-EMA ST (Table 5).

In the unadjusted models 4, it was found that a higher ST during a 15- and 30-minute time window pre-EMA was associated with feeling more anxious (Table 6).

Table . Associations between symptoms and sedentary time 15 and 30 minutes post–ecological momentary assessment.

Discussion

Principal Findings

To the best of our knowledge, this is the first study to assess the direction of the association between PA and ST measured with accelerometry and physical and psychological symptoms measured with EMA in patients with mild-to-very severe COPD. This study showed that feeling relaxed was positively associated with an increased step count shortly after completing the EMA. A higher step count before EMA completion was associated with feeling less relaxed, more short of breath, and tired. These findings suggest a potential bidirectional relationship between PA and psychological well-being. Furthermore, our results indicate that ST preceding EMA completion was associated with increased feelings of anxiety, underscoring the potential adverse effect of prolonged ST on psychological well-being in patients with COPD.

Steps

In this study, feeling more relaxed was the sole predictor for the number of steps 15 minutes post-EMA, after adjusting for relevant confounders. While this effect size may appear modest,

XSL•FO
RenderX

it should be interpreted in the context of the overall low step counts observed in this population. Given the median step counts of 19 to 20 steps per 15-minute window, even small increases may reflect meaningful changes in short-term activity patterns. Even minor increases in PA can have positive effects on symptoms, functional status, and quality of life in patients with COPD [13,14]. In contrast, a previous study in healthy older adults found no significant associations between feeling calm/relaxed and subsequent PA, nor between positive (happy and cheerful) and negative (anxious, stress, sad, and angry) affect and subsequent PA 15 and 30 minutes post-EMA [44]. Feeling more energetic was associated with increased PA for both 15- and 30-minute time windows in low-active adults [27]. In this study, feeling more energetic was associated with a higher step count 15 minutes post-EMA only in the unadjusted model. Contradicting results are found regarding the relationship between fatigue and PA. One study found no relationship between fatigue and PA in the 15 and 30 minutes post-EMA in low-active adults [27]. Conversely, other studies involving healthy older adults and patients receiving peritoneal dialysis demonstrated that higher fatigue severity and diminished energy were associated with reduced subsequent PA in the 15, 30, 60, and 120 minutes post-EMA [28,45]. These results suggest that higher fatigue results in lower probability of being physically active and in fewer minutes of subsequent PA [28,45]. In this study, feeling more tired was associated with a lower step count 15 and 30 minutes post-EMA only in the unadjusted models. Confounders such as employment status, GOLD stage, exacerbation history, and exacerbation-related hospitalizations might exert a detrimental influence on patients' energy and tiredness, potentially disrupting the relationship with engaging in PA [46,47]. Prior studies showed a positive relationship between improved mental state and engaging in PA in patients with COPD [48]. In this study, feeling more mentally fit was associated with a higher step count 15 minutes post-EMA only in the unadjusted model.

In this study, a higher step count 15 and 30 minutes pre-EMA was associated with feeling less relaxed, more short of breath, and tired. Previously, Hevel et al found no significant associations between step count and subsequent positive (happy and cheerful) and negative (anxious, stressed, sad, and angry) affect in healthy older adults [44]. In contrast, previous studies in nonactive adults and patients receiving peritoneal dialysis found that more PA minutes 15 and 30 minutes pre-EMA were associated with feeling more energetic, positive mood, and lower fatigue severity [27,28,44]. These studies generally demonstrate positive psychological effects after PA. Our findings deviate from these results, potentially because patients with COPD have different experiences with performing PA [37,49]. Physical barriers limit the ability of patients with COPD to engage in PA [8]. Patients frequently report that dyspnea, fatigue, and PA-induced coughing are distressing and discourage being physically active, potentially creating a vicious circle where symptoms discourage activity and inactivity exacerbates symptoms [7,8,14,49]. Consequently, increasing PA may exacerbate symptoms, leading to reduced feelings of relaxation and feeling more short of breath and tired [37].

Sedentary Time

In this study, no significant associations were found between symptoms and subsequent ST. The relationship between symptoms and ST using EMA has been understudied. Prior studies suggest that psychological symptoms such as anxiety, depressed mood, and dyspnea may generally contribute to increased ST in patients with COPD [9,50]. However, these effects may not be directly observed or exist in short-term analysis.

In this study, higher ST was linked to increased feelings of anxiety for both 15- and 30-minute time windows. Only a very small proportion of the study population had probable symptoms of anxiety according to the HADS. This underscores the significant impact of ST on anxiety, aligning with previous research [7].

Methodological Considerations

The current findings need to be interpreted in the light of the number of comparisons that were made in this study. Nonetheless, multiple findings in the same direction, rather than a single statistically significant result, suggest that these are not due to chance alone. Moreover, 'Bonferroni adjustments are at best unnecessary and, at worst, deleterious to sound statistical inference' [51]. This study revealed that EMA through a mobile app was feasible for symptom assessment in technically proficient patients with COPD. Only 3 of 34 patients had insufficient EMA data, and the average response rate (76.1%) is consistent with other feasibility studies exploring the use of EMA in patients with COPD and other clinical populations [26,28,52]. Random time intervals for the EMA assessment prevented patients from anticipating and adjusting their behavior. However, by using time windows surrounding the randomized time intervals of the EMA prompts, instead of examining naturally occurring beginning and ends of taking steps and ST, only partial PA sessions may have been captured. Although data showed a clear variability in step count day to day, we do not expect this to impact the findings as we examined associations between changes in PA, ST, and changes in EMA. The ActiGraph, generally valid and responsive for PA measurements in patients with COPD, had a technical error that invalidated data from 23 patients, reducing the study sample size [37]. The relatively small study sample size and the patients being technically proficient limit the generalizability of our findings. Furthermore, the analyses for symptoms beyond dyspnea and fatigue were exploratory in nature. As these associations were not hypothesized a priori, findings for symptoms such as mental fitness or cheerfulness should be interpreted with caution. Although 1035 EMA scores were related to PA and ST measurements, a larger sample of patients with COPD should be included in future research to test the generalizability and replicability of our findings, including longitudinal follow-up.

Clinical Implications and Future Directions

Future research is necessary to examine the complex associations between PA, ST, and symptoms in patients with COPD, as many external factors could have exerted an influence on patients' ability to perform PA, such as weather and social

XSL•FO
RenderX

context [9,37,49,53]. This study presents findings that contradict previous research, particularly regarding the effects of PA on mood and energy. While it is plausible that patients with COPD experience PA differently due to physical limitations, the study does not provide definitive answers about the underlying reasons for these discrepancies. The absence of a deeper exploration into these mechanisms highlights the need for further research. Future studies should aim to investigate potential explanations, including physiological, psychological, and contextual factors, to better understand how patients with COPD respond to PA and what drives these differences [27].

Conclusions

To conclude, a bidirectional association of feeling relaxed with engaging in PA was observed. More PA pre-EMA seemed to result in adverse physical states, including feeling more short of breath and tired. Furthermore, a longer ST pre-EMA seemed to result in an increased feeling of anxiety. Overall, these findings emphasize the complex relationships between PA, ST, and symptoms in the daily lives of patients with COPD.

Acknowledgments

This project is supported by grant 4.1.16.085 of Lung Foundation Netherlands, Leusden, the Netherlands; AstraZeneca Netherlands; Boehringer Ingelheim Netherlands; and Stichting Astma Bestrijding, Amsterdam, The Netherlands.

Data Availability

The datasets generated and analyzed during this study are not publicly available due to participant confidentiality and privacy concerns, and they are not available for sharing.

Authors' Contributions

BP acts as the guarantor of the content of the manuscript. MVH, YMJG, ZE, MSYT, CB, JBP, EFMW, MAGS, JHV, DJAJ, and MAS designed the study. MVH, YMJG, ZE, JBP, RTMS, EWMAB, JHV, and AWV were responsible for data collection. BP and QD were responsible for data analysis. BP, QD, SH-W, DJAJ, and MAS drafted the manuscript. All authors critically reviewed and revised the manuscript and approved the final version.

Conflicts of Interest

MVH and YMJG report research grant 4.1.16.085 from Lung Foundation Netherlands. MSYT reports research grant from Lung Foundation Netherlands. RTMS reports payment from GSK for lectures and from PENTAX Medical. EWMAB reports research grants from the Dutch Research Council (NWO) and the Netherlands Organization for Health Research and Development (ZonMw). DJAJ reports research grants from Dutch Foundation for Asthma Prevention and the Netherlands Respiratory Society (award), payment from Chiesi, Abbot, and AstraZeneca, and unpaid participation in the Better B steering committee and Wolfson Palliative Care Research Centre Advisory Board. MAS reports research grants from Lung Foundation Netherlands, Dutch Foundation for Asthma Prevention, AstraZeneca, TEVA, Boehringer Ingelheim, and Chiesi. BP, ZE, QD, CB, JBP, EW, MAGS, JHV, SH-W, and AWV declare that they have no conflict of interests.

Abstract

Background: Unsupervised cognitive assessments are becoming commonly used in studies of aging and neurodegenerative diseases. As assessments are completed in everyday environments and without a proctor, there are concerns about how common distractions may impact performance and whether these distractions may differentially impact those experiencing the earliest symptoms of dementia.

Objective: We examined the impact of self-reported interruptions, testing location, and social context during testing on remote cognitive assessments in older adults.

Methods: Participants from the Ambulatory Research in Cognition smartphone study were classified as cognitively normal (n=380) or as having very mild dementia (n=37). Participants completed daily tests of processing speed, working memory, and associative memory. At each assessment, participants were asked for their current location and social surroundings, which was used to quantify whether participants were either at home (or not) and by themselves (or not). After each assessment session, participants were asked if they experienced any interruptions. Mixed-effect modeling tested the interactions between location, social context, and clinical status. Additional analyses were conducted by removing sessions where participants reported that they were interrupted at any point during the testing period.

Results: Across all participants, momentary effects of environmental distractions were minimal. Specifically, when tests were completed in the presence of others, participants exhibited slightly increased variability in processing speed (P=.04). However, these momentary effects of environmental distractions were dependent upon cognitive status (P=.009). Cognitively normal older adults had better visuospatial working memory performance when they completed tests at home compared to when they completed tests away from home (P=.001). However, older adults with very mild dementia showed no effect of testing location on the same task (P=.36). Conversely, cognitively normal older adults did not differ in their processing speed at either testing location (P=.88). Older adults with very mild dementia were slightly faster when not at home (P=.04). Social context only impacted variability in processing speed for participants with very mild dementia (P=.04). When considering tests completed in the most distracting environments (away from home and in the presence of others), those with very mild dementia showed larger differences only on the visuospatial working memory measure. Additional analyses demonstrated that after removing sessions in which participants self-reported experiencing an interruption (1194/9633, 12.4% of all assessments), these small effects of environmental distractions on cognition remained, but were more apparent in those with very mild dementia.

Conclusions: Social context and location of unsupervised remote cognitive testing have small impacts on performance, but these impacts were not consistent across cognitive domains and were mostly limited to participants demonstrating the earliest symptoms of dementia. Remote cognitive testing provides valid and reliable data in older adults, but care should be taken to allow participants to report distractions that may occur during testing.

Introduction

It is becoming increasingly common to use remote cognitive assessments to track fluctuations in cognitive performance in older adults [1-6]. These tools are especially useful for measuring subtle fluctuations in cognition during the preclinical stage of Alzheimer disease (AD) [3,4,7-15]. However, because remote testing is typically done in a participant's home, usually without the supervision of a test proctor or clinician, it is hard to know the extent to which the surrounding environment is controlled and distraction-free. Distractions occur in approximately 7% - 10% of at-home cognitive testing sessions [8,16]. Such distractions can lead to worse performance on remote cognitive assessments because they might pull attention away from the task, which could lead to participants making more mistakes and having slower and more variable reaction times (RTs).

Ecological momentary assessment (EMA) is a powerful sampling method that leverages the variability in environmental factors to assess psychological processes in participants' everyday lives. EMA has been used to provide a more naturalistic and sensitive assessment of cognition (and other psychological factors) [2,17] and may provide a more reliable sampling of a participant's cognitive performance that matches their true cognitive ability [15,17]. EMA studies often consider external factors that might impact cognitive performance, such as time of day [18], mood or affect [19], current and recent stressors [20,21], everyday activities such as chores [7,22], and recent physical activities [23]. However, because EMA studies collect data during participants' everyday lives, it is possible that distractions introduced by the environment are more prominent and impact performance more when compared to in-clinic or even remotely proctored assessments. A recent review [24] suggests that testing location or social context can have some meaningful impact on performance on remote cognitive tests (both proctored and unsupervised), but the literature has been limited to assessments in a single age group or in a single cognitive domain, so the generalizability of the findings is unknown. Supporting this claim, a recent empirical study found that during remote cognitive assessments, participants who provided data for normative purposes performed better on measures of processing speed when they completed tests at home and also performed better on measures of recognition and working memory when they completed tests alone [25].

Depending on study goals, environmental distractions may be considered confounds that need to be controlled for in EMA studies of cognition. In studies of aging and neurodegenerative disease, researchers are interested in capturing subtle changes in cognition related to changes in neurological functioning, so understanding the effects of different sources of distraction is critical. Recent work has addressed the potential confounding effect of contextual factors such as environmental and social distractions on remote cognitive performance among cognitively impaired and cognitively unimpaired older adults [26]. Cerino et al [26] reported that there were small effects of environmental and social distractions that were evident on measures of visual short-term memory binding and spatial working memory. Although the effects were not large, they were still significant across all participants, even those with mild cognitive impairment (MCI), suggesting that environmental and social distractions can affect cognition beyond disease-related impairments.

It is important to consider the extent to which those showing the very earliest symptoms of dementia are affected by these distractors compared to cognitively normal individuals. That is, subtle deficits may become more apparent for those experiencing the very earliest symptoms of dementia when tests are completed "in the wild," away from home, or when around others. The goal of this study was to examine the impact of environmental and social distractions during remote cognitive testing in a well-characterized cohort of older adults enrolled in a study of normal aging and dementia. We hypothesized that symptomatic participants would be more impacted by environmental distractions compared to cognitively normal participants, especially when tests were taken in the least optimal settings (ie, both away from home and in the presence of others). Consistent with previous work [26], we operationalized testing location as assessments completed at home (versus not), and social environment as assessments that were completed alone versus in the presence of others.

Methods

Participants

Participants were recruited from studies of aging and dementia at the Knight Alzheimer Disease Research Center at Washington University School of Medicine in St. Louis. The Ambulatory Research in Cognition (ARC) study began in March of 2020. ARC is a custom-built smartphone app that assesses cognition with repeated brief assessments up to 4 times per day for one week [13]. Participants were invited to enroll after completing their annual cognitive and clinical assessment and began ARC testing shortly after enrolling. As data collection is still ongoing, we used a data freeze from June 2024 for the current analyses.

For the current analyses, participants were included if they (1) completed at least 10 sessions during their baseline ARC testing to ensure adequate engagement in the study and enough observations in different environments for comparisons and (2) had a clinical assessment (see below) within a year of starting their ARC testing to ensure an accurate classification of cognitive status.

Clinical Assessments

Clinical status was assessed using the Clinical Dementia Rating (CDR) [27]. The CDR rates cognitive and functional performance on a 5-point scale across 6 domains (memory, orientation, judgment and problem solving, community affairs, home and hobbies, and personal care). Participants and a collateral source (a close family member or friend) both underwent semistructured interviews to determine CDR scores, with CDRs of 0 indicating cognitive normality, 0.5 indicating very mild dementia, 1 indicating mild dementia, 2 indicating moderate dementia, and 3 indicating severe dementia. For this study, we grouped participants as either cognitively normal (CDR 0) or diagnosed with very mild dementia (CDR 0.5). The

XSL•FO
RenderX

parent study was designed to characterize the transition from cognitive normality to the very first signs of clinical symptoms of AD; therefore, most participants were cognitively normal (CDR 0), with the final sample consisting of 385 cognitively normal participants and 37 participants with a CDR of 0.5. Of the 37 participants with CDR 0.5, a total of 26 (70%) were clinically diagnosed with AD, and the rest with a dementia of different etiology, including Parkinson disease, Lewy body dementia, or uncertain etiology. CDR assessments were completed 7.64 (SD 7.78) weeks from their ARC assessment.

Smartphone Assessment

Methods for the procedures of ARC are detailed elsewhere, so are only briefly described here (for full details on the ARC platform, see studies by Nicosia et al [13] and Wilks et al [18]). Participants completed all ARC assessments on a smartphone (either their own or a study-provided device). ARC assessments were sent to participants using the native iOS (Apple Inc) or Android (Google LLC) notification systems pseudorandomly. Participants were instructed to complete the assessment as soon as possible within a 2-hour window. Participants completed 3 cognitive tasks (described below) up to 4 times per day over the course of a week. Figure 1 provides screenshots of each task presented on ARC.

Figure 1. Examples of grids, prices, and symbols tests from Ambulatory Research in Cognition (ARC).

Symbols

During this processing speed task, participants were randomly shown 3 pairs of abstract shapes and were asked to select which of 2 possible responses matched 1 of the 3 targets [17]. At each assessment, participants completed 12 trials lasting approximately 20 - 60 seconds. Consistent with our previous work [13,18,28], we analyzed symbols' performance in 2 ways. The first was the median RT of correct trials, which we use to capture differences in processing speed. We also calculated a measure of RT variability, the coefficient of variation (CoV). For both median RT and RT CoV, higher scores reflect poorer performance (ie, slower responding or greater variability).

Prices

This associate memory task presented subjects with 2 phases: a learning phase and a recognition phase. During learning, participants were instructed to learn and remember 10 item-price pairs that were presented on screen for 3 seconds per pair. The items were everyday shopping items (eg, foods or household supplies), and prices were randomly assigned 3-digit prices. During the recognition phase, participants were presented with an item they encountered during learning and 2 prices and were asked to choose which price was originally paired with the item. Each administration of this test requires approximately 60 seconds. The primary dependent measure for this task was the error rate during recognition, such that higher scores indicated poorer recognition.

Grids

In this spatial working memory task, participants were presented with images of three everyday objects (key, smartphone, and pen) on a 5x5 grid. Participants were told to remember the location of each item on the grid. After the encoding phase, participants were given a distractor task (locating Fs among a grid of Es). Following the distractor task, participants were asked to recall the location of each item on a blank grid. Participants completed 2 trials at each session (total time 30 - 40 s). The primary dependent measure for this task was the Euclidean distance for each item. Higher scores indicated that participants placed the items further away from the initially encoded location and suggested worse performance [17].

Current Environment and Social Context

At each ARC session, participants answered several questions about their experiences or situations at the time of the notification. The first question, which we used to operationalize testing location, asked, "Where are you right now?" Participants selected one of the following response options: my home, my work, school, another person's home, vehicle, outside, or other. We categorized participants' responses into either home (if they answered "my home") or away (all other responses).

The second question, which we used to operationalize social context, asked, "Who is with you right now?" Participants could select all that apply from the following options: nobody, partner or spouse, family, friends, coworkers, pet, and other. As above, we categorized participants' responses into either testing alone

XSL•FO
RenderX

(if they answered “nobody”) or not alone (all other responses). These environment and social context categorizations were consistent with a previous study [26]. As displayed in Table 1, most participants completed their tests at home and alone, with few reports in other contexts. As there was little variation within each category, we chose not to treat these as separate variables in analyses. Additionally, there is some debate in the field of EMA on whether “pets” should be counted as alone or not alone. We considered responses of “pets” as not alone, as it is likely that pets might also be a source of distraction for participants during remote cognitive assessments (eg, a dog barking at a passing car might be a salient distraction). The results were nearly identical when including “pet” responses as alone.

Table . Demographics of sample by CDR[a] status. Gender and race were self-reported.

Demographic variables	CDR 0 (n=380)	CDR=0.5 (n=37)	Statistic	*P* value
Age (years), mean (SD)	75.42 (5.93)	76.57 (6.32)	1.07 (42.76)[b]	.29
Gender, n (%)	226 (56.8)	14 (37.8)	5.17 (1)[c]	.02
Education (years), mean (SD)	16.49 (2.42)	16.08 (2.19)	1.08(44.90)[b]	.28
Race, n (%)				
White	322 (84.7)	33 (89.1)		
Black or African American	61 (15.1)	4 (10.8)		
Other	2 (< 1)	0 (0)		
APOE ε4[d] status, n (%)			8.80 (1)[c]	.003
ε4 carrier	129 (33.5)	22 (59.5)		
ε4 noncarrier	256 (66.5)	15 (40.5)		
Sessions complete, mean (SD)	23.22 (4.29)	21.92 (5.40)	1.42 (40.49)[b]	.16
Prices error rate, mean (SD)	0.29 (0.09)	0.37 (0.08)	–5.40 (45.43)[b]	<.001
Grids Euclidean distance, mean (SD)	0.74 (0.26)	0.95 (0.26)	–4.72 (43.23)[b]	<.001
Symbols median RT[e], mean (SD)	3.25 (1.08)	3.98 (1.27)	–3.39 (41.09)[b]	.002
Symbols RT CoV[f], mean (SD)	0.34 (0.08)	0.39 (0.10)	–2.91 (40.21)[b]	.006
Proportion completed at home, mean (SD)	0.80 (0.19)	0.86 (0.15)	–2.19 (48.76)[b]	.03
Proportion completed alone, mean (SD)	0.49 (0.32)	0.43 (0.32)	1.16 (42.93)[b]	.25

[e]RT: reaction time.

[f]CoV: coefficient of variation.

Self-Reported Interruptions

Upon completion of each session, participants were asked if they experienced any interruptions during the testing period. This item was used in additional analyses (described below) to account for sessions where participants were acutely aware of potential distractions.

Analytic Plan

Our primary analyses addressed how the environmental factors affect the relationship between CDR status and performance in remote unsupervised testing. In each linear mixed effects model, the outcome measure was either symbols median RT, symbols CoV, prices error rate, or grids Euclidean distance. We included fixed effects of age at ARC testing, years of education, self-reported gender (male or female), and number of completed sessions (to account for practice effects). We also included a fixed effect term for the proportion of sessions completed at home and the proportion of sessions completed alone to account for between-person differences in the testing location or context. That is, some people might complete more ARC assessments at home, and some might complete more assessments alone

XSL•FO
RenderX

than others. To account for within-person variance, we included a term for the reported location (ie, home or not home; coded 0 and 1, respectively) and social context (ie, alone or not alone; coded 0 and 1, respectively) at each ARC session. We included all 2-way interactions between CDR status, within-person location, and within-person social context, and the higher-order 3-way interaction as fixed effects. These terms allowed us to test the differential impact that environmental distractions had on both cognitively normal older adults and those with very mild dementia. All models included a random intercept for the participant.

In our second set of analyses, we removed sessions where, upon completion of each assessment session, participants reported being interrupted. We tested the hypothesis that if participants were aware of their distractions and reported them, then removing these sessions should greatly reduce or eliminate any effects of location or social context on cognitive performance. Conversely, if location and social context effects are still apparent, then we would demonstrate that environmental distractions impact remote cognitive performance beyond instances in which participants are overtly interrupted.

All mixed-effect models were conducted using R software (version 4.4.0; R Foundation for Statistical Computing) including the *lmer* package [29] and *P* values for mixed-effect models were estimated using the *lmerTest* [30] package. Follow-up comparisons were conducted using *emmeans* [31].

Ethical Considerations

All participants provided informed consent, and all procedures were approved by the Human Research Protections Office at Washington University in St. Louis (IRB# 201907164), and the research was conducted in accordance with the Helsinki Declaration. Participants' data were fully anonymized during the data collection process, and researchers cannot access any identifiable participant information without requesting access to the data via a formal data request to the Knight Alzheimer Disease Research Center Administrative Core. As described in Nicosia et al [13], participants were paid US $0.50 per completed assessment session. Participants also received bonus payments for completing all 4 sessions on any given day (US $1.00 per occurrence, max of US $7.00), completing at least 2 assessments per day for 7 days (US $6.00), and completing at least 21 assessments over 7 days (US $5.00). The maximum compensation possible for one 7-day assessment visit was US $32.00.

Results

Participant Demographics

The final sample consisted of 417 participants (see Table 1). Table 2 provides demographic and ARC task information on the full sample, grouped by clinical status. Participants were highly educated, most self-identified their race as White, and were a majority of females. Adherence was high with participants completing, on average, 23.11 (SD 4.41) out of a possible 28 sessions (82.54% adherence).

Table . Mean (SD) and percentage of testing locations and social contexts reported by participants for both cognitively normal and those with very mild dementia across the week of testing (maximum of 28 sessions).

Question	CDR[a] 0 (n=380)		CDR=0.5 (n=37)

[a]CDR: Clinical Dementia Rating.

XSL•FO
RenderX

As expected, participants with very mild dementia performed worse on the ARC assessments when aggregated across the week of testing. Further, there was a small difference in the proportion of tests completed at home, such that individuals with very mild dementia completed a greater proportion of tests at home compared to cognitively normal participants (n=704, 86% vs n=7131, 81%, respectively). There was no difference between cognitively normal participants and those with very mild dementia in the proportion of tests completed alone. Table 1 provides more detailed information regarding the response frequencies to both the location and social surrounding questions for both cognitively normal participants and those with very mild dementia.

Effects of Testing Location and Social Context

Consistent with our other publications in this sample [13,18,28,32], older age at the ARC assessment predicted worse performance on all ARC measures (Table S1 in Multimedia Appendix 1). Male participants made more errors than females on the prices test but were slightly better at the grids test. More years of education were also associated with better performance on prices and grids (but not symbols). Participants who completed more sessions performed better on grids and had faster processing speed and lower variability over time on symbols indicating evidence of practice effects on these tasks.

As seen in Table 3, neither the proportion of tests completed at home (*ß*'s=–0.131 to 0.072, *P*'s>.31) nor the proportion of tests completed alone (*ß*'s=–0.309 to 0.020, *P*'s>.06) was related to performance on any of the ARC tasks. When considering the session-level effects of testing location, there were no significant effects of testing location on ARC performance. Participants showed similar performance on all ARC measures regardless of testing location: prices (M_{home} 0.327, SE 0.007 vs $M_{\text{not home}}$ 0.354, SE 0.011, t_{9399}=–2.773, *P*=.006, Cohen *d*=–0.06, 95% CI –0.10 to –0.02), grids (M_{home} 0.816, SE 0.02 vs $M_{\text{not home}}$ 0.813, SE 0.03, t_{9217}=–0.118, *P*=.91, *d* < –0.01, 95% CI –0.04 to 0.04), symbols processing speed (M_{home} 3.52, SE 0.09 vs $M_{\text{not home}}$ 3.43, SE 0.10, t_{9399}=1.925, *P*=.054, *d*=0.04, 95% CI 0.00 to 0.08), symbols variability in processing speed (M_{home} 0.361, SE 0.007 vs $M_{\text{not home}}$ 0.372, SE 0.01, t_{9366}=–1.362, *P*=.17, *d*=–0.03, 95% CI –0.07 to 0.01). The main effect on prices performance is significant when calculating the simple effect; however, caution should be used when interpreting this effect, as it is likely driven by the interaction between testing location and social context.

Table . Mixed effect models of the interaction between CDR[a] status, testing location, social context on ARC[b] performance (N=417). Exact *P* values are presented in the text. Models adjusted for covariates, including age, years of education, self-reported gender, and number of completed sessions. Full model output is provided Table S1 in Multimedia Appendix 1.

This was also largely the case for session-level effects of social context. Participants showed similar performance, regardless of social context, on prices (M_{alone} 0.336, SE 0.01 vs $M_{\text{not alone}}$ 0.345, SE 0.009, t_{9504}=–0.871, *P*=.38, *d*=–0.02, 95% CI –0.06 to 0.02]), grids (M_{alone} 0.755, SE 0.03 vs $M_{\text{not alone}}$ 0.874, SE 0.03, t_{9333}=–4.398, *P*<.001, *d*=–0.09, 95% CI –0.13 to –0.05), and symbols processing speed (M_{alone} 3.43, SE 0.10 vs $M_{\text{not alone}}$ 3.52, SE 0.09, t_{9223}=–1.878, *P*=.06, *d*=–0.04, 95% CI –0.08 to

XSL•FO
RenderX

0.00). Again, this seemingly large effect is likely driven by higher-order interactions, and so caution should be used when interpreting this effect.

However, there was a significant effect on the variability measure from the symbols task, such that when participants completed sessions in the presence of others (mean 0.377, SE 0.008), they demonstrated increased variability in RTs on the symbols task compared to when they completed sessions alone (mean 0.356, SE 0.009; t_{9469}=–2.563, P=.04, d=–0.05, 95% CI –0.09 to –0.01).

Performance on 3 ARC measures was significantly impacted by both CDR status and testing location or social context (ie, significant 2-way interactions; Table 3). For grid performance, cognitively normal older adults performed better when they completed tests at home compared to when they completed tests away from home (M_{home} 0.714, SE 0.01 vs $M_{not\ home}$ 0.755, SE 0.02, t_{9036}=–3.317, P=.001). However, older adults with very mild dementia did not differ in their grids performance in different testing environments (M_{home} 0.918, SE 0.04 vs $M_{not\ home}$ 0.871, SE 0.06, t_{9036}=–3.317, P=.001). For symbols processing speed, cognitively normal older adults did not differ in either testing location (M_{home} 3.22, SE 0.05 vs $M_{not\ home}$ 3.23, SE 0.06, t_{9152}=–0.157, P=.88). However, older adults with very mild dementia showed a significant, albeit small, difference in processing speed based on their testing location (M_{home} 3.81, SE 0.17) vs $M_{not\ home}$ 3.63, SE 0.19, t_{9254}=0.925, P=.36).

As for social context, there was a significant interaction with CDR status on RT variability on the symbols task. When cognitively normal participants completed the test alone, they were significantly less variable compared to when they completed the tests in the presence of others (M_{alone} 0.337, SE 0.004 vs $M_{not\ alone}$ 0.346, SE 0.05, t_{9261}=–4.650, P=.02). This effect was larger for participants with very mild dementia who completed tests (M_{alone} 0.375, SE 0.02 vs $M_{not\ alone}$ 0.409, SE 0.01, t_{9510}=–2.085, P=.04).

Finally, across all participants, there was evidence that the combination of taking tests away from home and in the presence of others significantly impacted performance on prices and grids. Specifically, when tests were taken in the most suboptimal locations (ie, away from home and in the presence of others), participants, on average, made significantly more errors on prices (mean 0.359, SE 0.01) compared to when they completed the test in “optimal” contexts (ie, at home and alone; mean 0.323, SE 0.008; t_{9535}=–3.218, P=.001). This was also evident for grids as participants were, on average, worse when completing both away from home and in the presence of others (mean 0.917, SE 0.03) compared to when they completed tests at home and alone (mean 0.801, SE 0.02; t_{9170}=2.099, P=.04).

These lower-order interactions were qualified by 3-way interactions on grids (Figure 2) and symbols median RT (Figure 3). Decomposing the interaction suggested that when those with very mild dementia completed tests both away from home and in the presence of others, they had an average grids score of 1.049 (SE 0.06), which was significantly higher than when they completed tests at home and alone (mean 0.894, SE 0.05; t_{9399}=–2.754, P=.006, d=–0.05, 95% CI –0.09 to –0.01]). For processing speed, however, the difference between the optimal (mean 3.85 s, SE 0.18) and suboptimal (mean 3.83 s, SE 0.19) environments was not statistically significant (P=.88).

Removing Interrupted Sessions

Interruptions were reported on 1194 of 9633 completed sessions (approximately 12% of all sessions). Removing these sessions resulted in an overall similar pattern of effects (Table 4), albeit an attenuated effect. The previously described 3-way interactions between CDR status, testing location, and social context were still evident on the grids and symbols median RT. Thus, even after removing sessions during which participants reported experiencing an overt interruption, the effects of environmental distractions were still apparent, especially for those with very mild dementia.

Discussion

Principal Findings

The overall results of this study illustrate the importance of considering environmental factors in remote studies of cognition where participants may complete assessments in different locations and social contexts. The effect sizes of distractions on cognition were generally small in magnitude and likely would not invalidate remote testing, but distractions may be most important to consider in populations where cognitive impairment is evident.

Across participants, in-the-moment effects of testing location and social context were evident on measures of associative memory and visual working memory but not processing speed. When participants completed tests in the most distracting environments (both away from home and around others), they performed worse. However, for cognitively normal older adults, the impacts of these environmental factors were minimal, if at all apparent. On the other hand, participants with very mild dementia were the most sensitive to distractions, specifically when completing tests away from their homes and in the presence of others. These findings indicate that an inability to maintain performance in the face of distractions may be a novel indicator of very early neurodegenerative disease and emphasize the need for remote studies to carefully consider testing environments. While a strength of EMA is that it can allow for the measurement of cognition in a variety of environments and situations, the potential for distractions should at least be evaluated and, if necessary, included in statistical models. This is particularly true for studies enrolling individuals with very mild dementia symptoms.

The descriptive results from this study revealed that older adult participants engaged in remote cognitive assessments outside of their homes during 81% of assessments and in the company of others during 44% of assessments, both of which are environments that are likely to produce distractions. Our estimates of tests completed in these environments closely match that of Cerino et al [26], who found that older adults in their study reported testing at home in 78% of assessments and testing alone for 44%. Interestingly, Cerino et al [26] reported that participants with MCI completed slightly more tests at home compared to cognitively normal participants (P=.08). Results from our sample replicated these patterns as we found a significant difference between the frequency of tests completed at home between cognitively normal participants and those with a CDR of 0.5, indicating the presence of a very mild dementia. A CDR of 0.5 can be considered very similar to a classification of MCI [33,34]. This suggests that older adults with cognitive difficulties may spend more time at home or may avoid taking tests outside of the home, perhaps due to the impacts of environmental distractions.

Participants in our study have the option to report if they experienced a significant interruption during testing. Interrupted sessions were not uncommon for our participants, as nearly 12% of sessions were reported as having some form of interruption. Interestingly, the effects of environment, while

XSL•FO
RenderX

reduced, remained significant after removing sessions where participants specifically flagged interruptions. Thus, aspects of environmental context that may not rise to the level of an overt interruption may have deleterious effects on cognition, and these effects appear to be magnified in those with dementia symptoms.

Implications

The results of this study have several implications for EMA studies of cognition in older adults at risk for AD. First, the descriptive results showed that a large proportion of assessments are completed at home. Thus, it is possible that we are not fully sampling participants' everyday contexts as well as we can or that participants are more likely to only take tests when they are at home. Due to the age of our cohort, most of our participants are retired and therefore may spend most of their time at home. Although overall adherence was high in this study, it is also possible that our participants chose not to complete tests when they were away from home, which may have led to an underestimation of the effects we observed. In other words, it might appear that older adults enrolled in EMA studies prefer home environments over completing tests "in the wild." While EMA has a clear strength of being able to capture cognition (and other processes) in different environments, future studies should be aware that EMA studies of cognition in older adults might have limited sampling outside the home or in different social contexts because participants tend to complete assessments in minimally distracting and more controlled environments.

A second important implication of this work stems from our findings regarding the impact of environmental factors on cognition. Our participants frequently completed assessments in environments that could be considered distracting. Additionally, participants reported overt interruptions much more frequently than anticipated, during 12% of testing occasions. However, even after accounting for testing location, social context, and overt interruptions, the effects of environmental distractions had very little impact on performance for cognitively normal older adults. However, for those experiencing the earliest symptoms of dementia—in what could be considered the MCI stage, the effects of distractions were stronger, although still at a small effect size. EMA studies should routinely sample for location and social context and allow participants to report interruptions so that these can be included in statistical models. This is particularly important for studies that enroll participants with cognitive impairment.

These findings also have implications for understanding how distractions and interruptions impact functioning during everyday cognitively demanding tasks. Everyday tasks such as driving, managing money and medications, preparing meals, and general housekeeping require several different processes and are important for maintaining functional independence [35,36]. Being interrupted or distracted during these activities might lead to severe outcomes such as accidents or taking the wrong medicine. Our results suggest that techniques or interventions that teach individuals how to minimize distractions, especially during cognitively demanding tasks, might be useful to minimize adverse outcomes.

Limitations and Future Directions

While the results of this study are intriguing and provide insight into the impact of environmental distractions on unsupervised cognitive assessments in older adults, it is worth noting some limitations. The sample used in this study consisted of older adults who are largely retired and therefore, may spend more time at home (which was reflected in the high proportion of tests completed at home, roughly 80%). This also likely contributed to the large standard errors for our estimates, especially among older adults with very mild dementia. Examining these effects in a cohort of younger participants, who are likely still employed and dealing with more day-to-day activities that require them to be out of the house, may more effectively examine the impacts of environmental distractions.

This study also relied on self-reports of testing location and social context, which may not capture objective levels of environmental distractions. Future research could consider incorporating continuous passive monitoring of environmental factors to better contextualize the effects. For example, GPS tracking could be used to detect differences in cognitive performance as a function of participants' distance from home. Likewise, passive monitoring of noise levels from participants' testing devices could be used to objectively quantify distractions in their environment. Additionally, our question regarding "interruptions" was not open-ended, and so we could not capture differences in the types of interruptions participants experienced. For example, notifications from other applications that popped up during the testing may differ in their distraction and impact on performance compared to interruptions from a family member calling for the participant. Future research should consider gathering more detailed information about the types of distractions or interruptions experienced by participants. Finally, this study focused only on the baseline assessment from ARC and how participants' self-reported environmental factors were related to cognitive performance. Future work could investigate if there are longitudinal changes in participants' environmental contexts (frequency of testing at home or alone) and how that is related to cognitive changes over time.

Conclusions

Unsupervised EMA cognitive assessments are a unique data collection method that more closely represents how participants use cognition in their daily lives, but tests are often completed in distracting environments. Our results suggest that effects of environmental distractions, such as overt interruptions during testing and the location and social context in which tests are completed can have small impacts on cognition, and these effects were most apparent for older adults showing early symptoms of dementia. The effect sizes attributable to distractions in cognitively normal participants were very small and are not likely to threaten the validity or reliability of cognitive testing acquired in natural environments on mobile devices; thus, our results continue to support the validity of unsupervised ambulatory cognitive assessments.

Abstract

Background: Ecological momentary assessment (EMA) offers an effective method to collect frequent, real-time data on an individual's well-being. However, challenges exist in response consistency, completeness, and accuracy.

Objective: This study examines EMA response patterns and their relationship with sensed behavior for data collected from diverse studies. We hypothesize that EMA response rate (RR) will vary with prompt time of day, number of questions, and behavior context. In addition, we postulate that response quality will decrease over the study duration and that relationships will exist between EMA responses, participant demographics, behavior context, and study purpose.

Methods: Data from 454 participants in 9 clinical studies were analyzed, comprising 146,753 EMA mobile prompts over study durations ranging from 2 weeks to 16 months. Concurrently, sensor data were collected using smartwatch or smart home sensors. Digital markers, such as activity level, time spent at home, and proximity to activity transitions (change points), were extracted to provide context for the EMA responses. All studies used the same data collection software and EMA interface but varied in participant groups, study length, and the number of EMA questions and tasks. We analyzed RR, completeness, quality, alignment with sensor-observed behavior, impact of study design, and ability to model the series of responses.

Results: The average RR was 79.95%. Of those prompts that received a response, the proportion of fully completed response and task sessions was 88.37%. Participants were most responsive in the evening (82.31%) and on weekdays (80.43%), although results varied by study demographics. While overall RRs were similar for weekday and weekend prompts, older adults were more responsive during the week (an increase of 0.27), whereas younger adults responded less during the week (a decrease of 3.25). RR was negatively correlated with the number of EMA questions (r=−0.433, P<.001). Additional correlations were observed between RR and sensor-detected activity level (r=0.045, P<.001), time spent at home (r=0.174, P<.001), and proximity to change points (r=0.124, P<.001). Response quality showed a decline over time, with careless responses increasing by 0.022 (P<.001) and response variance decreasing by 0.363 (P<.001). The within-study dynamic time warping distance between response sequences averaged 14.141 (SD 11.957), compared with the 33.246 (SD 4.971) between-study average distance. ARIMA (Autoregressive Integrated Moving Average) models fit the aggregated time series with high log-likelihood values, indicating strong model fit with low complexity.

Conclusions: EMA response patterns are significantly influenced by participant demographics and study parameters. Tailoring EMA prompt strategies to specific participant characteristics can improve RRs and quality. Findings from this analysis suggest that timing EMA prompts close to detected activity transitions and minimizing the duration of EMA interactions may improve RR. Similarly, strategies such as gamification may be introduced to maintain participant engagement and retain response variance.

Introduction

Background

Ecological momentary assessment (EMA), also known as experience sampling or in situ (situated) self-reporting, is a powerful method for capturing real-time insights into an individual's health and well-being. Leveraging the convenience and ubiquity of mobile devices, EMA has been particularly effective in longitudinally monitoring conditions such as depression and mental well-being [1,2], mobility [3], physical activity [4], and fatigue [5].

The strength of EMA lies in its ability to minimize recall bias [6,7] and provide more fine-grained longitudinal data compared with traditional observation methods or retrospective reporting [8,9]. Participants can answer questions without traveling to a research lab, reducing a burden that is already great for individuals with Alzheimer disease and related dementias. Data collected through EMA reveal both within-day and between-day fluctuations in health and well-being [10], laying a foundation for timely, in-the-moment interventions. Furthermore, these responses provide a rich source of patient-reported outcome measures. When combined with objective, sensor-based data representing digital phenotypes, EMA enables the comparison of digital behavior markers with self-reported data.

Despite these advantages, EMA implementation faces challenges, especially in the variability, completeness, and accuracy of participant responses to prompts. Factors such as distraction, self-awareness, boredom, time of day, and interruption burden [11] can impact participant responses. Addressing these issues is essential for maintaining the integrity of research findings. Furthermore, the design of notification strategies may dramatically impact response compliance and quality [12,13].

In this paper, we conduct an examination of EMA response completeness and quality across a spectrum of settings. By leveraging data from multiple studies, we enhance the robustness and generalizability of our conclusions. This broad approach also allows us to consider variables previously unexplored in EMA research. By correlating EMA responses with sensor-derived biomarkers, we will better understand the contextual factors influencing participant engagement with EMA prompts. The findings from this study will inform refinements in EMA methodology and guide future research to improve the reliability of EMA-derived data and the effectiveness of just-in-time interventions.

Previous Work

In-the-moment sampling builds a foundation for designing effective just-in-time interventions [14]. McDevitt-Murphy et al [15] used such a technique to combat anxiety by prompting individuals to write about their worries and initiate physical activity. Similarly, Mair et al [16] found such interventions improved physical activity in older adults, while Perski et al [17] constructed a technology-driven in-the-moment intervention to reduce substance abuse and promote healthy behaviors. Brenner and Ben-Zeen [18] found that letting individuals see the difference between their predicted future EMA reports of mood and actual EMA responses improved the effectiveness of their intervention.

EMA benefits must be weighed with the cost of an increased interruption load. Frequent requests for self-report often lower responsiveness [13]. Many factors have been considered that impact responsiveness. These include the impact of EMA prompts while a person is performing physical activities [19,20] or activities that require concentration [21]. Jeong et al [22] and Rintala et al [23] studied the relationship between a person's location (eg, at home vs away from home) and responsiveness, while Pizza et al [24] and Ziesemer et al [25] found that engagement in social activity was an important consideration. Several studies consider whether prompt time of day influences likelihood of response [12,26-30]. Aminikhanghahi et al [31] found that prompting during transitions between activities improved participant responsiveness. Recently, investigators observed a relationship between the complexity of an EMA interaction and responsiveness [32]. They responded by shortening the questions [33], simplifying the interface [21], and making use of voice input [34].

Researchers also observed that the quality of responses decreases over time [35], becoming bistable or skewed [36], more habitual [37], and less variable [38-40]. Such trends threaten the reliability of research results. For example, Verbeij et al [41] observed decreased convergent validity between reported and objective social media use over 3 weeks of reporting [41].

These findings allow researchers to better design EMA-based studies and control for such factors in their analysis. One difficulty, though, is that some of the findings are contradictory. While Jeong et al [22], McMillan et al [27] and Ziesemer et al [25] reported higher response rates (RRs) when a person was alone, Pizza et al [24] observed no significant impact of social setting and Ponnada et al [26] reported a higher RR when a person was with family or friends. Regarding time of day, some studies found that participants responded more often during afternoons and evenings [26,28,42], while others [43,44] observed more responses early in the day. Khanshan et al [19] found RRs to be higher while participants were active, while Boukhechba et al [29] found higher activity was correlated with missing more responses. These discrepancies may indicate the influence of other population and study parameters. We address the need to consider these factors by performing a multistudy analysis.

Furthermore, Wrzus and Neubauer [45] emphasized the need to employ sensors in the understanding of the interplay between participant behavior, EMA responsiveness, and response quality. Stach et al [46] observe that mobile notification responsiveness is influenced not only by the app delivering the notification but also by user demographics. In our analysis, we leveraged continuously collected sensor data to examine the relationship between EMA responses (as patient-reported outcome measures), digital markers extracted from sensor data (digital phenotyping), and demographics across multiple studies. This comprehensive approach enabled us to uncover patterns and develop recommendations for optimizing EMA methodologies.

Study Goal and Hypotheses

In this study, we performed statistical analysis of EMA responses and sensor data from 9 clinical studies. The overall goal was to provide insights into EMA response patterns that can be used to design and improve future in-the-moment monitoring and intervention studies. We analyzed data from 454 participants to validate the following hypotheses:

First, EMA RR will vary with prompt time of day, number of questions, and sensor-observed activity.

Second, EMA response quality will decrease as a function of the number of days that have elapsed in the study.

Third, both RR and response quality will be impacted by a participant's behavior context, as modeled by markers extracted from mobile data.

Fourth, differences in EMA RRs and response patterns will exist between studies, influenced by participant demographics (ie, participant age) and study purpose (ie, cognitive intervention vs observational).

Methods

EMA Studies

Daily EMA responses were collected between October 2015 and December 2023 for a total of 454 participants across 9 distinct studies. Reporting of the EMA steps is consistent with the STROBE CREMAS (Strengthening the Reporting of Observational Studies in Epidemiology Checklist for Reporting Ecological Momentary Assessment Studies) guidelines [47]. In each study, participants received prompts to answer EMA questions using an in-house app running on a smartwatch or tablet. Participants were trained on how to interact with the app by a research assistant and completed practice prompts and tasks before data collection commenced.

The EMA prompts were randomly distributed within predefined time blocks throughout the day. We adjusted these time blocks when necessary to fit participant schedules. When a prompt was issued, an audio tone was played to alert the participant. The participant would then read the question and select their response from options on a mobile screen. If there was no response within 5 minutes, the prompt was reissued, up to a maximum of 5 attempts (2 attempts for dyad study). If the participant still did not respond, we recorded this as a nonresponse and did not issue further prompts until the next designated time block. Parameters for the studies are summarized in Table 1. In total, these comprise 145,853 EMA prompts with 115,283 sets of responses.

[f]Audio prompt to describe what tasks were assisted by memory strategies that day.

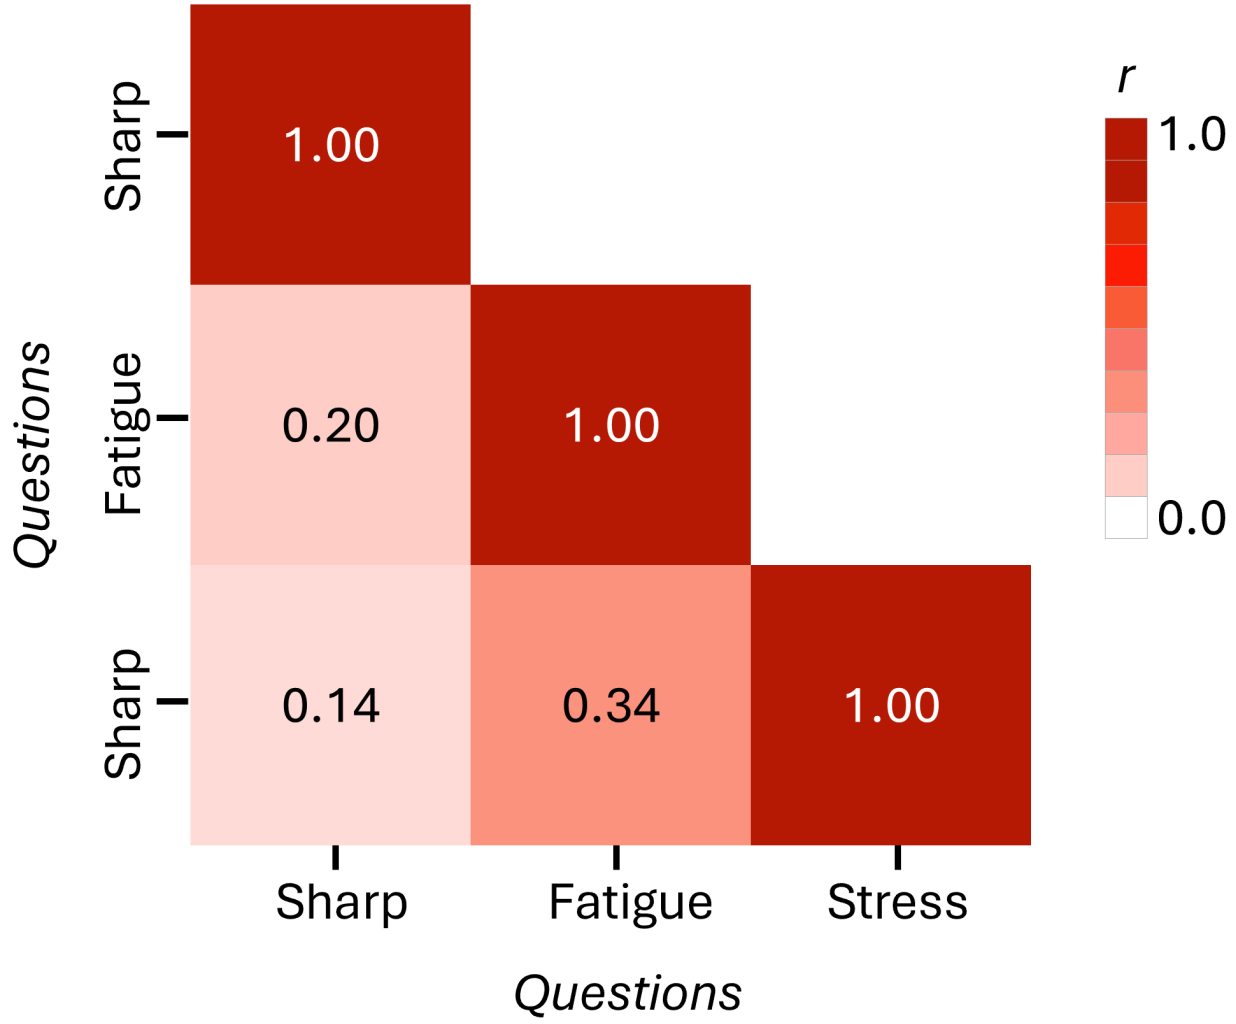
Well-being has been defined multiple ways in the literature [48-51]. Many studies rely on 1-time questionnaires, like the Satisfaction With Life Scale [52], to measure well-being at a single time point. However, well-being is dynamic, fluctuating

XSL•FO
RenderX

across different times and contexts [53]. EMA allows us to capture individuals' daily behaviors within their natural environments alongside real-time self-reports on well-being. In this analysis, we focus on three dimensions of well-being: mental sharpness, physical fatigue, and stress.

Each study included subjective questions that examined (1) Qsharp = the person's mental sharpness, (2) Qfatigue = the person's physical fatigue, and (3) Qstress = the person's level of stress, all self-reported and relevant to the point in time (eg, immediately and up to the previous 2 h) when they received the query. The Likert scales varied between studies, so we normalized the values to a 1 - 5 range. Where needed, we inverted responses for negative questions so that a higher-valued response is more positive in each case (eg, Qsharp=5 indicates feeling greater amounts of mental sharpness; Qfatigue=5 indicates feeling less physically fatigued; Qstress=5 indicates feeling less stressed. Multimedia Appendix 1 plots the relative frequency of each response to the 3 question categories. The studies are ordered primarily by the cognitive health status of participants and secondarily by age. As the plots demonstrate, most of the responses are high but do vary among studies. Notably, the similarity in response between stress and fatigue is higher than other question pairs. This finding is consistent with the correlation that exists between responses to the 3 questions, shown in Figure 1.

Figure 1. Correlation between participant responses to the three question types.



Ethical Considerations

These studies were reviewed and approved by the institutional review boards (IRB protocol 14460) at Washington State University and the University of California at Davis (No. 19784). To participate in any of the studies, participants needed to understand English and sign an informed consent; each person received compensation between US $20 and US $125 for their participation. All data were anonymized before performing analyses.

Statistical Analysis

RR and Quality

We conducted statistical analyses on the data to examine RR, completeness, and quality for each participant and study. Our app records each time a prompt is delivered to the participant. From these records, we calculate RR as the ratio of occurrences when a participant answered at least 1 question to the total number of prompts. The analysis also considers the prompt time of day (morning before 12 PM, afternoon between 12 PM and 5 PM, and evening after 5 PM), day of week, study duration,

XSL•FO
RenderX

and number of questions per prompt. Researchers suggest that user demographics may impact preference for EMA delivery strategies [21]. We examine this factor by considering differences among the studies and between the set of studies involving older adults (aged 50 y or older) and those involving younger adults.

Response completeness reflects the percentage of questions that were answered for the occasions when the participant responded. We excluded nonquestion tasks, such as daily *n*-back shape tests (all but dyad) and audio descriptions of the day's activities (func, mn, cs, dyad, gsur1, and gsur2). Rather than impute missing values, analysis of EMA-reported values only considers completed responses.

Response quality measures habituation that may occur over the duration of the study, resulting in less response variance and state awareness. As reported elsewhere [54-56], we quantified careless responses as the percent responses that fall near (within 0.2) each participant's mode response and also calculated response variance. Changes in response quality may occur over the course of the study as a motivation to provide high-quality responses wanes. Thus, we computed the change in variation and careless responses between the first and second half of the study for each participant.

To gather sensor-derived behavior context, we collected continuous sensor data from Apple watches for 95 participants in the bb study and all participants from the dyad, func, cs, mn, mc, sh, gsur1, and gsur2 studies. In the ihs study, we collected data from ambient sensors installed in participant homes. The smartwatches collected acceleration and rotation readings at 10 Hz and recorded location (latitude, longitude, and altitude) every 5 minutes, or more frequently when movement exceeded a baseline. Data were stored on the watch, encrypted, and downloaded to a password-protected server when the watches were returned. From the raw location data, we defined the participant's home as the location visited most often between 2 AM and 9 AM. We then calculated the distance and bearing from home for each location. Behavior context features were defined as "activity level" (total acceleration) and time "at home" (fraction of time spent at home), calculated for 30 minutes ending at the time the participant provides an EMA response. The data collection app was developed in-house using Swift. Collecting data at these rates ensured 1 full day of data on a single charge.

For studies collecting data only during the day (Table 1), participants wore the watch on their nondominant arm during the day and charged it at night. In studies collecting both day and night data, participants were given 2 watches—one worn during the day and charged at night, and the other worn at night and charged during the day. In the smart home study, EMA responses were reported using a tablet; in all other studies, they were reported via the smartwatch.

In the smart home study, 2 - 4 sensors were placed in each room. These were either passive infrared motion sensors with an ambient light sensor or magnetic door sensors with an ambient temperature sensor. Motion sensors detected movement, providing location data within the home. Activity level was estimated by counting motion sensor readings. If an external door was opened and closed, followed by at least 5 minutes of no motion sensor activity, the participant was designated as out of home. The "at home" context quantified the fraction of time spent at home in the 30 minutes before an EMA response.

Another context feature was proximity to a change point. A change point occurs when there is a shift in the underlying process of a time series, such as transitioning from one activity to another. In an earlier work by Aminikhanghahi et al [57], we designed an algorithm to detect these points from continuous sensor data and found that interacting with participants during these times improved RRs and task success. We used the same method here to determine proximity to a change point.

We calculated correlations between the 3 context features (activity level, at home, and change point) and response compliance. Here, a lack of response to a particular prompt is assigned a "compliance" value of 0.0, a complete response is assigned a value of 1.0, and a partial response (some questions answered, some not) is assigned in the range 0.0 - 1.0, corresponding to the relative number of questions that were answered.

Study Differences

In this analysis, we selected 9 studies as the basis for comparing EMA delivery strategies and responses. The selection was based on the consistency of the technical data collection tools and hardware, which minimized the influence of these factors on the results. A single software interface was used to deliver EMA prompts across all studies, and the same app collected sensor data in all smartwatch studies, following a protocol similar to that used in the smart home study. Context features were extracted uniformly from the sensor data across datasets.

Participants in all studies were instructed to perform their normal daily routines without changing their behavior to accommodate the data collection. This consistency allowed us to focus on the differences that existed between the settings. Specifically, the participant groups differed across studies in terms of location (4 regions within the United States), age, and cognitive health, supporting generalization of the findings to other EMA studies. The studies also differed in length and number of EMA questions and tasks. These differences represent the focus of our analysis.

We examined differences in EMA response dynamics across the 9 studies. Our approach is twofold; we report results for each study individually and collectively and analyze differences in EMA responses within and between these studies. This technique will allow us to examine the extent to which EMA response patterns differ between studies, using within-study changes as a comparison baseline. We use dynamic time warping (DTW) as a similarity measure because the technique measures similarity between time series that differ in length as well as values. In the case of the Qsharp question, we also visually compare responses over time for studies that focus on cognitive health support for older adults (bb and mn) with observational studies involving cognitively healthy adults (dyad, gsur1, and gsur2).

To deepen the analysis, we fit ARIMA (Autoregressive Integrated Moving Average) models to the aggregated EMA

responses for each question type. The mean response was computed across participants for the first 48 responses, producing a single representative time series. The resulting model parameters indicated how well the shape of responses over time could be modeled.

Results

RR Findings

RR across all participants was 79.95%. This is within 0.76% of the 79.19% average rate Wrzus and Neubauer [45] reported in a survey of 417 EMA studies. Among the prompts that received participant responses, the response completion rate was 88.37%.

Figure 2 plots RR for the studies, ordered from largest to smallest. Response variance is quite different among the studies. Notably, response variance increased as the mean RR decreased. Table 2 shows the overall most popular time of day for responding to EMA prompts. However, these results vary based on participant age. Only considering studies with older adults (age 50 y or older), participants were more responsive in the evening than morning (by 3.95) or afternoon (by 3.58). In contrast, younger adult RR remained fairly uniform throughout the day, with afternoon showing the highest rate. Weekday and weekend prompts yielded very similar RR overall (a difference of 0.04). However, this varied by study and age group. Specifically, while weekend response was higher by 3.25 for younger adults, the rate decreased for older adults by 0.27. These findings highlight the role that participant demographics play in understanding EMA responsiveness; prompt time alone may not be a strong indicator of responsiveness.

Figure 2. Response rate mean and variance. Rates are shown in sorted order; variance is multiplied by 10 to align the plots.

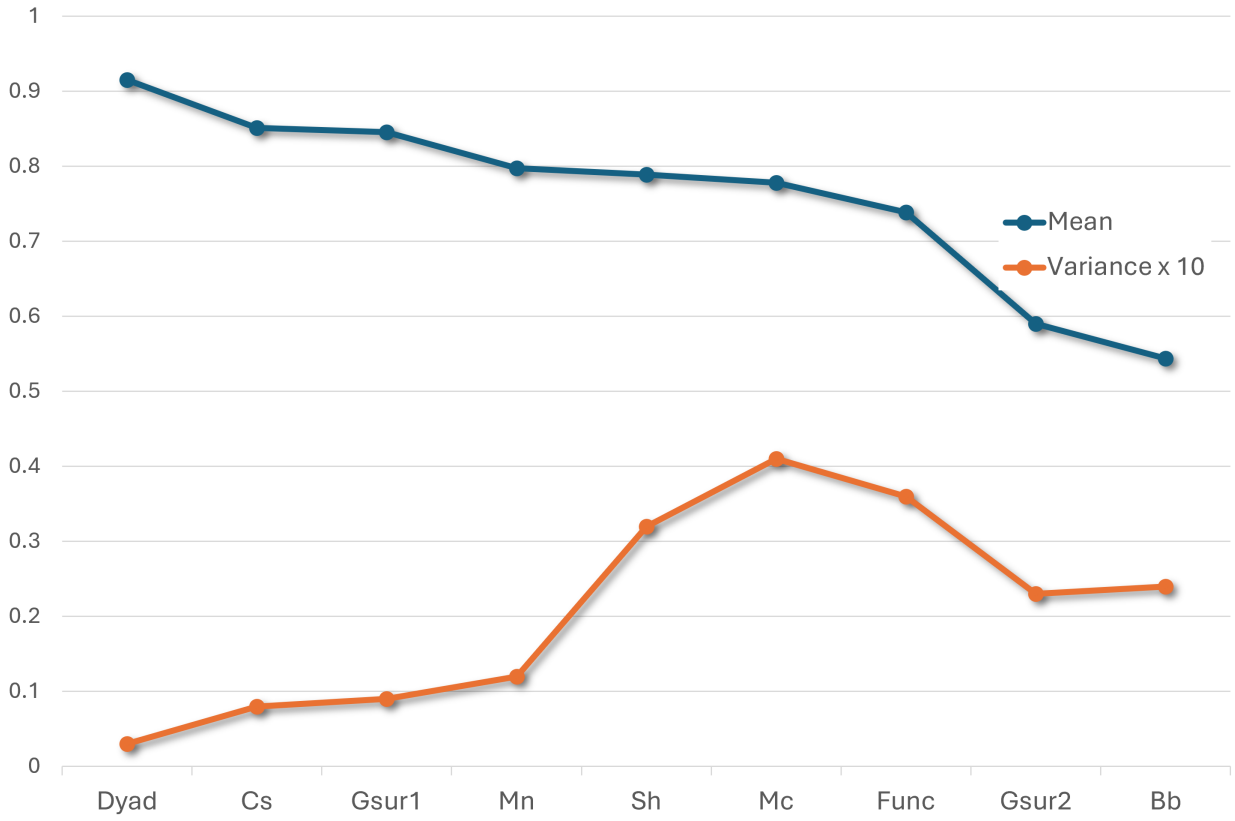

Table . Response rate (%) based on prompt time of day and day of week.

Time		Overall response rate (%)	Response rate among older adults (%)	Response rate among younger adults (%)
Time of day				
	Morning	79.02	80.60	64.86
	Afternoon	79.08	80.97	64.97
	Evening	82.31	84.55	64.45
Day of week				
	Weekday	80.43	82.46	63.93
	Weekend	80.39	82.19	67.18

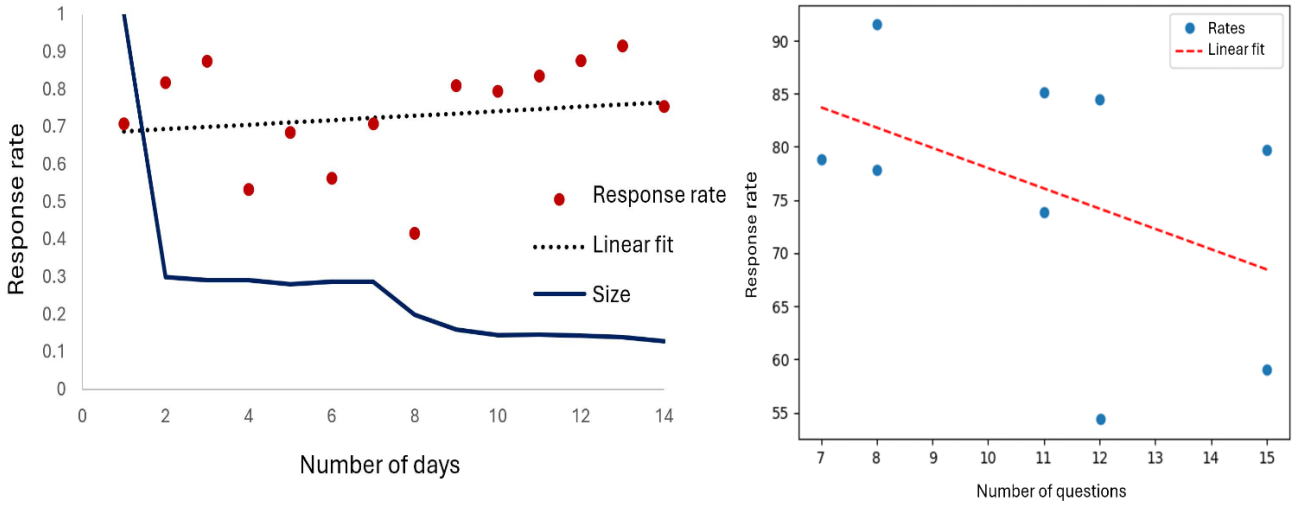
Figure 3 (left) plots EMA RR as a function of the number of days that elapsed since the beginning of the study for each participant. The linear fit line has a positive slope of 0.078, indicating that the duration does not negatively impact RR. At the same time, the fraction of participants still collecting data is much smaller at the end of this time span. A nonsignificant small positive correlation exists between the study duration and RR (r=0.100, P=.29). This may be due to the EMA prompts becoming more integrated into the participant's routine and their gaining familiarity with the questions and methods of responding.

Figure 3 (right) shows RR as a function of the number of questions asked at the EMA prompt, together with the fitted line. Correlation between the number of questions asked during an EMA prompt and RR is moderate and negative (r=−0.433, P<.001). The line fitting this trend has a slope of −1.90. This finding is consistent with previous work indicating that individuals are less likely to respond when each EMA prompt requires a large time interruption and corresponding task burden [37].

Figure 3. Left: response rate based on number of study days and relative sample size at that time point (fraction of original sample). Right: response rate as a function of the number of questions asked at the EMA prompt.



Response Quality

Table 3 summarizes participant responses and response quality. The average response value across all studies is relatively high, as is the percentage of responses near the mode. There was a noticeable shift toward response uniformity over time, evidenced by a significant increase in carelessness and decrease in variance. Results from individual studies are shown in Multimedia Appendix 2. Although the earlier analysis showed that RR did not decline over the study, the increase in careless responses and decrease in variance indicates a possible increase in habitual responses to EMA questions [37] as participants got bored or felt time pressure to respond to EMA notifications. Some studies inserted a break of 1+ months during data collection. For these studies, we calculated changes within the period before the break and the period after the break. The trends remain the same: carelessness increased and variance decreased over time. These changes are smaller, possibly due to the decreased time (typically 7 d) being examined.

Table . Summary of response averages and quality.

Metric	Value
Qsharp average response (variance)	3.524 (1.072)
Qfatigue average response (variance)	4.157 (0.758)
Qstress average response (variance)	4.432 (0.652)
Careless %	55.71
Interparticipant variance	0.611
Carelessness change	0.22 (*P*<.001)
Variance change	−0.363 (*P*<.001)
Prebreak carelessness change[a]	0.04 (*P*<.001)
Prebreak variance change[a]	−0.082 (*P*<.001)
Postbreak carelessness change[a]	0.09 (*P*<.001)
Postbreak variance change[a]	−0.329 (*P*<.001)

[a]func, mn, bb, and sh studies.

Alignment With Sensor-Observed Behavior

Relationships between RRs and sensor-detected states were also examined. A correlation of r=0.045 (P<.001) exists between RR and activity level over the previous 30 minutes, r=0.174 (P<.001) between RR and time spent at home over the previous 30 minutes, and r=0.124 (P<.001) between RR and nearness to detected activity change points. Multimedia Appendix 3 summarizes the results for individual studies.

RR correlation with activity level is positive but small. This finding, considered together with the discrepancies observed in previous studies [19,29], may indicate that the nature of the person's activity needs to be examined to understand the impact on prompt response. Correlations with at-home time and change points were larger, although still small. Individuals may not want to interrupt their activities, particularly in social situations, to answer lengthy EMA questions. In these contexts, they may ignore the prompt and wait until the next time block. As with our previous study examining RR and change points in smart homes [31], we observe that prompting near a change point improve responsiveness for all studies.

EMA Differences Between Studies

Results from the previous analyses reveal that differences in EMA response compliance and quality may occur as a function of study and participant characteristics. Here, we delve further into EMA response differences between studies. First, we measure the distance (inverse similarity) between EMA time series using DTW. Across all studies and participants, the average within-study DTW distance was 14.141 (SD 11.957) overall (sharp 15.357, highest dyad=36.111, lowest bb=11.486; fatigue 15.014, highest dyad=36.489, lowest bb=10.299; stress 12.051; and highest dyad=33.511, lowest bb=7.069).

In contrast, the average between-study DTW distance was 33.246 (SD 4.971) overall (sharp 44.848, highest dyad/bb=81.448, lowest mc/bb=16.262; fatigue 29.365, highest mn/func=54.927, lowest mc/bb=12.434; stress 25.526, highest mn/func=52.05, lowest mc/bb=8.759). This represents a 135% distance increase over the within-study distances. The large increase indicates that while response variability exists between participants, an even larger difference exists between studies. Table 1 lists some of the parameters that may influence these differences; further investigation may identify more contributing factors.

Plots of the aggregated EMA responses for the 3 question types are shown in Figure 4. The shapes of the aggregated time series are different between the 3 question categories. The Qsharp trend is consistently positive, while there are less noticeable trends for the other questions.

Because 2 of the studies (bb and mn) represent interventions, we examine differences in the response trends between these studies and the 2 observational studies with cognitively healthy older adults (dyad and cs). Aggregated over all 9 studies, the slope of the response fitted line is 0.018, with a y-intercept of 3.181. The fitted line for the intervention studies has a slope of 0.023 (an increase of 0.005) and y-intercept of 2.745 (a decrease of 0.436), while for observational studies with cognitively healthy older adults, the fitted line has a slope of 0.005 (a decrease of 0.013) and y-intercept of 3.449 (an increase of 0.614). Here, we observe that older adults receiving interventions start at a lower self-reported mentally sharp value but indicate that the sharpness increases over the study duration. In comparison, the cognitively healthy adults start at a higher sharp reported value and have a lesser amount of change in reported values during the study.

RenderX

Figure 4. Aggregated ecological momentary assessment response sequences for (top left) Qsharp, (top middle) Qfatigue, and (top right) Qstress. Aggregated ecological momentary assessment responses to the Qsharp question for (bottom left) cognitive health intervention studies and (bottom right) cognitively healthy adult studies. All Qsharp plots are accompanied by a linear fit line.

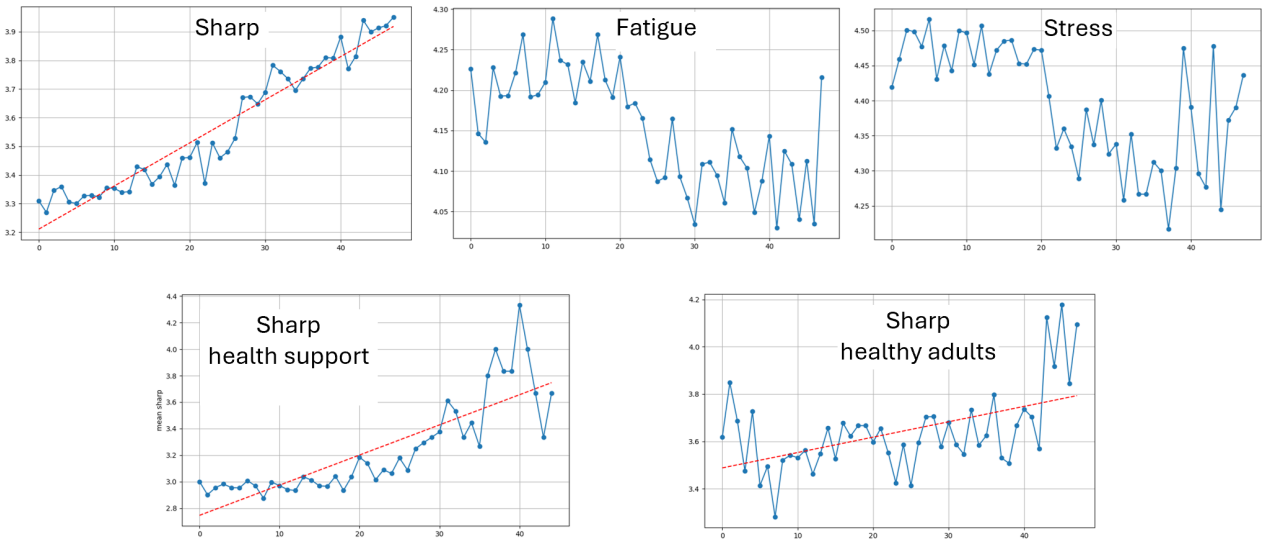

Table 4 presents the ARIMA parameters for the response categories sharp, fatigue, and stress. The log-likelihood values are high for all models, indicating a good fit. Similarly, the negative Akaike Information Criterion and Bayesian Information Criterion values suggest that the models strike a balance between fitting the data well and avoiding unnecessary complexity. The *P* values for the Moving Average of order 1 terms (*P*<.001 for all categories) indicate that errors at lag-1 are significant for predicting the next value in the time series. In addition, the Ljung-Box test results, with values greater than 0.05, suggest that the residuals are not significantly autocorrelated, meaning the models capture relevant patterns beyond mere autocorrelation.

Table . ARIMA (Autoregressive Integrated Moving Average) parameters for response categories.

Metric	Sharp	Fatigue	Stress
Log likelihood (higher is better)	74.19	72.39	64.09
AIC[a] (lower is better)	−142.39	−140.79	−124.17
BIC[b] (lower is better)	−136.84	−137.09	−120.47
MA(1)[c]	−0.63 (*P*<.001)	−0.67 (*P*<.001)	−0.61 (*P*<.001)
Ljung-Box test	0.85	0.21	0.07

[a]AIC: Akaike Information Criterion.

[b]BIC: Bayesian Information Criterion.

[c]MA(1): Moving Average of order 1.

Discussion

Principal Results

Early detection and intervention, crucial for reducing health care costs and enhancing quality of life, depend on timely reports of health status. This cross-study analysis highlights the pivotal role of EMA design in obtaining frequent, accurate EMA responses. In particular, we observed that participant demographics and study parameters markedly influence EMA response values, compliance, and quality. In particular, timing of EMA prompts varied in effectiveness depending on participant age. On the other hand, the negative impact of lengthy EMA interactions was consistent across all of the studies. Supporting eyes-free or hands-free interactions [21,34] may reduce interruption burden. Similarly, employing more frequent but shorter EMA sessions, or µEMA [26], may improve responsiveness. These findings support the first hypothesis and highlight the need to tailor EMA prompt strategies to specific participant and study characteristics.

A consistent observation was an increase in habitual, careless responses over the study duration, supporting the second hypothesis. In this study, 2087 of the 17,939 sessions (11.63%) were started but not completed, so researchers may consider strategies such as randomizing question or task order [58], gamifying the data collection process [8], or allowing selected questions to be skippable [59], as some may hold more interest. Additional factors, such as time pressure from concurrent activities or individual personality traits [55], may also influence responses. Ultimately, these considerations can be included in the study design.

XSL•FO
RenderX

Integrating sensor-based behavioral context is key to improving EMA studies. As hypothesized in the third hypothesis, our analysis revealed a significant relationship between sensor-derived biomarkers and EMA responsiveness. Analyzing these biomarkers could benefit personalized EMA design. In addition, timing EMA prompts close to detecting activity transitions may improve RR and quality.

Finally, our results showed that consistent with the fourth hypothesis, EMA response dynamics varied according to study parameters such as participant age and study type. We observed that response values increased more dramatically for intervention than observational studies, perhaps due to participants viewing their intervention involvement as beneficial, as noted in previous literature [60]. The response series were well fit by statistical models such as ARIMA. Such models provide a basis to compare EMA trajectories between groups and predict future response patterns.

Limitations

This study had several limitations. Although we examined factors like study purpose and participant age, other variables, such as education, race or ethnicity, employment status, environment, and cognitive or physical health, were not examined. In addition, we did not consider the impact of breaks of 1 or more days in data collection. Restarting data collection after a break could affect EMA compliance and response quality.

Another limitation involves the duration of the studies. While some studies spanned 6 months or more, others lasted only 2 weeks. Extending the duration of all studies would enhance the generalizability of our time series findings. The sample sizes also varied considerably, with smaller young adult samples compared with older adult studies. In addition, slight differences in EMA question wording between studies, though normalized, may have influenced responses. Greater uniformity in future studies would provide more consistent data.

A further limitation was the lack of diversity in medical conditions. While we focused on individuals with varying levels of cognitive decline, other physical or psychiatric conditions were not represented. Including a wider range of medical conditions in follow-up studies would provide a more comprehensive understanding of EMA responses across different health conditions.

While the studies were consistent in their data collection hardware and software, technology influences results through factors like accessibility, battery life, ease of use, device familiarity, and extractable digital markers. Future studies can systematically consider alternative technologies.

Finally, this analysis concentrated on a subset of well-being factors. Since well-being encompasses broader emotional, social, and physical domains, future research can include additional dimensions for a more holistic analysis. In particular, a next step can be to evaluate the impact of rural versus urban residence as well as the quality of the build environment on EMA responses.

Conclusions

This study offers insights into the factors that influence EMA responses and lays the groundwork for further exploration. Future studies should broaden the range of participant, study, and interaction characteristics to better inform EMA design strategies. In addition, expanding the range of sensor-based behavioral markers will enhance understanding of how changes in routine and behavior can enrich EMA data collection. Addressing these areas will help refine EMA methodologies, leading to more personalized and effective health monitoring and intervention technologies.

Abstract

Background: There has been a surge in the development of apps that aim to improve health, physical activity (PA), and well-being through behavior change. These apps often focus on creating a long-term and sustainable impact on the user. Just-in-time adaptive interventions (JITAIs) that are based on passive sensing of the user's current context (eg, via smartphones and wearables) have been devised to enhance the effectiveness of these apps and foster PA. JITAIs aim to provide personalized support and interventions such as encouraging messages in a context-aware manner. However, the limited range of passive sensing capabilities often make it challenging to determine the timing and context for delivering well-accepted and effective interventions. Ecological momentary assessment (EMA) can provide personal context by directly capturing user assessments (eg, moods and emotions). Thus, EMA might be a useful complement to passive sensing in determining when JITAIs are triggered. However, extensive EMA schedules need to be scrutinized, as they can increase user burden.

Objective: The aim of the study was to use machine learning to balance the feature set size of EMA questions with the prediction accuracy regarding of enacting PA.

Methods: A total of 43 healthy participants (aged 19 - 67 years) completed 4 EMA surveys daily over 3 weeks. These surveys prospectively assessed various states, including both motivational and volitional variables related to PA preparation (eg, intrinsic motivation, self-efficacy, and perceived barriers) alongside stress and mood or emotions. PA enactment was assessed retrospectively via EMA and served as the outcome variable.

Results: The best-performing machine learning models predicted PA engagement with a mean area under the curve score of 0.87 (SD 0.02) in 5-fold cross-validation and 0.87 on the test set. Particularly strong predictors included self-efficacy, stress, planning, and perceived barriers, indicating that a small set of EMA predictors can yield accurate PA prediction for these participants.

Conclusions: A small set of EMA-based features like self-efficacy, stress, planning, and perceived barriers can be enough to predict PA reasonably well and can thus be used to meaningfully tailor JITAIs such as sending well-timed and context-aware support messages.

Introduction

In light of financial, staffing, and other pressures on societal and health care systems linked to aging populations and the increased prevalence of chronic diseases related to sedentary lifestyles and other behavioral patterns [1], a growing number of digital health apps aim to promote positive lifestyle changes [2]. Such apps have the potential to improve health outcomes [3], prevent diseases [4], and enhance the quality of life for individuals [5]. For instance, encouraging physical activity (PA) and heart-healthy habits can help prevent serious health issues like coronary heart disease, diabetes, and cancer [6]. Yet, long-term adherence to PA presents a significant challenge [7]. Despite the well-documented benefits of regular exercise for overall health and disease prevention, many people struggle to maintain consistent PA [7].

To improve the effectiveness and adherence to PA, just-in-time adaptive interventions (JITAIs) are being investigated to tailor personalized and contextualized digital health support, often enabled by mobile health technologies such as wearable sensing devices and smartphones [8,9]. JITAIs offer a promising solution to tackle issues around physical inactivity, enabling effective behavior change and habitualization by providing personalized and timely support to individuals (eg, sending motivational messages to incentivize movement after prolonged periods of inactivity). JITAIs are configured to use real-time data and context awareness to deliver the "right" interventions precisely when they are needed the most [8,9]. JITAIs based on passive sensing have already been applied to various areas including eating disorders [10], mental health conditions, obesity and weight management, PA promotion [11], and smoking cessation [12].

Tailoring JITAIs based on passively sensed contextual factors (PSCFs), such as location, activity type or levels, daily weather conditions, or an individual's heart rate over time, is commonly observed in the literature. However, these passively sensed features face challenges in capturing relevant signals, which enable accurate and reliable characterizations of user contexts. These accurately represent what matters to a user at a given time, for example, informing the decision rules within a JITAI. To establish relevance, accuracy, and reliability, it would be necessary to validate passively sensed feature sets against the subjective user experience, difficult to do in the context of emotions and self-regulation that play a central part in the enactment of health behaviors such as PA [13]. Therefore, tailoring PA-fostering JITAIs based on PSCF comes with a considerable risk of misaligning intervention timing and content with users' current states. Misaligned interventions may annoy users or could hinder engagement leading to drop out from JITAI use [9,14]. In literature, self-report measures of momentary affect and motivation have been shown to be closely related to actual PA [15,16]. This raises the question whether these self-reports—referred to as ecological momentary assessment (EMA)—could directly be used as an addition or alternative to tailoring JITAIs via PSCF.

The EMA can present a valuable option for collecting near-real-time information on the experiences, interests, abilities, needs, behaviors, or other contextual circumstances of individuals in their natural context [17,18]. The advantages of EMA lie in providing rich, context-specific data with reduced memory biases, facilitating a deeper understanding of human behaviors and experiences directly tied to the individual. EMAs are therefore widely used across various fields to gain insights into psychological and behavioral dynamics [18]. Although EMA has shown tremendous potential in capturing individuals' momentary experiences, its use in PA adherence prediction has not been widely explored. Additionally, EMA comes with challenges such as participant burden and reactance [18]. Participant burden refers to the issue that asking too many questions or asking questions too frequently can leave participants annoyed, potentially causing them to ignore EMA prompts or discontinue their participation entirely [19]. Reactance, on the other hand, can be another outcome of overly frequent or extensive inquiries, which might also unduly influence participants' perceptions or behaviors [18]. Compared to EMA deployment in limited-duration study settings, these concerns are even more relevant when EMA is intended to inform JITAI tailoring over prolonged periods of time (ie, months or years in real-world applications). Thus, alongside investigating whether EMA can be used to accurately predict PA engagement, it is critical to identify the most predictive EMA questions that allow for a sufficiently accurate prediction of PA engagement without overburdening the user.

Accordingly, we investigated whether EMA can be used to predict PA engagement and thereby inform the contextualized tailoring of JITAIs. Further, from a practical perspective, we focused on understanding design implications and strategies to balance concerns of EMA fatigue [20,21] with traditional optimization and feature selection techniques in machine learning (ML). The ML techniques can more efficiently uncover hidden patterns and relationships in the data compared to traditional survey validation methods. This work is novel in exploring the viability of EMA for the timewise tailoring of JITAIs—in terms of "when a JITAI should optimally be delivered"—and in preparing such tailoring not directly based on observed variable thresholds but on prediction outcomes. These overarching aims are reflected in the following guiding research questions (RQs):

- RQ1: How accurately can EMAs predict PA engagement or adherence?
- RQ2: Which motivational, emotional, or volitional psychological states captured through EMAs will best predict PA? What is the smallest set of predictors that balances acceptable user burden with practically sufficient prediction accuracy?

Based on the existing EMA literature [22], we expect that EMA can inform behavioral predictions as they closely reflect a participant's perceived state, which can often be related to subsequent behavior. Regarding the constructs that could inform the prediction of PA from EMA, health behavior models, such as the Integrated Behavior Change Model [23], the Health Action Process Approach [24], or the Temporal Self-Regulation Theory [13] alongside our prior work on predictors of PA [15], suggest motivational and volitional qualities of self-regulation are closely related to PA engagement. This includes constructs

XSL•FO
RenderX

such as intrinsic motivation, intention, action planning, and self-efficacy alongside anticipated contextual barriers and momentary affect (eg, current mood or stress). Therefore, we expect these factors to be strong predictors of PA engagement in this study.

Methods

Study Design

The EMA data used in this paper were collected in our prior investigation [15], aimed at understanding the determinants and barriers of PA engagement. Following informed consent and after completing psychometric and demographic (see Table S1 in Multimedia Appendix 1) questionnaires in an web-based survey, participants began the study's EMA phase. During this phase, 4 EMA prompts were sent to the participants on a daily basis at fixed time points (9 AM, 1 PM, 5 PM, and 9 PM) over the course of a 3-week study period. Additionally, participants were also able to report PA independently of those fixed EMA prompts. After the 3 weeks of EMA, another web-based questionnaire was sent to the participants, to assess compliance and reactivity. However, the analyses in this study focus on the EMA data.

Ethical Considerations

The study received ethics approval from the University of Salzburg, Austria (GZ 11/2020). Informed consent was provided by all participants prior to study enrollment and covered all primary and secondary analyses. Study participants were compensated with US $32 and received personalized feedback based on their data after the study concluded [25]. All data in this paper were anonymized.

EMA Measures

While selecting EMA items, we aimed to align with the structure proposed in contemporary models of health behavior, such as the Health Action Process Approach [26], the Integrated Behavior Change Model for PA [23], or the Temporal Self-Regulation Theory [13]. These models propose a 2-step process to explain the implementation of health behaviors such as PA. This process consists of (1) a motivational phase, which leads to the formation of intentions and (2) a volitional phase that bridges the gap between intention and health behavior enactment.

To reflect these 2 steps in our study design, we first sampled candidate predictors proposed by these models as relevant to the motivational phase at each EMA prompt. This included measures of momentary mood (10 items from the Positive and Negative Affect Schedule [27]: happy, relaxed, active, irritated, concerned, depressed, nervous, stressed, energetic, and tired) and stress :2 items from the Perceived Stress Scale (PSS) [28]. The German version by Schneider et al [29] anticipated barriers to PA ("How well would your given circumstances allow you to be physically active at the moment?"; BarrPA), and pain as a barrier to PA ("At the moment, do you have physical complaints that impede physical activity?"). Furthermore, the morning prompt contained items assessing sleep quality ("How good was your sleep?"; SleepQlt), the time of falling asleep ("When did you fall asleep?"; ST), and the waking time ("When did you wake up in the morning?"; WT), which could also be either barriers or resources for PA engagement.

Next, we prospectively asked the participants about their intentions to be physically active ("Do you intend to be physically active in the next 4 hours?," yes or no). Only if they responded with "yes," we further assessed volitional determinants of health behavior enactment such as planning specificity ("How specifically did you plan this physical activity?"; ActPlan), self-efficacy ("How strongly do you believe you can enact your plan under the given circumstances?"; ActPlanSE), and momentary intrinsic motivation ("Independent of the circumstances, how motivated are you right now to be physically active?"). Given the practical purpose around supporting adherence or enactment of planned and intended PA, selecting for positive PA intention provides reasonable grounds.

All of these items were developed or adjusted to fit the specific needs of this study. Except intention and sleep duration, they were measured on a horizontal slider from 0-not at all to 100-very much. Within each EMA prompt, participants finally reported their PA retrospectively, ("Have you been physically active in the last 4 hours?," yes or no), which we used as the primary outcome in our analyses (see Haag et al [15] for cross-validation of these PA self-reports against wearable data). For this EMA sampling, we first used the Smarteater app (internally developed by the University of Salzburg), and in a later recruitment phase, switched to the m-Path platform [30]. However, each participant only used 1 platform, and assessments were identical on both platforms. Therefore, data quality was not impaired due to switching between the two platforms. For the full list of EMA items, please refer to Table S2 in Multimedia Appendix 1.

Study Participants

Participants were healthy individuals who self-reported having no limitations in their ability to perform PA, and did not describe themselves as competitive athletes. As of June 2022, a total of 49 participants were enrolled in the data collection, which was conducted in a phased manner. Of these, 10 participants dropped out before completing all 3 weeks. However, the data from 4 of the 10 dropouts were still used for this investigation since they filled out enough EMA prompts to be included over 1 week. The final sample included 43 participants (31 female and 12 male) between 19 -67 years of age (mean 39.14, SD 15.53) years. In total, 16 reported high, 22 moderate, and 5 low activity levels in the International Physical Activity Questionnaire [31] completed at the beginning of the study. Based on the participants' self-reported height and weight, their BMI ranged from 19.0 to 39.6 (mean 24.4, SD 3.4) kg/m^2, with 2 participants being obese (BMI≥30.0 kg/m^2), 11 overweight (BMI=25.0 - 29.9 kg/m^2), and 29 with normal weight (BMI=18.5 - 24.9 kg/m^2). The BMI for 1 participant was omitted due to being unrealistic (ie, unreasonable self-reported height and weight).

For further details on study setup, procedure, as well as the primary outcomes, please see Haag et al [15].

Data Cleaning and Feature Engineering

Each EMA prompt contained at least 16 questions. Some questions in the EMA prompts included conditional subquestions (eg, planning specificity only when a PA was intended) Questions requiring per-day-level measurements (eg, sleep quality and duration) were limited to 1 morning prompt per day. This approach resulted in 41 distinct questions that were assessed in the EMA. For practical reasons, we only considered the prospective and momentary questions as predictors of retrospectively assessed PA in the subsequent analysis since they are better suited for modeling the likelihood of upcoming PA adherence at runtime. Further details of the EMA questions can be found in Table S2 in Multimedia Appendix 1.

During the data cleaning process, EMA questions with less than a 30% response compliance rate were dropped as data augmentation on such low compliance rates could introduce a bias in the models [32]. EMA prompts for which participants did not report whether they performed the PA were also discarded; this was done retrospectively. For example, if a participant did not report engaging in PA within the last 4 hours at 1 PM, their 9 AM prompt data were excluded from the analysis. The times participants fell asleep and woke up were self-reported once only in the first EMA of the day. Therefore, empty cells for sleep and wake time for EMA prompts 2, 3, and 4 were populated with values from the first EMA of each day. Any remaining missing values for sleep hours, wakeup time, and sleep qualitywhen participants did not respond to the day's first EMA prompt were replaced with their respective median values up to that point in time. The categorical EMA questions with "yes or no" answers were transformed to binary values (1/0). The StandardScaler from the *Scikit-learn* package [33] was used to scale all the continuous variables to unit variance. This standardization of input features can be beneficial for the performance and convergence of ML algorithms.

Model Training and Validation

For modeling, a representative selection of common ML methods, including logistic regression, decision tree, support vector machine [34], k-nearest neighbor (KNN) [35], random forest (RF) [36], and extreme gradient boosting (XGBoost or XGB) [37] was used to compare the model prediction performances. The decision to choose traditional ML models for exploration over neural networks was made, given the relatively small size of the dataset, since neural networks typically require an extensive dataset for training. The data were split into training or test sets (in a ratio of 80:20) using the *Scikit-learn* package [33]. A stratified 5-fold cross-validation method on the training dataset was used to evaluate model performance and hyperparameter tuning [38]. The stratified k-fold cross validation method was chosen to ensure that each fold's class distribution similar to the overall class distribution in the dataset. This is particularly useful when dealing with imbalanced datasets, where one class may have significantly more instances than the others. All models were then evaluated on the test dataset. The GridSearchCV scoring method from *Scikit-learn* [33] was used to find the optimal hyperparameters.

Model prediction performances were compared using the area under the receiver operating characteristic curve, as it is a more appropriate measure compared to simple accuracy, especially for imbalanced datasets [39]. The area under the receiver operating characteristic curve visualizes the performance of the model at various probability thresholds for classification and helps in selecting an appropriate threshold that balances the trade-off between true positives and false positives.

To overcome data imbalance, we attempted upsampling with the synthetic minority oversampling technique (SMOTE) [40] that is implemented in the Python library *imbalanced-learn* [41] on the training data. We trained the models with the upsampled data and compared their internal validation results on the test dataset.

For identifying the top features predicting whether PA took place within a given EAM slot, we used the recursive feature elimination (RFE) technique from *Scikit-learn* [33]. RFE is primarily used in ML to select the most relevant and important features from a given dataset. It recursively trains the model using subsets of features and ranks them based on their contribution to improving prediction outcomes. By iteratively eliminating less important features, RFE provides an optimal subset of features that maximizes the model's performance. After the RFE, we used the Shapley Additive Explanations (SHAP) framework [42] for understanding the feature importance within the best-performing models. The models were built in Python 3.8 using *Scikit-learn* (version 1.2.0) package [33]. The entire training process was conducted on a Windows 11 operating system with 64 GB RAM, a dual-core Intel Core i9 processor, and an Nvidia graphics card (Nvidia RTX A4000) with 16 GB memory.

Results

Overview

Following data cleaning, 23 of 41 EMA questions fulfilled the minimum data compliance requirements and were used as features for building the models and predicting the compliance or noncompliance of PA. In this section, we first outline the performance of the range of selected candidate ML models in predicting PA engagement when all the features were used in training. Thereafter, we will show the results of feature importance in predicting PA engagement using the RFE technique and a SHAP value visualization. We conclude with a practical discussion on selecting an appropriate model or ensemble and feature set, contextualizing the work around more general concerns in model training and selection for dynamic personalization based on EMA.

PA Prediction Performance of Various Model Using All Available Features

Figure 1 shows the area under the receiver operating characteristic curve of various models in a 5-fold cross-validation on training data, and Table 1 presents their area under the curve (AUC) scores on training and test sets. XGB, KNN, and RF models have shown the best performance and achieved a mean AUC score of 0.87 (SD 0.02) on 5-fold cross-validation. However, among them, XGB achieves a slightly higher AUC score (0.87) on the unseen test set. We also tested the upsampling technique SMOTE on the training data;

XSL•FO
RenderX

however, as shown in the 2 rightmost columns in Table 1, this did not significantly improve the test set AUC score. Since SMOTE does not improve the performance on the test set, it was not used for further analysis.

Figure 1. (**A**) XGB, (**B**) SVM, (**C**) KNN, (**D**) LR, (**E**) DT, and (**F**) RF show the performance of selected machine learning models in 5-fold cross-validation using all the features. AUC: area under the curve; DT: decision tree; KNN: k-nearest neighbor; LR: logistic regression; RF: random forest; ROC: receiver operating characteristic curve; SVM: support vector machine; XGB: extreme gradient boosting.

Feature Importance

Overview

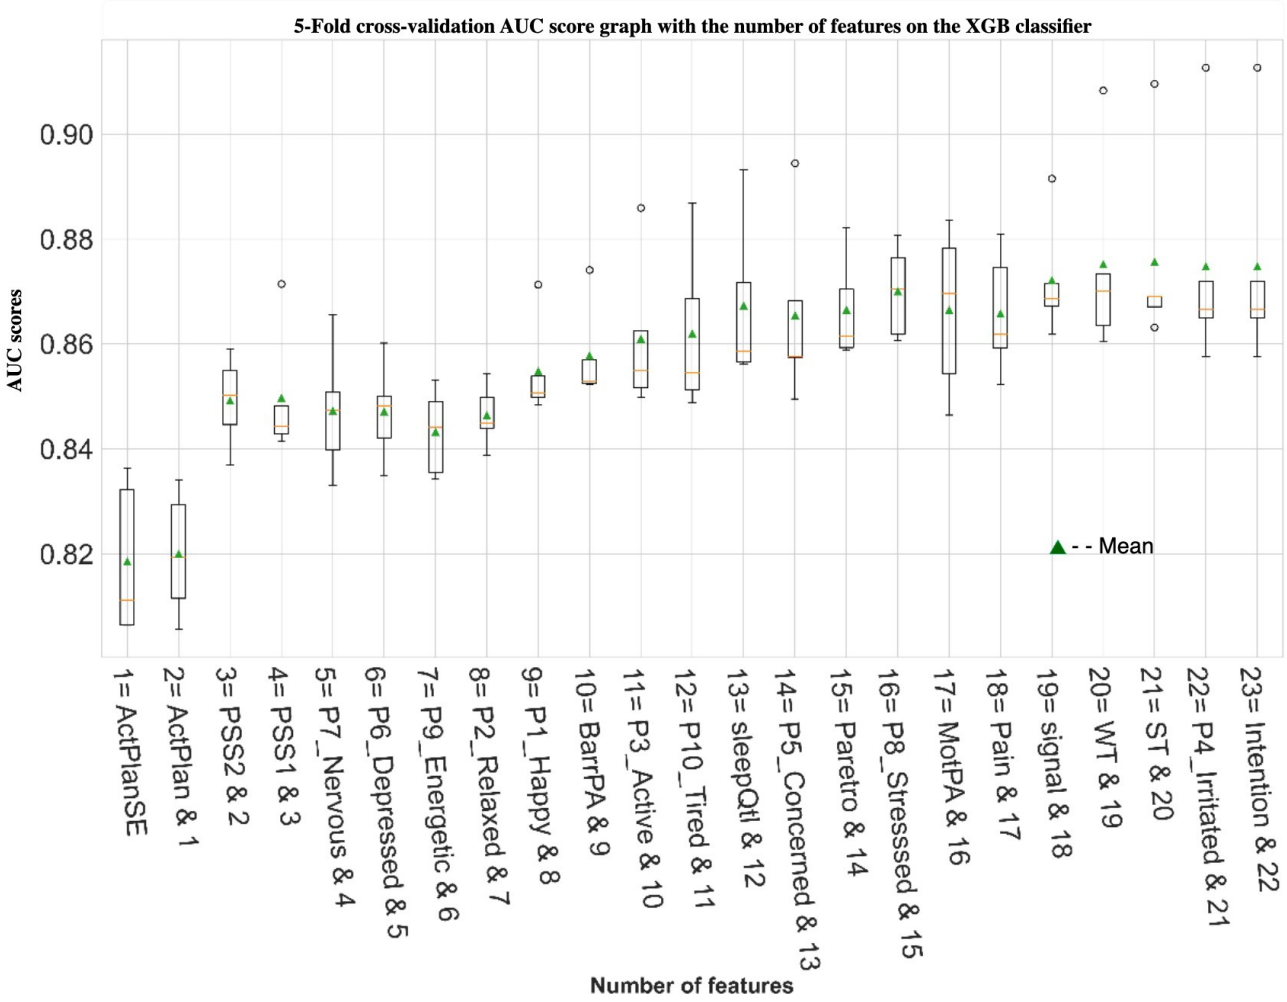
To reduce potential questionnaire fatigue [20] caused by the extensive EMA survey length and finding the smallest but accurate subset of EMA questions for predicting the PA, after finalizing the best-performing model on all 23 features, we focused on understanding the feature importance in predicting PA. Since the XGB model showed slightly better performance on the test dataset (Table 1) compared to RF and KNN, explorations into feature importance were done exclusively for XGB .

Recursive Feature Elimination

Figure 2 shows the selected top-n (n=number 1, 2, 3, etc) features identified by RFE, alongside with a box plot of the corresponding AUC scores for the XGB classifier. As depicted in Figure 2 , for the XGB models, the highest mean AUC score (0.87) is achieved when using 13 features and remains the same even when all 23 features are used. Interestingly, a competitive AUC score of 0.85 is achieved with just 3 features, which combine ActPlan and ActPlanSE as indicators of volitional intention, along with PSS2 as a marker of stress. An increase to an AUC score of 0.86 is only achieved when using 10 or more features.

XSL•FO
RenderX

Figure 2. XGB models with growing feature set sizes: boxplots of AUC scores with a number of features using recursive feature elimination. The numbers (1, 2, 3, etc) indicate the top n-number of features and their names. Feature sets are listed as "additonal_feature & X (identifier of compounded prior features)." AUC: area under the curve; XGB: extreme gradient boosting.



SHAP Value–Based Feature Importance

Figure 3 shows a SHAP value graph of the top 13 features and their contributions in PA prediction by the XGB model. For brevity, we present SHAP values of 13 features, as subsequent features do not improve the AUC score (as apparent in Figure 2). SHAP value graph indicates the correlations through which different features contribute to the model's output for individual predictions.

Similar to the RFE (Figure 2), items ActPlanSE (self-efficacy) and ActPlan (PA planning specificity) remain the top 2 features with the most notable impact on model output (indicated by wide impact score spread combined with decisive directionality on the horizontal axis). The positive SHAP values indicate that the feature increases the PA enactment prediction, while negative values indicate the opposite. The color of the bar represents the feature value (red for high and blue for low). The slight difference in the feature ranking by RFE and SHAP value is due to differences in their feature selection methodology and objective of feature selection. RFE focuses on improving overall model performance metrics, whereas SHAP values aim to provide interpretable explanations for individual prediction by a given feature.

Discussion

Principal Findings

In this study, we explored the viability of predicting PA engagement based on common supervised ML methods with features drawn from EMA data collected in the participants' natural contexts. Conceptually, if PA engagement or nonengagement can be predicted, this can inform the timing of issuing JITAIs. For instance, if negative engagement is predicted, motivational messages of encouragement, or more specific planning or replanning, can be sent. Since EMA requires the active involvement of the user, we also explored which features or questions of the EMA were key determinants for effectively predicting PA engagement. This exploration offers a framework for informing trade-off decisions that can help in designing JITAI systems that take valuable information derived from EMA without overburdening the users.

EMA and PA Engagement Prediction

Regarding RQ1 on how accurately EMAs and ML models can help predict PA engagement, all the ML models (Table 1) produce AUC scores of 80 or higher on test data that were not seen by the models in training. When considering smaller performance differences, both XGB and RF models performed best on both cross-validation (mean 0.87, SD 0.2) and test sets (AUC 0.87 and 0.86, respectively), broadly indicating that the questions used in the current EMA could be a viable option for PA engagement prediction and can complement the tailoring of passive sensing–based JITAIs to foster PA.

While such performance levels would not satisfy strong reliability requirements (eg, in health diagnostics), they can arguably be reasonably used in JITAI settings around fostering long-term PA, where occasional type 1 or type 2 errors do not have grave consequences. Compared to previous work on the same dataset, which used non-ML models to investigate determinants of PA enactment in a theory-driven manner [15], this study adopts a practical approach on the potential of operationalizing EMA for actively driving JITAIs independently of preconditions, such as the PA being explicitly intended. Thereby, favoring model performance over analyses intended to inform theory building for feature composition.

XSL•FO
RenderX

The outcomes of automated feature selection corroborate earlier findings [15] with non-ML modeling, as feature importance analysis indicates that self-efficacy (ActPlanSE) and planning specificity (ActPlan) are the key relevant predictors of PA engagement. Here, self-efficacy represents a participant's confidence in their ability to engage in the intended activity, and planning specificity refers to how specifically they had planned that activity. This result also falls in line with other previous publications indicating a close relationship between PA engagement and these volitional components [43-45]. Further, analysis based on RFE on the XGB model (Figure 2) indicates stress (PSS1 and PSS2) as another potentially relevant factor that can be a qualifier for PA outcomes. This association of stress and PA is also consistent with previous EMA literature [16].

Psychological Considerations and Contextualization in Theory

In light of the dual-process models of health behavior [13,23] that the present data collection was based upon, it is not surprising to see the volitional constructs (ActPlanSE and ActPlan) ending up having greater feature importance. However, even though we found a resemblance to these psychological models, our results are not to be confused with an evaluation of such models. Instead, our findings represent a practical investigation of the ML methodology being applied to determine which ones (within a given set of candidate EMA items) could be used for a runtime system to predict PA adherence and control adaptive interventions accordingly. This implies that the proposed feature selection might be very different in another set of potential predictors and necessitates the interpretation of our findings in light of our specific EMA design.

For example, consider the intention item or feature that was ranked at the very bottom of our RFE (Figure 2). From a theoretical point of view, intention would often be seen as the pivotal point in health behavior engagement [24]. Therefore, it may seem very surprising that intention (Figure 2) is being ranked the least predictive feature in our dataset. This discrepancy originates in the structure of our EMA, with ActPlanSE and ActPlan only being assessed if participants report to have the intention for PA. Therefore, these features would have missing values for each episode where no intention is reported. In these cases, values of the volitional determinants were replaced with zeros. Thus, the binary intention data are encoded in ActPlanSE and ActPlan. In the RFE process, the presented models will have picked up on this characteristic and ranked intention itself very low since it does not contain additional information if ActPlan or ActPlanSE is included. However, this does not imply that we can forgo the assessment of intention since it is only meaningfully possible to assess planning and self-efficacy when an intention is given. In practical terms, this would imply that the precondition of intention being given would be wrapped into the wording for an ActPlan item if it were to be presented without an explicit item on intention preceding it (ie, "In case you are intending to exercise, how specifically have you planned").

Nonetheless, the indicated feature combination including ActPlan and stress items corresponds well with expectations that can be derived from the aforementioned dual-process models of health behavior [13,23,26], representing elements that can be seen to capture aspects of both a motivational phase and a volitional phase.

Trade-Off Between EMA Burden and PA Prediction Accuracy

The potential viability of the sets of EMA questionnaires selected for this study was informed by psychological theories. However, the list of questions as a whole is clearly too burdensome for being of practical use in guiding JITAIs. As indicated in the EMA literature [19-21], questionnaire fatigue or overload is a real concern for practicality. As shown in Figure 2, an AUC of over 0.85 is achieved by just using the top 3 features (ie, ActPlanSE, ActPlan, and PSS2) as compared to the maximal achievable AUC of 0.87 when all the 23 features were used. Moreover, as evidenced by the RFE process, the maximal AUC score of 0.87 is already achieved with 13 features, indicating that beyond these 13 features, the rest other features are not adding additional benefit for predicting PA engagement. Even within these 13 features, after adding an item from the stress questions (PSS1 and PSS2), Positive and Negative Affect Schedule mood questions (P7_nerves, P5_concern, P1_happy, P6_depressed, and P7_energetic) are arguably not adding significant improvements in AUC score to justify their inclusion as frequently asked items in a practical longer-term deployment. The PA-friendly external circumstances (BarrPA) and the absence of barriers and sleep quality (SleepQlt) do minor improvement of the AUC score and could be candidates for inclusion with the EMA for research purposes but would likely not be included in a production system, as the improvements are negligible for practical purpose.

For most practical purposes and keeping the EMA questionnaire burden to the minimum, in settings where an intention for PA is given (eg, supporting the engagement of a PA plan), a deployed JITAI model could be driven by just 3 EMA items (ActPlanSE, ActPlan, and PSS2). If the intention is not given, the first item could be rephrased as indicated earlier.

Design Implications

For the practicality of JITAIs or any intervention intended for fostering PA to be driven by regular EMA in live deployment situations, it is essential to select EMA questions effectively and avoid causing EMA fatigue. In relation to RQ2, about which concepts will best inform PA engagement prediction (as shown in the Feature Importance section), features (EMA questions) related to self-efficacy, planning, and stress have reasonable PA prediction power. These outcomes indicate that the long list of potentially relevant EMA questions used in PA prediction can be effectively cut short to a degree where real-world deployments of JITAIs with decision rules or trigger points [14] being informed by EMAs appear plausible. In addition, the proposed XGB model can be integrated into existing digital health platforms or mobile apps for effective EMA-based JITAIs and fostering PA engagement.

Limitations and Future Work

This study is formative with regard to surveying potentially relevant EMA constructs and measures. It does not include

XSL•FO
RenderX

observations or testing of the app of the derived models in practical deployment, which is a clearly indicated step for future work. The study also included a relatively small number of participants (n=43) and a limited time frame (3 weeks). To ensure the generalizability of the ML model (XGB) for automated physical activity prediction and the customization of JITAIs across diverse demographics, further research with larger sample sizes and longer study durations is needed. Additionally, in this study setup, the EMA frequency was established at 4 times a day. Future work should explore the impact of varying EMA frequencies per day on the predictive capabilities of the model for PA.

Conclusions

This paper presents a formative investigation into EMA's effectiveness in predicting PA implementation and whether EMA can be of practical use in gathering temporal context for JITAI decision-making. The outcomes with common supervised ML models, especially XGB with a mean AUC score of 0.87 (SD 0.02), indicate that EMA can offer relevant PA prediction power and thereby has the potential to complement more common passive sensing JITAI-tailoring approaches. Furthermore, the investigation around finding the right trade-off between EMA question load and PA engagement, prediction-accuracy of ML models indicates that self-efficacy (ActPlanSE) and planning specificity (ActPlan) play the most important role in determining the PA prediction under the assumption that initial intention to perform PA was already given. Three features, ActPlanSE, ActPlan, and PSS2 (stress), allowed for achieving an AUC score of 0.85 as compared to the maximum AUC score of 0.87 when all the 23 EMA questions were used.

Acknowledgments

The authors thank all study participants and all addtional contributors for their time and cooperation. The authors especially thank Sebastian Gruber and Christoph Zeiner for their support during the design and early analysis of this study.

Conflicts of Interest

None declared.

Abstract

Background: Adolescence through emerging adulthood represents a critical period associated with changes in lifestyle behaviors. Understanding the dynamic relationships between cognitive, social, and environmental contexts is informative for the development of interventions aiming to help youth sustain physical activity and limit sedentary time during this life stage. Ecological momentary assessment (EMA) is an innovative method involving real-time assessment of individuals' experiences and behaviors in their naturalistic or everyday environments; however, EMA compliance can be problematic due to high participant burdens.

Objective: This systematic review synthesized existing evidence pertaining to compliance in EMA studies that investigated wake-time movement behaviors among adolescent and emerging adult populations. Differences in EMA delivery scheme or protocol, EMA platforms, prompting schedules, and compensation methods—all of which can affect participant compliance and overall study quality—were examined.

Methods: An electronic literature search was conducted in PubMed, PsycINFO, and Web of Science databases to select relevant papers that assessed movement behaviors among the population using EMA and reported compliance information for inclusion (n=52) in October 2022. Study quality was assessed using a modified version of the Checklist for Reporting of EMA Studies (CREMAS).

Results: Synthesizing the existing evidence revealed several factors that influence compliance. The platform used for EMA studies could affect compliance and data quality in that studies using smartphones or apps might lessen additional burdens associated with delivering EMAs, yet most studies used web-based formats (n=18, 35%). Study length was not found to affect EMA compliance rates, but the timing and frequency of prompts may be critical factors associated with missingness. For example, studies that only prompted participants once per day had higher compliance (91% vs 77%), but more frequent prompts provided more comprehensive data for researchers at the expense of increased participant burden. Similarly, studies with frequent prompting within the day may provide more representative data but may also be perceived as more burdensome and result in lower compliance. Compensation type did not significantly affect compliance, but additional motivational strategies could be applied to encourage participant response.

Conclusions: Ultimately, researchers should consider the best strategies to limit burdens, balanced against requirements to answer the research question or phenomena being studied. Findings also highlight the need for greater consistency in reporting and more specificity when explaining procedures to understand how EMA compliance could be optimized in studies examining physical activity and sedentary time among youth.

Introduction

The transition from adolescence (aged 10-18 years) to emerging adulthood (aged 18-29 years) represents a critical developmental period [1] that is often associated with significant changes in lifestyle behaviors [2-4]. To establish more effective interventions or programs to help youth (ie, adolescents and emerging adults) promote or sustain more physical activity (PA) and limit sedentary time (ST), there has been growing interest in studying the dynamic relationships between youths' cognitions, social and environmental contexts, and movement behaviors. Research has consistently shown greater PA and less ST being beneficial for several health outcomes for both adolescents and emerging adults including self-reported health status, chronic diseases such as obesity and cardiovascular disease, and indicators of mental health [5,6]. Ecological momentary assessment (EMA) is an innovative method for collecting intensive longitudinal data to better understand the dynamic predictors of these critical health-promoting behaviors [7]. In brief, EMA involves repeated real-time assessment of individuals' experiences and behaviors in their real world and natural environments, which do not require participants to recall extended periods of time, helping to reduce participant recall biases and increase ecological validity [8]. These methods have been implemented in several studies to date, helping to advance knowledge related to real-time correlates of PA and ST among youth. While there has been considerable progress in this field, EMA compliance can, at times, be problematic among the youth population. Our understanding of EMA compliance among movement behavior studies remains poor and thus warrants greater attention to help inform the development of future and more effective EMA protocols.

Data collection efforts involving repeated participant observations such as EMA allow researchers to study the temporal patterns and momentary processes that influence movement behaviors while allowing for the disaggregation of data into between-subjects and within-subjects for analysis [9]. EMA methods have evolved over time, beginning with more traditional methods such as paper and pencil diaries and repeated telephone calls, to the integration with technology using palm computers or SMS text messaging, and now smartphone apps developed for EMA [10]. There are several sampling approaches used in EMA, each suited to different types of research questions and contexts. In signal-contingent sampling, participants are prompted to provide data at random or within predetermined intervals. In contrast, data are only collected after the occurrence of specific events in event-contingent sampling. Given the ubiquity and rapid technological advances of smartphones to reduce some of the participant burden, it is not surprising that EMA research among adolescent and emerging adulthood populations has risen over recent years. Delivering EMA protocols through smartphones is often considered a feasible and acceptable method to collect intensive longitudinal data among youth samples due to their high rates of device use [11,12]. In other words, the utilization of smartphones has the unique potential to improve our understanding of correlates of PA and ST, but poor adherence to the EMA protocol may bias the associations observed, ultimately hindering opportunities to develop effective interventions.

Despite the aid of technology, EMA using smartphones remains a burden-heavy method for data collection for participants. Its repeated self-report nature requiring conscious effort lends itself to potentially substantive missing data as answering prompts in naturalistic settings may not always be feasible. For example, participants may not be able to answer an EMA prompt in a timely manner due to engagement in sport or PA, being prompted in unsafe contexts (eg, while driving), or if the prompt was sent at an inconvenient time (eg, socializing with friends or napping). For these reasons, it is understood that missingness in EMA research is inevitable as an increased burden leads to lower study compliance. However, missing data that results from a low EMA response rate raises questions about the quality of the data being collected. Despite its time-consuming nature, compliance with EMA is essential for the validity or representativeness of daily phenomena that may influence movement behaviors among youth [13].

Compliance is commonly defined as the ratio of the number of measurement occasions participants completed divided by the maximum number of measurement occasions allowed by the protocol of the EMA study [14]. Conducting an EMA study involves multiple decision-making processes to determine the protocol, including but not limited to the EMA assessment tool and platform, compensation, study duration, assessment frequency, sampling scheme, and questionnaire density [15]. Missingness and low compliance can impact the data quality and be susceptible to misinterpretation. For example, systematic missingness could introduce bias as the resulting data does not reflect the true distribution of behaviors. Similarly, the overall sample may not represent the intended population and limit generalizability. Missing data also reduces sample size, which decreases the statistical power of the study or increases the variability of estimates. Finally, if there is missing data at critical times (eg, ignoring prompts during stressful times or missing prompts because they are engaging in PA within a PA study), the trends could be misinterpreted. While there are techniques to impute missing data, imputing EMA data can be challenging due to the inherent dynamic nature of the data and lead to inaccurate results. Given that compliance is critical to understanding the representativeness of the collected data and earlier publications pushing for compliance reporting for EMA

XSL•FO
RenderX

studies [7,16,17] it is crucial to understand the factors and study methodological features that may be influencing EMA compliance.

Indeed, studies have examined the application of EMA in youth. Previous reviews have focused on summarizing or reporting the main characteristics of studies that apply EMA to study mental health or psychopathology in daily life. A paper by Mason et al [18] examined the association between EMA-measured contextual factors and dietary intake in youth. Liao et al [16] conducted a systematic review of common EMA methods of diet and PA research in youth. In a previous systematic review of EMA protocol and compliance in adolescents, Wen et al [12] concluded that compliance was similar for studies longer than 3 weeks compared to studies less than 1 week. Interestingly, another systematic review of EMA studies in the adult population found no identified associations between any features of the EMA protocol and the compliance rate [17]. Given that youth populations may not fully understand what would be required in an EMA study, or can also be generally ambivalent toward research, it is crucial to understand potential methods and practices that may result in greater compliance. The existing reviews included EMA studies that focused on a wide range of health outcomes, which makes it difficult to disentangle the potential impact of EMA protocols for specific behavioral outcomes. Movement behaviors, which can include PA and sedentary behaviors may be particularly unique, as the continual collection of movement behavior data through self-reports or device-based assessments may represent an additional source of participant burden. A more nuanced understanding of EMA compliance in movement behavior studies is needed. In addition, compliance cannot be solely interpreted without considering the quality of EMA design, as poor design features also lead to a greater burden and decreased compliance. Suggested guidelines for reporting EMA study protocol, such as the Checklist for Reporting of EMA Studies (CREMAS) framework, have been adopted by EMA researchers to evaluate the quality and report the design features in a standard manner [16].

Therefore, the purpose of this systematic review was to apply the CREMAS guidelines to (1) synthesize the existing evidence on compliance for EMA studies focusing on wake-time movement behaviors (ie, PA and ST) among adolescent and emerging adult populations, and (2) evaluate the quality of the included EMA studies. We summarize the repeated measure methodologies used when examining PA and ST behaviors and describe any salient factors that may positively or negatively impact EMA compliance.

Methods

Protocol and Registration

Before conducting this systematic review, a protocol was developed and preregistered on PROSPERO (submitted October 21, 2021; registration number CRD42021282093). The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines were followed [19], and items were reported using the PRISMA checklist (Multimedia Appendix 1).

Search Strategy

An electronic literature search was conducted in the PubMed, PsycINFO, and Web of Science databases on October 19, 2022. First, titles and abstracts of papers were searched using the following terms: (“ambulatory assessment” OR “experience sampling” OR “ecological momentary assessment” OR “EMA” OR “ESM” OR “daily diary”) AND (“physical activity” OR “exercise” OR “sedentary” OR “movement behavior” OR “movement-based behavior” OR “posture” OR “sport” OR “sitting” OR “screen” OR “inactivity” OR “leisure activity”) AND (“young adult*” OR “youth” OR “college student*” OR “university student*” OR “emerging adult*” OR “adolescence” OR “adolescent” OR “high school students” or “secondary school students” OR “post secondary students”). The same search strategy was used across all 3 databases.

Inclusion and Exclusion Criteria

We included studies that met the following criteria: (1) published in a peer-reviewed academic journal, (2) full text was available, (3) published in the English language, (4) delivered EMA prompts at least one time each day during the study period (minimum requirement for daily diary studies), (5) provide quantitative data for movement-based activity (ie, PA or ST; to exclude protocol papers), (6) provide quantitative compliance data (% or number of completed) for EMA prompt responses, and (7) the sample consisted of adolescents or young adults (aged 10-29 years). Papers were excluded if (1) the population included a mix of participants older or younger than the target age range (ie, <10 or >29 years of age), (2) the study design was an intervention, (3) the paper reported on multiple studies that used EMA, or (4) the paper was not the first study to publish using a particular data set (ie, an EMA study was only counted once when multiple publications came from the same EMA project; the first publication was included in these instances so each study protocol was only represented once).

Study Selection

All records found from the database searches were imported into Covidence systematic review software (Veritas Health Innovation). Duplicates were removed before titles and abstracts were screened independently by 2 reviewers (SW and AC) for initial inclusion. All studies retained after the title and abstract screening were retrieved as full papers and further assessed for final inclusion by 2 reviewers independently. Disagreements at both screening stages were resolved by discussion during review team meetings.

Data Extraction and Synthesis

For all studies that met our inclusion criteria, the lead author (SW) extracted the following data into an Excel (Microsoft Corp) data entry form: (1) authors and year of publication; (2) sample characteristics (ie, sample size, country, mean age of sample); (3) EMA device or platform; (4) types of movement activity that was assessed, including whether it was self-reported or device-measured; (5) coassessment of diet; (6) study duration; (7) prompting schedule (event or time or signal contingent); (8) prompt frequency; (9) number of items for each prompt; (10) prompt times; (11) compensation or types of incentive; and (12) reported details about compliance (rate, inclusion criteria, and

XSL•FO
RenderX

missing data relationships). Multimedia Appendix 2 [20-68] presents the extracted data. In addition, a random sample of 20% of the included papers was independently extracted by a second review team member (AC) for validation (interrater reliability >80%). The compliance rate was calculated for studies that reported the total number of surveys completed or the average number of surveys completed by dividing by the total number of expected delivered surveys as reported by the prompting scheme in the paper's methods. Given the population, many studies had different prompting scheduled for school days versus weekend days. Therefore, we considered the maximum or most burdensome day when calculating the density of prompts (number of prompts per day).

A quality score for each study was calculated using a modified version of the Checklist for Reporting of EMA Studies (CREMAS) [16]. The checklist was used to assess if descriptions were provided for EMA technology, EMA protocol training, study duration, prompting scheme, prompting frequency, study attrition, prompt latency, missing data, and limitations of EMA. Each item was scored with 0, 0.5, or 1 (representing No, Somewhat, Yes). Scores ranged from 0 to 9, with greater scores representing higher quality. Scores can be found in Multimedia Appendix 2 [20-68].

Given the heterogeneity in the samples and methods in the studies that met the inclusion criteria, further analysis through conducting a meta-analysis was not appropriate. We proceeded with our objective of conducting a narrative synthesis, and studies were reviewed and compared on a variety of characteristics, including PA/ST assessment method, EMA platform, number of study days, prompting schedule, prompting frequency, number of prompts per day, compensation, and the comeasurement of diet. Differences in compliance between groups in each category were analyzed using Kruskal-Wallis tests. Additionally, potential interactions between significant factors were presented in contingency tables as many of the factors we examined could coexist with each other to compound burden (EMA delivery scheme × study duration × prompt frequency). For example, very intensive prompting (multiple times per day) may only be tolerable for a short period of time in comparison to end-of-day prompts completed 1 time per day.

Results

Overview

Our systematic search conducted at 2 time points (ie, November 2021 and October 2022) captured a total of 2841 papers, of which 2129 papers were duplicates and therefore removed. A total of 712 remaining papers were initially screened. After title and abstract screening, an additional 462 papers were deemed irrelevant, with the remaining 250 papers proceeding for full-text screening. Following the full-text review, 201 papers were found to have not met the eligibility criteria, resulting in 49 papers retained for data extraction and included in this review [20-68]. A PRISMA diagram for selecting the final papers for synthesizing is presented in Figure 1.

Study Quality

Table 1 presents the quality scores of the final papers. The average CREMAS score was 6.84 (SD 1.26). All studies reported (yes or somewhat) the study duration, prompting scheme, and prompting frequency. However, studies most infrequently reported on if and how participants were trained on the EMA protocol (n=18, 37% not reported), how missing data were handled (n=28, 57% not reported), attrition (n=26, 53% not reported), and latency (n=42, 86% not reported). These results highlight the continued variability in reporting critical attributes within PA and ST research among adolescents and emerging adults when applying EMA methodologies.

Table 1. Study (n=49) quality scores based on the adapted CREMAS[a] tool.

CREMAS item	Yes, n (%)	Somewhat, n (%)	No, n (%)
EMA[b] technology	35 (71)	12 (25)	2 (4)
EMA[b] training	23 (47)	8 (16)	18 (37)
Study duration	48 (98)	1 (2)	0 (0)
Prompting scheme	47 (96)	2 (4)	0 (0)
Frequency	48 (98)	1 (2)	0 (0)
Attrition	11 (22)	12 (25)	26 (53)
Latency	3 (6)	4 (8)	42 (86)
Missing data	19 (39)	2 (4)	28 (57)
Limitations of EMA[b]	26 (53)	10 (20)	13 (27)

[b]EMA: ecological momentary assessment.

Descriptive Statistics

PA was the primary outcome in 40 (82%) of the 49 studies. More studies used self-reports of PA and ST (n=29, 59%) than device-based assessments (n=20, 41%) to measure movement behaviors. For compensation, 9 (18%) studies provided some form of course credit, 12 (24%) studies provided only monetary compensation, and 5 (10%) studies provided both options. In contrast, 1 study explicitly stated that no compensation was provided for participation, and another 22 (45%) of the 49 studies did not report how participants were compensated.

Although most studies were conducted in the United States (n=36, 73%) among nonclinical samples (n=46, 94%), there was substantial heterogeneity in the EMA study methodologies. For example, the sample size of these studies ranged from 8 to 1493 participants (mean 179.77, SD 272.43), study durations from 1 to 30 days (including 4 studies that used multiple waves of EMA data collection periods [29,48,53,61]), and a variety of prompting schedules being applied. A total of 12 (24%) studies consisted of daily dairies, whereby participants were asked to respond to a single EMA prompt once each day [27-29,31,35,39-41,54,59,62,66]. Another 36 (73%) studies involved multiple prompts each day, including 4 studies that used event-contingent prompting [20,36,44,65]. These 4 studies required participants to self-report eating episodes [65], or the prompts were triggered by their current location [44] or current activity [20,36]. Among the 32 studies with only a time-based sampling component (predetermined sets of prompts being administered), prompting schedules included random prompts during predetermined time intervals (n=30, 61%; eg, one random prompt for each 2-hour interval), prompts at a fixed schedule (n=8, 16%; eg, every 30 min during waking hours), or prompts at a personalized time (n=1, 2%; eg, participant's blood glucose check schedule). One study did not report the prompting scheme. A total of 13 (27%) of the 49 studies did not report the length of the EMA surveys. Of the studies that were reported, the number of items per prompt ranged from 1 to 45 (mean 11.78, SD 8.80). There was a negative but nonsignificant correlation between the length of the survey and compliance rate (r=–0.10; P=.57).

Compliance Results

Overall, compliance data were extracted for 48 studies, as we could not extract the compliance rate for 1 study that reported the average number of event-contingent prompts responded to [64]. The compliance rate was calculated for studies that reported the total number of surveys completed or the average number of surveys completed by dividing by the total number of expected delivered surveys as reported by the prompting scheme in the paper's methods. Importantly, it should be noted that 13 (27%) of the 48 studies reported dropping participants from their analyses—which invariably improved calculations of compliance. Decision rules to exclude participants in final analyses varied, with various thresholds of minimum compliance ranging from 30% to 80% missing data or removal of participant data if compliance rates were beyond 2-3 standard deviations. It may also be possible that the remaining 35 studies also removed participant data without being specified. Among the 48 studies with reported compliance, the mean compliance was 80.63% (range 40.2%-99.3%). The mean compliance, however, was higher among the daily diary studies (91.03%; range 88.3%-96%) than studies with multiple prompts each day (77.16%; range 40%-95%).

Overall, mean compliance among the daily diary studies was relatively high and consistent across studies. Compliance was greater than 88% in all studies, with study durations ranging

XSL•FO
RenderX

from 6 to 30 days of data collection. Among the 12 daily diary studies, 10 studies reported using web-based platforms, including 1 study that also used paper and pencil reporting. One study was phone-based, and 1 study did not report the modality of EMA collection. All studies were published after 2013, but 9 of these daily diary studies were published within 5 years of this conducted review.

The mean compliance among studies with multiple prompts per day was more variable when compared to daily diary studies, with reported compliance as low as 40% to as high as 94%. In examining prompt type and duration of EMA studies, there were no distinct patterns to compliance based on whether studies applied fixed or random prompting scheduled duration of the EMA studies. There is more variability when examining the interactions between prompt schedules and study duration (range 71.45%-90%), but with a caveat that some include only a small number of studies (eg, only 2 studies that used a fixed prompting schedule for less than 1 week).

With regard to prompt schedules, among these multiple EMA prompt studies, there was a substantial number of studies (n=8) that included very high numbers of EMA surveys being delivered per day (range 17-68). Interestingly, the mean compliance of these studies was higher (82.10%; range 50.20%-99.30%) when compared to studies (n=27) that included 3 to 9 prompts per day (76.43%; range 40%-89.30%). Two studies did not specify the number of prompts they sent each day. Studies with the most intensive EMA protocols (ie, ≥17 prompts per day) had compliance of greater than 82%, apart from 1 study with 50% compliance. The highest compliance rate (99%) was reported by Kanning et al [50], who intensively delivered EMA prompts every 45 minutes for 1 day to study the real-time association of PA with affect. Three studies used extra devices to send electronic EMA surveys, while 4 studies used paper and pencil EMA methods.

Upon closer examination of studies prompting participants between 3 and 9 times each day, 19 of the 27 studies were found to have had compliance above 75%. Interestingly, 2 studies used paper and pencil as the modality of EMA collection; however, both studies had compliance between 76% and 77%. Studies with lower compliance varied in sample size (ie, 20 to 284 participants), study duration (ie, 4 to 30 days), prompting schedules, forms of compensation, and year of publication (ie, 2013-2022).

Factors Related to Compliance

Due to the small sample size of studies in various categories of synthesizing, nonparametric Kruskal-Wallis tests were performed to determine the effects of the factors on median compliance rates. These results are presented in Table 2. The results indicated nonsignificant differences for the movement behavior assessment method (χ^2_2=0.2; *P*=.88); number of items per prompt (χ^2_3=1.2; *P*=.75); number of days (χ^2_3=1.1; *P*=.77); or compensation structure (χ^2_4=3.9; *P*=.42). There was a statistically significant difference between compliance based on prompting frequency (χ^2_3=15.2; *P*<.001) and the binned number of prompts per day (χ^2_3=1.2; *P*<.001). Furthermore, a statistically significant difference was observed for compliance based on the prompting schedule (χ^2_4=9.9; *P*=.04) and compliance based on the EMA platform (χ^2_5= 9.5; *P*=.04). Additional linear regression analyses did not find a statistically significant relationship between the number of study days and the number of prompts per day (coded as continuous variables) with compliance. There was no statistically significant difference in mean compliance between the studies that only used objective assessments (n=15; 81.57%) versus self-reported PA (n=33; 80.20%; t_{46}=–0.11; *P*=.46). There was no statistically significant difference in compliance between the studies that had PA as the primary outcome (40/48, 81.22%) versus not (8/48, 77.66%; t_{46}=–0.23; *P*=.41).

Discussion

Principal Findings

This systematic review addressed a current knowledge gap by synthesizing the body of literature that has used EMA methodologies to investigate adolescents' and emerging adults' movement behaviors for the purpose of identifying protocol-related factors that influence EMA compliance. Only 1 previous study has specifically examined factors related to compliance among youth. Heron et al [11] conducted a systematic review to provide best practices by identifying common approaches and challenges and providing reporting guidelines for compliance; however, do not specifically identify factors besides recommendations for staff to complete compliance check-in and implement compliance-based incentives. While there is substantial heterogeneity among the included EMA studies, the pooled compliance rate was high and comparable to that reported in previous reviews. Unlike the few findings in previous literature, this review identified several specific EMA design factors based on the CREMAS checklist (ie, delivery scheme, study duration, and prompt frequency), including factors that interact to influence participants' compliance in responding to EMA surveys. It should be noted, however, that the disparities in compliance attributable to EMA design factors were rather small as this population surprisingly responded consistently to prompts. This being said, there were no major discrepancies based on the factors we analyzed that led to considerable missingness.

Associations Between PA Assessment Tool and Compliance

A total of 20 studies measured PA using an accelerometer which may have reduced self-report biases and recall errors attributable to self-reported instruments [69] but potentially increased the burden associated with the study overall. We observed no significant difference in EMA compliance based on the PA assessment method. This suggests that compliance rates to EMA are not better when participants must wear a separate device (but do not have to self-report their PA levels through EMA). Despite the potential additional burden of wearing an accelerometer (uncomfortable, unfashionable, or inconvenient), participants did not reduce response rates to EMA.

Associations Between EMA Duration, Prompting Schedule, and Compliance

Overall, there was no difference in compliance between schedules of different study lengths. Most studies lasted between 7 and 14 days (n=21). Our findings suggest that the timing and frequency of EMA prompts may be a more critical factor in EMA design when attempting to optimize compliance. Logically, participants are more likely to respond if prompts align with their schedule or if they occur at predictable intervals. Therefore, the frequency of EMA prompts must be balanced to minimize the burden while providing researchers with sufficient representative EMA data for analysis. At the same time, longer study durations (eg, ≥14 days) may provide more representative data on participants' behavior and experiences but can be perceived as more burdensome and result in noncompliance. One potential explanation could be that participants have incorporated EMA into their routines, and the behavior of responding has become a habit. It is important to acknowledge, however, that while participants may initially be able to handle the prompting schedule, longer EMA studies may be subject to temporal influences like schedule changes (eg, summer break for adolescents and transition to another work schedule for emerging adults) that could threaten compliance rate.

Ultimately, researchers should consider the minimum required number of days or prompts per day necessary to answer their research question based on the nature of the phenomena being studied. How frequently are movement behaviors or the predictors of the behavior expected to change? These considerations need to be weighed against participants' daily schedules and routines. For example, some studies involving adolescents intentionally did not prompt participants during school hours, which stands to be missed when this population tends to have opportunities to be physically active (eg, physical education, clubs, and athletics) [70]. Researchers could take this further and use adaptive sampling techniques to adjust the frequency based on contextual factors such as weekday school attendance or prompting participants between structured class times (ie, recess time or transitions between classes). In addition, most studies used only an interval-based design (n=27). These studies had the highest compliance, which supports the assumption that receiving prompts at consistent intervals is less disruptive than prompts at random and unpredictable times. Additional consideration may include the use of passive-sensing (eg, wearable monitoring) in conjunction with EMA or active-sensing, requiring participants to respond to prompts being delivered.

Associations Between the EMA Platform and Compliance

We found that the platform used to deliver the EMA study or protocol could significantly impact compliance and data quality. In our sample of studies, most studies (n=16) used a web-based format (Qualtrics survey) to administer EMA. However, we did not disentangle how the link was provided to participants. For example, some researchers may have emailed the link, whereas

XSL•FO
RenderX

others sent an SMS text message to participants. Both options still capitalize on the convenience of mobile devices. While carrying an extra device (n=13) may have been initially novel to youth, it may be considered burdensome now, especially in studies that require participants to wear an accelerometer to capture movement behavior. Due to the increased prevalence of smartphone ownership in adolescents, it is expected that EMA researchers will adopt smartphones or smartphone apps to lessen the additional burdens associated with delivering EMAs. Within smartphone apps, it is worth considering additional factors that may influence compliance, such as the user interface or design of the platform or the use of gamification aimed at increasing engagement [71]. Intensive self-monitoring is becoming more acceptable or feasible, especially in studying health and mental health, and there is evidence of youth and emerging adults using self-care health-tracking apps in daily life with high engagement [72]. But beyond wearable devices, the adoption of self-monitoring motivating factors is still in the early stages of PA research [70].

Associations Between EMA Response Frequency and Prompts Per Day and Compliance

The adoption and maintenance of movement behaviors in youth are complicated as there is a combination of factors with different possible temporalities. Due to the feasibility and to support more advanced theories, more studies have included multiple prompts per day (ie, 12 daily diary studies vs 36 studies that prompted numerous times per day). However, we observed that the daily diary studies had higher compliance. While more frequent prompts provide more comprehensive data for researchers, this also increases participants' burdens. Frequency should depend on the research question, the population being studied, and the EMA platform being used.

Associations Between Participant Compensation Type and Compliance

Most included studies did not adequately report their compensation mode or protocol (n=21). Based on the studies that did report compensation type, there was no difference between providing monetary compensation or course credit. With monetary compensation, there are also different levels and the potential need to determine a rate per unit of burden, which is beyond our analyses. Beyond incentives, researchers should consider additional motivational strategies to encourage compliance with more burdensome schedules. For example, participants could be more compliant if the research question feels relevant and reminded of the importance of the research they are participating in. Alternatively, participants may prefer reporting on positive health behaviors, depending on whether the study participants were able to or interested in reviewing their data and the relationships found. Due to self-presentation bias, researchers must emphasize that all data are valuable to prevent participants from not responding if they did not engage in positive health-enhancing behaviors such as PA. Importantly, aesthetically pleasing apps that minimize usability issues will likely be critical factors that help maximize compliance in EMA studies examining PA and ST among youth [69].

Combinations of Different EMA Features and Compliance

In addition to studying the independent impact of EMA design parameters, this study provided unique contributions to the literature by inspecting the combinations of different EMA design features and their associations with compliance among youth. Based on the studies included, we found that daily diaries consistently provided an average of at least 90% compliance regardless of study duration. However, it should be noted that even the more burdensome delivery schemes with multiple EMA prompts per day with 7-14 days of study duration had relatively higher compliance rates, primarily when the prompts were delivered at random times. As the daily EMA prompts increase to 9 prompts or more, the predictable fixed interval yields the highest compliance rate. The caveat is that only 1 EMA study in this category provided the highest compliance rate (99%), but the study consisted of only 1 day of intensive prompting. There was no noticeable interaction between EMA prompting density and study duration, except that longer EMA studies with multiple random prompts per day (<9) had relatively lower compliance (75%).

Strengths and Limitations of This Review

This review follows a preregistered search strategy, evaluates compliance to EMA by individual and design factors, and assesses an understudied age range. While this review addresses a critical gap in our current knowledge, several limitations exist. First, we did not account for sample size in our analyses. Second, other relevant EMA studies may not be identified in this review based on our preregistered search criteria. This may be particularly important with the high likelihood of some publication biases, with potential studies with low participant compliance remaining unpublished. Third, and similarly, many of the studies excluded or dropped participants' data with lower compliance from analyses, which may bias our findings to reveal higher study compliance. Nevertheless, EMA studies often have selection bias such that participants who join anticipate being able to be compliant. Our results are still useful as we can still learn from which features are most relevant and predictive of compliance among all these high compliance studies. Fourth, our analyses are based on what was reported in the papers—authors were not contacted to provide additional information when reporting was inadequate. Fifth, the outcome of this study was compliance which we used as a proxy for participant or study burden. Many studies have directly measured burden through usability scales or qualitative studies. Moreover, we did not extract the constructs assessed by the studies through EMA. It is possible that some constructs are more cognitively difficult and cause more burden leading to lower compliance due to participants avoiding completing them. One of our exclusion criteria removed papers that reported on multiple studies; while this simplified data analysis, this may have reduced the information our review gathered on compliance. We excluded papers that reported on multiple studies to maintain consistency in the studies analyzed. Given we were assessing the quality of reporting, authors may have needed to reduce the details of study methods in their papers to meet journal word counts, which obscure insights into compliance trends. Additionally, if the second study described

XSL•FO
RenderX

in the paper is an improved iteration of the first study, this contaminates the pooled analyses. Finally, following the CREMAS guidelines, we only extracted data if studies reported on various factors outlined in the checklist, which may exclude extracting potentially relevant details such as what participant training entailed or what attrition rates were.

Recommendations and Future Directions

This systematic review closely followed each reporting criterion within CREMAS. Additionally, the study explores interactions between some of the more salient factors likely to impact EMA compliance in PA and ST research. Although there was no precise combination of factors that were indicative of higher compliance, especially among delivery schemes with multiple EMAs each day, it should be reiterated that the research design needs to fit the research question and the phenomena of interest—and researchers should think about how to minimize participant burden wherever possible. Importantly, as EMA research continues to increase rapidly in this field, authors must report as much as possible about the design of the study and compensation so future researchers can replicate successful designs.

Beyond what was examined in this review, other factors must be further explored as factors associated with EMA compliance. The first is related to participant training. We did not extract the quality or quantity of EMA training or levels of participant contact in each study—although this was not reported in most studies. Especially with the adoption of mobile devices, researchers must be able to support participants in the case of technical difficulties. Additionally, reporting on difficulties encountered and their impact on compliance would be beneficial, particularly as more studies adopt passive sensing devices to assess PA and ST. Second, more specificity in terms of participant recruitment would also be helpful. How participants were recruited for EMA studies may be particularly important. There may be certain response biases that exist, as participants may not fully understand the high degree of participant burden in community sampling (eg, going into places and spaces to recruit) when compared to participants who were required to reach out to a study team or make an effort to go into a lab or receive in-person training for the study. Moreover, the length of the EMA survey may play a role. We found that the studies with the most EMA prompts per day had high compliance rates, but this may be due to short surveys. The length of time it takes to complete the surveys (number of questions per survey or total completion time) may be a metric for future study. Additionally, greater transparency is needed in reporting, as many papers only report on the number of items that were analyzed when many more items could have been collected. Additionally, this paper was not able to further examine if the amount within the compensation structure matters, as most papers did not disclose the structure. As this may be an important factor, papers should report this information for future analysis. Preregistration on platforms such as the Open Science Framework may help to address this shortcoming. Finally, while the papers all reported on compliance, less than half the studies reported on missing data relationships by assessing if data were missing at random or related to demographic factors. More attention and reporting should be encouraged around patterns of missingness (sporadic, complete attrition after a given point, only during specific windows). Similarly, as compensation is often used as a technique to encourage compliance, the amount of compensation or details on the compensation structure should be reported for future researchers to specifically examine this factor.

Conclusions

As EMA methodology becomes more prevalent in movement behavior research among youth, it is imperative to understand the potential impact of specific EMA protocol features on study compliance to reduce participant burden and enhance data quality. While this intensive data collection effort involving repeated observations of the participants enables researchers to study the temporal patterns and momentary processes that influence PA and ST, compliance is critical for data quality and validity of the inferences that can be made. Although overall findings did indicate relatively high EMA compliance for PA and ST studies among adolescents and emerging adults, there were some differences based on delivery schemes, study duration, and prompt frequencies. Greater consistency in reporting and more specificity when explaining procedures are required to understand further how EMA compliance could be optimized among this population.

Abstract

Background: Frail older adults are at greater risk of adverse health-related outcomes such as falls, disability, and mortality. Mild behavioral impairment (MBI), which is characterized by neurobehavioral symptoms in individuals without dementia, is a crucial factor in identifying at-risk groups and implementing early interventions for frail older adults. However, the specific role of social functioning, which encompasses social interaction and loneliness levels, in relation to frailty within this group remains unclear.

Objective: This study investigated the association between frailty status, social interaction frequency, and loneliness levels among older adults with subjective cognitive decline (SCD) or mild cognitive impairment (MCI) while adjusting for MBI symptoms in 2 contexts: the presence and severity of MBI symptoms.

Methods: Older adults with SCD or MCI were recruited from an outpatient clinic specializing in the early diagnosis and care management of dementia at a community health center, as well as from a community service center in Seoul, South Korea. Using an ecological momentary assessment approach, participants reported their daily social interaction frequency and loneliness level via a mobile app, 4 times daily for 2 weeks. Frailty status, the outcome variable, was assessed using the Korean version of the frailty phenotype questionnaire. Additionally, MBI symptoms were assessed using the 34-item MBI-Checklist covering 5 domains. Multinomial logistic regression analyses were performed to investigate the association between frailty status (robust, prefrail, and frail), and the independent variables, adjusting for the presence or severity of MBI symptoms.

Results: Among the 101 participants analyzed, 29.7% (n=30) of participants were classified as prefrail, and 12.8% (n=13) of participants were classified as frail. Higher average daily social interaction scores were consistently associated with lower odds of a frail status compared to a robust status. This was evident in the models adjusted for both the global presence (relative risk ratio [RRR] 0.18, *P*=.02) and global severity (RRR 0.20, *P*=.02) of MBI symptoms.

Conclusions: Frequent social interaction was inversely associated with frail status in older adults with SCD or MCI, even after adjusting for the presence and severity of MBI symptoms. These findings highlight the potential of social functioning as a modifiable factor for addressing frailty among older adults at risk of cognitive and functional decline. Future prospective studies using real-time measurements are needed to refine these findings and further investigate additional risk factors and functional outcomes in this group.

Introduction

The demographic shift toward an increasingly aging population presents significant public health challenges, with a prominent focus on aging-related adverse health outcomes such as frailty. Frailty is a multidimensional syndrome characterized by a decline in physiological reserve across multiple systems, leading to increased vulnerability to stressors and adverse outcomes. These outcomes include physical limitations, such as impaired mobility, muscle weakness, fatigue, cognitive decline, social isolation, and psychological distress [1-3]. Frailty manifests through physical, cognitive, and psychological components, often resulting in increased risks of falls, disability, hospitalization, and mortality [1,2,4]. Physically, frailty impairs an individual's ability to perform daily activities, while cognitively, it may exacerbate the risks of memory and attention deficits [1-6]. Social and psychological factors also play a role, as frailty is often associated with social isolation and depressive symptoms [3,7]. Frailty and prefrailty incidences were estimated at 43 and 151 new cases per 1000 person-years, respectively, indicating that approximately 1 in 6 community-dwelling older adults may be frail [8]. Frailty is more common in women, older individuals, those with a lower socioeconomic status, and individuals with comorbid chronic diseases and disabilities [1,8-10].

Subjective cognitive decline (SCD) refers to a self-perceived decline in cognitive performance without objective evidence of cognitive impairment [11,12]. Mild cognitive impairment (MCI) represents a state between normal cognition and dementia, characterized by a cognitive decline more pronounced than expected for an individual's age and educational level, but without significant interference in daily activities [13,14]. The co-occurrence of frailty and early-stage cognitive decline has been well documented, with studies showing an increased likelihood of frailty in older adults with SCD or MCI. Two systematic reviews and meta-analyses have offered solid evidence of this relationship [15,16]. Specifically, a cross-sectional study of 2386 individuals with SCD revealed that they had a higher likelihood of being prefrail or frail, compared with individuals with normal cognition, even after controlling for factors such as sociodemographic characteristics, physical functionality, psychosocial aspects, and biochemical influences [12]. The Victoria Longitudinal Study, which followed 632 individuals without dementia, also showed that increased frailty was associated with a more rapid memory decline [5]. Therefore, it is essential to identify individuals with SCD or MCI who are at risk of becoming prefrail or frail, and to implement preventative interventions that focus on modifiable lifestyle and health factors.

Although not all cases of frailty and early cognitive impairment are reversible, evidence supports the potential reversibility of both conditions, including SCD and MCI, through the early detection of at-risk groups and the application of tailored interventions [2,15,17,18]. In addition, factors such as age, sex, and activities of daily living are associated with frailty and cognitive decline [19-22], and mild behavioral impairment (MBI) is also correlated with higher levels of frailty and an increased risk of cognitive decline [2,3]. MBI, which emerges later in life, is a neurobehavioral syndrome characterized by sustained and impactful neuropsychiatric symptoms across 5 domains: decreased drive and motivation, affective dysregulation, impulse dyscontrol, social inappropriateness, and abnormal perception or thought content [23]. MBI is considered a precursor to, or concurrent with, MCI, affecting older adults with either normal cognition or SCD [23]. Significant associations have been observed between certain MBI domains and increased frailty risk in individuals with MCI [3]. Additionally, frailty was associated with both the presence and severity of MBI, especially in men [2]. These findings underscore the importance of assessing MBI to detect risks before the onset of frailty and dementia and warrant the application of interventions for its potential modification.

Psychosocial functioning, which encompasses how individuals engage with society and adapt to environmental challenges, is also an influential factor associated with frailty [24]. Infrequent social interactions, which reflect the quantitative aspects of an individual's limited contact with others [7], and loneliness or perceived social isolation are important factors in this context [25]. Although a definitive theory connecting limited social interaction, loneliness, and frailty has yet to be established, various studies have indicated that reducing social isolation and loneliness in later life can significantly improve overall well-being, underscoring the need for collective consideration of how these factors impact physical health [7]. The English Longitudinal Study of Aging demonstrated that social isolation and loneliness increased the risk of frailty in older adults [26]. Furthermore, given the significant impact of social isolation and loneliness, addressing even moderate levels of these factors is important, as they are associated with an increased risk of worsening frailty [27]. Understanding these psychosocial factors is vital in the broader aging context, as they affect not only physical health but also psychological well-being, thereby potentially influencing older adults' overall quality of life and health care needs [7]. Therefore, the interplay between psychosocial factors and health outcomes underscores the importance of holistic approaches in developing geriatric and preventive strategies.

The ecological momentary assessment (EMA) provides a dynamic and immediate record of personal experiences. It is particularly effective for older adults with cognitive decline, offers a comprehensive view of their everyday social lives, and yields more nuanced insights than conventional global measures [28]. By capturing patterns of daily social interaction or loneliness levels, the EMA addresses restrictions on time or recall bias [29]. However, the relationship between frailty, social interaction, and loneliness levels, particularly in the context of MBI symptomatology, remains underexplored, while few studies have used EMA to examine the real-time social functional status

XSL•FO
RenderX

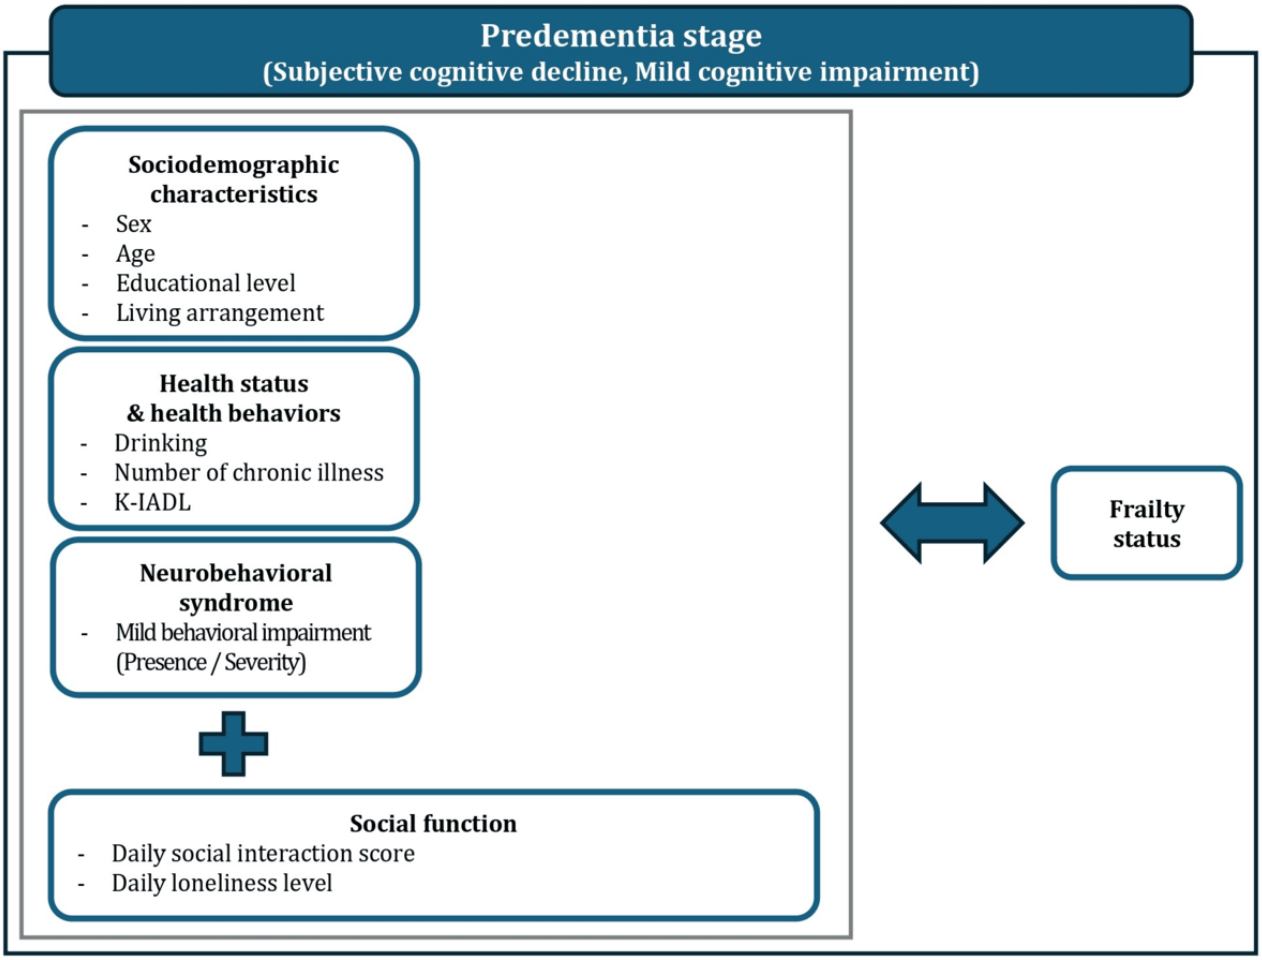
among older adults with cognitive decline. Therefore, this study aimed to investigate the cross-sectional relationships between social interaction frequency, loneliness levels, and frailty status among older adults with SCD or MCI in two contexts: (1) adjusting for the presence of MBI symptoms and (2) adjusting for the severity of MBI symptoms. We hypothesized that, similar to MBI symptoms, both the frequency of social interactions and the level of loneliness would be significantly correlated with frailty. This exploration is anticipated to yield deeper insights into psychosocial factors related to frailty among individuals with SCD or MCI.

Methods

Design

Our study represents the first wave of a 3-year prospective longitudinal study aimed at developing functional prediction models based on behavioral and psychosocial indicators for older adults with SCD or MCI. The study protocol was published elsewhere [30]. The following is a detailed explanation of the variables considered in this study. We constructed the conceptual framework of our study, based on the social-ecological model for older adults [31] and the successful aging model proposed by Rowe and Kahn [32], as shown in Figure 1.

Figure 1. The proposed conceptual framework illustrates the relationship between frailty status, social interaction, and loneliness levels, while adjusting for the presence and severity of mild behavioral impairment symptoms among older adults with subjective cognitive decline or mild cognitive impairment. Based on the social-ecological model for older adults and the successful aging model proposed by Rowe and Kahn, individual determinants include sociodemographic characteristics, health status, and health behaviors. Social function, including daily social interaction frequency and daily loneliness level, is also considered. K-IADL: Korean Instrumental Activities of Daily Living scale.



Participants and Setting

For the larger 3-year longitudinal study, we initially estimated the required sample size using R (generalized linear mixed model, effect size=0.30, k=2, power=0.80, α=0.05, df=30), yielding a minimum of 106 participants. The study protocol has been published elsewhere [30]. The effect size was selected based on prior studies examining the relationship between frailty and social-behavioral factors, which reported moderate effect sizes in similar aging populations [33,34]. Based on these findings, we adopted an effect size of 0.30 as a conservative estimate, to reflect a moderate expected effect while ensuring robustness in our calculation. To account for potential attrition, we adjusted the sample size to 127 participants, anticipating a 20% dropout rate. This adjustment aligns with established guidelines that emphasize careful assessment of attrition rates in aging populations, particularly given the health-related challenges that contribute to higher dropout rates [35,36].

XSL•FO
RenderX

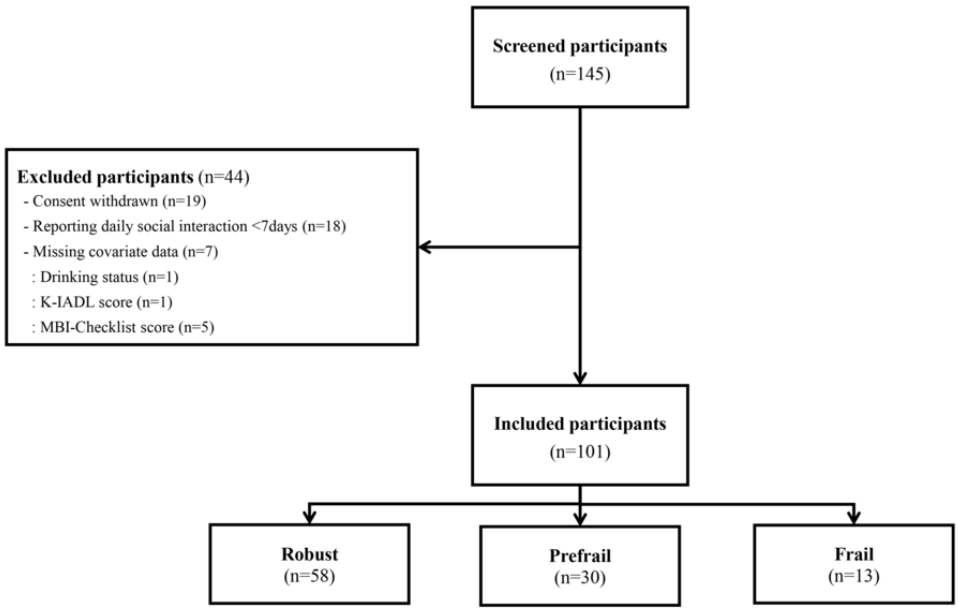
We initially recruited 145 individuals from a dementia relief center and a community service center in Seoul, South Korea (SCD: n=91; MCI: n=54) between October 2022 and November 2023. The dementia relief center houses an outpatient clinic that specializes in early diagnosis and care management of dementia, whereas the community service center serves as a place for older adults to engage in recreational and wellness programs, irrespective of a dementia diagnosis. Specific criteria were applied to recruit study participants from each center. The common inclusion criteria for the study participants were as follows: (1) older than 65 years, (2) ability to use a smartphone, (3) ability to respond to momentary questionnaires via a mobile app, and (4) ability to provide written consent for participation.

Individuals who met the inclusion criteria were selected for the SCD group. Participants were either (1) individuals from the dementia relief center who, according to a nurse's report, had neither been diagnosed with MCI nor dementia; or (2) individuals recruited from the community service center through convenience sampling, who self-reported having no history of MCI or dementia diagnosis and scored above 24 on the Korean Mini-Mental State Examination, second edition. Further, we confirmed SCD in individuals from both the dementia relief center and the community service center by ensuring that they provided an affirmative response to the question, "Do you think your memory has gotten worse, compared with the previous year?"

The MCI group consisted exclusively of participants clinically diagnosed with MCI by medical doctors at the dementia relief center. This group was screened to include only individuals who scored above 18 on the Korean Mini-Mental State Examination, second edition. Participants were excluded if they were (1) illiterate; (2) diagnosed with neurological diseases such as epilepsy, stroke, Parkinson disease, or other types of brain damage; (3) diagnosed with psychiatric diseases such as schizophrenia or bipolar disorder; and (4) undergoing critical illness treatments such as chemotherapy, had severe cardiovascular disease, or had abused substances (including narcotics or alcohol) within the last 3 years.

After excluding individuals who withdrew their consent (n=19), those who reported EMA responses for less than a week or reported no EMA responses per day (n=18), and those with missing covariate data (n=7), 101 individuals were included in the final sample. The participant selection process is illustrated in Figure 2.

Figure 2. Sequential steps involved in the recruitment and selection of study participants. We recruited 145 individuals aged ≥65 years from a dementia relief center or a community service center in Seoul, South Korea. The figure depicts the subdivision of these individuals into 3 groups: 58 with robust, 30 with prefrail, and 13 frail, based on specific inclusion and exclusion criteria. K-IADL: Korean Instrumental Activities of Daily Living scale; MBI: mild behavioral impairment.



Measures

Frailty

Frailty status was the primary outcome variable in this study. Frailty was assessed using the Korean version of the frailty phenotype questionnaire (FPQ), which is specifically designed to screen for the Fried Frailty Phenotype in community-dwelling older adults [37]. While the Fried Frailty Phenotype requires direct measurements of gait speed, grip strength, and physical activity, the FPQ has been validated as an effective proxy for these assessments. Among Korean older adults, the FPQ demonstrated satisfactory diagnostic accuracy for the Fried Frailty Phenotype, with an area under the curve of 0.89, a high sensitivity of 81.7%, and a specificity of 82.5% [37].

The FPQ is particularly well-suited for epidemiological research due to its low resource requirements and ease of administration,

XSL•FO
RenderX

making it a practical screening tool for community-dwelling older adults where detailed clinical assessments may not be feasible. The FPQ comprises 5 questions addressing the key aspects of frailty: fatigue (exhaustion), resistance (weakness), ambulation (slowness), inactivity, and weight loss. Scoring from 0 to 5, where 0 indicates robustness, 1-2 indicates a prefrail status, and ≥ 3 indicates a frail status.

Daily Social Interaction Frequency and Level of Loneliness

Daily social interaction frequency and level of loneliness were the main independent variables. Daily social interaction frequency was measured to reflect quantifiable aspects of social contact, while the level of loneliness was assessed to capture one's perceived view of the consequences of social contact [7]. While the level of loneliness is often measured with a single directional question about one's loneliness status, a solid assessment method for social interaction has yet to be established [7]. Despite the complexity and heterogeneity of its indicators, social isolation can be quantitatively assessed by aggregating various factors into a composite index [7]. Building on a prior study that determined social activity frequency by inquiring about the frequency of participant engagement in socially interactive activities among older adults without clinical signs of dementia rated on a 5-point scale [38], this study quantitatively assessed the daily frequency of social interaction.

Given the cognitive challenges faced by our participants with SCD or MCI, simplifying the data collection process was essential to reduce participant burden and ensure consistent and reliable responses. For this reason, we did not differentiate between types of social interactions (eg, in-person, phone-based), as the study's primary goal was to explore the overall relationship between social engagement and frailty in older adults with cognitive decline.

The EMA method was particularly well-suited for this purpose because it allowed us to collect real-time data on both the frequency of social interactions and participants' perceived loneliness. This approach minimizes recall bias, particularly relevant for individuals with cognitive difficulties. A mobile EMA app was used. With smartphone ownership rates among older Korean adults in 2023 reaching 97.2% for those aged 60-69 years and 72.9% for those aged 70 years and older [39], the feasibility of this method was significantly enhanced.

The EMA method facilitated real-time data collection through a mobile phone app that set off alarms 4 times daily (upon waking and 3 times during mealtimes) over 2 weeks. Each alarm prompted participants to answer 2 questions. The first question assessed the frequency of social interactions since upon waking or since the last mealtime: "How many times have you had a social encounter?" Participants recorded the number of face-to-face meetings, phone calls, or video calls lasting more than 5 minutes using a 5-point Likert scale (0 for "no contact," 1 for "once," 2 for "two times," 3 for "three times," and 4 for "four or more times"). The second question assessed loneliness: "At this moment, how lonely do you feel?" using a similar 5-point Likert scale (0="very lonely" to 4="not lonely at all"). Both questions were asked 4 times a day at set intervals (upon waking and after breakfast, lunch, and dinner). Figure 3 shows the captured screens from the mobile app. The research staff provided follow-up contacts for troubleshooting as needed. Participants received gifts worth US $50 after completing the 2-week data collection period.

XSL•FO
RenderX

Figure 3. The mobile app screens captured 2 questions that assessed daily social interaction frequency and loneliness levels. Daily social interaction frequency was measured by asking, “How many times did you interact with others, including face-to-face meetings, phone calls, or video calls lasting more than five minutes?” Responses were categorized into 5 options: no contact, once, twice, 3 times, and 4 or more times. Loneliness levels were measured by asking, “At this moment, how lonely do you feel?” Responses were also categorized into 5 options: very lonely, lonely, neutral, not lonely, and not lonely at all. Both questions were administered 4 times daily at specific intervals (upon waking and after breakfast, lunch, and dinner).

We implemented 4 strategies to ensure accurate EMA data collection. First, we provided comprehensive training sessions, including repeated practice, to ensure participants could use the mobile app independently. Second, we provided detailed instructional manuals for completing the response process (Multimedia Appendices 1-3). Although the EMA questions are simple, we addressed potential challenges given that the participants were individuals with SCD or MCI. Third, we established a helpdesk for assistance with any app-related issues during the follow-up period. Last, we offered direct support as needed, with written contact information provided to ensure participants could reach researchers via phone or in person. These measures aimed to enhance participants’ understanding and proficiency, contributing to more accurate data collection. Approximately 15 participants requested assistance during the study, mainly due to issues with mobile EMA alarms not triggering due to internet connectivity issues or difficulties with smartphone lock functions. Researchers provided phone guidance and, when necessary, conducted in-person visits to resolve the issues and offered additional training.

XSL•FO
RenderX

The quantity of social interaction and the level of loneliness were indicated as daily mean scores based on previous studies [28,40,41]. Data processing involved calculating the maximum daily social interaction frequency as the final daily score. For instance, if a participant reported varying frequencies of social encounters throughout day 1, the highest frequency reported that day was recorded as the final score. The average daily social interaction score was then determined by summing the scores and dividing them by the total number of valid responses. Similarly, the average daily loneliness score was calculated by adding the total loneliness scores recorded each day (with at least one response) and dividing them by the total number of valid response days.

Presence and Severity of MBI Symptoms

The presence and severity of MBI symptoms were included as key covariates. The Mild Behavioral Impairment Checklist (MBI-C) was used to assess the onset of sustained and impactful neurocognitive symptoms in the predementia stage [23]. The MBI-C systematically evaluates symptoms across the five domains of MBI, persisting for at least 6 months: (1) decreased motivation, (2) affective dysregulation, (3) impulse dyscontrol, (4) social inappropriateness, and (5) abnormal perception or thought content. Each symptom was initially assessed dichotomously (yes/no), followed by a severity rating of mild (1), moderate (2), or severe (3) [23].

In this study, the Korean version of the MBI-C was used to evaluate the presence and severity of MBI symptoms. The MBI-C, a brief screening tool previously validated, was implemented to detect MBI in line with established criteria [3]. The MBI-C has been translated into various languages including Korean. Psychometric evaluation of the Korean version demonstrated significant correlations with the Neuropsychiatric Inventory in individuals with amnestic MCI (r=0.25, P<.01) and non-amnestic MCI (r=0.36, P<.05) [42,43]. In this study, Cronbach α for the MBI-C was 0.89. For presence assessment, we used a dichotomous method for both domain-specific and global MBI symptoms, with a cut-off score > 0 indicating the presence of MBI symptoms [2]. Severity was assessed as either (1) domain-specific, where the sum of scores from each individual domain was calculated; or (2) global, involving the cumulative sum of scores across all domains [2].

Covariates

Frailty encompasses numerous biological, physiological, and environmental changes that typically occur during the aging process [21]. Therefore, we considered sociodemographic and health-related characteristics, health behaviors, and functional limitations as covariates. The demographic characteristics of participants included sex (male/female), age group (<70, 70-74, 75-79, and ≥80 years), educational level (<9/≥9 years), and living arrangement (living alone/residing with others).

For health-related characteristics, we considered the total number of chronic illnesses diagnosed, including hypertension, diabetes, cardiovascular diseases, cerebrovascular diseases, gastrointestinal diseases, chronic respiratory diseases, chronic kidney diseases, and musculoskeletal conditions. Participants' cognitive status was dichotomously categorized as SCD or MCI based on their responses, which were recorded to evaluate the inclusion criteria. Health behavior aspects included drinking status (active drinker/nondrinker). Owing to the limited sample size of former or current smokers (n=2), smoking status was excluded from the statistical analysis.

As demonstrated in previous studies, dependence on managing higher levels of functional performance is associated with frailty [21,22]. Therefore, functional limitations were assessed using the Korean Instrumental Activities of Daily Living (K-IADL) scale, which measures the ability to perform complex daily tasks such as cooking, grooming, housekeeping, shopping, financial management, transportation, laundry, short-distance walking, making phone calls, and managing medications [44]. Each item on the K-IADL scale is rated from 0 to 4, with higher scores indicating greater dependency. The K-IADL's validation, conducted with older adults aged older than 65 years, demonstrated strong internal consistency (Cronbach α=0.94), high interrater reliability (κ value=0.81-0.95), and test-retest reliability correlation (≥ 0.70) [44]. In this study, high K-IADL scores indicated diminished functional capabilities and were analyzed as continuous variables.

Statistical Analysis

Descriptive statistics were used to outline the general characteristics of the participants and compare differences between the robust, prefrail, and frail groups. Categorical variables are presented as counts and percentages, while continuous variables are summarized as means with SDs.

To assess the normality of continuous variables, we performed the Shapiro-Wilk test. If the data were normally distributed and variance was equal, analysis of variance was applied to compare differences between groups. When normality was not met or variance was unequal, the Kruskal-Wallis test was used. A chi-square test was used to assess differences in categorical variables between groups, with the Fisher exact test applied when the expected cell count was less than 5.

We conducted multinomial logistic regression analyses to examine the association between frailty status, social interaction frequency, and loneliness levels among older adults with MCI or SCD. Frailty status was the primary outcome variable and was categorized into 3 groups: robust, prefrail, and frail. Social interaction frequency and daily loneliness levels were the independent variables, assessed using EMA.

To account for potential confounding effects, MBI symptoms were included as a key covariate. Additionally, other confounders, including sex, age group, educational level, living arrangement, number of chronic illnesses, cognitive status, health behaviors, and functional limitations, were selected based on their established relevance to frailty and social engagement in previous studies [2,3,19-22].

Separate multinomial logistic regression models were performed to adjust for MBI symptom presence and severity. All independent variables were simultaneously entered into the model to ensure consistency and comparability across analyses. Multicollinearity was assessed using the variance inflation factor to confirm that the included variables were not highly correlated. Model fit was evaluated using the generalized

XSL•FO
RenderX

Hosmer-Lemeshow test and model specification was checked for validity. Statistical significance was set at $P<.05$ and all analyses were performed using Stata software (version 16; StataCorp).

Ethical Considerations

This study was approved by the Institutional Review Board of Severance Hospital, Yonsei University Health System (number 4-2022-0637). In accordance with ethical guidelines, all participants provided their written informed consent prior to their inclusion in the study. To ensure ethical integrity, individuals with severe cognitive decline who were assessed as incapable of making informed decisions regarding participation were excluded from the study.

Results

Participants' General Characteristics

Table 1 presents the general characteristics of participants. A total of 101 participants were included in the analysis; 58 (57.4%) were categorized as robust, 30 (29.7%) as prefrail, and 13 (12.9%) as frail. Significant differences were observed between the groups in age and global MBI symptom severity. The mean age and SDs for each group were robust (74.9, SD 5.1 years), prefrail (75.7, SD 6.5 years), and frail (82.0, SD 4.9 years), with corresponding age ranges of 65-87, 65-89, and 73-89 years, respectively. For global MBI severity, the median score for all participants was 3 (IQR 1-9.5). The robust group had the lowest median severity score (2, IQR 1-4.5), while the frail group exhibited the highest severity (9, IQR 3-23.5).

Table 2 displays a descriptive summary of social interaction frequency and loneliness levels for all participants, stratified by frailty status. We summarized the average maximum daily social interaction score by calculating the average of each participant's daily maximum scores across the study period, resulting in a single, average score per participant. No significant differences were observed in the mean average maximum daily social interaction scores among the groups: robust (3.0, SD 0.8), prefrail (2.9, SD 0.9), and frail (2.4, SD 0.9). Similarly, no significant differences were found in the mean average maximum daily loneliness levels, with scores of 3.4 (SD 0.5) for the robust group, 3.3 (SD 0.6) for the prefrail group, and 3.1 (SD 0.9) for the frail group.

Table 2. Descriptive statistics of daily social interaction frequency and loneliness levels by frailty status.

	Total (N=101)	Robust (n=58)	Prefrail (n=30)	Frail (n=13)	*P* value
Social interaction frequency per day					
Range	0-4	0-4	0-4	0-4	
Mean (SD)	2.9 (0.8)	3.0 (0.8)	2.9 (0.9)	2.4 (0.9)	.08
Loneliness level per day					
Range	0-4	1-4	0-4	0-4	
Mean (SD)	3.4 (0.6)	3.6 (0.5)	3.3 (0.6)	3.1 (0.9)	.06

Figure 4 illustrates the variations of the average daily social interaction scores and average daily loneliness levels categorized by frailty status. The robust group is characterized by the highest median values in daily social interactions and the lowest loneliness levels compared with prefrail and frail groups. In contrast, the frail group demonstrates the lowest median social interaction frequency and the highest loneliness levels. Furthermore, the density distribution of mean maximum daily social interaction scores and mean maximum daily loneliness level by frailty status is illustrated in Multimedia Appendices 4 and 5. While the overall distribution is right skewed across all participants, the frail group exhibits a relatively higher density in the lower frequency of social interactions compared with the robust or prefrail group (Multimedia Appendix 4). In addition, the frail group shows a relatively lower density of participants experiencing lower loneliness levels compared with robust and prefrail groups, even though the overall distribution is right-skewed (Multimedia Appendix 5).

Figure 4. Distribution of average daily social interaction score and average daily loneliness level by frailty status. This figure displays the median levels and range variability of both average daily social interaction score and average daily loneliness levels among participants, categorized into robust, prefrail, and frail groups.

Primary Outcomes

Association Between Daily Social Interaction Frequency, Daily Loneliness Level, and Frailty Adjusting for the Presence of Global MBI Symptoms

Table 3 illustrates the relationship between frailty, daily social interaction frequency, and daily loneliness level after adjusting for the presence of global MBI symptoms. After adjusting for the presence of global MBI symptoms, neither the average maximum daily social interaction score (relative risk ratio [RRR] 0.74, *P*=.42) nor the average maximum daily loneliness level (RRR 0.89, *P*=.76) were significantly associated with prefrail status. Similarly, no significant relationship was observed between the average maximum daily loneliness level and frail status (RRR 0.27, *P*=.10). However, participants with higher average maximum daily social interaction scores were significantly less likely to be frail (RRR 0.18, *P*=.02). Sociodemographic and health-related characteristics also showed significant associations with frailty. Participants with SCD were less likely to be prefrail compared with those with MCI (RRR 0.31, *P*=.03), while older age was associated with a higher likelihood of being frail (RRR 1.56, *P*=.001). Figure 5 displays the average predictive marginal effects of sociodemographic characteristics, health status, global MBI symptom presence, and social functioning on the probability of being classified as robust, prefrail, or frail.

Table 3. Multinomial logistic regression model for the association between frailty, global MBI-symptom presence, daily social interaction frequency, and level of loneliness (N=101) (Wald χ222=52.04).

Association Between Daily Social Interaction Frequency, Daily Loneliness Level, and Frailty Adjusting for the Severity of Global MBI Symptoms

Table 4 presents the associations between frailty, daily social interaction frequency, and daily loneliness levels after adjusting for the severity of global MBI symptoms. When adjusting for the severity of global MBI symptoms, no significant associations were observed between prefrail status and either the average maximum daily social interaction score (RRR 0.76, *P*=.48) or the average maximum daily loneliness level (RRR 1.19, *P*=.69). Likewise, no significant relationship was identified between frail status and average maximum daily loneliness level (RRR 0.27, *P*=.14). However, a significant inverse relationship was found between the average maximum daily social interaction scores and frail status (RRR 0.20, *P*=.02). Additional sociodemographic and health-related factors were associated with prefrail status. Participants with SCD were less likely to be prefrail compared with those with MCI (RRR 0.33, *P*=.04). Moreover, participants with more severe MBI symptoms were more likely to be prefrail (RRR 1.09, *P*=.04), and older age remained significantly associated with being frail (RRR 1.53, *P*=.002). Figure 6 presents the average predictive marginal effects of sociodemographic characteristics, health status, global MBI symptom severity, and social functioning on the probability of being classified as robust, prefrail, or frail.

Discussion

Principal Findings

This study demonstrated a significant association between frailty and the frequency of daily social interaction in a cohort of 101 individuals at risk of dementia in South Korea. Specifically, higher average daily social interaction scores were significantly associated with lower relative risk ratios of being frail, even after adjusting for the presence and severity of global MBI symptoms. These findings underscore the potential role of daily social interaction frequency as a modifiable behavioral factor in individuals at the early stages of dementia and frailty risk.

Our study found that frail older adults exhibited more severe MBI symptoms than robust or prefrail groups. This observation aligns with prior research suggesting a potential link between frailty and the severity of MBI symptoms [2]. Furthermore, our findings indicate that frail older adults had lower average maximum daily social interaction frequency and higher loneliness levels compared with robust or prefrail groups. Unlike previous studies that assessed social interaction or loneliness at a single time point [7], our study used a 2-week tracking period. This approach also builds on previous research exploring how frailty in older adults, characterized by decreased mobility and difficulty with daily activities, may contribute to reduced social engagement, increased loneliness, and further functional decline [7].

Our findings also align with existing evidence showing that both the presence and severity of global MBI symptoms are associated with frailty. This underscores the importance of assessing both cognitive and behavioral impairments when identifying individuals at risk of dementia [2]. However, given the relatively small sample size of frail individuals in this study, these findings should be interpreted with caution. Nonetheless, our results support prior research linking neuropsychiatric symptoms, such as psychosis, not only to an elevated risk of dementia but also frailty, which is often associated with accelerated cognitive decline [45]. To strengthen these observations, future research should consider analyzing larger cohorts with detailed assessments of domain-specific MBI symptoms and frailty. Such studies could yield more robust evidence, further elucidating the relationship between specific MBI domains and frailty and reinforcing their potential as targets for early intervention in individuals at risk of dementia and functional decline.

Our findings are consistent with those of a previous study that used data from the Korean Frailty and Aging Cohort Study, which found that less frequent contact with acquaintances was associated with a higher prevalence of frailty [46]. Similar patterns have been observed worldwide. For instance, a 1-year

XSL•FO
RenderX

prospective cohort study in Japan demonstrated that greater social isolation, measured using the Lubben Social Network Scale, increased the risk of developing prefrail status [47]. Among Italian community-dwelling older adults, a significant relationship was found between frailty and higher levels of social isolation, measured using the Friendship Scale, and frailty [48]. Although the precise mechanisms through which social connections influence frailty are not yet fully understood, growing epidemiological evidence suggests that social interactions can affect health outcomes through psychosocial, behavioral, and biological pathways. A lack of social interactions, for instance, can amplify the sympathetic nervous system and the hypothalamus-pituitary-adrenal axis, thus leading to a chronic mild inflammatory state, which is characteristic of frailty syndrome [49-51]. Limited social interactions can also increase stress-related hormones such as glucocorticoids, impacting immune functions and potentially affecting the biological aspects of frailty [52]. Furthermore, frequent social interactions can motivate frail older adults to engage in cognitively and physically stimulating activities, providing daily support and health management resources [52,53].

Overall, our findings underscore the importance of social interaction correlates to frailty among older adults. This issue is particularly relevant in East Asian societies, where traditional family structures and intergenerational support are highly valued [54]. However, the rapid demographic shift toward an aging population and declining family size in developed East Asian countries, such as South Korea, Japan, and China, poses challenges to maintaining adequate social contact for older adults [54,55]. This phenomenon may increase the risk of frailty in older adults who lack sufficient social engagement due to changing family dynamics [56]. Furthermore, in developed countries, where health care systems are more established, promoting social functioning could be a cost-effective, nonpharmacological intervention to reduce frailty and its associated health care burden [57,58]. These findings suggest that public health policies aimed at enhancing social interactions, particularly for those at risk of cognitive decline, could reduce frailty and promote healthy aging in both East Asian and developed countries more broadly.

Our study did not establish a significant correlation between daily loneliness and frailty, in contrast to previous research. This discrepancy may be attributed to 2 primary reasons. First, our method of measuring loneliness was based on a single direct question covering a 2-week period. While we aimed to reflect on the participants' subjective perceptions of their social interactions, a more in-depth, long-term study may be necessary to capture the full complexity of loneliness. A systematic review and meta-analysis of the relationship between loneliness and physical frailty in community-dwelling older adults indicated that baseline loneliness could predict worsening frailty, although longitudinal evidence is limited [59]. Therefore, future studies should focus on the cumulative effects of comprehensive potential factors prevalent in older adults, such as decreased physical activity, poor sleep quality, and malnutrition [59-61]. Additionally, these studies should examine these factors within the context of social vulnerability and frailty, while controlling for the effects of social networks [61].

Second, unlike the frequency of social interactions, loneliness is a subjective feeling, and perceptions of loneliness can vary significantly among individuals [7]. Typically, loneliness is seen as a negative response to the gap between actual and desired relationships [62]. However, the threshold for feeling lonely often depends on sociocultural context or personal standards [63,64]. Therefore, using more nuanced, context-specific questionnaires could lead to a deeper understanding of loneliness [7]. Nonetheless, given that our study participants were older adults at risk for dementia, using numerous detailed questionnaires might not be the most feasible approach. An alternative method could involve analyzing patterns among participants who provide similar responses to brief, directional questions, and then prospectively studying their perceptions of loneliness in response to specific events in a real-time setting. This approach could yield valuable insights into subjective experiences of loneliness in this population.

Comparison With Prior Work

A key strength of our study lies in its detailed exploration of the relationship between social interaction and frailty status among older adults with SCD or MCI. By categorizing frailty into robust, prefrail, and frail groups, our findings build upon and extend previous research, indicating that older adults with higher levels of daily social interaction are less likely to exhibit frailty, even after accounting for cognitive and behavioral symptoms. While these findings align with prior research suggesting the protective effects of social interaction on health, our study adds nuance by examining these relationships specifically within older adults at risk of cognitive decline.

Our results support existing evidence that frail older adults exhibit lower social interaction frequency and higher loneliness levels compared with their robust and prefrail counterparts. These findings underscore the importance of social interaction as a critical behavioral dimension for health outcomes in older adults at risk of both cognitive and functional decline. While causation cannot be established, our findings suggest that fostering social connections may mitigate frailty risks and promote better health outcomes.

What distinguishes our study is its use of real-time data collection methods, which allowed us to capture day-to-day variations in social functioning with greater accuracy [40]. This approach offers a more granular understanding of how social interaction relates to frailty and cognitive status, building on prior retrospective studies. By applying real-time assessment within the context of frailty and cognitive decline, this study strengthens the evidence base for social interaction as a modifiable factor and highlights the need for future research to explore causative pathways.

Although the immediate practical application of these findings in clinical settings may be limited, this study contributes to the growing understanding of the relationship between social function, frailty, and cognitive decline. It highlights the potential for improving social engagement interventions that may reduce physical challenges targeted to older adults with SCD or MCI. Future research should focus on identifying the specific types, patterns, and contexts of social interaction that are most effective in reducing frailty and promoting health. Longitudinal and

XSL•FO
RenderX

interventional studies will be crucial in establishing causation and designing tailored interventions to enhance social functioning in these at-risk populations.

Limitations

This study had several limitations. First, the sample size of 101 participants, particularly the small sample size of the frail group, may limit the generalizability of the findings. A larger and more diverse sample could yield more robust results and allow for detailed analyses across different subgroups. Second, the cross-sectional design of the study enabled the identification of associations but did not establish causation. Prospective longitudinal studies are necessary to determine the directionality of the relationships among frailty, MBI symptoms, and social functioning. Additionally, Alzheimer disease pathology, hormonal changes, and chronic inflammation are potential mechanistic links between frailty and cognitive decline. While this study focuses on social interaction, physiological dimensions such as physical activity, metabolic health, and nutritional status were not assessed to minimize the participants' measurement burden during the 2-week survey period. The primary aim of our study was to demonstrate how capturing temporal patterns in social functioning could inform daily life modifications to support health. Future research should integrate complementary physiological measures to enhance understanding and inform more comprehensive intervention strategies in longitudinal or experimental studies to better understand the directionality of these relationships. For example, studies using matching designs over extended timespans would be essential. Third, this study relied on self-reported data for loneliness levels and the tools used to measure daily social interaction frequency and loneliness levels, which may be susceptible to social desirability bias, which could influence how participants report their feelings and circumstances. Future analyses could incorporate digital devices, such as actigraphy, to log social interaction frequency and patterns, thereby integrating supplementary objective measures. Additionally, qualitative aspects of loneliness, such as its depth and contextual nuances, may require more comprehensive assessment methodologies. Tools like daily diaries or note-taking functions are advisable for future EMA approaches to capture more detailed information on the types and quality of social interactions. Moreover, framing questions with both positive and negative perspectives could mitigate response patterns where participants consistently answer in one direction, enhancing the robustness of findings in larger studies. Fourth, the use of a self-reported frailty assessment via the FPQ may introduce recall bias or inaccuracies in participants' self-perceptions. While the FPQ is a validated and practical screening tool for community-dwelling older adults, it may lack the granularity of more detailed clinical assessments. Future studies could consider integrating tools such as the Clinical Frailty Scale to capture a broader spectrum of frailty characteristics and enhance precision in frailty classification. Finally, while our study provided step-by-step guidance and a helpdesk for participants to navigate the EMA app, applying the EMA approach via mobile devices to older adults less familiar with mobile technology requires more comprehensive and detailed guidance. Ensuring that participants can use the mobile app independently is an essential step for successfully replicating this study methodology.

Conclusions

Our study suggests that daily social interaction is associated with frailty status among older adults with SCD or MCI, irrespective of the presence or severity of MBI symptoms. This finding builds on previous research, highlighting the positive potential of improving social interaction to reduce frailty risk among older adults with cognitive decline. To deepen understanding and enhance timely intervention strategies, future studies should explore the qualitative aspects of social interactions and frailty in greater depth. While the immediate clinical application of these findings may be limited, the use of real-time assessment in social functioning offers a promising path for further investigation. Integrating real-time social data with objective measures could provide a more personalized and comprehensive approach to care.

Abstract

Background: Considering the high prevalence of mental health conditions among young people and the technological advancements of artificial intelligence (AI)–based approaches in health services, mobile health (mHealth) apps for mental health are a promising way for low-threshold and large-scale mental health promotion, prevention, and intervention strategies, especially for young people. However, insufficient evidence on health-promoting effects and deficient user-centric designs emphasize the necessity for participatory methods in the interventions' development processes.

Objective: This study aimed to explore young people's everyday experiences using an AI-based mHealth app for mental health promotion based on ecological momentary assessments and ecological momentary interventions. Our analysis of qualitative data focused on exploring young people's use patterns in daily life and mental health–promoting effects.

Methods: We conducted problem-centered interviews and focus groups with a subsample of 27 young people aged 14 to 25 years, who were among the participants of 2 microrandomized trials testing and evaluating an AI-based mHealth app (AI4U

XSL•FO
RenderX

training). Our study used a participatory approach, with "co- and peer researchers" from the dialogue population actively engaged in research processes and data analysis. Structural content analysis guided the qualitative analysis.

Results: Participants reported enhanced emotional self-awareness and regulation in daily life through the ecological momentary assessments and ecological momentary interventions. Young people appreciated the AI4U training for managing emotions and stress. They had no trust issues regarding disclosing their mental health via the AI4U training in daily life. Some faced challenges integrating it into their daily routines and highlighted the value of autonomy in use decision-making processes.

Conclusions: Our findings reveal that young people benefited from enhanced emotional awareness and management through the use of the AI4U training, appreciating its anonymity for facilitating emotional disclosure. The results suggest that enhanced self-directed use may improve daily life integration, although participants noted that they sometimes avoided using the AI4U training during distress despite recognizing its potential benefits. These findings indicate the importance of balancing directed use and autonomy in digital interventions to harmonize compliance with effectiveness in daily life. We highlight the importance of participatory research for tailored digital mental health solutions.

Introduction

Digital Mental Health Interventions for Young People

According to the Global Burden of Disease study, almost 14 million young people in Europe aged 10 to 24 years in 2019 met the diagnostic criteria for a mental health condition [1]. The onset of most mental health conditions has been found to occur in youth or early adulthood, and there is an evident link between occurrence in early life and persistence or exacerbation in adulthood, highlighting the importance of early interventions [2-5]. Research calls for holistic and multi- and transdisciplinary approaches for mental health promotion (eg, improving resilience and strengthening protective factors) and more tailored interventions for young people [2]. There is evidence indicating that existing services are underused by young people due to social factors such as stigma, embarrassment, lack of trust in mental health professionals, and structural barriers related to the availability and accessibility of proper support [2,4,6-8]. The desire for self-reliance and autonomy grows from puberty into early adulthood and constitutes a further major barrier in seeking informal or professional help for mental health problems among young people [9].

Technological innovations provide new forms of efficient, large-scale, and low-threshold health services. With the growing accessibility to technology, smartphones have become powerful tools, making mobile approaches to mental health care and promotion services increasingly popular [10-13]. The widespread use of smartphones among young people makes them an attractive platform for mobile health (mHealth) apps or digital interventions aimed at promoting mental health through self-help features [14-23]. Evidence-based mHealth apps have the potential to target a wide range of users, promoting mental health and preventing mental health conditions in both clinical and nonclinical populations [10]. Most currently available reimbursable digital health applications in Germany meet the evaluation criteria for patient-relevant clinical benefits [24]. Digital self-monitoring of symptoms or behavior (eg, via ecological momentary assessments [EMA]) allows for the collection of ecological valid data on mental health outcomes and precise clinical assessment [11,21,25-27]. On the basis of EMA data, real-time and context-dependent personalized intervention suggestions (eg, ecological momentary interventions [EMI] or, synonymously, just-in-time adaptive interventions) for improving mental health can be provided to the user and subsequently evaluated [28-32]. Interventions that are based on real-time data may further increase user adherence and engagement and improve effects on mental health [10].

Research emphasizes the importance of personalization in mHealth apps as it simplifies the process for users to find suitable interventions and can improve the effectivity of the selected interventions [10]. Modern artificial intelligence (AI) methods pave the way for new and targeted forms of mHealth services [33-35]. AI is used for a variety of tasks, including risk prediction and prognosis, diagnostic classification, and personalization of interventions, among others [34,36]. In the context of personalizing mHealth apps, time-series models such as recurrent neural networks have been proposed to build a dynamic and predictive model of individual behavior based on which interventions can be optimally selected [32,35]. This allows for a personalized and adaptive allocation of EMI.

However, time expenditure and the potential of mHealth apps as an additional stressor in daily life have been recently identified as major barriers to daily mHealth app use among young people [37]. In addition, studies still face high attrition rates and low engagement from young participants, such as in the study by Peuters et al [15], in which young people reported neglecting several features of the mHealth app, mainly due to time constraints. Interviews with homeless young people using an EMA-based mHealth app revealed that repetitive and predictable questions and answer options quickly led to boredom among the participants [38].

Public health literature increasingly calls for research to guarantee active engagement with dialogue populations in the

XSL•FO
RenderX

research process to enhance the acceptance and implementation of health promotion and prevention measures [39-44]. This approach ensures the inclusion and empowerment of affected individuals, including marginalized groups, in research processes that impact them and establishes transformative knowledge through the integration of new perspectives. Exploratory qualitative research and participatory approaches are essential to inquire about the existing gaps in understanding how mHealth app use can be optimized. Digital services, especially for young digital natives, require a collaboration on equal terms among and active participation by health care professionals, developers, and individuals from the dialogue population, and successful coproduction especially requires the integration of potential users early in the development process [11,17,45,46]. An in-depth understanding of expectations or experiences of people regarding digital mental health care approaches is crucial for the development of effective and trustworthy solutions [47].

However, qualitative studies on people's real-world experiences with mHealth apps based on EMA have predominantly centered on specific groups, such as patients with bipolar disorder [48], patients with depression [49], or homeless young people [38], or on family research [50]. One study conducted interviews with college students on their experience with an EMA-based mHealth app aimed at improving emotional well-being [51]. However, the participation period was rather short, averaging 10 days, and the evaluation focused on methodological and design-related research questions rather than on individual effects on mental health. Qualitative data on the use of EMI tend to be lacking. One study investigated the effects of a mobile meditation intervention through participant interviews [52]. However, Xie et al [52] targeted adults diagnosed with clinically elevated levels of depression or anxiety. To our knowledge, no existing qualitative study using principles of participatory research has explored the subjective effects of an AI-based mHealth app on the mental health and emotional resilience in daily life of healthy young people.

Study Objectives

The objective of this qualitative study was to explore the perspectives of young people (aged 14-25 years) on the use of an AI-based digital training administered via a smartphone-based app for personalized mental health promotion in youth based on EMA and EMI (AI4U training). We were particularly interested in their views regarding use and integration of the mHealth app into everyday life and the subjective effects on their mental health, especially health-promoting effects. The following research questions were addressed:

1. What are young people's subjectively perceived health-related effects of the AI-based mHealth app?
2. How do young people perceive the use of an AI-based mHealth app designed to promote mental health in everyday life based on EMA and EMI?

Methods

Study Design

Study Background

This qualitative study formed part of the "AI4U—artificial intelligence for personalized digital mental health promotion in youth" living laboratory. Living laboratories strive to foster collaboration between science and society and engage target or dialogue populations and stakeholders from a diverse range of relevant sectors to explore and study innovative models of action such as innovations in health services [53]. The living laboratory AI4U was dedicated to the participatory development, optimization, and evaluation of an AI-based mHealth app for personalized mental health promotion in youth (AI4U training). The living laboratory involved the direct participation of relevant stakeholders, users from the dialogue population, and an interdisciplinary research group embedded in a transdisciplinary infrastructure to ensure ongoing quality management, sustainability appraisal, and dissemination. Optimization and initial evaluation of the AI4U training involved 3 separate consecutive microrandomized trials (MRTs) in line with the multiphase optimization strategy [54]. In the MRTs, participants aged 14 to 25 years were recruited and asked to complete the 40-day AI4U training using an mHealth app, with a target sample size of 60 participants for each MRT. In the 3 within-subject MRTs, participants were repeatedly randomized using a 1:1 ratio to either AI-based allocation of EMI components based on EMA ratings or to a random allocation of EMI components at a maximum of 210 decision points per participant to examine the effect of the AI algorithm on proximal outcomes in youth. EMA ratings consisted of questions on momentary (positive and negative) affect, activities (eg, physical activity), and perceived contexts (Multimedia Appendix 1). Further details on the living laboratory AI4U can be found in previous papers [55-57].

This study focused on qualitative data collected as part of the first 2 MRTs (MRT 1 and MRT 2) to allow for adaptation and optimization of the mHealth app based on subjective experiences. Due to the participatory approach of the AI4U living laboratory, young people from the study's dialogue population were involved early in the study. A female researcher (SH) was employed as a "peer researcher." This ensured the active participation of young people in many aspects of the decision-making processes (including study design, implementation, and dissemination). "Co-researchers" (JS, SD, and 2 others), that is, young people of the same age as the dialogue population with no pertinent qualitative research experience, were included in project-related research processes by taking part in "participatory research workshops". Similar to research workshops held with qualitative researchers, these workshops aimed to increase the quality of data analysis through joint interaction [58,59]. Co-researchers met on a regular basis with the research team (SH and CG) to participate in qualitative research. To enable adequate participation, co-researchers received training on core competencies in qualitative research (eg, interviewing and data analysis) and were involved in various stages of the research processes throughout the study. Key

XSL•FO
RenderX

elements were the participatory development of interview topic guides, joint moderation of focus groups (FGs), and subsequent discussion of preliminary results [56]. Similar participatory health research has shown that participatory evaluation processes with nonscientific co-researchers from a project's dialogue population promotes the generation of transformative knowledge and facilitates shared decision-making in qualitative research, particularly between academic researchers and co-researchers [60].

Interventions

The AI4U training is a digital training that consists of four innovative forms of digital mental health promotion, which users can apply directly in their everyday lives: (1) EMA [25,26], (2) EMI [29,31,61], (3) AI [62-64], and (4) a web-based dashboard for digital monitoring and feedback. The AI4U training was delivered over a 40-day intervention period in addition to public mental health care as usual available through the German health and social care system. The digital training consisted of at least one face-to-face session with a coach and an EMI administered through a smartphone-based app for adaptive real-time and real-world transfer. The sessions with the coach provided guidance on the content and structure of the training and were complemented by optional sessions with counselors for young people receiving care from educational counseling services. The AI4U training consisted of a 10-day introductory period with self-monitoring using EMA (8 per day) and a 30-day training period with self-monitoring using 6 EMA per day. EMA entries could be viewed on a dedicated digital dashboard using a web browser. The AI4U training intended to improve resilience, fostering a compassionate self-image and strengthening self-care skills in everyday life (Multimedia Appendix 1). Following each MRT, the digital training was optimized further based on feedback from participants at the end of the study and data from qualitative interviews.

Sample

We recruited participants for the qualitative process evaluation consecutively among the young people who had used the AI4U training for the previous 40 days. For this, we used a purposive sampling strategy to select participants with relevant insights into the use and impact of the AI4U training. This method allowed us to specifically target individuals who met predefined criteria, such as various age groups or users with various degrees of adherence. In addition, we aimed for a balanced gender distribution and inclusion of young people from varying socioeconomic and educational backgrounds (Multimedia Appendix 2). We contacted participants via email to inform them of the purpose of our interviews and the possibility of study participation.

Data Collection

We used the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist [65] to ensure a clear and thorough description of the qualitative research methodology (Multimedia Appendix 3). Problem-centered interviews (PCIs) were held between October 2022 and November 2023. The FGs were held between December 2022 and July 2023. All interviews were conducted remotely using a video-based online tool. Experienced researchers (SH and CG) conducted the PCIs. In line with our participatory approach, one of our co-researchers (JS and SD) moderated the FGs. They signed a confidentiality agreement a priori and were provided with a guide for remote FGs (Multimedia Appendix 4). To ensure the quality of data collection, we practiced the moderation beforehand in a participatory research workshop, and co-researchers were supported by one of our research assistants with adequate scientific expertise (SH and CG).

For the PCIs and FGs, we used semistructured topic guides (Multimedia Appendix 5). The topic guide for the FGs was developed together with our co-researchers during our participatory research workshops. Both interview methods covered questions on (1) the use of the AI4U training in everyday life, (2) the evaluation of the EMA and EMI, and (3) trust factors in the AI4U training. Although the interview topic guides largely overlapped, the PCIs focused on the subjective health-promoting effects of the AI4U training, whereas these aspects were not a primary discussion point in the FGs. We used Microsoft PowerPoint slides (Microsoft Corp) to visualize the EMI and the dashboard interface to facilitate feedback on the key content of the AI4U training. After each FG, there was a short discussion between the co-researcher and the co-moderator to reflect on first impressions or discuss potential field notes taken.

Data Analysis

The PCIs and FGs were held in German, audio recorded, and transcribed verbatim. For the transcription, we used f4 automatic speech recognition (Dr. Dresing & Pehl GmbH). Transcripts were subsequently pseudonymized and revised by student assistants. SH conducted data analysis using structural qualitative content analysis [66,67]. After reading of and familiarization with the data material, particularly interesting or important text passages were highlighted. In accordance with the semistructured interview topic guides, we created thematic categories and corresponding descriptions of coding rules for each of the categories. We then started with open coding of data material, facilitating the exploration of previously undisclosed themes. This process was followed by a subsequent categorization of coded text passages according to the thematic categories previously defined. If emerging codes were not suitable to any of the previously defined categories, we inductively added new thematic categories or codes. We coded transcripts using the MAXQDA 2020 software (VERBI GmbH) [68]. Validation procedures within the data analysis process encompassed multiple stages. After reviewing the initial coding tree within our research team (SH, CG, and SK), we modified and structured it accordingly. The coding trees and passages from the FG transcripts were subsequently thoroughly examined and validated with the co-researchers (JS, SD, and 2 others) in 2 distinct participatory research workshops. We marked the codes and subcodes that emerged through cocreation and validation in the participatory research workshop in the coding trees of the MAXQDA files accordingly (Multimedia Appendix 6). In a third participatory research workshop, we examined all the text passages previously highlighted as interesting and discussed and interpreted their potential meaning together.

Ethical Considerations

This study was funded by the Ministry of Science, Research, and Arts of the State of Baden-Württemberg, Germany (study period from January 2021 to June 2024), and approved by the Medical Ethics Review Committee II of Heidelberg University (Mannheim Medical Faculty; reference 2022-550). All participants provided written informed consent. For underage participants, we also obtained informed consent from parents or legal guardians. Participation in the study was voluntary. Consent could be withdrawn at any time without giving reasons. Participants were covered by liability and commuting accident insurance for the duration of the study. Participant data were analyzed and exchanged exclusively using study pseudonyms. The pseudonymized data were securely stored and processed in accordance with the General Data Protection Regulation. Participants received a compensation of €20 (US $22.40) in the form of a voucher redeemable at various stores across Germany.

Results

Sample Characteristics

Overall, 114 young people completed the 40-day AI4U training during the first 2 MRTs (N=57 in MRT 1 and N=57 in MRT 2). Of those 114 young people, we included 27 (23.7%; 13/57, 23% from MRT 1 and 14/57, 25% from MRT 2) in our qualitative study distributed across 16 PCIs and 3 FGs with 3 to 5 participants each (Multimedia Appendix 2). In the PCIs, the youngest participant was aged 14 years, and the oldest was aged 25 years (mean age 20.38, SD 3.78 years), whereas in the FGs, the youngest participant was aged 18 years and the oldest was aged 25 years (mean age 21.36, SD 1.84 years). Most participants had obtained their high school diploma or were already pursuing higher academic education (20/27, 74%). The average duration of the PCIs was 44 minutes, and the average duration of the FGs was 1 hour and 11 minutes. In the PCIs, gender distribution was even (8/16, 50% male individuals and 8/16, 50% female individuals). For MRT 1, we conducted 2 FGs divided by gender and with an equal number of participants (3 participants in each FG). The third FG with participants of MRT 2 was composed of 5 female individuals only.

Overview

The following sections report on the subjective perspectives of participants on the effects of the AI4U training on their mental health, safety and trust considerations, the integration and role of the AI4U training in everyday life, and the value of self-directed use behavior. As the AI4U training was primarily administered through a smartphone-based app, participants used the terms *AI4U training* and *mHealth app* interchangeably in the interviews. Content within parentheses in the following sections reflects the relative frequency, and content within square brackets reflects attribution of participant statements made during the PCIs or FGs. *P* stands for *participant*. Multimedia Appendix 2 provides the participant characteristics.

Subjectively Experienced Effects Following the AI4U Training

Mood Monitoring via EMA Seemed to Increase the Mental Health Awareness of Young People

Most participants (PCIs: 14/16; FGs: 7/11) reported that the awareness of their acute mental health status via EMA led to improved self-consciousness of emotions and subsequent self-reflection. One person especially appreciated the following:

> *...that it made you very aware of your own emotions. And just that, I found, often helped in some way, because then I frequently...had to think about how I was feeling at the moment. And I really liked that. Um, yes, just to become more aware of yourself and your own feelings.* [PCI_P27; page 103]

Participants mentioned that EMA were especially helpful to understand the reasons or contextual factors behind their emotions, that is, why they were feeling distressed (PCIs: 6/16; participant FG2_P1):

> *How do I feel, why do I feel this way? It makes you a bit more reflective. Understanding the reasons behind your emotions, why you behave like that, contributes to feeling better. I do feel that I learned something about myself through this.* [PCI_P16; page 134]

One interviewee argued that understanding contextual triggers enabled her to classify emotions on a more “objective level” (PCI_P16; page 60), whereas another participant (PCI_P13) highlighted that EMA helped reconsider recent emotional reactions as less severe upon further reflection.

Several young people (PCIs: 7/16; participant FG3_P3) highlighted that they aimed to sustain their mental health awareness over the long term, reflected more consistently on their daily experiences, and focused on the positive aspects in their everyday life even after the study period:

> *But I have to say, after I returned the [study phone], I had this feeling of emptiness [laughs]. Simply because I somehow mentally got used to these [EMA]. So, whenever something happened during the day, I immediately thought, “Okay, this has contributed to me being like a four out of seven in terms of my disappointment or something.” So, it definitely became ingrained in my mind.* [FG3_P3; page 55]

Some participants (PCIs: 6/16; FGs: 3/11) reported being interested in their long-term behavior or emotional trajectory and accessed the dashboard rather at the end of the study period. They described the dashboard and its visualizations of EMA responses as interesting but with rather low value relevant to their mental health promotion (PCIs: 6/16; FGs: 3/11):

> *[The dashboard]...was and is not a surprise because these are things that I have learned about myself for a long time. That's why I simply believe that it wasn't so surprising to see it, because I've repeatedly thought about these things before.* [PCI_P26; page 182]

XSL•FO
RenderX

However, some participants (PCIs: 5/16; FGs: 4/11) reported that they would have likely used the dashboard more frequently if it had been integrated into the app and not only accessible via a browser on a laptop.

EMI Appeared to Improve Emotion Regulation and Health-Promoting Routines in the Daily Life of Young People

According to a number of participants (PCIs: 7/16), EMI assisted in regulating emotions more effectively:

> *...I just felt mentally calmer and maybe you didn't see the problem as the central problem, but everything was put into perspective a bit and it, um, yes, it mentally brought me down a bit and calmed me down.* [PCI_P22; page 186]

Through improved emotion regulation, several participants (PCIs: 3/16) mentioned learning that emotions, especially negative ones, were transient. For 2 of the 27 of the participants (PCI_P12 and PCI_P22), this health-related knowledge was retained in the long term. One participant reported that the EMI "Emotions as a Wave" (Multimedia Appendix 1) was particularly helpful:

> *I've always seen emotions as something that keeps coming back and stays, not something that fades away. But "Emotions as a Wave" is something that has changed my perspective on emotions itself because...it taught me that emotions can also pass and that resulted in me becoming a calmer person, actually.* [PCI_P12; page 100]

The breathing intervention was used as a health-promoting routine for relaxation and composure throughout the day by several individuals (PCIs: 5/16; participants FG3_P3 and FG3_P4) even after completing the AI4U training. Many participants (PCIs: 10/16; FGs: 6/11) reported that the "Moments of Joy" and "Positive Data Log" interventions stimulated positive affect by helping them focus on the enjoyable aspects of a day and diverting their attention from the negative ones. Another participant described the "Moments of Joy" intervention as helpful in becoming more "self-efficacious" (PCI_P14; page 188), realizing the extent to which she could also influence her own happiness or satisfaction. Another 2 of the 27 participants (PCI_P14 and PCI_P28) reported that they became aware of the importance of breaks in their daily lives:

> *...Whenever I have school assignments, I let them influence me a lot. I knew that before, but I've learned a bit that they shouldn't completely fill my daily life, that I should still give myself more time. And the app helped me in setting that up somehow.* [PCI_P28; page 212]

When comparing EMA with EMI, a few participants (PCI_P17, PCI_P18, and FG2_P2) emphasized the particular benefit from EMA, whereas one described the EMI as "nice to have" but not necessary (FG2_P2; page 122). However, others (PCIs: 3/16) argued that perception of emotions via EMA was their first step toward change. Some participants (PCIs: 3/16) noted that EMA alone would be insufficient to develop new health-promoting routines. One participant reasoned that awareness of their own emotions enabled them to better manage them through the proposed EMI:

> *[The EMA have] caused me to simply become more aware of how I feel. And I think that led to better understanding these feelings and, as a result, either changing or accepting them. So, yes, just being able to handle them better...And especially the [EMI] could often make a difference there. For me, it was really often with nervousness that the [EMI] helped, for example.* [PCI_P27; page 211]

Young People's Trust Factors on Data Disclosure During Use of an mHealth App

Transparent Data Handling Seems to Be a Crucial Factor for Young People's Confidence in Data Protection

As long as young people were confident that their data would not be misused, they reported that data disclosure via smartphones was not a use barrier (PCIs: 3/16; FGs: 3/11). A total of 4 of the participants (PCI_P15, PCI_P28, FG1_P2, and FG2_P2) stressed that transparency about the use of their data was crucial. Another 2 participants (FG1_P2 and FG1_P1) found it acceptable for the app to collect data only based on voluntary input and expressed concern about the collection of information that was not self-entered. Some participants (PCIs: 4/16; participant FG2_P3) felt more secure using the AI4U training because it was developed by professionals and used within an official study. In comparison, mHealth apps from an app store were deemed as less trustworthy by 2 participants (PCI_P28 and FG2_P3).

Some argued that, given the vast amount of personal information on the internet, data disclosure is something one "can't prevent anyway" (PCI_P22 [page 233] and PCI_P21 [page 48]), and for others, it "doesn't matter now anyway" (PCI_P21 [page 48] and FG2_P1 [page 97]). In total, 2 participants (PCI_P17 and PCI_P26) emphasized that one is used to providing personal information on their smartphone in everyday life. Therefore, it did not feel as if one was conveying information to someone else:

> *I didn't really feel like I was sharing anything, but rather that I was doing it for myself...I mean, I'm used to handling a smartphone and I always write my notes on the iPad. So, it wasn't strange for me to type something on a device.* [PCI_P26; page 63]

In total, 2 participants reported not perceiving the AI4U training as "invasive," particularly when compared to algorithms on social media (FG3_P3 [pages 259 and 263] and FG3_P4 [page 287]). Some (PCIs: 3/16) noted that the app could probably not make any meaningful use of the personal data anyway. One interviewee emphasized her autonomy and personal agency in data sharing:

> *I'm generally not the type of person to think, "Oh God, data privacy," and that something private will be stolen from me, because I still feel like I'm an independent person. If an AI knows more about my emotions, I don't know how it could influence me in*

XSL•FO
RenderX

> *the long run. I just don't see the risk there.* [PCI_P26; page 67]

Anonymity as a Necessary Requirement for Sharing Emotions

One participant noted that one had to "get used to" to being asked about their mental health or described it as an unfamiliar "change" (PCI_P15; page 4). For some (PCIs: 4/16; participant FG1_P3), disclosing emotions via the EMA felt unusual at first:

> *I first had to get used to the idea that there's now an app, to which I should somehow describe my feelings, in some tasks that was the case. That was definitely something to get used to, but...somehow it subsided a bit, I would say. You just really got used to the fact that there's no human there. Yeah, but it was a bit strange at the beginning...* [FG1_P3; pages 94-116]

Many participants (PCIs: 9/16) argued that they developed trust in the AI4U training because they did not perceive it as a real person or a human stranger. According to several participants (PCIs: 4/16), this significantly facilitated the expression of emotions:

> *So [it] definitely made it easier [to trust the app]. I believe I would have had a lot more reservations, if I had known that it was a human responding to me, especially because it would be a person I don't know. And an AI is still an AI, even if your subconscious mind sometimes forgets that, but I think it definitely made it easier for me to talk about it and to overcome that barrier.* [PCI_P27; pages 249-251]

Young people reported feeling that their data were more securely handled than with humans and highlighted the barriers to sharing emotions during face-to-face communication as a reason (PCIs: 6/16; participants FG1_P3 and FG2_P1). Reported concerns of some young people (PCIs: 3/16; participant FG2_TN1) focused, for instance, on the fear of nonacceptance, judgment, and intimate disclosure typical in interactions with humans. According to some of them, the AI4U training was "just" an app that, unlike friends, could not misuse the data about their mental health:

> *On one hand, I felt safe, so to speak, because I know that an AI can't really do much with [my information]. If I tell a person about it, I'm exposing myself to the person, and I don't know what the person does with the information. And that wasn't the case with the AI.* [PCI_P16; page 36]

Certain participants (PCIs: 6/16) reported that an mHealth app allows for a certain emotional distance and anonymity as a prerequisite for being open about their own emotions:

> *...you don't see the direct reaction of people. The app accepts that. You can input everything and I believe you can be more honest with such an app, than if a person would ask me when I'm really feeling bad in a situation, "How are you?" I would probably still say, "Yeah, I'm fine," but with the app, well, nobody really gets to know...It provides a bit more anonymity, I would say.* [PCI_P14; page 42]

The AI4U training was sometimes described as a "neutral diary" and catch basin for emotions that provided feedback based on objective data, not subjective assessment, for instance, compared to feedback from a therapist (PCIs: 4/16). Another participant (PCI_P12) identified this neutral feedback as stabilizing and more reliable and accurate, in contrast to human feedback.

Integration of AI4U Training Into Young People's Everyday Lives

Role of the mHealth App in the Daily Lives of Young People

Given that some participants (PCIs: 6/16) reported having a strict daily routine and everyday stress, they mentioned that they expected the AI4U training to assist them by helping reduce daily stress and monitor their mood. Some participants (PCIs: 6/16; FG3_P4) emphasized that they would not have paused their daily routine without the prompt from the AI4U training:

> *The app allowed me, so to speak, to take breaks, because it prescribed them to me. So, I think that when such an impulse comes from outside, telling you "now do it," you're more likely to do it, otherwise you always find an excuse...* [PCI_P14; page 164]

One participant highlighted that this heightened the awareness of her daily life structure and the importance of self-care within it:

> *In daily life, nothing reminds me...to check on my well-being. It doesn't mean that my everyday life is very bad, but it's about the fact that my everyday life is sometimes so hectic that I forget to take care of my well-being, my mental state...We're so focused on our tasks that we forget about ourselves...and the app reminded one...to pay attention of what one should actually take care of, because the basic mindset shapes your everyday life. If you're not doing well, you won't perform at school, for example.* [PCI_P12; pages 34-50]

Several young people (PCIs: 6/16; participants FG3_P3 and FG3_P2) pointed out that they preferred using the AI4U training when experiencing discomfort in daily life. One participant remarked that she completed the EMA more frequently when experiencing negative emotions:

> *I feel like I tended to do them more when I wasn't feeling well...And when I was feeling good, I thought, "Oh well, I don't need to enter it now, I'm doing fine."* [PCI_P23; page 102]

In total, 2 participants (PCI_P27 and FG3_P3) considered it less necessary when the app suggested interventions when they were feeling well. Another 2 participants (PCI_P17 and PCI_P22) reported that, when they were in a positive mood, they clicked through the EMA more quickly and superficially. One participant reflected on the AI4U training as rather an option to be accessed on an ad hoc basis in times of acute need:

> *I do think it could be a permanent companion, since one doesn't have to use it every day, if you realize, today I don't need it, today I'm fine.* [PCI_P14; page 172]

XSL•FO
RenderX

Without an urgent need, young people noted that they prioritized social interactions, especially if their daily life rhythm was quite strict, for example, due to work or educational duties (PCIs: 11/16; participant FG3_P1):

> *...I prefer to go to yoga or something similar and think about [my emotions] there, rather than having to fill out on my phone six times a day how I feel, where it just fell short. Eventually, I already knew the questions by heart and just clicked through them quickly.* [FG3_P1; page 295]

One participant (PCI_P29) mentioned refusing the AI4U training in acute situations of stress or negative feelings, preferring suggestions when he calmed down moments later. During stressful times, 2 participants (PCI_P23 and PCI_P15) were skeptical about repeatedly entering their emotions into EMA or EMI. However, another participant (FG2_P2) reflected that he neglected the app's suggestions in challenging situations even when they could have been helpful.

Some participants (PCIs: 7/16) noted that the health-promoting routines they had learned during the AI4U training were practiced less frequently after the study period. Others (PCIs: 3/16) observed that, without a reminder, it was more difficult to maintain enough self-discipline for engaging in health-promoting routines. According to 2 participants (PCI_P14 and PCI_P23), habits were difficult to change, especially with increased stress and demands in everyday life. A few participants reported being less inclined to disrupt their routines (PCIs: 3/16):

> *I just think my daily routine is quite pre-structured with things that I can't change fundamentally. So, I have to go to school when I have to go to school...I wouldn't say that [the AI4U training] has restructured anything in that regard.* [PCI_P28; page 204]

In total, 2 participants (PCI_P24 and PCI_P25) felt that they might not be in as great need of mental health training compared to young people with actual mental health conditions:

> *It felt more for, uhm, sick people...who have serious problems in everyday life...I believe that it is much better received by them than it is by us (mhm), because it sometimes just felt like it wasn't tailored exactly to us. So, what I expected was not what it turned out to be.* [PCI_P24; page 27]

Experiences With and Challenges Integrating the AI4U Training Into Daily Life

Overall feedback on daily life integration of the AI4U training was mixed. Most participants argued that app use was feasible when being at home or alone or when having a flexible daily rhythm (PCIs: 11/16; participants FG1_TN2 and FG2_TN2), and more challenging when they were on the go, in public, at work, or at school (PCIs: 10/16; FGs: 8/11). According to some participants (PCIs: 7/16), EMA or EMI were skipped when they spent time with their friends or family. A few participants (PCIs: 3/16; FGs: 4/11) reported feeling uncomfortable when they had to justify smartphone use to friends who perceived it as impolite, or when the alarm disturbed others. A total of 2 participants (PCI_P15 and PCI_P28) expressed discomfort or concerns about others witnessing them and judging their engagement with the intervention:

> *I somewhat refrained from EMI, especially at school or in public, as I was concerned about what my classmates might think if suddenly I close my eyes and sat at my desk.* [PCI_P15; page 18]

Some participants (PCIs: 5/16; FG2_P2) indicated that use significantly depended on an individual's daily rhythm and was linked to the time of day and adaptability of daily duties. Several participants (PCIs: 8/16; FG2_P1) noted that a self-determined daily routine made it easier to integrate the AI4U training. Some (PCIs: 6/16; FGs: 3/11) reported that, when time was limited or the environment was unsuitable, EMA or EMI were either rushed through or skipped completely. A few participants (PCIs: 3/16) observed that, as the AI4U training became part of their daily routine, its use became less demanding.

Some participants (PCIs: 6/16; FGs: 3/11) reported EMA as less time-consuming and easier to fit into their daily lives compared to EMI. However, they reported that it was dependent on the perceived complexity of the EMI. For instance, a few (PCIs: 3/16; FGs: 3/11) perceived the "Breathing Intervention," "Moments of Joy," and "Positive Data Log" interventions (Multimedia Appendix 1) of the AI4U training appealing due to their simplicity, the lack of mental strain, and the feasibility to integrate them into daily life. More complex interventions such as "Emotional Compass" were often considered too challenging to apply in a daily life context, resulting in limited impact (PCIs: 9/16; FGs: 5/11). Others argued that EMI required increased mental effort and, consequently, more time (PCIs: 3/16; FGs: 5/11):

> *I declined EMI more often than EMA, because I found them more challenging to integrate into everyday life, especially while being on the go.* [PCI_P27; page 179]

Some participants agreed that the alarm of the EMA prompts was sometimes distracting (PCIs: 6/16; FGs: 6/11) and 6 EMA per day were too demanding to be conducted regularly as requested (PCIs: 3/16; FGs: 5/11):

> *I probably wouldn't have needed [the EMA] for myself so frequently. Maybe it would have been enough for me two times a day, in the morning or evening, or perhaps midday, and then an EMI in the evening. That would probably have been the best approach for me.* [PCI_P22; page 178]

One participant (PCI_P28) mentioned that she felt bad declining prompts, whereas others reported that they felt "pressured" (PCI_P23; page 318) or "confined" by the app (FG2_P2; page 118). As a consequence, a number of participants (PCIs: 6/16; FG3_P4) described that they sometimes felt forced to conduct the AI4U training. A few (PCIs: 4/16; FGs: 4/11) sometimes perceived the AI4U training as an additional stressor:

> *It was difficult to integrate the app into my daily life in a way that made sense, that I can take away what they wanted to provide me, like doing EMI and such. For me, it was more of a stress factor (laughs) that I should take a break and do the EMI...* [FG3_P1; page 43]

XSL•FO
RenderX

As reported by some (PCIs: 8/16), it was burdensome to pause or interrupt ongoing activities in their daily lives. One participant noted having felt distracted by the alarms:

> *I also found it a bit distracting...When you're trying to focus, you're repeatedly pulled out of that focus to do [the EMA or EMI]. I found it a bit challenging to sit down in the library and start doing breathing exercises. So, I have to say, integrating it into my daily routine was relatively difficult and, I must admit, a bit tiring.* [PCI_P24; page 19]

Young People's Preferences Regarding Flexible and Self-Directed AI4U Training Use

Young People Demand Autonomy in Daily AI4U Training Use Behavior

From the perspective of some individuals, the temporal postponement of the EMA and EMI (PCIs: 5/16; participants FG1_P3 and FG2_P3) or muting the alarms (participants PCI_P27, FG1_P2, and FG1_P3) should be more flexible. Several young people (PCIs: 7/16; FGs: 7/11) expressed a desire for more self-determination in use behavior, such as having a stored calendar with personalized availability and preferred use times. Others (FGs: 5/11) suggested options for self-selection, for instance, via 2 variants of an EMI or a shortened version that they could choose from.

A few participants (PCIs: 9/16; FG1_P1 and FG3_P4) argued that increased self-determination could improve daily life integration and reduce the pressure, which some individuals experienced during the study period:

> *I believe it would be better for me personally to use it, if I had more control over inputting information myself...But given the frequency with which the app is now, with the EMA almost five times a day, I just don't think that's feasible for me.* [PCI_P23; page 302]

One participant (PCI_P23) remarked that the AI4U training had to fit into her daily routine without altering her habits or making her feel compelled to do so. Another participant emphasized that denying a prompt was always an option, and therefore, she had less of a problem with the app's suggestions:

> *I mean, we always had the option to do the exercises ourselves...You always have the option to simply decline. Then you can still choose your own exercise.* [FG3_P3; page 249]

Young People Seem to Value Control in Content Selection and Decision-Making Processes

A few participants (PCIs: 3/16; FG3_P3) mentioned that they did not want to rely entirely on the app's decision-making processes and expressed some doubts regarding the app's ability to consistently capture their emotions accurately:

> *I think it's quite individual. I also don't believe that, to be honest, it is possible in the long run for [the app] to adapt to everyone, to all [personality] types. I can't quite imagine that right now.* [PCI_P25; page 166]

Consequently, certain participants demanded an active role in influencing the degree of personalization, for instance, through a feedback function on the individual perceived usefulness of the EMI (participants PCI_P15 and PCI_P17; FGs: 3/11). In total, 3 participants from the FGs highlighted the importance of being able to deviate from the app's content suggestions (FGs: 3/11). One participant emphasized the value of the interplay between self-directed use and app suggestions:

> *I would find it quite good if there was perhaps an app that still allows for some personal control despite AI. Because of course, the AI is hugely advantageous as it suggests something and maybe recognizes patterns that one might not have noticed, and providing EMI accordingly, but perhaps an additional option would be good, where you could say, "No, I don't feel like doing this EMI, I would prefer to choose another one." Sometimes you don't really know which exercise is appropriate, and then the AI might have an advantage because it has already collected data.* [FG1_P1; page 124]

Some of our participants (PCIs: 4/16; FGs: 3/11) underscored that meaningful change can only occur through individual initiative. They emphasized a certain degree of willingness to change and openness to self-reflection as prerequisites for long-lasting change in health-promoting routines:

> *I believe that an app can indeed accomplish something like that. However, as a human being, you must have the ability. You have to be able to receive information or something and work with it...The app can definitely [help], if you look at the dashboard and are a reflective person with a lot of self-awareness who can work very well with oneself, then definitely.* [PCI_P12; page 88]

This was also highlighted by another participant, who emphasized that the AI4U training only set prompts, whereas actual processing and change had to be self-motivated:

> *No, I managed to [strengthen my skills and handle my emotions better in everyday life] on my own, but the app mainly helps in getting started with it and...become more aware of your emotions...So, before I can learn to deal with my emotions, I have to perceive them first. And the app helped with that. It didn't help me so much with processing them, but processing mainly happens through the perception and then acceptance of my emotions.* [PCI_P17; page 214]

Another participant stated that he did not want to be controlled by an mHealth app and did not want an app to dictate a journey toward self-optimization:

> *If, for instance, it was an app that somehow had the message, "You have to become better or whatever," then I would have dropped out of the study...I don't want an app to dictate to me that things have to be better or whatever.* [PCI_P11; pages 186-188]

Discussion

Self-Reflection and Regulation of Negative Affect Improved During the AI4U Training

Our qualitative results point toward the positive impact of sampling emotions (via EMA) and real-time mobile interventions based on moment and life context (via EMI) on the mental health of young people. There was broad consensus across our participants that the EMA were helpful for self-reflection on emotions and their respective triggers. Previous qualitative studies have reported similar enhanced self-awareness among young people after engaging in EMA for up to 3 weeks [18,38,50,51]. Participants reported that the EMI embedded in the AI4U training improved emotion regulation and helped relativize negative emotions and unwind from daily challenges. Aligned with this, an existing mHealth app that provides digital cognitive reappraisal strategies to young people has resulted in reduced impulsivity among users [18]. Other mHealth apps have elicited similar positive effects on participants' emotion regulation and reduction in stress or anxiety levels [12]. Our findings suggest that EMA may foster emotional awareness, which, in turn, seems to enhance the subjective effectiveness of EMI in managing and adapting to those emotions.

Young People's Trust in Disclosing Emotions on Digital Devices Is Driven by Anonymity

People's trust is crucial for the willingness to share data and can be shaped by the perceived usefulness, sensitivity, and anonymity of personal health data [69]. As our participants tested the AI4U training as part of a research study and trusted the confidential data processing, they did not report any concerns regarding data security. For adequate trust in a digital intervention, qualitative studies highlight young people's demand for transparent data handling underlying evidence-based approaches, credibility of the developers, and young people's direct involvement through cocreation in the development process [46,70].

However, trust to disclose emotions was also driven by our participants' perception of the mHealth app as nonhuman. According to them, the AI4U training provided a sense of emotional distance and anonymity compared to face-to-face communication and significantly facilitated the unveiling of emotions via EMA. Previous qualitative research has identified that anonymity on digital applications reduces young people's fear of stigma associated with the disclosure of mental health issues [46]. There seems to be no significant difference in young people's willingness to share data about mental health online compared to their willingness to disclose information about alcohol consumption, physical activity, or academic performance [71]. Our participants valued the AI4U training's neutrality, especially when compared to the risk of judgment or potential misuse of data on mental health when interacting with friends, family, or mental health professionals. Our findings align with those of existing studies and suggest that discussing and sharing mental health issues on digital devices from scientific app providers is not a barrier for young people.

Young People's Flexible Engagement With mHealth Apps While Balancing Everyday Commitments

Some participants highlighted the prioritization of personal activities over AI4U training use when feeling well and resilient within their routines. In line with this, previous studies have identified a rather situational use pattern where an mHealth app is used only when immediate needs arise or in preparation for expected challenges [37,52]. In contrast, a few participants avoided using the AI4U training when experiencing extreme negative emotions. A previous study also identified high levels of overall negative affect among young people as negative contributors to their compliance rates with subsequent EMA prompts [72]. Our results suggest that there might be within-participant ambiguities in young people's views on the training's role in daily life. Some of our participants also acknowledged that it probably would have been most beneficial to engage with the mHealth app and follow the prompts during moments of emotional distress or psychological discomfort. Participants recognized that, without the AI4U training, they would not have allocated time for mental health–promoting activities in their daily life and noted that the AI4U training helped them become more aware of the need to take breaks, which they found difficult to implement without the training. In fact, it is tempting to speculate that EMI tailored to current needs, emotional state, and contextual factors may, in part, need to be perceived as disruptive to existing habits and daily life structures to nudge individuals and initiate change in psychological processes and mechanisms. In other words, timely interventions might be essential for achieving the intended health-promoting effects. To address this, future development should further strive to strike the right balance among minimizing perceived interference, optimizing acceptance, and ensuring that interventions are accessible and used during crucial moments when they can have the most impact.

Our findings suggest that young people tended to integrate the AI4U training into their existing daily routines and preferred to approach it in a flexible and nonbinding manner, that is, engaging with EMA or EMI depending on their personal capacity. Our participants perceived the AI4U training more as a "tool" used while maintaining user agency. Nonnegotiable commitments such as work or academic duties were central in their daily lives, and participants reported being rather reluctant to pause any of their ongoing activities to use the AI4U training. Time constraints and lack of alignment with other daily activities have previously been identified as major barriers to the use of mental health services among young people [6]. In line with previous research, young people tended to answer EMA questions rather superficially when being occupied with other tasks [51], and an increased stress level in young people is a predictor of noncompletion of subsequent EMA prompts [72]. According to some of our participants, it was difficult to integrate the AI4U training into their daily routines, and some felt stressed by the frequent alarms. However, the AI4U training already allowed for muting notifications, the interactions were rather brief (approximately 1 minute for EMA), and not every prompt included an EMI. Our participants were informed about the mute function during prestudy briefing sessions. Similarly, our research team emphasized during those briefing sessions

XSL•FO
RenderX

that the training's intention was not to interfere with daily life. Nevertheless, it seems that this did not result in all participants developing a relaxed attitude toward responding to the EMA or EMI or muting the notifications.

In another study, college students received up to 19 EMA per day but did not report feeling burdened by completing them [51]. This study used context- and signal-dependent prompts to avoid interrupting participants during specific levels of smartphone activity, for instance, if the data showed that they were in the process of sending an email. This approach may have contributed to young people feeling less overwhelmed. mHealth apps with gamification elements, a comprehensive backstory narrative, mini games, or performance levels have demonstrated lower attrition rates and enhanced resilience effects in young people compared to less gamified but equally evidence-based mHealth apps [73]. Image-based EMA prompts or prompts via wearable devices could also reduce use burden and enhance compliance among young people [51]. Future mHealth app development requires further participatory co-design to promote a continuous engagement of young people in mental health–promoting approaches.

Healthy young people may have found that their existing routines were effective and already helped them navigate their day-to-day activities, leaving little reason to change them. In contrast, those who are psychologically distressed may find that their coping mechanisms or routines hinder their daily lives. This experience might lead to greater openness toward the necessity of modifying these routines, for instance, through interventions such as EMI. In a previous cluster-randomized controlled trial, the absence of immediate and significant mental health–promoting effects among a nonclinical sample of healthy young people was attributed to their low baseline distress levels [19]. Thus, it is important to note that healthy people might report more disadvantages because they benefit less from the training.

A Balance Between Self-Determination and Guidance in Daily App Use Behavior Stimulates Compliance

Some of our participants suggested that a greater self-directed use behavior could improve daily life integration, and some highlighted the value of an active involvement in the personalization process. In their development process into adulthood, young people pursue increased autonomy and independence, which also influences their mental health help-seeking behavior in daily life [9]. Their desire for shared decision-making approaches is in line with existing research on attitudes of young people toward mHealth apps. Previously, young people have stressed that an app should never replace human judgment and demanded an active role in steering AI decision-making processes or intervention and content selection [55,56,74]. This was introduced as the concept of "personalized personalization" [55]. Interviews with young people on other mHealth apps have shown that not the quantity but, rather, the timing of EMA throughout the day is challenging, and preset times of use would enhance adherence [38]. In the AI4U training, participants were allowed to set their activity times in advance and had the option to reschedule or trigger an EMA or EMI themselves if necessary. However, it seems that this flexibility was not clear to everyone. On the basis of those results, the option to choose a different EMI is now suggested more proactively in newer versions of the AI4U training. In addition, there is an increased emphasis on individual decision-making power in use behavior. It is important to note that, given the MRT design, only half of the EMI assignments in the AI4U training were AI based. Thus, this does not allow us to clearly draw conclusions about the quality of the AI decision-making processes.

A recent study cautions against increased customization by young people themselves given that "participants may express their desire for customizability in an interview situation, but in reality, they may respond better to clearer design, short interactions with the app, and easy access" [37]. This aligns with feedback from several participants, who reported difficulties in maintaining health-promoting routines learned during the study without the app, resulting in less frequent implementation or complete nonimplementation of these practices. In addition, some participants highlighted that excessive freedom of choice can be overwhelming, suggesting that AI can provide valuable support in this context.

The results point toward the important interplay between AI and human decision-making for an optimal user experience among young people. The challenge for future development processes of mHealth apps is to balance self-determination with targeted external guidance in use and decision-making to achieve the highest health-promoting outcome.

Limitations

A major limitation of this study is the homogeneity of our study sample. Most of the interview participants (20/27, 74%) had obtained their high school diploma or were pursuing higher education. Participants in the PCIs and FGs were mainly students from disciplines including medicine, social work, business, and psychology. Thus, the recruitment strategy of this qualitative study reached predominantly young people who already actively engaged with mental or physical health and social behaviors in their everyday lives or academic education. Most students probably experienced higher levels of academic stress, and their strict daily schedules might have biased our results on daily life integration of the AI4U training. For students of such demanding academic fields, a high level of self-reliance is to be expected, which might also have influenced our results on demanded autonomy. Furthermore, we were unable to recruit young people from diverse migration backgrounds. Almost all the participants of this qualitative study (26/27, 96%) were born in Germany. Currently, there is limited research on the effects of mHealth apps on marginalized individuals from lower socioeconomic or with migration backgrounds [12,17,45]. Limited access to mHealth apps and a lack of alignment between digital interventions and the needs of marginalized individuals potentially limits their health-promoting effects and negatively influences compliance rates [75-77]. In addition, we recruited only a small number of participants, and the gender distribution was not evenly balanced. Due to low inclusion of young men in MRT 2, conducting a second FG with male individuals was not possible. Efforts to address data saturation by increasing the number of male participants in the PCIs did not yield the

XSL•FO
RenderX

intended balance. A recent review on mHealth apps indicates a comparable skewness toward more female participants [17]. A potential explanation for this might be that help-seeking behavior is often associated with weakness [6,78]. There is a need for better understanding why particularly young men underuse health promotion services and what it takes to better engage this subgroup. One study, for instance, used a participatory approach to address gender differences in help seeking and mental health needs [79]. By adding gamification elements centering on sports (ie, football), they aimed for a more preference-based development process of an mHealth app particularly targeted at young men.

Some young people perceived the AI4U training as an additional stressor, with some participants highlighting that this stress was intensified by their desire to meet the requirements for adequate study participation. Young people also perceived the use of a second study smartphone for the AI4U training as burdensome. Hence, we cannot ascertain whether the stress stemmed from participation in the study or the app format itself. Due to the MRT study design, participants were unable to determine whether an EMI was based on random or AI-based assignment. Therefore, statements made in the interviews and FGs about the quality of the suggestions for EMI and the AI features must be interpreted with caution. We conducted the interviews and FGs with a subsample of all AI4U participants and only recruited participants for our qualitative study among the participants of MRT 1 and MRT 2. Therefore, generalizability of individual statements to the entire study population across all MRTs is limited.

Conclusions

The approach of this study allowed for an in-depth understanding of young people's experiences and views on the use of an AI-based mHealth app (AI4U training). Participatory approaches throughout the qualitative research process enabled the shared decision-making and empowerment of young people. The major contribution of our study is that, unlike previous qualitative studies that interviewed young people on their attitudes and preferences on mHealth apps or health promotion services [70,74], we elicited insights on real-world user experiences and subjectively experienced mental health–promoting effects. mHealth apps provide young people with an anonymous environment in which they can open up but that simultaneously allows for the maintenance of control over health-promoting actions. According to young people, an AI-based mHealth app can improve emotional resilience, self-awareness, and health-promoting routines in daily life. Our study also highlights some challenges with integrating an mHealth app into the structured routines of healthy young people. Therefore, flexibility and adaptability seem to enhance the reach, effectiveness, and scalability of an mHealth app.

Acknowledgments

Please note that the authors SD and JS were not officially affiliated with the Department of Psychiatry II, University of Ulm and BKH Guenzburg, Guenzburg, Germany as part of an ongoing working contract. Rather, they participated in our study as co-researchers, i.e. study participants. With that, they were an external part of the research team at the Department of Psychiatry II, University of Ulm and BKH Guenzburg, Germany and were compensated per participation in the participatory research workshops. The authors would like to extend their sincere appreciation for Benedikt Pfeiffer and Tanja Brackman, who constantly attended the recurring participatory research workshops. The authors would like to thank their team member and research associate Sonja Schneiderat, who also works as a school social worker and supported the critical analysis of the findings based on her practical experience. They are also thankful for the support of their student research assistants (Marla Kordes and Beatrice Müller), who assisted in the transcription processes and literature research. The authors' sincere thanks especially go to all participants of the problem-centered interviews and focus groups, without whom this study would not have been possible. This work was funded by a living laboratory grant from the Federal Ministry of Science, Research, and Arts of Baden-Württemberg, Germany, to UR, GK, SK, and DD (grant 31–7547.223–7/3/2); a Deutsche Forschungsgemeinschaft (German Research Foundation) Heisenberg professorship to UR (grant 389624707); and a grant from the Hector II Foundation awarded to JF. The sponsors had no role in the collection, analysis, and interpretation of the data; the writing of the report; or the decision to submit the paper for publication.

Authors' Contributions

UR, CR, SK, DD, GK, JF, EW, CG, and SH designed the study. SH and CG conducted the qualitative data collection. SH analyzed the qualitative data. The co-researchers (JS and SD) regularly engaged in participatory research workshops and helped SH prepare data material and validate the results of the qualitative analysis. SH wrote the first draft of the manuscript. All authors read and approved the final manuscript.

Abstract

Background: Ecological momentary assessment (EMA) is a valuable method for capturing real-time data on behaviors and experiences in naturalistic settings. However, maintaining participant engagement in longitudinal (ie, multiburst) EMA studies remains challenging, particularly when collecting intensive data over extended periods. Understanding factors affecting completion rates is essential for designing more effective EMA protocols and interpreting results accurately.

Objective: This study investigated factors influencing EMA completion rates in a 12-month intensive longitudinal study among young adults in the United States, examining both time-varying factors and stable individual characteristics.

Methods: Young adults (N=246, ages 18-29 years) participated in the Temporal Influences on Movement and Exercise (TIME) study, responding to smartphone-based EMA prompts during biweekly measurement bursts (4-day periods of intensive sampling), with continuous passive data collection via smartwatches. Each burst included signal-contingent prompts delivered approximately once per hour during waking hours, resulting in an average of 12.1 (SD 1.3) prompts per day. Multilevel logistic regression models examined the effects of time-varying temporal factors (time of day, day of week, season, and time in study), contextual factors (phone screen status, phone usage, and location), behavioral factors (sleep duration, physical activity levels, and travel status), and psychological factors (momentary affect and stress) on prompt completion. Models also included time-invariant demographic characteristics (sex, race, ethnicity, education, and employment) and tested interactions between time in study and other predictors.

Results: Mean completion rate was 77% (SD 13%). Hispanic participants showed lower odds of completion compared to non-Hispanic participants (odds ratio [OR] 0.79, 95% CI 0.63-0.99; *P*=.04) and employed participants were less likely to complete prompts than unemployed participants (OR 0.75, 95% CI 0.61-0.92; *P*<.01). Having the phone screen on at prompt delivery substantially increased completion odds (OR 3.39, 95% CI 2.81-4.09; *P*<.001), while being away from home reduced completion likelihood, with particularly low odds when at sports facilities (OR 0.58, 95% CI 0.47-0.74; *P*<.001) or restaurants and shops (OR 0.61, 95% CI 0.51-0.72; *P*<.001). Short sleep duration the previous night (OR 0.92, 95% CI 0.87-0.99; *P*=.02) and traveling status (OR 0.78, 95% CI 0.75-0.82; *P*<.001) were associated with lower completion odds. Higher momentary stress levels predicted lower completion of subsequent prompts (OR 0.85, 95% CI 0.78-0.93; *P*<.001). Completion odds declined over the 12-month study (OR 0.95, 95% CI 0.94-0.96; *P*<.001), with significant interactions between time in study and various predictors, indicating changing patterns of engagement over time.

Conclusions: Findings highlight the dynamic nature of EMA engagement in longitudinal multiburst studies and underscore the importance of considering time-varying and time-invariant factors in study design and analysis. This study provides valuable insights for researchers designing intensive longitudinal studies in behavioral science and digital health. Potential strategies for optimizing EMA protocols could include tailoring prompt schedules to individual contexts and developing adaptive sampling techniques.

ecological momentary assessment; longitudinal study; compliance; mobile health; young adults

Introduction

Traditional cross-sectional and retrospective self-report measures are prone to substantial limitations in studying health behaviors and psychological processes [1]. Cross-sectional designs only provide a snapshot, lacking insight into within-person variations over time and context [2,3]. Retrospective surveys require participants to summarize or recall experiences over lengthy periods, introducing recall biases that distort reports [2,3]. For example, physical activity levels likely vary within days and across days of the week in systematic ways obscured in generalized retrospective reports [3,4]. Aggregated retrospective summaries also fail to capture specific within-day or day-to-day fluctuations in behaviors, feelings, thoughts, and exposures that may be highly predictive of outcomes [3]. Traditional designs lacking temporal specificity severely limit understanding of the microtemporal relationships between psychological factors and behavioral choices hypothesized by many health behavior theories and models [1-3,5]. Intensive longitudinal designs using ecological momentary assessment (EMA) are needed to overcome these limitations and capture predictive within-day and day-to-day variations [1-3].

EMA overcomes many limitations of traditional designs by using repeated natural sampling of current behaviors, experiences, and contexts [1-3]. EMA prompts participants to provide real-time self-reports multiple times per day in natural environments, reducing recall biases [1-3]. Capturing microtemporal fluctuations via intensive longitudinal EMA enables examination of within-day and day-to-day variations in behaviors and putative causal factors, unavailable in traditional designs [1-3]. For example, EMA allows modeling of physical activity as a function of rapidly changing variables such as location, affect, and stress measured at the same momentary time scale [6-9]. EMA's temporal precision permits study of directionality and time-varying effect magnitudes [10]. EMA's ecological validity also facilitates idiographic analysis of dynamic relationships among variables unfolding uniquely for each person [10,11]. Thus, intensive longitudinal EMA provides new opportunities to understand microtemporal influences on health behaviors.

However, EMA is prone to missing data due to noncompletion with intensive sampling protocols [12,13]. This can bias results if missing data are systematic [12,13]. For example, individuals may be less likely to comply when under stress or engaging in unhealthy behaviors, distorting conclusions [12,13]. It is critical to maximize completion, which remains a challenge in long-term studies [14]. Completion rates vary widely in EMA research, ranging from 42% to 99% with a mean of 82% [12]. Lower completion is associated with minority ethnicity, low socioeconomic status, and mental health symptoms [12]. Additionally, time-varying factors such as affect, social context, and time of day have been found to predict EMA compliance [15]. Completion also decays over time, with gradual drop-offs or sudden declines [13]. This complicates separating true change from artifactual patterns. It is important to note that most EMA studies are relatively short-term, typically lasting from a few days to several weeks, with some extending to a few months [12]. Longer-term studies, particularly those extending beyond 6 months, are relatively rare in EMA literature. This limited duration of typical EMA studies restricts our understanding of long-term patterns in compliance and the sustainability of intensive longitudinal designs. Systematically missed EMA prompts reduce statistical power and can preclude multilevel modeling approaches common for EMA data [1,12,14,16]. Thus, optimizing and tracking completion is essential for valid EMA studies. Understanding factors influencing completion is critical for interpreting findings and guiding effective retention strategies. Further, most prior research on EMA completion has focused on single measurement burst or limited measurement burst designs [1,3,12]. Consequently, there is a significant gap in our understanding of EMA compliance in multimeasurement burst designs with frequent bursts, particularly regarding changes in completion rates over extended periods and interactions between time-varying and time-invariant factors across time [1,3,12]. This lack of knowledge presents a critical challenge for researchers aiming to implement long-term, intensive EMA protocols, as it limits our ability to anticipate and mitigate compliance issues in such designs.

The Temporal Influences on Movement and Exercise (TIME) study combines 12 months of smartwatch data collection and EMA in young adults [16]. Young adulthood is a high-risk period for declining physical activity and deteriorating sleep patterns [17,18]. The TIME study's intensive EMA protocol also enables examining how psychological and contextual variables relate to completion. Specifically, the length of follow-up (across 12 months), in combination with passive data collection (accelerometer data collection), and frequent intensive EMA "bursts" represent advances in EMA research. For example, the study can evaluate whether EMA completion rates decay more steeply when participants report higher stress levels or more negative affect. Additionally, it can examine if factors such as sleep quality, physical activity levels, or social interactions interact with time to predict changes in compliance. Findings from these analyses may point to the need for adaptive EMA protocols that tailor prompt frequency, timing, or content

XSL•FO
RenderX

based on detected psychological states, behaviors, or contextual factors, potentially improving long-term engagement and data quality. The 12-month duration also permits evaluating long-term patterns such as seasonal variations. Thus, the TIME study provides a unique opportunity to elucidate participation and engagement factors important for future intensive longitudinal research.

Therefore, this study aims to evaluate the TIME study's EMA completion rates and predictors. Specifically, the purpose of this study was to examine whether time-varying temporal, contextual, behavioral, and psychological factors (eg, time of day, day of week, screen status, location, days enrolled in study, time elapsed from last active phone use, sleep duration the prior night, current day activity level, current day average stress, previous hour physical activity, previous hour affect state, and previous hour stress level) and time-invariant personal characteristics (eg, sex at birth, race, ethnicity, education, and employment status) were associated with EMA completion rates. Investigating these patterns through an unprecedented, year-long intensive protocol provides critical methodological insights into the feasibility, sustainability, and data quality of long-term EMA studies. These findings can guide interpretations of results from longitudinal multiburst EMA studies, as systematically missed EMA prompts may distort conclusions by underrepresenting critical moments or obscuring true temporal relationships between variables. Identifying factors linked to completion can inform refinements to future EMA protocols and retention strategies to enhance data quality and representativeness. By understanding predictors of nonresponse, researchers can develop targeted strategies to reduce systematic missingness, such as implementing adaptive sampling techniques or personalized engagement approaches. These refinements aim to preserve statistical power by maximizing response rates, particularly during critical periods or states prone to missingness, ultimately providing more valid and reliable results for understanding real-time health behaviors and experiences. This study represents an important step in elucidating the sustainability and validity of long-term intensive EMA for studying health behaviors, offering empirical evidence to support best practices for designing and implementing longitudinal multiburst EMA studies that balance data quality with participant burden and engagement.

Methods

Design

The TIME study used a 12-month intensive longitudinal multiburst design using personal smartphones to continuously monitor young adults' health behaviors and associated psychological processes. As detailed in the study protocol [16], participants serve as their own controls in a within-subject case-crossover framework, capturing dynamic fluctuations in behaviors and predictors over time and context. Passive sensing via smartwatch and phone sensors provides continuous measurement of activity behaviors and contextual factors such as time and location hypothesized to reactively influence those behaviors [16]. Intermittently prompted EMAs on smartphones gather self-reports on reflective cognitive factors such as intentions and self-control. This innovative combination of continuous passive monitoring and bursting EMA surveys provides rich temporal data on factors influencing physical activity, sleep, and sedentary time. The extensive 12-month duration enabled studying maintenance as well as adoption of health behaviors.

Ethical Considerations

The study was approved by the institutional review board at the University of Southern California (USC; HS-18-00605). The study was performed in accordance with the ethical standards as laid down in the Declaration of Helsinki and its later amendments. All participants provided informed consent to have their deidentified data published in journals. Participants were compensated up to US $100 for each 4-week period (US $1260 total). This included US $10 for each EMA burst period they completed, with at least 8 prompts per day. In addition, if a participant answered more than 11 EMA prompts on a given burst period day, the participant receives a US $5 bonus per day.

Participants

The study recruited young adults across the United States (N=246). Inclusion and exclusion criteria were assessed by self-report during the screening process. Inclusion criteria for the study were as follows: (1) aged 18-29 years living in the United States, (2) intention to engage in recommended levels of moderate to vigorous physical activity (≥150 minutes/week moderate or ≥75 minutes/week vigorous intensity) within the next 12 months, (3) use an Android-based smartphone as their only primary personal mobile device with no intention to switch to a non-Android phone, (4) able to speak and read English, and (5) plan to reside in a home with Wi-Fi connectivity during the study period. Exclusion criteria were (1) physical or cognitive disabilities that prevent participation; (2) health issues that limit physical activity; (3) any diagnosed sleep disorders; (4) unable to wear a smartwatch or answer EMA surveys at home, work, school, or another location where a substantial amount of time is spent; (5) spends more than 3 hours/day on a typical weekday or weekend day driving; (6) owns an Android phone version 6.0 (or older), or if the app will not function on the phone due to other technical issues; (7) currently owns and wears a smartwatch; (8) uses a pay-as-you-go data plan or data plan with less than 2 gigabytes of data per month; or (9) currently pregnant. Participants were recruited regardless of baseline activity level. A variety of recruitment methods were used to recruit socioeconomically and racially or ethnically diverse young adults, including (1) sending emails to individuals enrolled in a USC longitudinal cohort study of young adults, (2) referrals from existing participants (word of mouth), and (3) contacting participants identified using ResearchMatch, a national health volunteer registry [19].

Of 246 participants fully enrolled in the TIME study, 3 were excluded due to missing key demographic information, specifically sex at birth and age, reducing the subject-level sample size to 243. Within this cohort, 29 participants were further removed from the analysis due to missing phone data, including screen state or phone usage, thereby decreasing the sample size to 214. Additionally, missing accelerometer data

XSL•FO
RenderX

from the watch led to the exclusion of 5 participants, culminating in a sample of 209. Lastly, missing EMA data necessitated the removal of 2 participants, resulting in a final analytical sample of 207. See Multimedia Appendix 1 for a more detailed overview of participant exclusions.

Protocol

Data were collected between March 2020 and August 2022. Due to health and safety concerns arising from the COVID-19 pandemic, all study procedures were conducted remotely. Potential participants filled out a web-based interest form to screen eligibility (n=1202). For eligible and interested potential participants, a videoconference orientation and consent session over Zoom (Zoom Communications) was then scheduled (n=645). This session involved reviewing all parts of the study, obtaining informed consent, and downloading the custom TIME study smartphone app onto the participant's smartphone (n=332). During the orientation session, participants received instructions on how to use the study app to complete EMA surveys. During the following week, individuals participated in their first 4-day EMA measurement burst period (further described below), during which the TIME app triggered surveys once per hour during the participant's waking hours. Participants who successfully completed at least 8 surveys per day during this first EMA measurement burst period were fully enrolled in the study and mailed a smartwatch (N=246). If completion was below 8 surveys/day for the first measurement burst period, participants were unenrolled from the study. Among the fully enrolled cohort (N=246), 228 participants remained active in the study during the first 3 months. By month 6, the number of participants had decreased to 186, and only 123 participants completed the full-year study. The overall attrition rate was 50%.

EMA data were collected using the custom TIME app developed for Android smartwatches and smartphones. While more information about the app can be found in the study protocol paper [16], the app consists of an auditory prompting with a smartphone notification, followed by a welcome screen, followed by EMA items with one item per screen, and lastly a thank you screen. The app was downloaded directly to a participant's personal Android phone from the Google Play Store but was only accessible to authorized study participants. Once the participant received the smartwatch by mail, the TIME app was downloaded to the watch paired with the smartphone. EMA surveys were prompted in four ways: (1) daily sleep-wake time surveys to tailor prompt timing to participants' schedules, (2) end-of-day surveys each evening, (3) 4-day measurement burst periods every 2 weeks with signal-contingent prompting approximately every hour, and (4) context-sensitive surveys based on passive sensing of location and activity. Participants also completed web-based questionnaires at baseline, 6 months, and 12 months, and an exit interview. This study focused on the completion of the 4-day measurement burst EMA prompts.

EMA measurement bursts were scheduled every 2 weeks, resulting in up to 26 burst periods throughout the year-long study, totaling 104 days of intensive data collection per participant. The burst periods were randomly scheduled but structured to always include 2 weekdays and 2 weekend days, with a minimum of 7 days between each burst. Each burst encompassed 4 consecutive days of data collection, with signal-contingent prompts occurring multiple times daily. These prompts were randomly triggered approximately once per hour during participants' waking hours, specifically between 10 and 50 minutes past each hour to prevent consecutive prompts from occurring too close together. Participants received a notification via the TIME app 1 day before each burst period was set to begin. This notification provided participants with a one-time option to delay the start of the burst by 2 days if needed.

To encourage ongoing participation and attentiveness, the researchers implemented several engagement strategies, including (1) texting participants when their EMA completion declined, (2) providing financial incentives based EMA completion, (3) allowing participants with high completion (ie, wearing the smartwatch for more than 23 hours/day on 24 days/month, answering more than 24 of the end-of-day EMA smartphone prompts/month, answering more than 11 EMA smartphone prompts/day during measurement bursts, and answering more than 50% of the micro-EMA questions prompted on the smartwatch) to keep their smartwatch at the end of the study, (4) sending quarterly participant newsletters, and (5) providing a report-back of individual data to participants who completed the study. Participants were oriented to the study protocol and given a number and instructed to text the study staff with any questions, concerns, or technical issues. On a weekly basis, staff review data uploaded to the study server and contact participants by email or SMS text messages, which is another avenue to address technical issues. After completing each EMA prompt, participants were shown a humorous and lighthearted "thank you" message. A bank of 250 unique messages was used to maintain novelty throughout the study. On a weekly basis, staff review data uploaded to the study server and contact participants by email or SMS text message in the case of missing data to encourage compliance and address technical issues. Additionally, 20% of the EMA prompts included attention check questions. These questions were designed to be both entertaining and unambiguous, allowing researchers to assess whether participants were paying attention and responding thoughtfully to the EMA questions. More information regarding the attention check questions as well as a qualitative evaluation of participant engagement can be found elsewhere [20].

Activity Monitoring

Raw accelerometer data (using the embedded triaxial accelerometer) were collected on the phone and watch at ~50 Hz continuously. After data collection, the raw accelerometer data from the smartwatch were processed using the monitor-independent movement summary (MIMS) unit algorithm [21]. The MIMS-unit algorithm computes a summary of total movement within an epoch and has been used to identify percentile cutoffs for physical activity among young adults at a population scale [22]. MIMS-unit values were calculated for 1-second epochs for all the raw acceleration data collected from the wrists.

XSL•FO
RenderX

Location Sensing

Location data (latitude and longitude) were gathered once per minute using the built-in GPS features on the phone. By the end of each day, the location data were converted to location clusters, which were then used for self-reported location labeling. First, at midnight, the app clustered the entire day's location data using the DBSCAN (density-based spatial clustering of applications with noise) algorithm [23]. Then, for each day, the clustered points were combined with the previous day's cluster points and were clustered again using DBSCAN to generate location clusters for the participant, but this time considering all clusters identified since the start date. A cluster was formed when there were at least 5 stay points at that location; a stay point was defined as spending at least 5 minutes continuously in one 10 m radius (4th decimal precision for longitude/latitude). The global clusters were saved as polygons of bounding points (using the concave hull [24]).

In real time, the app also checked if the current location was within an already identified cluster for at least 3 minutes; if this condition was satisfied, the phone presented a location question to gather semantic labels. If participants answered this survey, then the label was saved for the cluster. The question was presented again for this cluster until the labeled cluster was *confirmed* (when 80%+ of the labels for that location were the same, and at least 4 labels were reported). Once the label was confirmed for a cluster, no location question was prompted for this cluster again until an additional 60 days had passed, after which the question was presented again. If the location was again confirmed, another 60 days would pass without questions about the cluster; otherwise, more questions were asked until a label was again confirmed.

Measures

Table 1 provides an overview of the measures used for analysis in this study, divided by the type of variable.

Table 1. Variables used in the analysis of ecological momentary assessment prompt completion.

Type	Variable	Collection method
Time-varying temporal	• Time of the day • Type of day (weekday/weekend) • Months enrolled in the study • Season (Reference=Summer)	• EMA[a]
Time-varying contextual	• Active phone screen state (Reference=Phone not actively being used at time of prompt) • Phone usage (time since last phone use) • Physical location	• EMA
Time-varying behavioral	• Sleep duration the prior night • Previous 10-minute physical activity (as an ordinal and continuous variable) • Daily status (eg, sick or traveling)	• Accelerometer • EMA
Time-varying psychological	• Affect state on previous prompt • Stress level on previous prompt	• EMA
Time-invariant demographics	• Sex at birth • Age • Race • Ethnicity • Education • Employment status	• Questionnaire

[a]EMA: ecological momentary assessment.

EMA Completion

The primary outcome of interest is prompt completion (ie, 1=completed and 0=not completed) as defined by responding and completing the full survey within the 10 minutes of the initial prompt. If a response is not provided, up to 2 reprompts will be provided at 5-minute intervals. After 10 minutes, the EMA survey becomes inaccessible and is recorded as not completed. The completion rate was measured at the prompt level and represents the availability of data.

Time-Varying Factors

Temporal

Temporal covariates were measured to examine associations with prompt completion.

- Time of the Day:
  Time of the day was grouped into 4 categories: "morning" (8 AM to 12 noon), "afternoon" (12 noon to 4 PM), "evening" (4 PM to 8 PM), and "night" (8 PM to midnight). Time of the day was then dummy coded with "morning" as the reference category.
- Type of Day:

XSL•FO
RenderX

Each day was coded as a weekday or a weekend day (Saturday and Sunday) as a categorical variable. The type of day was then dummy coded with weekday as reference.

- Months Enrolled in the Study:
  In this study, the number of months in the study was used as a predictor for nonresponse.
- Season:
  Season of the year (summer, spring, fall, and winter) was used to better understand the role of seasonality on prompt response, with summer serving as the reference category.

Contextual

Time-varying contextual covariates were measured to examine associations with prompt completion.

- Active Phone Screen State:
  For each survey, a variable was created to display whether a prompt occurred when the phone was in active use with the screen on. Phone screen status was dummy coded with screen off as reference (screen off=0 and screen on=1).
- Time Since Last Phone Use:
  The time difference between a given prompt and the last active phone screen locking event (ie, when the active use session ends) was calculated as time since last phone use. However, a ceiling of 60 minutes was set, based on the prior work, to avoid long time gaps due to sleep time or the device being off. If the prompt occurred during active phone use, then the time difference was logged as 0 minutes.
- Location:
  Participants provided semantic location labels. The question asked, “Where are you right now?” with 21 answer options: “home,” “work,” “school/college,” “park/playground,” “sports field/court/golf course,” “gym/health club/fitness center,” “friend’s/romantic partner’s place,” “family member’s place,” “restaurant/bar/café,” “store/shopping venue,” “church/place of worship,” “movie theatre/entertainment venue,” “beach/pool,” “transit center/bus stop,” “medical clinic/hospital,” “in car/vehicle/train,” “salon/barber/spa,” “library/museum,” “gas station/convenience store,” “parking lot/structure,” “hotel/motel,” and “other.” First, all location points within a 5-minute interval were gathered, and then the point closest in time to the prompt was selected. Finally, among all semantic location labels reported for this cluster, the one with the largest count was picked. Only the most frequently occurring labels were included: “home of participant,” “home of relatives or friends,” “work or school,” “shop or restaurant,” and “indoor or outdoor sport place.” Finally, all other location labels that did not occur frequently were tagged as “other” locations. The location dummy variable was coded with “home” as a reference category.

Behavioral

Time-varying behavioral covariates were also explored.

- Sleep Duration the Prior Night:
  Sleep duration was calculated as the time difference between the retrospective wake-up time on the day of the survey and the retrospective bedtime on the preceding night.
- Daily Status:
  Daily status was meant to code whether the participant noted that they were sick or traveling on that day as these states can affect responsiveness to EMA prompts.
- Previous 10 Minutes Physical Activity:
  MIMS in the previous 10 minutes were calculated to determine proximal activity predictors. These data were analyzed in 2 different forms to examine the relationship between recent physical activity and EMA completion. First, we treated MIMS as an ordinal categorical variable to test for potential threshold effects and nonlinear relationships between activity intensity and EMA completion. We established activity intensity categories based on the distribution of MIMS values in our sample and aligned with conceptually meaningful activity intensity levels: “missing data”: no accelerometer data available; “less than 10 MIMS per minute”: representing primarily sedentary behavior and light physical activity; “10-15 MIMS per minute”: representing moderate-intensity physical activity; “greater than 15 MIMS per minute”: representing vigorous-intensity physical activity. These cut-points were determined through exploratory analysis of our dataset, examining the distribution of MIMS values during known activity types reported by participants, and selected to create meaningful distinctions between different activity intensities relevant to our research questions [21,25]. Second, we also analyzed MIMS as a continuous variable to examine the potential linear relationship between activity intensity and EMA completion probability. This dual analytical approach allowed us to determine whether physical activity's effect on EMA completion follows a threshold pattern (better captured by distinct categories) or a dose-response relationship (better captured by a continuous measure). Additionally, using both approaches serves as a sensitivity analysis to ensure our findings are robust across different analytical methods.

Psychological

Time-varying psychological factors were also explored.

- Previous Prompt Positive Affect State:
  Positive affect was measured using a set of questions asking participants to rate their current mood, such as happy, energetic, and relaxed, on a scale from 1 (not at all) to 5 (extremely), and we created a composite score out of these 3 items for the positive affect at each EMA prompt.
- Previous Prompt Stress Level:
  Stress was assessed using a single-item measure that asked participants to rate their current stress level on a scale from 1 (not at all stressed) to 5 (extremely stressed) at each EMA prompt.

Time-Invariant Covariates

Time-invariant covariates were recorded using a self-reported questionnaire at the beginning of the study. Sex at birth (binary variable: Female=1 Ref=Male), race (categorical variable), education (ordinal variable), and employment status (binary variable: 1=employed, 0=other) were all used in this study to examine completion as they have been previously used in previous studies.

XSL•FO
RenderX

Data Analysis

Data analysis was conducted using multilevel logistic regression models to examine predictors of EMA prompt completion (yes/no) over the 12-month study period. This approach was chosen to account for the nested structure of the data, with multiple observations (level 1) clustered within participants (level 2). Five separate models were constructed to investigate different sets of predictors. Separate models were used due to the large number of predictors and the potential for multicollinearity among certain variables. This approach allowed us to examine specific sets of predictors and interactions in detail while maintaining model stability and interpretability. Additionally, using separate models enabled us to explore different aspects of EMA completion behavior (eg, contextual factors and psychological states) without overfitting the data or compromising statistical power. The use of multiple models also provided means to cross-validate findings and assess the robustness of predictor effects across different model specifications. Model 1 focused on demographics (sex, age, race, ethnicity, education, and employment status), time in study (both between- and within-subject effects), and date and time variables (season, day of week, and time of day). Model 2a examined demographics, time in study, phone status (screen on/off and usage in prior hour), physical context (location), and physical activity (categorized into levels based on MIMS units). Model 2b was similar to 2a but treated physical activity as a continuous variable. Model 3a investigated demographics, time in study, sleep duration (categorized as short, normal, or long), daily status (sick or traveling), and lagged positive affect. Model 3b was similar to 3a but replaced positive affect with stress. All models included both between-subject and within-subject effects for time-varying predictors, representing their deviations from the grand and subject mean, respectively. This allows for the separation of between-person differences and within-person fluctuations in the predictors. Interaction terms between time spent in the study and other predictors (eg, sex, phone status, affect, and stress) were also included in each model to examine how the influence of various factors on EMA completion might change over the course of the study. We examined interactions between time spent in the study (both between-subject and within-subject effects) and a range of factors. These included demographic characteristics such as participant sex, contextual factors like phone screen status before reci and phone usage in the prior hour, and behavioral measures such as physical activity levels. Additionally, we investigated how time spent in the study might moderate the effects of psychological factors on EMA completion, focusing on interactions with positive affect and stress levels. All of these interaction terms were included to assess whether the influence of these factors on EMA completion rates changed as participants progressed through the year-long study period. By incorporating these interactions, we aimed to capture the dynamic nature of factors influencing EMA compliance over time and to identify any temporal patterns in participant engagement with the study protocol. The outcome variable in all models was the binary completion status of each EMA prompt (1=completed and 0=not completed). Odds ratios (ORs) with 95% CIs were calculated for each predictor, representing the change in odds of EMA completion associated with a one-unit increase in the predictor.

Results

Descriptive Results

Among the final analytical sample (n=207), 55.56% (n=115) identified as female, 43.48% (n=90) as White, and 30.43% (n=63) identified as Hispanic. In terms of education and employment, 45.41% (n=94) had a college degree or higher, and 59.9% (n=124) were fully employed. The mean age of the participants was 23.45 (SD 3.12) years.

Prompt Completion Descriptive Statistics

This intensive design resulted in an average of 12.1 (SD 1.3) prompts per participant per day, and 939.7 (SD 444.7) prompts per participant over the course of the whole survey (up to 1 year). On average, each participant had 51 (SD 30.5) days nested within 15.5 (SD 8.4) bursts. The overall mean completion rate for participants in the analytical sample was 0.77 (SD 0.13), indicating 77% of prompts were completed.

Factors Predicting Prompt EMA Completion

Multilevel logistic regression analysis was conducted to examine time-varying and time-invariant predictors of EMA prompt completion over the 12-month study period. All models can be found in Table 2.

XSL•FO
RenderX

Time-Invariant Demographic Factors

Several time-invariant demographic factors were found to significantly predict EMA completion odds across multiple models. In Model 2a, sex at birth played a role, with females showing lower odds of completion compared to males (OR 0.78, 95% CI 0.63-0.96; *P*=.02). While no significant effect of age was observed in any model, race and ethnicity were important predictors. Model 1 showed that Asian participants had lower odds of completion compared to White participants

XSL•FO
RenderX

(OR 0.74, 95% CI 0.58-0.95; *P*=.02), and Hispanic participants showed lower odds of completion compared to non-Hispanic participants (OR 0.79, 95% CI 0.63-0.99; *P*=.04). Education level emerged as a positive predictor in Model 2a, with higher education levels (college and above) associated with increased odds of EMA completion (OR 1.39, 95% CI 1.03-1.77; *P*=.01). In contrast, employment status was negatively associated with completion across models, as fully employed individuals showed lower odds of completion than those who were not (OR 0.75, 95% CI 0.61-0.92, *P*>.01 in Model 1).

Time-Varying Temporal Factors

Multiple regression analyses revealed several significant time-varying temporal factors influencing EMA completion odds. In Model 1, time of day played a crucial role, with nighttime associated with lower odds of completion compared to morning hours (OR 0.76, 95% CI 0.62-0.93; *P*>.01). Interestingly, no significant difference was found between weekdays and weekends across all models, suggesting that the day of the week did not statistically impact completion rates. Seasonal effects were observed in Model 1, with higher odds of completion in spring (OR 1.05, 95% CI 1.00-1.10; *P*=.04) and winter (OR 1.06, 95% CI 1.01-1.11; *P*=.01) compared to summer. The duration of participation in the study showed a significant within-subject decrease in completion over time (OR 0.95, 95% CI 0.94-0.96, *P*<.001 in Model 1), indicating declining completion odds as participants progressed through the study.

Time-Varying Contextual Factors

Models 2a and 2b highlighted the importance of phone-related factors for EMA completion. Having the phone screen on before answering the survey significantly increased the odds of completion (OR 3.39, 95% CI 2.81-4.09, *P*<.001 in both models), while higher within-subject phone usage in the prior hour decreased completion odds (OR 0.80, 95% CI 0.77-0.83, *P*<.001 in Model 2a; OR 0.82, 95% CI 0.81-0.83, *P*<.001 in Model 2b). Physical location was also a significant predictor in these models, with being outside the home generally associated with lower completion odds. For example, compared to being at home, participants were less likely to complete EMAs when at work or school (OR 0.70, 95% CI 0.65-0.75, *P*<.001 in Model 2a).

Time-Varying Behavioral Factors

The study found significant associations between behavioral factors and EMA completion odds across different models. In Models 3a and 3b, sleep duration from the prior night emerged as an important predictor, with short sleep duration (less than 6 hours) associated with lower completion odds (OR 0.92, 95% CI 0.87-0.99; *P*=.02) compared to normal sleep duration. Model 2a examined physical activity levels in the 10 minutes preceding the EMA prompt, finding that lower activity levels were generally associated with higher completion odds compared to high activity levels (ORs ranging from 1.16 to 1.35, all *P*<.001). However, when physical activity was used as a continuous variable (Model 2b), no significant effects were observed. Models 3a and 3b found that traveling was associated with decreased completion odds (OR 0.78, 95% CI 0.75-0.82, *P*<.001 in both models) although no significant effect was found for being sick.

Time-Varying Psychological Factors

Affective states and stress levels from the previous prompt showed significant associations with completion odds in Models 3a and 3b. Model 3a indicated that neither between-subject nor within-subject positive affect was statistically associated with completion odds, suggesting that the experience of positive emotions at the prior EMA prompt may not influence subsequent EMA completion behavior. However, Model 3b showed that within-subject stress levels had a significant negative association with odds of completing the subsequent EMA prompt (OR 0.85, 95% CI 0.78-0.93; *P*<.001), and it implied that participants were less likely to complete EMA surveys when experiencing elevated stress during the prior EMA prompt.

Interactions

The analysis revealed several significant interaction effects across different models, providing insights into how the influence of various factors on EMA completion odds changed over the course of the study. In Model 1, an interaction effect was observed between participant sex and within-subject time spent in the study, suggesting that females may experience a slightly faster decline in survey completion odds as the study progresses, relative to males (OR 0.99, 95% CI 0.98-1.00; *P*>.01; see Figure 1A). Model 2a showed interaction effects between screen status and within-subject time spent in the study (OR 0.97, 95% CI 0.95-0.99; *P*<.001), indicating that while having the phone screen on substantially increased completion odds initially, this positive effect diminished over time in the study (see Figure 1B). Similarly, the interaction between phone usage in the prior hour and within-subject time in the study (OR 0.98, 95% CI 0.97-0.99; *P*<.001) suggests that the negative impact of recent phone usage on completion odds became less pronounced as participants progressed through the study (see Figure 1C). Additionally, Model 3b revealed interactions between psychological factors and total time a participant stayed in the study (between-subject time effect). Model 3b revealed a significant interaction between within-subject stress levels and the duration of total time participants remained in the study (OR 1.02, 95% CI 1.01-1.04; *P*>.001). While the main effect of within-subject momentary stress was negatively associated with EMA completion, participants who remained in the study longer exhibited a less pronounced negative impact on survey completion behavior compared to those who dropped out at an earlier stage (see Figure 1D).

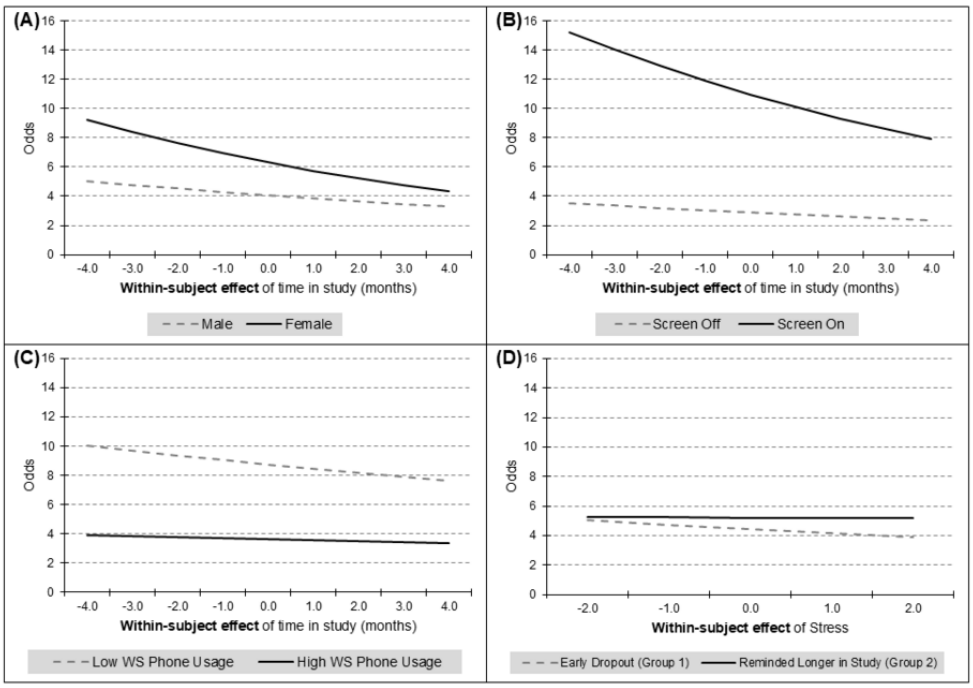
Figure 1. Interaction effects of key predictors and study duration on EMA completion. These plots illustrate the interaction effects between key predictors and study duration on momentary EMA completion odds. (A) Interaction effect between sex and within-subject time duration in study (ie, the deviation from each participant's average month-stayed in the study) on completion odds as analyzed in Model 1. (B) Interaction effect between phone screen state and within-subject time duration in study on completion odds as examined in Model 2a. (C) Interaction effect between within-subject phone usage (ie, the deviation score from each participant's average phone usage) and within-subject time duration in study on completion odds, also in Model 2a. (D) Interaction effect between within-subject momentary stress (ie, the deviation score from each participant's average stress) and between-subject study duration (ie, early dropout vs reminded longer in study) on completion odds as detailed in Model 3b. EMA: ecological momentary assessment; WS: within subject.



Discussion

Principal Findings

This study examined factors influencing EMA completion in a 12-month intensive mutiburst longitudinal study among young adults. Our findings reveal a complex interplay of time-varying temporal, contextual, behavioral, and psychological factors and time-invariant individual characteristics that affect EMA completion over time.

Our findings revealed an interesting pattern regarding phone-related factors. While having the phone screen on at the moment of prompt delivery substantially increased the odds of EMA completion, greater phone usage in the prior hour predicted lower completion odds. This seemingly contradictory result may reflect different aspects of device engagement. Having the screen on at prompt delivery represents immediate accessibility and attention to the device, facilitating a quick response. In contrast, higher prior usage may indicate engagement with competing activities on the phone (eg, social media, games, and work tasks) that could reduce willingness to interrupt these activities to complete a survey. Additionally, higher prior usage might indicate a pattern of more fragmented attention or task-switching, making participants less likely to commit to completing the multiquestion EMA. This pattern suggests that EMA designs might benefit from leveraging moments when the device is already in use, while being mindful that excessive prior engagement with the device might create competing demands on user attention.

The observed seasonal effects on completion rates, with higher odds of completion in spring and winter compared to summer, likely reflect behavioral patterns related to indoor or outdoor activity. Research has shown that physical activity levels vary seasonally, which could affect availability for completing assessments [26]. During spring and winter, participants may spend more time indoors, where their phones are more readily accessible and there are fewer competing activities. In contrast, summer months often involve more outdoor activities, travel, and social events where participants may be physically separated from their devices or less willing to interrupt activities to respond to prompts. These seasonal variations could also be attributed to changes in daily routines, such as academic schedules for students or shifts in work patterns [27]. Seasonal changes in mood, particularly seasonal affective disorder, might impact participants' willingness to respond to EMA prompts [28]. Environmental factors like daylight hours and weather conditions have also been found to influence smartphone usage patterns [29], potentially affecting EMA completion rates. Further, the lower completion odds observed outside the home environment, particularly at work or school, highlight the impact of daily routines and competing demands on participants' ability or willingness to respond to prompts. These findings align with previous studies that have identified location and daily activities as important factors in EMA completion [1,7]. Understanding these influences could help researchers design more adaptive EMA protocols that account for predictable fluctuations in participant engagement throughout the year.

XSL•FO
RenderX

Behavioral and psychological states also significantly influenced the odds of EMA completion. Short sleep duration on the previous night and higher levels of physical activity in the preceding 10 minutes were associated with lower completion odds, suggesting that fatigue and engagement in other activities may impede EMA participation. These findings are consistent with previous research indicating that sleep and activity patterns can affect EMA completion [13]. Specifically, studies have shown that poor sleep quality and shorter sleep duration are associated with lower EMA compliance rates [13,30]. This may be due to increased fatigue or cognitive impairment following insufficient sleep, which can reduce participants' motivation or ability to respond to prompts. Regarding physical activity, higher levels of activity, especially during vigorous exercise, have been associated with decreased likelihood of responding to EMA prompts [7,31]. This could be due to the physical unavailability to interact with devices during exercise or the disruption of attention to prompts during activity engagement. Momentary stress was negatively associated with EMA completion rates. The negative association with stress aligns with previous research suggesting that heightened stress can reduce compliance with study protocols [30]. These results underscore the complex relationship between momentary psychological states and EMA engagement, highlighting the need for further research in this area.

Individual characteristics, including sex, race, ethnicity, education, and employment status, were found to be significant predictors of EMA completion. These findings highlight concerns about accessibility and representation when designing and implementing longitudinal multiburst EMA studies, as they may influence participants' ability or willingness to engage with the protocol over time. The observed differences in completion rates across demographic groups align with previous research indicating disparities in EMA compliance [12]. Specifically, studies have found lower compliance rates among racial and ethnic minorities [12,13] and individuals with lower socioeconomic status [32]. Gender differences have also been observed, with some studies reporting lower compliance among males [30], although findings on gender disparities are mixed and may depend on the study context and population.

The decline in completion rates over the course of the study, as indicated by the significant within-subject effect of time, is a common challenge in longitudinal EMA research [1,12]. This decline may reflect participant fatigue, waning motivation, or changes in the perceived value of participation over time [13,33]. The interaction effects observed between time in study and other predictors provide valuable insights into how the influence of various factors on EMA completion evolves throughout a long-term study. For example, the diminishing effect of phone screen status on completion rates over time suggests that participants may become less responsive to this cue as the study progresses [34]. Similarly, the changing relationship between time in study and psychological factor (stress) indicates that the impact of momentary states on compliance may shift as participants become more accustomed to the EMA protocol [30]. The observed interactions between time spent in the study and various predictors, including sex and psychological states, further emphasize the dynamic nature of EMA engagement over extended study periods. These interactions suggest that the factors influencing compliance may shift over time, potentially due to changes in participant motivation, study fatigue, or evolving life circumstances [35].

While within-subject effects of time reveal important patterns in individual trajectories of EMA completion, the between-subject time in study interactions warrant separate consideration. These interactions provide insights into differences between participants who remain in the study for longer periods versus those who drop out earlier. The interaction with stress levels suggests that participants who remained in the study longer were better able to maintain compliance despite experiencing stress. These findings highlight the complex relationship between participant retention, EMA completion, and psychological factors, emphasizing the need to consider both short-term fluctuations and long-term engagement patterns when interpreting EMA data [1,36].

Limitations

Several limitations should be considered when interpreting these results. First, the study sample was limited to young adults in the United States, potentially limiting generalizability to other age groups or cultural contexts. Second, the use of Android smartphones exclusively may have introduced selection bias and limits the applicability of findings to users of other mobile platforms. Third, the COVID-19 pandemic occurred during the study period, potentially influencing participants' daily routines and psychological states in ways that may not be representative of typical conditions. Additionally, while our models accounted for a wide range of factors, unmeasured variables may still have influenced EMA completion odds. These could include individual differences in personality traits (eg, conscientiousness), technology literacy, or specific life events not captured by our assessments. The use of single-item measures for some psychological constructs (eg, affect and stress) may not fully capture the complexity of these states. Finally, due to the large number of observations per person, this study had statistical power to detect very small effects. While statistically significant, these small effects may not be substantially or clinically meaningful, and their practical implications should be interpreted cautiously. Finally, given the large number of predictors tested in our models, it is important to note that some of the findings may be spurious due to multiple testing. While we have confidence in our overall results, individual predictor effects, especially those with borderline significance, should be interpreted with caution and validated in future studies.

Implications

These findings have important implications for the design and implementation of future EMA studies. Researchers should consider tailoring prompt schedules to individual participants' routines and contexts to maximize completion rates, as suggested by Nahum-Shani et al [10]. However, it is crucial to recognize that overly tailored designs may yield less representative data if prompts are only delivered during convenient times. This could potentially bias the sample toward certain contexts or psychological states, undermining the ecological validity of the data. Therefore, a balance must be struck between optimizing

XSL•FO
RenderX

completion rates and maintaining the representativeness of the collected data. The development of adaptive sampling strategies that account for participants' current state and context could help maintain engagement over extended study periods, but these strategies should be designed to ensure adequate sampling across various contexts and states. The development of adaptive sampling strategies that account for participants' current state and context could help maintain engagement over extended study periods [37]. The observed demographic differences in completion rates suggest that targeted strategies may be necessary to ensure equitable representation in EMA data collection. These strategies may include providing additional support or incentives for groups with lower completion rates or developing culturally sensitive approaches to EMA implementation.

The strong influence of contextual factors such as phone use on EMA completion odds highlights the potential for leveraging smartphone features to enhance EMA engagement. For example, researchers might explore the use of smartwatch-based prompts or other wearable devices to increase the accessibility of EMA surveys [34]. The findings regarding psychological states and completion rates suggest that researchers should carefully consider the timing and frequency of prompts, potentially incorporating measures of participant burden or adjusting protocols based on reported stress levels.

Conclusions

This study provides valuable insights into the factors influencing EMA completion in a year-long multiburst intensive longitudinal study. The findings highlight the complex and dynamic nature of participant engagement with EMA protocols, emphasizing the need for thoughtful study design and analysis to maximize data quality and representativeness. The observed interactions between time in study and various predictors underscore the importance of considering temporal dynamics in EMA research, particularly for long-term studies. Future research should continue to explore strategies for optimizing EMA methodologies, such as adaptive sampling techniques and the integration of passive sensing data, to enhance our understanding of real-time experiences and behaviors in naturalistic settings. By addressing the challenges identified in this study, researchers can work toward developing more effective and sustainable EMA protocols, ultimately improving the quality and utility of intensive longitudinal data in behavioral science research.

Abstract

Background: Health care workers (HCWs) are at risk of experiencing psychological distress, particularly during the COVID-19 pandemic. Psychological self-monitoring apps may contribute to reducing symptoms of depression, anxiety, and trauma exposure by enhancing emotional self-awareness. This study focused on how a basic psychological self-monitoring app was experienced by HCWs during the COVID-19 pandemic in Quebec by exploring users' experience and factors contributing to their adherence.

Objective: This study aimed to explore HCWs' experiences with a psychological self-monitoring app, including if their satisfaction with the app, their perception of its contribution to self-awareness, and their experience of distress influenced their adherence to the app.

Methods: HCWs in Quebec were invited to respond weekly to questions about their well-being via a mobile app. A convergent mixed methods design was used. Sample data (N=424) were collected from the app, a postparticipation questionnaire was administered, and 30 semistructured interviews were conducted. Correlations and hierarchical multiple regression models were conducted to examine possible factors influencing participants' adherence, and a thematic analysis was used to further explore their experience.

Results: Over a 12-week-period, mean adherence to the psychological self-monitoring app was 74.5% (SD 29.4%) and mean satisfaction was 80% (SD 20%). Most participants perceived that the app contributed moderately (165/418, 39.5%) or a lot (140/418, 33.5%) to enhancing their self-awareness. The significant regression model ($F_{5,401}$=6.59; P<.001) suggested that around 7.6% of adherence variation could be explained by satisfaction (β=.16; t_{401}=3.14; P=.002) and the app's perceived contribution to self-awareness (β=.15; t_{401}=2.88; P=.004). Biological sex (369/419, 88.1% female and 50/419, 11.9% male), age (mean 40.8, SD 9.9 y), and the experience of psychological distress at least once in 12 weeks (228/420, 54.3%) were not statistically significant predictors of adherence. Emergent themes from the 30 interviews highlighted participants' experiences. Psychological self-monitoring was seen as an introspective practice, with reports of enhanced self-awareness and self-care practices. Interviewees generally considered the app as practical, but it did not suit everyone's preferences. Potential app enhancements were provided by the participants.

Conclusions: A simple psychological self-monitoring app could be an interesting tool for HCWs who wish to improve their self-awareness and prevent psychological distress, particularly in health crises such as pandemics.

KEYWORDS

psychological self-monitoring; self-monitoring app; adherence; user experience; health care workers; well-being

Introduction

Background

Workers in health and social services networks (health care workers; HCWs), are exposed to various stressful occupational situations [1,2]. They are reported to be prone to psychological distress [3,4], characterized by painful mental and physical symptoms often assessed through self-reported measures of posttraumatic stress (PTS), anxiety, and depression [5]. Furthermore, times of crisis such as the COVID-19 pandemic can be particularly distressful for HCWs [6]. A recent meta-analysis reported that the prevalence of depression and anxiety among HCWs was 37% and 39%, respectively [7], while another found that 47% of the HCWs experienced burnout, 38% experienced anxiety, 34% experienced depression, 30% experienced acute stress disorder, and 26% experienced PTS disorder [8].

Exploring and assessing efficient ways to support HCWs is crucial. On the basis of the National Institute for Health and Care Excellence recommendations [9], a continuous monitoring of various reactions could be an effective strategy for identifying individuals at risk and preventing the development of mental health disorders. Hence, psychological self-monitoring can be defined as the examination of one's personal condition through one's thoughts, emotions, behaviors, and consequences.

Studies suggest that psychological self-monitoring may promote emotional self-awareness, which is the ability to recognize and describe one's mood [10]. For example, in a qualitative study (N=21) tracking mood and physical activity in participants with bipolar disorder, half of the participants reported that psychological self-monitoring helped them recognize their emotional states and link them to factors such as sleep or exercise, thereby promoting behavioral changes [11]. Thereon, researchers have found that emotional self-awareness plays a mediating role in the relationship between psychological self-monitoring and psychological distress reduction [12-16]. Subsequently, awareness of a state of stress would lead the person to use coping strategies to adapt and cope with a situation or an environment [17]. Emotional self-awareness has been identified as an important factor for the well-being of prospective HCWs [18]. Hence, fostering emotional self-awareness with psychological self-monitoring might reduce psychological distress among HCWs, thereby improving their well-being.

To facilitate psychological self-monitoring, using digital technology is a promising solution, particularly during a pandemic [19,20]. Reviews have shown that mobile devices can improve users' psychological well-being even without professional guidance [21-24]. Notably, apps that reduce psychological distress symptoms often invite users to practice psychological self-monitoring [12,25-28]. However, those apps offer other components and features, such as behavioral interventions and educational modules. There is limited understanding of psychological self-monitoring's isolated influence on mental health management, and no studies previously focused on HCWs.

In addition, a major issue raised by researchers is the actual use of a digital tool. In a systematic review of available digital self-help interventions, indications of sustained use, such as the completion of all assessments or the use of the apps for more than 6 weeks, varied from 0.5% to 28.6% [29]. In this regard, adherence is the term often used to describe how much a technology is used [30] and is mostly measured by the number of logins, completed modules, or completed activities [31]. Measures of adherence have been positively associated with positive psychological outcomes in digital interventions [31]. A younger age and a biologically female sex were found to positively influence adherence [32,33]; however, research is needed to identify other factors [34].

Exploring users' experience could provide a holistic perspective on their interaction with the psychological self-monitoring app. User experience reflects the perceptions and responses resulting from the use of a digital tool [35]. It can be investigated by analyzing induced feelings, judgments, and behaviors [36], and both qualitative and quantitative approaches can be used.

In parallel, the expectation-confirmation model suggests that app users form expectations, and their satisfaction is determined by how well those expectations match their actual experience [37]. In this context, satisfaction could be conceptualized as an overall evaluation of user experience with the psychological self-monitoring app [38]. Considering that satisfied users are more likely to sustain app use [32,37,39,40], a positive association could be hypothesized between adherence and satisfaction with a psychological self-monitoring app. According to the same model, perceived usefulness is proposed to be another key factor influencing adherence [37], a finding supported by reviews [32,33,41]. Indeed, users who feel that a psychological self-monitoring app positively influences their psychological state or their emotional self-awareness may perceive the app as useful, and thus, have higher adherence. However, the experience of psychological distress may or may not influence adherence, as conflicting results are found in the literature [34,42-47]. In a psychological self-monitoring app, a higher adherence could possibly be expected from users who experienced psychological distress, as they might have felt a greater need to monitor their psychological state.

Objectives

In short, studies suggest that a psychological self-monitoring app could help users become more aware of their emotional state and could lead to improvements in well-being management. Further exploration is needed to discover the user experience with a simple psychological self-monitoring app and potential factors associated with its adherence. This study investigated Canadian HCWs' use of a basic psychological self-monitoring

XSL•FO
RenderX

app during the first 2 COVID-19 waves in Quebec [48-50]. The first objective was to examine whether adherence to a basic psychological self-monitoring app was associated with participants' satisfaction, perceived app contribution to enhance emotional self-awareness, and the presence of psychological distress, when adjusting for age and biological sex. It was hypothesized that adherence would be higher whenever participants (1) had an increased satisfaction, (2) had an increased perception of the app's contribution to emotional self-awareness, and (3) experienced psychological distress during their self-monitoring. The second objective was to explore user experience through thematic analysis of qualitative data.

Methods

Study Design

Considering the exploratory aims of this research, a convergent mixed methods design was adopted [51]. Quantitative data were collected from a psychological self-monitoring app and an online questionnaire. Qualitative data were collected from individual interviews.

Study Population

Participants were Canadian HCWs mostly working in urban areas of Quebec's integrated health and social services centers. They had participated in a program implemented during the COVID-19 pandemic to monitor HCWs' psychological distress with an app. Inclusion criteria were having access to a smartphone and to Wi-Fi and working during the participation period in 1 of the 8 following integrated health and social services centers: University of Montreal Hospital Centre, Est de Montréal, Centre-Sud de Montréal, de-la-Capitale, Montérégie, Laval, Des Îles, and Estrie-CHUS. There were no exclusion criteria as all HCWs in these centers were invited to participate. Convenience sampling was used and participation to each phase of the project was voluntary. For the first objective, 424 users (n=369, 87% women; n=50, 11.8% men; and n=5, 1.2% missing data) accepted to fill out a postparticipation questionnaire. Participants' age ranged from 18 to 68 (mean 40.8, SD 9.9) years and their years of work experience ranged from 0 to 43 (mean 13.6, SD 9.6) years. For the second objective, the analyzed data were collected from a subsample of 25 women and 5 men who were randomly selected for an interview. Their age ranged between 24 and 57 (mean 43, SD 9) years, with 0 to 30 years of work experience (mean 15, SD 9 years).

Ethical Considerations

Ethical approval for the research project involving the self-monitoring app was granted by the University of Montreal Hospital Centre research ethics committee (reference: MP-02-2021-8963). Approval for this secondary analysis was granted by the University of Montreal's research ethics committee in education and psychology (reference: 2023-4981). Informed consent was obtained from all individual participants included in the study. While participants did not receive monetary compensation, they were eligible to win 1 of 40 Can $50 (US $36.35) prepaid cards. All study data were deidentified and identifying details were removed from verbatims to ensure confidentiality.

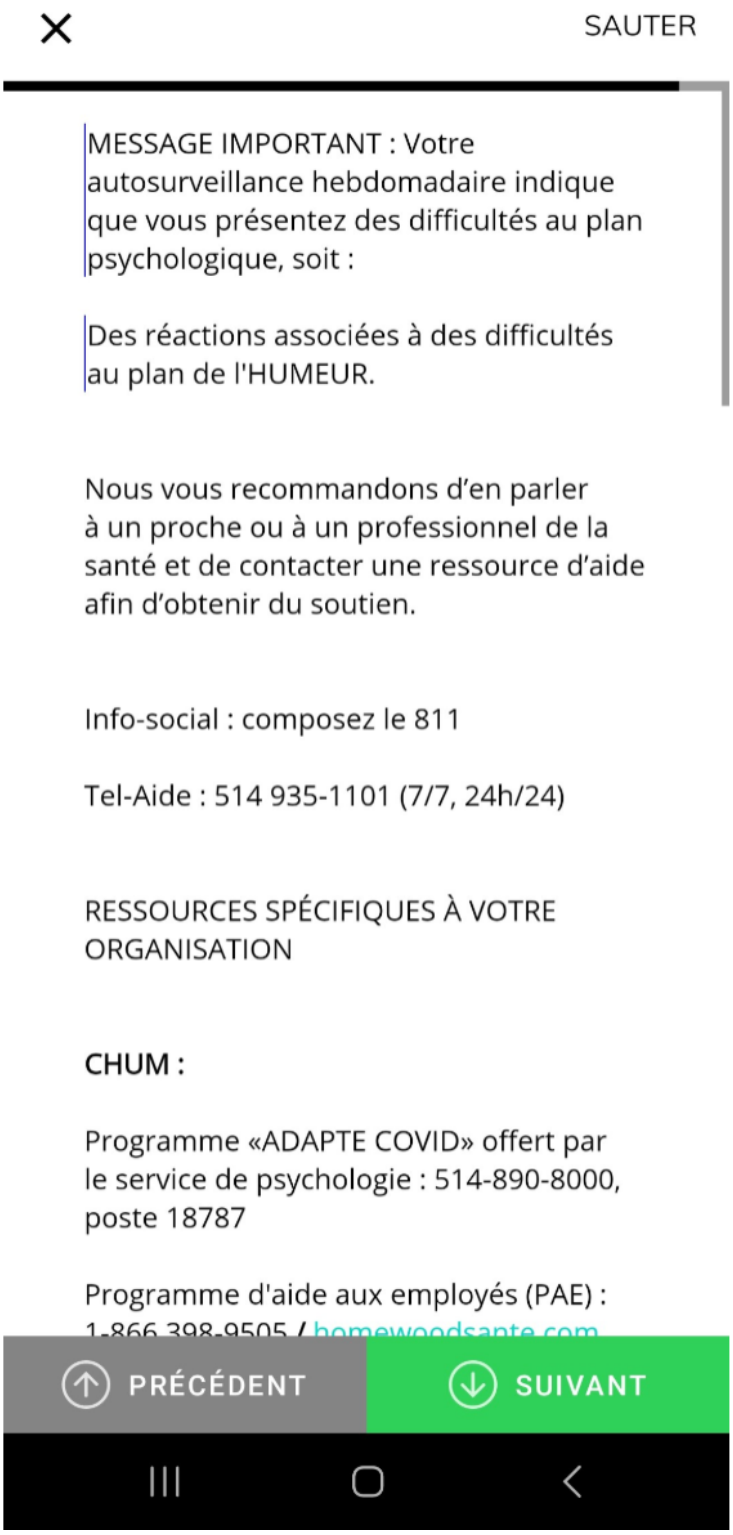
Procedure

Between May 2020 and February 2021, 831 HCWs voluntarily participated in a psychological distress self-monitoring program. Following methodological aspects of the ecological momentary assessment [52], participants were asked to answer a series of questions on an app each week over a 12-week period. They installed the Avicenna app, formally known as Ethica, a platform that enables researchers to collect data provided by their participants [53]. The app sent weekly notification prompting self-monitoring with subsequent reminders every 12 hours. Data collection was confidential.

On the app, the questions assessed several elements related to COVID-19 exposure, perceived availability of social support, and perceived quality of life (Multimedia Appendix 1). In addition, anxiety, PTS, and depression symptoms were measured by validated questionnaires (see the Instruments and Measures section). When a participant's self-reported responses reached the significant threshold of one or more of these 3 validated questionnaires, the participant received a message indicating the presence of significant distress, followed by a list of available resources (Figure 1). If no significant distress was detected, only the list of resources was displayed. In the event of suicidal ideations, the regional helpline's contacts details were displayed on the next page. In addition, an email was automatically sent to the project coordinator, who ensured a follow-up call with the participant.

XSL•FO
RenderX

Figure 1. Screenshot of the psychological self-monitoring app in case of distress.



After the longitudinal data collection phase, between February and April 2021, users were invited to complete a postparticipation questionnaire hosted on the SurveyMonkey site [54]. Multiple-choice questions were asked to assess user experience with the psychological self-monitoring app, including perceived satisfaction and perceived contribution of the app to self-awareness (Multimedia Appendix 2). Formal psychometric validation was not conducted before deployment. However, to support content validity and face validity, items were designed based on existing frameworks for evaluating digital tools and were reviewed by the multidisciplinary researchers for clarity and relevance. Out of the 194 respondents interested in a telephone interview to further explore their experience, 30 were randomly selected. Interviews were individual, led by the research coordinator and lasted 15 minutes on average. They were transcribed by members of the research team, who ensured confidentiality by removing any data that could identify specific individuals.

Instruments and Measures

Outcome: Adherence to the Psychological Self-Monitoring App

Adherence was measured using each participant's completion rate. Completion rate was calculated by considering the frequency of completed weekly monitoring over 12 weeks. An adherence rate of 100% meant that the participant used the app 12 times, as intended.

Association 1: Satisfaction

Satisfaction was measured in the postparticipation questionnaire, which was specifically developed for this study. Participants rated their satisfaction with the app used for psychological self-monitoring (eg, ease of installing the app and user-friendliness of the app) on a scale between 0 and 10, which represented "extremely dissatisfied" and "very satisfied," respectively.

Association 2: Perceived Contribution of the App to Self-Awareness

Perceived contribution to self-awareness was also measured in the postparticipation questionnaire. Participants rated the extent to which psychological self-monitoring on the app raised awareness or prompted reflection about their well-being. Responses varied according to a 4-point Likert scale, corresponding to 0="not at all," 1="a little," 2="moderately," and 3="a lot."

Association 3: Experience of Psychological Distress

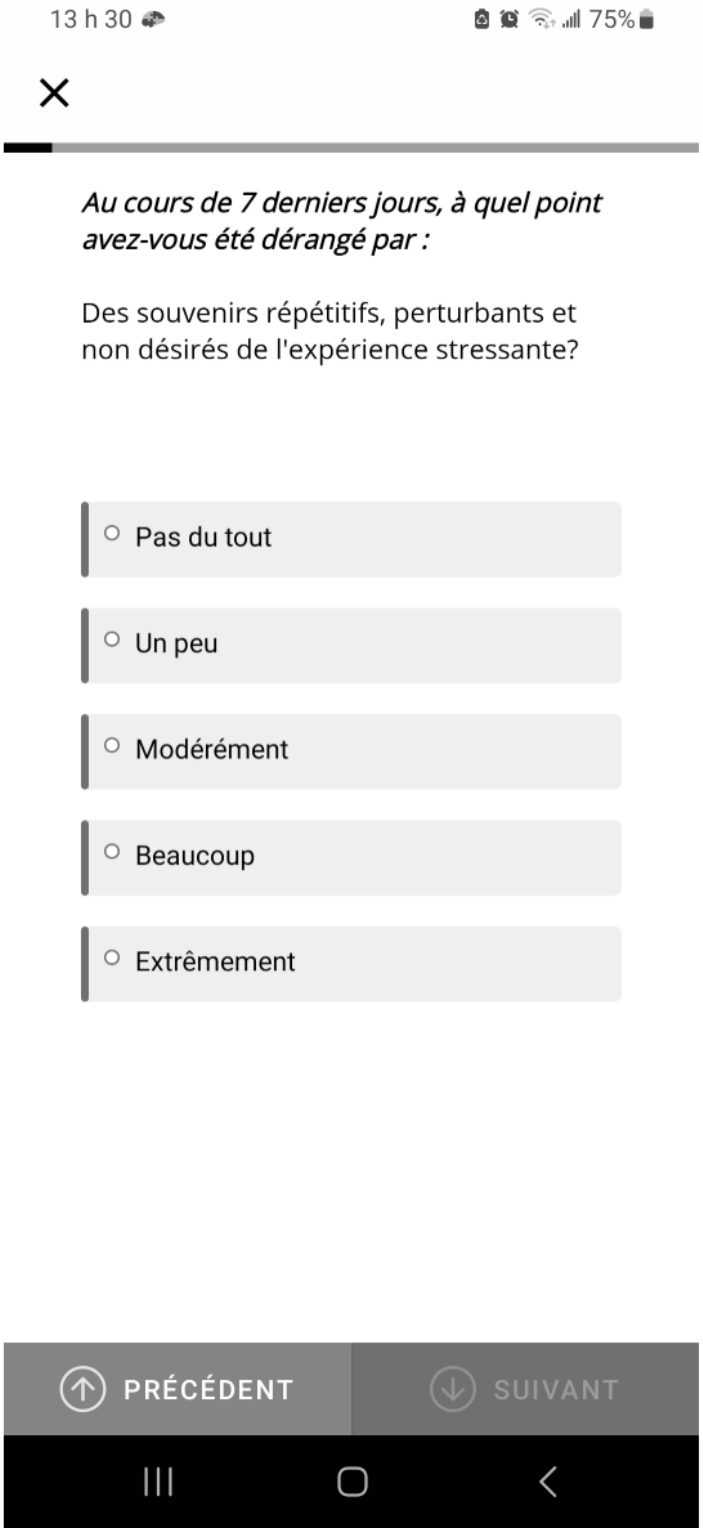
Psychological distress was measured by considering 3 validated psychometric tests that participants weekly filled in the psychological self-monitoring app. During psychological self-monitoring, if at least one score reached the threshold for at least one of these questionnaires, significant psychological distress was identified. This variable was coded either as 0="absent" or 1="present."

The Generalized Anxiety Disorder-7 [55] is a 7-item questionnaire assessing general anxiety symptoms. Participants indicated on a 4-point Likert scale (0="not at all," 1="several days," 2="more than half the days," and 3="nearly every day") how often they have been bothered over the past week by each symptom. An example of an item is "feeling nervous, anxious or on edge." The total score ranges from 0 to 21 and was calculated by adding up the scores for all 7 items. A total score of ≥10 (cut-off) indicated moderate or severe generalized anxiety symptoms. In this study, participants filled the French version of the questionnaire weekly. It has been validated with an excellent internal consistency (Cronbach α=0.90) [56].

The PTSD Checklist for DSM-5 [57] is a self-report questionnaire assessing the severity of PTS symptoms. Participants indicated how bothered they were over the past week by each symptom on a 5-point Likert scale (0="not at all," 1="a little bit," 2="moderately," 3="quite a bit," and 4="extremely"). An example of an item is "repeated, disturbing, and unwanted memories of the stressful experience" (Figure 2). A total score was calculated by adding up the scores for all items and the cut-off was set at 13. In this study, participants filled an abbreviated (8 items) French version, which was previously validated [58,59] with a sensitivity of 0.9, a specificity of 0.23, and a Cronbach α of 0.87.

XSL•FO
RenderX

Figure 2. Screenshot of the psychological self-monitoring app assessing posttraumatic stress symptoms.



The Patient Health Questionnaire-9 (PHQ-9) [60] is a 9-item questionnaire assessing depressive symptoms. Participants indicated how much they have been bothered over the past week by each symptom on a 4-point Likert scale (0="not at all," 1="several days," 2="more than half the days," and 3="nearly every day"). An example of an item is "little interest or pleasure in doing things." A total score was calculated by adding up the scores for all items, and the cut-off was set at 10. In this study, participants filled the French version, which was previously validated with a Cronbach α of 0.86 [61,62].

User Experience

To address the second objective, individual telephone interviews were conducted. These semistructured interviews followed a grid (Multimedia Appendix 3). Its development was inspired by the Mobile App Rating Scale, a reliable tool for classifying and assessing the quality of mobile health apps [63]. It was

XSL•FO
RenderX

adjusted to align with the research objectives, exploring subjects such as experience and satisfaction with the app, psychological self-monitoring, emotional self-awareness, coping strategies, and app use.

Data Analysis

Statistical Analysis

SPSS Statistics (version 29.0.1.0; IBM Corp) was used to carry out the analysis. Missing data were not statistically addressed considering they composed less than 5% of each examined variable. Statistics were computed based on available data for each variable.

First, descriptive statistics were used to examine frequency, average, and SD for each variable. Next, bivariate correlations explored relationships among biological sex, age, app adherence, satisfaction, perceived contribution to self-awareness, and psychological distress, with $P<.05$ considered statistically significant. Correlation strengths were classified as small ($r\approx0.10$), medium ($r\approx0.30$), and large ($r\geq0.50$) [64]. Finally, a hierarchical multiple regression was conducted to further examine whether satisfaction, perceived contribution to self-awareness, and psychological distress influenced adherence to the psychological self-monitoring app. Confounding variables were participants' biological sex and age.

During the review processes, nonparametric tests were conducted to examine whether there were significant differences between app users who did not participate in either the questionnaire or the interview, those who only participated in the questionnaire, and those who participated in both the questionnaire and the interview. Subsequently, inconsistencies were identified in the coding of psychological distress, specifically regarding the cut-off score used for the PHQ-9. While a cut-off score of ≥10 is widely accepted for identifying major depression [60], some data had been coded using a threshold of ≥9. To address this issue, a consistent cut-off score of ≥10 was used for PHQ-9, a rigorous reprocessing and verification of all study variables were done, and all analyses were carefully rerun to ensure the accuracy and reliability of results.

Thematic Analysis

An inductive and progressive thematic analysis was conducted using Braun and Clake approach [65] to analyze data from 30 interviews. Analysis began with a familiarization with the material, followed by generating initial codes for significant excerpts aligned with the study's aims. These codes were reviewed to ensure they reflected participants' statements. Next, codes were compiled into a separate file for sorting into potential themes, grouping salient units into progressively named and refined themes. Patterns within each theme were organized into subthemes, and an interjudge agreement was sought between first and second author to enhance clarity. Results were documented in a table with central themes, subthemes, codes, and verbatim excerpts, culminating in a thematic map summarizing the findings. In this paper, fictive names were attributed to participants.

Results

Sample Analysis

Out of the 831 app users, 407 (49%) did not complete the postparticipation questionnaire, while 424 (51%) did, including 30 (3.6%) participants who also took part in an interview. The study sample consisted of users who completed the questionnaire, including those interviewed. Descriptive statistics for this study sample are presented in Table 1. To assess potential selection bias, users who did not complete the postparticipation questionnaire were compared with the study sample (Table S1 in Multimedia Appendix 4). Results of Mann-Whitney *U* and chi-square tests indicated no significant differences in biological sex ($P=.58$) or psychological distress ($P=.77$). However, study sample was on average older ($U=74{,}310$; $P=.02$; $r=-0.08$) and had significantly higher adherence scores ($U=54{,}513$; $P<.001$; $r=0.33$) than nonrespondents. In addition, participants who were interviewed were compared to those who only completed the questionnaire (Table S2 in Multimedia Appendix 4). Results of Mann-Whitney *U* and chi-square tests indicated no significant differences in age ($P=.15$), biological sex ($P=.41$), satisfaction ($P=.56$), psychological distress ($P=.96$), or perceived contribution to self-awareness ($P=.25$). However, interviewees had significantly higher adherence scores ($U=3994$; $P=.002$; $r=0.14$) than those who only completed the questionnaire.

Table 1. Characteristics of questionnaire respondents and interview participants.

Characteristics	Questionnaire respondents (n=424)	Interview participants (n=30)
Age (y), mean (SD)	40.8 (9.9)	43 (9)
Satisfaction (0 to 10), mean (SD)	8.0 (2.0)	8 (2)
Adherence (%), mean (SD)	74.5 (29.4)	88 (23)
Biological sex, n (%)		
Female	369 (88.1)	25 (83.3)
Male	50 (11.9)	5 (16.7)
Perceived contribution to self-awareness, n (%)		
Not at all	20 (4.8)	0 (0)
A little	93 (22.2)	6 (20)
Moderately	165 (39.5)	9 (30)
A lot	140 (33.5)	14 (46.7)
Psychological distress, n (%)		
Present	228 (54.3)	16 (53.3)
Absent	192 (45.7)	14 (46.7)

Correlation and Regression Analysis

For the study sample, a correlation analysis was conducted to examine relationships among the research variables (Table 2). Adherence was found to have small but significant positive associations with both satisfaction (r=0.19; P<.001) and perceived contribution to self-awareness (r=0.20; P<.001). In addition, a moderate positive correlation was observed between satisfaction and perceived contribution to self-awareness (r=0.37; P<.001). Regarding psychological distress, small negative correlations emerged with age (r=−0.18; P<.001) and satisfaction (r=−0.11; P=.03), suggesting that participants who experienced psychological distress tended to be younger and reported lower satisfaction with the app. No significant association was found between psychological distress and adherence (P=.08).

[a]BS: biological sex.

[b]PD: psychological distress.

[c]PCSA: perceived contribution to self-awareness.

[d]Not applicable.

A hierarchical multiple regression analysis was conducted predicting adherence with age and biological sex entered first, satisfaction with the app, perceived contribution to self-awareness, and presence of psychological distress entered second (Table 3). The first model with age and biological sex was not statistically significant ($F_{2,404}$=0.79; *P*=.46). The second model, which included all predictors, was statistically significant ($F_{5,401}$=6.59; *P*<.001), accounting for 7.6% of the variance in adherence. Specifically, satisfaction (β=.16; t_{401}=3.14; *P*=.002) and perceived contribution to self-awareness (=0.15; t_{401}=2.89; *P*=.004) were significantly associated with adherence, indicating that individuals with higher satisfaction or perceived contribution to self-awareness scores had higher adherence. However, the psychological distress was not a statistically significant predictor of adherence (*P*=.07).

Table 3. Multiple hierarchical regressions analysis of adherence.

Models	*B*	β (SE; 95% CI)	*t* test (*df*)	*P* value	R^2
Model 1					.004

User Experience Themes

Overview

Interviewees' characteristics are provided in Table 1. From the thematic analysis, 3 main themes emerged (Textbox 1). The first theme regrouped instances in which participants described psychological self-monitoring as an introspective practice, imbued with reports of self-awareness and self-care. The second theme characterized the app as practical but not a one-size-fits-all, and presented how different app properties influenced user experience. The last theme regrouped potential enhancements that the participants mentioned to improve their experience.

Textbox 1. Thematic analysis of user experience interviews.

Introspective practice

- Self-awareness: Taking time to pause; focusing; acknowledging; reacting to alerts
- Self-care: Being more attentive; talking to support system; consulting primary care physician; practicing self-compassion; problem-solving

Simple app but not a one-size-fits-all

- Practical use: Ease of use; time efficiency; portability
- Kinds of questions: Clarity; repetitiveness; range
- Presence of notifications: Incentive; bothersome
- Display of resources: Relevant; rarely used

Potential enhancements

- Feedback: Weekly overall assessment; relativity to other users; progress tracking
- Writing space: For reflection; for context
- Beyond self-monitoring: Psychological tools; discussion forum; maintaining simplicity

Introspective Practice

Participants reported a rather unanimous view of psychological self-monitoring. Most participants viewed completing the weekly questionnaires as a moment for reflection and self-awareness, allowing them to pause and consider their well-being. This opportune time allowed them to take a step back to focus on their state, allowing its recognition. Some participants added that psychological self-monitoring enhanced awareness of psychological fluctuations over the weeks:

> *When I was answering the questions, it was [helpful] because I had the time to ask myself the question and to question myself: am I stressed? Are there things that get to me more than before?... It seemed to make me aware of what was really going on around me, and it gave me an indicator of "am I more stressed than usual? Is it getting to me? How do I see things around me? Are things going well, or not so well?"* [Sam]

> *I found that [using the app] had benefits, in the sense that it helped us to make certain realizations, that it helped us to take a moment to stop when it's not always something we think about doing.* [Maria]

Half of the participants in this subsample received a message alerting of a significant psychological distress, leading to varied reactions. Some participants were not surprised by the warning. Feeling it aligned with their internal state, they considered the psychological self-monitoring app reflected their experience:

> *[The distress warning] didn't surprise me because I know myself well and I'm really familiar with mental health problems, so I was able to see what was going on.* [Maria]

> *It just echoes something I was feeling, but having an external message perhaps helped me to confirm that feeling a bit. Logically, it's not just me imagining things that aren't going well and I do have the right to say to myself that there's something wrong and that it's not just me imagining things.... In any case, this message confirms that I have to be "easy" on myself. That's what it's saying.* [Mark]

Interestingly, a participant with lasting distress reported her frustration to be repeatedly "told again" about it and recommended less frequent self-monitoring:

> *I don't remember how many weeks it lasted..., but I knew I wasn't doing well so I was still going to be told that I wasn't doing well. [The distress warning] is still going to come out....You know, I don't need to be told again, I know it's about the same level. But I think, for someone who doesn't know or who wants to assess or who's in between, I think it's important to do it often.* [Nicole]

However, others were caught off guard. Initial reactions of surprise, irritation, anger, or denial were reported in the interviews, as demonstrated in the subsequent quotes. Acknowledging the distress warning as a reflection of their questionnaire responses was reported as an important step toward self-awareness and self-care practices:

> *[Receiving the distress warning] was still a surprise, it really annoyed me, I always had warnings...Except it was because I was in denial!...it's just that it was*

XSL•FO
RenderX

> *spitting all my distress and confusion and despair right back in my face....at first, I was genuinely irritated. I was getting tired of it; it was getting on my nerves. Later, at some point during the summer when I was filling in the damn questions, I was like "why do I feel this way? why do I feel like bawling?" Then, at some point, I was answering the questions and I was so uncomfortable I had tears. Then, I was like "OK, let's stop burying our heads in the sand!"* [Jude]

> *I was actually surprised, because I wasn't expecting [to receive the distress warning]. I didn't really think anything was wrong.... It really made me react. It got to me....I found [the psychological self-monitoring app] helpful in the end. It was a help. Maybe it prevented me from falling into depression or whatever.* [Riley]

For some participants, the distress warning was seen as a "wake-up call" (Victoria) or "a kick in the butt" (Charlie) that prompted them to take actions, such as consulting their physician (Charlie). Other actions taken after receiving the warning included being more attentive to one's condition, being kinder to oneself, seeking and adopting concrete solutions for individual stressors, etc:

> *[The distress warning] led me to call my psychiatrist and talk about it...When it asked the famous question "Would you be better off dead?" I answered "yes." But I answered the question. I was honest with myself. I was surprised by my message, but I tell myself it's a reflection of my answers.* [Megan]

However, participants who did not receive the distress warning also reported adopting changes prompted by the psychological self-monitoring practice. Actions included reducing media exposure; talking with family, friends, and colleagues about their mental health; asking for help from their manager; and seeking work-life balance. This mobilization was often propelled by their reaction to their responses when filling out the questionnaires:

> *When I say more negative things in the app, I try to verbalize them a little more with my family...or I try to change my way of seeing things too...I try to put things into perspective a little, and tell myself that how I felt was normal.* [Sophia]

A small proportion of participants specified that they might have adopted those changes without psychological self-monitoring. However, they presumed that they would have delayed action or waited for their condition to worsen before acting:

> *[Self-monitoring] actually made it a bit easier to take the decision to say "I've got this job to do, but it won't be at all costs," to give myself limits. [Without the app], maybe it would have taken longer to set up, maybe it would have come later. Maybe it would have taken on proportions that would have been a bit more troublesome.* [Mark]

> *I saw that things were starting to go downhill more and more, so I stopped listening to the press briefings....I even deleted my [social media account] just to give you an idea....Otherwise, I started doing more yoga, to switch things up while I waited for the pool to reopen. [Without the app], maybe it would have taken longer for me to realize what was going on.* [Julia]

Interestingly, about half of the interviewees viewed psychological self-monitoring itself as a self-care practice, considering the app as an effective psychological self-help tool. As demonstrated in the following quotes, some even integrated it into their routine, and it became a habit to the point of waiting for the weekly notification:

> *I thought that [psychological self-monitoring] was a moment for me, I always did it at the same time, after reading the newspaper on Saturday, and it was a bit of a retrospective of my week, part of my little ritual of taking care of myself, after my newspaper, my coffee, and then I wondered how I was doing.* [Mika]

> *It's so useful. I found it interesting because every week, you were practically waiting for the app to tell you "you have a new survey to do." It allowed me to keep up to date with where I was...I thought it was a great, relevant tool, [especially] for someone like me who has generalized anxiety disorder.* [Megan]

> *It allows me, even now [post-participation], to take more time, to self-monitor, to look at how I'm doing, to stop and say to myself "well, is this good? Or am I going the wrong way?"* [David]

A minority of participants reported that psychological self-monitoring did not have a significant impact on the way they managed their well-being. Notably, they considered that they were already managing well on their own or that no particular actions were needed:

> *I'm not sure [the app influenced my actions], maybe like 10%-5%....I'm quickly looking for solutions and thinking about how I can think differently.* [Clara]

> *[When I got the distress warning] I wasn't really surprised...But I didn't feel that I necessarily needed help, you know, I read a lot about that and maybe that's why I didn't seek specific help, I didn't feel that it was that problematic in relation to work.* [Patricia]

A Practical App but Not a One-Size-Fits-All

Overall, participants found the psychological self-monitoring app practical, which seems to have contributed to their satisfaction. They appreciated that the app was simple, easy to use, and not time-consuming (approximately 5 minutes on average). In addition, the app's accessibility on smartphones contributed to its portability and practicality:

> *I often did it at work between two things. It paged me, I did it straight away. I found it practical. It's good because it doesn't take long to do.* [Charlie]

> *[The app] was friendly, easy, I liked it, I had a reminder, "oh yes, I have to answer." Again, it's fast.*

XSL•FO
RenderX

> *The fact that it's an app, we all agree, it's on a different level compared to the paper questionnaires, we can agree that it was a lot easier.* [Sara]

Few participants reported technical issues, such as glitches and the absence of notifications, which negatively affected their experience and adherence. Very few contacted the research coordinator for help:

> *At a certain point, it just sort of fell through. I don't know why, I had some sort of technical problem and it didn't work. And after that, I kind of lost interest and disengaged.* [William]

How participants perceived the questions seemed to have influenced their experience and overall satisfaction. First, most of the participants found the questions clear and direct. The use of Likert scales made psychological self-monitoring easy and fast, with very few participants reporting that the questionnaires were long and that it was sometimes hard to choose between 2 scales:

> *The highlights [of the app]? The questions. I mean, they were clear. It wasn't complicated.* [Julia]
>
> *What I liked about the app was that it was easy to use. The questions were simple. Sometimes I'd get stuck between two answers. I said to myself that it's normal because they're not development questions....In general, the questions were quite explicit.* [Frederick]

Second, users had to answer a wide range of questions. Some participants reported finding them extensive because personal and professional aspects were included:

> *[The questions] were so broad, it seemed to cover every area of mental health you could experience. I was really positively surprised.... [My expectations were] exceeded even, because it was all subjects that I didn't expect that I might have difficulties with in my life,...it's things that you don't think about, it's so banal, but it's true that it was affected by COVID.* [Sophia]
>
> *I liked the app and the questionnaires because there was a lot of professional and personal portions to see what affected me the most.* [Sabrina]

However, a significant portion of participants found them too centered on either psychological symptoms or COVID-19. For instance, a participant expressed less interest in questions about COVID-19 exposure from patients. Three participants (David, Mika, and Isabelle) explicitly mentioned the desire to skip the questions they perceived as less relevant to them, such as PTS symptoms assessed in the PTSD Checklist for DSM-5:

> *I work in a hospital, but I'm in a field where I'm not close to patients. So there were questions about [exposure to COVID-19] where I felt a little less concerned, even though yes, the pandemic affected my work very, very directly...It's as if there were questions, I would have liked to skip sometimes, because I thought "well, it's not for me."* [Axel]
>
> *[As improvements,] if it would have been possible to skip the PTS thing since it never applied to me. I could have eliminated a third of the questions because, unless you've been through a trauma while you're answering, I mean, it's quite surprising that this aspect changes when you haven't been through a trauma.* [Isabelle]

Nevertheless, few participants mentioned a sense of comfort knowing that the app was tailored for HCWs' well-being, particularly during times of crisis. They invited their colleagues to participate in the research project, showed interest in using the psychological self-monitoring app for more than 12 weeks, or suggested to make such apps available for all HCWs:

> *I found [the app] recomforting. It was like someone was...thinking about taking care of my well-being.* [Remy]
>
> *It went really well. It was very positive and I'd be happy to use it again if there were ever another study like that with this app.* [Riley]
>
> *I think that [the psychological self-monitoring app] is something that needs to be deployed among HCW, because I don't think we realize how much more distressed we [actually] are...I could even be a spokesperson and say, "Look, it bothered me so much at the beginning..." I found it tiring, but it was salutary for me. I wasn't really expecting it, but that's what it was.* [Jude]

The repetitiveness of the weekly questions generated divided opinions. On one side, it was redundant, and some participants admitted paying less attention or being more passive when filling out the questionnaires. On the other side, it was predictable. Some participants appreciated knowing what would be asked of them in advance and revealed paying more attention to their state during the week. Regardless, the repetitiveness allowed some to identify trends and changes over the 12-week period:

> *Since it was always the same questions from week to week, I found that it made things easier once you got used to the questions.... I'm someone who's introspective and self-observant, so in the week between answering the questionnaires, I paid a bit more attention....I knew what to pay more attention to.* [Maria]
>
> *I found the questionnaire relatively long, and at a certain point, you come to know the questions and generally, yes, there's variability in some places, but there are other questions that haven't varied all that much.* [Mika]
>
> *I thought the questions would change over time. But I found that they were always pretty much the same questions. At some point, not that you want to, but it becomes automatic when you answer the question. You think less about it because it's the same questions....But still, sometimes yes it was the same question, but sometimes I didn't give the same answer either, and it made me think. You know, what did I*

XSL•FO
RenderX

> *do this week that made me more tired, or more stressed? It gave me time to stop and think.* [David]

The notification reminding participants to complete the psychological self-monitoring seemed to have impacted their satisfaction and adherence. As expected, notifications served as an incentive; participants who did not receive any notification reported either forgetting to complete their monitoring or losing interest in the app:

> *The good thing was that even if sometimes I forgot to take part in the study during the day...the app would remind me that I hadn't completed it. I found that interesting. I found it practical.* [Frederick]

At the same time, a few participants expressed dissatisfaction with the timing of notifications. Participants found that those sent at inconvenient hours, such as during sleep, were bothersome and preferred more control over notification timing:

> *The only annoyance I've had with the app is the notifications. I turned off the app's notifications because it was ringing at midnight or 5am on days off. I was a bit at a loss.* [Audrey]

Regarding help resources displayed upon the completion of the questionnaires, most participants reported not using them despite finding them relevant. Furthermore, a minority of participants reported not noticing those resources, and a few were confident they were not displayed, possibly due to technical issues:

> *I took [screenshot of the resources] and I really took it as a helping hand, saying "we're really here, whatever happens..."But it was really circumstances that made me turn more to my parents, to my partner, to friends.* [Sabrina]

Potential Enhancements

When discussing their expectations and recommendations for the psychological self-monitoring app, participants mentioned several desired features not currently offered. First, many expressed a desire for feedback after completing the questionnaires, suggesting that a form of result, such as an overall assessment, would enhance their experience. Some suggested a score or a graphic to help them track their progress through the weeks. In the following extract, a participant mentioned her expectation to see an overall assessment of other users:

> *A comment on what more could have been done, for example, is to have a view of the longitudinal evolution. From one week to the next, is it "better"? Is it less good? In other words, having feedbacks.* [Mark]
>
> *What I also expected was to have an overall picture, my overall picture at the end, over the course of the weeks. Like a small graph, it's going well, it's not going well, something like that. Then, I also expected to have an overall portrait of the people who participated in general so I could have a comparison too. Are we all in the same state of mind? Or is it just that...you know, sometimes you feel a bit alone out there, wondering if you're...normal.* [Alex]
>
> *As improvements, a visual or an awareness for people to see, let's say, the percentage of COVID or the percentage of how people actually assess their stress. It's always the same questions but you can't really see the results...see the survey pulse. It would have been fun to see how people felt and whether we're part of the people who are on average more stressed, less stressed, etc.* [Sam]

Second, a few participants mentioned an interest for a writing space within the app. Some envisioned using it to provide context for their answers, as they felt certain responses were influenced by unrelated events and wished to add comments. Others wanted it as a journaling space to reflect on their feelings and thoughts while completing the questionnaires:

> *It's easy with answer choices, but each time, I had a comment that I would have added. I don't know how to say this...In addition to the answer choices, I would have liked if there was a little box, 200 words, because in the end I was often left wanting more, thinking "yes but."* [Sara]
>
> *Perhaps I was expecting to have spaces for answers and comments, as if to clarify my thoughts? It wasn't in the app.* [Axel]

Finally, some participants expressed a desire for features that extend beyond self-monitoring. For example, a few participants suggested integrating psychological tools within the app, such as the informational sheets sent by email and tailored coping strategies. One participant [William] also mentioned the possibility of chatting with other users or counselors:

> *Maybe the app could suggest things, maybe that's why there's no colour, why it's more neutral.* [Clara]
>
> *[To enhance the app] if, say, I'd had a bereavement because of COVID, if I'd been told, on the basis of what I'd answered in the questionnaire, "we can see that you've experienced such and such a thing this week, try such and such a thing."* [Axel]
>
> *Perhaps there could have been tools for sharing with others who are in the same situation as us....You know, when you're told "be careful, it's red," maybe there could be exchange groups or chat rooms with other people like us, with counselors. It could have been something great.* [William]

However, many participants appreciated the app's simplicity and recommended maintaining that aspect:

> *[To enhance the app], I don't really know, because it's important that it's not too long. I'm not sure that adding things is relevant.* [Patricia]
>
> *No [suggestions], I'd keep it that way. What I liked was that it was short. That too was appreciated. It didn't take an hour. I liked that, but no, I don't see what could be different.* [Emily]

Discussion

Principal Findings

Overview

This mixed methods study aimed to explore Canadian HCWs' experience with a psychological self-monitoring app. To examine whenever satisfaction, perceived contribution to self-awareness, and experience of psychological distress influenced users' adherence, a multiple hierarchical regression analysis was performed on quantitative data while adjusting for age and biological sex. To further explore user experience, thematic analysis was performed on qualitative data.

Over 12 weeks, the average adherence rate to the psychological self-monitoring app was 74.5%. This can be characterized as high considering that only 0.5% to 28.6% of research participants using self-help apps or programs for depression and anxiety sustain their use after 6 weeks [29,66]. Statistical analysis suggested that approximately 7.6% of adherence's variation could be explained by satisfaction with the app and perceived contribution to self-awareness. Thematic analysis of qualitative data offered a more profound exploration of participants' experience. Mixed methods findings are discussed following the key areas Chan and Honey [67] identified in their integrative review on users' perceptions: satisfaction, ease of use, helpfulness, technical and perceived issues, and improvements. Then, the specific case of psychological distress is discussed.

Satisfaction

The high satisfaction rate of 80% was unexpected given that the psychological self-monitoring app was primarily intended for data collection. Interface design is known to significantly impact satisfaction and adherence [68], with visual appeal [69] and personalization [70] enhancing user experience. The Avicenna app used for psychological self-monitoring offers limited design options, but the qualitative component of this study may help explain the discrepancy between our results and prior research. Interviewees clarified the unexpectedly high satisfaction rate, emphasizing the app's practicality, simplicity, and time efficiency. Unlike in the study by Alqahtani and Orji [71], no one criticized the basic interface. This suggests that users are more likely to adhere to a psychological self-monitoring app they perceive as convenient, consistent with findings from other studies [41,72]. Thus, even a very basic psychological self-monitoring app can offer a satisfactory user experience.

It could also be explained by the way satisfaction was conceptualized. In this study, it was defined broadly as an overall reflection of users' appreciation of their experience with the app. When measured, satisfaction was explained to participants with nonexhaustive examples ("eg, ease of installation, friendliness, etc"). Due to this large definition, participants may have prioritized assessing ease of use over design. As noted by Ng et al [73], satisfaction often overlaps with other user engagement indicators such as usability and acceptability, and further research is needed to clarify its definition in the context of mental health apps.

Ease of Use

Furthermore, interviews revealed that a key facilitator of app's adherence and satisfactory experience was its ease of use. Psychological self-monitoring required users to answer questions that were perceived as clear, straightforward, and requiring minimal efforts. This could corroborate with other studies suggesting that users prefer apps that avoid cognitive overload [33]. Given that participants were HCWs in a health crisis, a simple and intuitive app may be suitable for this population, providing a straightforward experience under stressful conditions.

Helpfulness

In parallel, satisfaction rates may have been influenced by users' perceptions of the app's usefulness or helpfulness. This study hypothesized that the usefulness of a psychological self-monitoring app lies in its ability to enhance emotional self-awareness and found that perceived contribution to self-awareness was positively associated with both satisfaction and adherence, corroborating previous reviews [32,41]. Notably, 305 out of 424 respondents (71.9%) perceived that the app contributed at least moderately to improving their emotional self-awareness. This is illustrated with how interviewees characterized their experience as introspective. Completing questionnaires about COVID-19 exposure and its impacts on psychological state seemed to have heightened participants' attention to their well-being. This finding is significant for HCWs, who are expected to prioritize their patients' needs over their own, particularly in time of health crisis.

This result is particularly interesting for interviewees experiencing psychological distress. Some were surprised when the app alerted of significant distress, suggesting varying levels of emotional self-awareness before monitoring. Those surprised likely had lower initial emotional self-awareness and found the app valuable for enhancing it, possibly leading to higher perceived contribution to self-awareness, satisfaction, and adherence. Conversely, participants already aware of their distress may not have felt that the app significantly improved their self-awareness, likely impacting the perceived contribution to self-awareness, satisfaction, and adherence. Overall, initial emotional self-awareness might influence user experience and adherence, indicating the need for further research in this area.

In addition, some interviewees integrated the use of the app into their weekly routine. Developing a habit of psychological self-monitoring can not only enhance users' adherence [33,72] but may also persist after discontinuing app use [74]. Longitudinal studies are required to assess the potential long-lasting effects of psychological self-monitoring on users' practices.

Furthermore, many participants reported taking steps to maintain or enhance their well-being, regardless of whether they were experiencing distress. This reinforces the idea that self-awareness is crucial for adopting coping strategies [17] and that it can mediate the positive association between psychological self-monitoring and well-being [12-16]. Notably, some interviewees hinted that psychological self-monitoring may have facilitated earlier emotional self-awareness and

XSL•FO
RenderX

mobilization, potentially preventing psychological distress among HCWs.

Technical and Perceived Issues

The most frequently reported barrier to app use was the absence of reminders or their inconvenient timing. Reports indicating that reminders positively impact adherence, while their absence negatively affects it, align with a systematic review [70]. In addition, few interviewees were bothered by reminders displayed at inconvenient times. This corroborates previous findings suggesting detrimental effects of reminders sent at inconvenient times or places on app adherence [33].

Some interviewees reported finding the psychological self-monitoring questions redundant or too centered on a certain aspect. Those criticisms may hint at users' diverse monitoring needs. The app did not offer the option to customize questions, limiting users' ability to tailor their psychological self-monitoring experience to their individual preferences. Considering the critical role of app personalization [70,75], allowing users to select the questionnaires they find most pertinent to monitor may foster a more relevant experience. Thereon, the app admittedly did not adopt a user-centered approach. The fact that some HCWs expressed comfort, knowing the app was deployed out of concern for their well-being, suggests that users may value apps specifically tailored to them.

Improvements

Reported suggestions to improve the app consisted of adding features to enhance psychological self-monitoring and supposedly self-awareness. A common recommendation involved incorporating feedback mechanisms, such as displaying results or summaries within the app. Many interviewees expected some form of feedback or visual outcome. This desire aligns with existing evidence highlighting the perceived usefulness [66,76] and effectiveness [77] of feedback in mental health apps, as well as users' interest in tracking progress or trends in their behavior through visual or numerical summaries [33]. More specifically, providing users with their scores on assessment tools and allowing comparisons with aggregated results from other users could further enhance self-awareness and engagement, as suggested in studies of apps targeting anxiety and depression [75,78,79].

In addition, few interviewees suggested integrating a writing space either to add contextual information or to journal about their experience. Thereon, a study suggested that a mood-tracking and journaling app can enhance introspection [80], and another study found that journaling was associated with improvements in psychological well-being of users with a predisposition for self-reflection [81].

While a proportion of interviewees liked the app for its simplicity, some suggested including more complex features and components within the app, namely educational content and discussion forums. These recommendations suggest unmet needs for psychological information and social connections, which can negatively impact user experience and adherence. Indeed, health information and social opportunities were found to increase users' intention to engage with well-being apps [33]. This suggests that an app offering psychological self-monitoring as its only feature may not be suitable for users who have needs beyond an active monitoring of their psychological well-being. Integrating tools to help users manage psychological well-being, along with personalized strategy recommendations based on individual distress profiles, could improve the perceived relevance of the app. Prior research has shown that tailoring interventions to users' specific profiles, rather than offering a wide range of generic strategies, tends to increase engagement and perceived usefulness [82].

As previously reported, participants also mentioned a desire to choose the questions they are asked, the timing they receive the reminders, and the frequency of their self-monitoring. As hinted in other studies [71,75,83], this result highlights the importance of not overlooking personalization opportunities, even in basic self-monitoring apps. Promoting user interaction with the app by offering options to customize certain components may help reduce perceptions of repetitiveness or inconvenience and increase alignment with individual preferences, ultimately supporting greater adherence [70].

Experience of Psychological Distress

Correlation analysis suggested an association between age and psychological distress, with younger participants reporting more distress than older participants. This result aligns with the research by Park et al [84], in which younger adults reported greater distress and less social support, mindfulness, and emotion regulation skills than older adults during the pandemic. In the same vein, an observational study used socioemotional selectivity theory, suggesting that older adults are motivated to optimize their emotional experiences in the limited life that they have left [85], to explain similar result in their 29-wave longitudinal survey [86]. These findings underscore the vulnerability of younger HCWs and the importance of ensuring that support strategies are accessible and relevant to their specific needs.

Although the presence of psychological distress was negatively associated with satisfaction and that satisfaction was positively associated with adherence, the correlation between psychological distress and adherence was not statistically significant (P=.08), suggesting a potential trend that warrants further investigation. Previous studies found conflicting results regarding psychological distress and adherence to mental health apps [34,42-47]. The hypothesis that users in distress would adhere more to a psychological self-monitoring app as they might feel a greater need to thoroughly monitor their state was infirmed. The expectation-confirmation model [37] and the technology acceptance model [78] are 2 complementary models that may help explain these results.

According to the first one, users' expectations and needs play a crucial role in their satisfaction and subsequent adherence. Some participants were satisfied with the app's simple features, as it met or exceeded their expectations, positively influencing satisfaction and adherence. Others might have had higher expectations and needs that the basic psychological self-monitoring app did not fulfill, leading to lower satisfaction and reduced adherence. This could be particularly the case of distressed users, who might have expected features and

XSL•FO
RenderX

components in the app that could help alleviate their distress, such as the recommended inclusion of psychoeducational materials and personalized strategies. This would align with prior research showing that psychological self-monitoring apps are most effective at reducing psychological distress when they include additional components, such as behavioral interventions and educational modules [12,25-28]. Hence, the app may have not met the heightened expectations of distressed users, leading to a lower satisfaction. Nevertheless, it seems that it was not detrimental to the point of affecting adherence. Indeed, some distressed users may have had other expectations that were met and that supported their adherence, despite an overall lower satisfaction. These insights highlight the importance of considering users' various expectations and to clearly communicate to users what they can expect from an app to prevent deception.

The technology acceptance model further complements this perspective by emphasizing how 2 key factors, perceived ease of use and perceived usefulness, mediate the relation between external factors (eg, user characteristics and system features) and adherence [78]. In this study, although the app may have been perceived as easy to use, its perceived usefulness among participants experiencing psychological distress may have been limited, particularly those who were self-aware. Once again, these users were likely seeking concrete tools or strategies to manage their distress, which the app did not provide. As such, self-monitoring alone may not have been perceived as helpful by individuals in significant distress, possibly leading to reduced satisfaction and early discontinuation of use due to unmet needs. However, adherence may be influenced by other factors, such as users' intrinsic motivation, which might not be directly impacted by psychological distress.

Moreover, results suggest that users, whenever in distress or not, can experience positive outcome from a basic psychological self-monitoring app. While psychological distress can be associated with less satisfaction, it does not necessarily deter users from adhering to the app or perceiving it as beneficial. This suggests that even if the app does not fully meet the expectations and needs of users, certain aspects may still provide value, leading to continued use and perceived usefulness. Future research, notably randomized controlled trails, is needed to rigorously assess the impact of minimalist psychological self-monitoring apps on multiple well-being outcomes.

Clinical Implications

These findings have clinical implications, suggesting that psychological self-monitoring could benefit individuals struggling with self-awareness by enhancing emotional self-awareness and encouraging self-care, and facilitating early detection of distress to prevent further aggravation. Organizations could propose psychological self-monitoring programs to support well-being, particularly in professions at high risk of burnout and turnover. Although this study focused on Canadian HCWs' experience during the COVID-19 pandemic, research, including randomized controlled trials, is needed to assess psychological self-monitoring app effects. However, findings suggest that the app helped some users open up to their support system about their mental health, including their managers and colleagues. Mental health clinicians could incorporate psychological self-monitoring apps into their practice as part of a comprehensive plan, using collected data to explore clients' symptoms and coping strategies. Clinicians should focus on offering personalized feedback and educational materials.

Limitations and Future Studies

Several limitations should be considered when interpreting the present findings, and external validity must be approached with caution. First, participation bias and convenience sampling may have influenced both the quantitative and qualitative results. Although all 831 app users were solicited to fill the postparticipation questionnaire, only 424 (51%) responded, and 149 (17.9%) agreed to be interviewed. Comparative analyses between participants and nonparticipants were conducted posteriori and suggested that higher participation in the research study was associated with greater adherence, with interviewees showing the highest adherence. This trend may indicate that more engaged or satisfied users were overrepresented, potentially leading to an overestimation of adherence and other positive outcomes such as user experience. While the mixed methods approach is a strength, a sequential design could have provided deeper insights, particularly for users with lower adherence, satisfaction, or those experiencing psychological distress.

Second, regarding sample characteristics, a predominance of biologically female participants was observed, representing 88.1% (369/419) of the quantitative sample and 83% (25/30) of the qualitative sample. However, this heterogeneity is consistent with the health care workforce population in Quebec where a similar sex disproportion has been reported in 2023 [87].

Third, the generalizability of the findings to other regions should be considered cautiously. Crisis support resources offered in the app were specific to users' institutions and pandemic-related initiatives. Nevertheless, the psychological distress levels observed in the sample are comparable to those reported in meta-analyses of HCWs' mental health during the COVID-19 pandemic, and the instruments used to assess distress were consistent with those used in international studies [7,8,48,49]. It is therefore reasonable to believe that the findings could be similar for other HCWs in industrialized countries during the COVID-19 pandemic.

Finally, psychological self-monitoring was assessed through self-reports collected on a weekly basis, introducing a potential recall bias. To enhance accuracy, ecological momentary assessment typically consists of 6 assessments per day [88]. However, data suggest that users may have different preferences and offering a customizable self-monitoring frequency could represent a more acceptable alternative, potentially improving user experience and adherence.

This study findings reinforce the idea that a one-size-fits-all approach limits the potential of apps and digital interventions, even when users perceive them as easy to use and helpful. Notably, satisfaction and perceived contribution to self-awareness accounted for less than 8% of the variation in

XSL•FO
RenderX

adherence. In the context of psychological self-monitoring for HCWs, additional app characteristics and features need to be explored to better meet users' diverse needs. Future research should incorporate available design recommendations [68,89] while paying close attention to the specific needs and preferences reported by HCWs in this study. More broadly, the COVID-19 pandemic has highlighted the urgent need for proactive programs to support HCWs during crises. Although robust evidence for the effectiveness of psychosocial interventions remains limited [90], the findings suggest potential benefits of basic psychological self-monitoring apps. Further research is warranted to evaluate their impact on psychological well-being and to identify optimal design features that maximize adherence, satisfaction, and mental health outcomes.

Conclusions

A simple psychological self-monitoring app could be an interesting tool for individuals who want to improve their emotional self-awareness and proactively adopt self-care practices. This study presented how HCWs in a health crisis may benefit from such apps. Some of the adherence to the app could be explained by how satisfied users were and how usefully they thought the app contributed to enhancing their self-awareness. Complementary features, such as access to feedback and psychological tools, may enhance the user experience. Simplicity, ease of use, tailoring, and customization options should be considered when developing psychological self-monitoring apps.

Acknowledgments

The authors would like to acknowledge all workers in health and social services networks for their part during the COVID-19 pandemic. The authors would like to thank all the participants for taking the time to participate in this research. This work was funded by the Fonds de Recherche du Québec—Ministère de l'Économie et Innovation.

Abstract

Cost savings were achieved with the use of a smartphone-based care management platform, considering several health care resources following knee arthroplasty procedures without negatively impacting clinical outcomes.

Trial registration: ClinicalTrials.gov NCT03737149; https://clinicaltrials.gov/study/NCT03737149

(JMIR Mhealth Uhealth 2025;13:e46047) doi:10.2196/46047

KEYWORDS

telerehabilitation; telehealth; telemedicine; rehabilitation; physiotherapy; mobile health; knee arthroplasty

Introduction

The number of knee arthroplasty procedures performed in the United States has increased annually, accompanied by rises in health care resource use and costs [1]. Risk-sharing and bundled payment plans have been implemented with the goal of improving care and controlling costs through the sharing of financial responsibility for a 90-day joint replacement episode-of-care (EOC) [2]. Approximately 36% of the EOC cost has been attributed to postdischarge services [3]. In-person outpatient physiotherapy (PT) has been the standard of care (SoC) postoperatively but is associated with significant cost and may be overused following uncomplicated knee arthroplasty [4]. Telerehabilitation and mobile health delivery of PT has gained popularity in recent years [5]. The aim of this study was to compare costs of a smartphone-based care management platform (sbCMP) with traditional care in adult patients undergoing knee arthroplasty.

Methods

Study Design and Analysis

Patients undergoing primary total or partial knee arthroplasty were randomized (block randomization, block size of 4) to receive institutional SoC (control group) or sbCMP (treatment group) using the mymobility app (Zimmer Biomet), as previously described [6]. The 90-day health care intervention collected information on PT visits, manipulations under anesthesia, non-SoC physician visits, all-cause readmissions, emergency department (ED) visits, and urgent care visits.

Costs associated with the use of each resource were estimated from multiple sources [4,7,8]. The cost of the sbCMP was estimated based on the maximum cost per patient. Costs were multiplied across number of uses; the average cost per patient was calculated using the entire cohort as the denominator and compared between groups by a 2-tailed student *t* test. Costs in the noncrossover treatment group (patients who did not receive traditional PT in the original study) were also calculated. One-way and two-way deterministic sensitivity analyses were performed.

Ethical Considerations

The multicenter randomized controlled trial (ClinicalTrials.gov NCT03737149) received central Institutional Review Board approval (20182103). All patients voluntarily provided written informed consent upon enrollment, with the opportunity to withdraw at any time. Smartwatches were provided (approximately US $329 in value). Data were deidentified prior to analyses.

Results

Preoperative patient characteristics as well as baseline and postsurgical clinical outcomes were similar between the two groups [6]. The estimated costs associated with health care resources are presented in Table 1. The number of events was lower in the treatment group in each category except for

XSL•FO
RenderX

non-SoC physician office visits. Patients using the sbCMP had significantly fewer ED visits and readmissions. The average cost per patient was approximately US $732 lower in the treatment group after including the cost of the sbCMP. The reduction in the number of in-person PT visits accounted for the bulk of the potential savings in the cohort, with costs approximately US $400 less in the treatment group. The average number of PT visits in the control and sbCMP groups were 9.75 (SD 3.98) and 5.40 (SD 5.51), respectively. Considering only noncrossovers, average costs were further reduced to approximately US $186 per patient through 90 days (Table 2). Sensitivity analyses demonstrated cost savings across all scenarios (Multimedia Appendix 1).

Table . Estimated costs associated with resource use as a function of treatment group.

Variable	Cost per unit (US $)[a]	Control arm (n=244)			Treatment arm (n=208)			*P* value
		Frequency, n	Total cost per group (US $)	Average cost per patient (US $)	Frequency, n	Total cost per group (US $)	Average cost per patient (US $)

Total			400,207	1640.19		188,855	907.96	.001
Cost reduction			—	—		211,352	732.24	

[a]Reference citations indicated the studies from which the costs were derived.

[b]Estimates based on categorical collection of physiotherapy visits used. Categories included 1 - 3 visits, 4 - 6 visits, 7 - 9 visits, 10 - 12 visits, and 13 or more visits. Given the largest category did not include an upper bound, the lowest number of visits in each category was applied, providing conservative estimates in both groups.

[c]Weighted mean accounting for location (home, outpatient, or both).

[d]Represents only emergency department visits that did not result in admission. Readmissions associated with an emergency department visit are categorized only as readmission, without impacting emergency department visit rate.

[e]ED: emergency department.

[f]MUA: manipulations under anesthesia.

Table . Resource use and estimated costs within the treatment noncrossover group, where in-person physiotherapy was not used.

Variable	Treatment group noncrossover (n=61), n	Total cost per group (US $)	Average cost per patient (US $)

Discussion

This analysis demonstrated cost savings for patients using the sbCMP for self-directed rehabilitation following primary knee arthroplasty. Most savings were derived from the reduction in PT, the most common resource used. Cost savings were also achieved with the sbCMP for all health care resources except physician office visits. It is possible that this increase in office visits is the result of improved communication between patients and their care team via real-time messaging. This may have prompted additional unexpected office visits for postoperative concerns, which may have prevented more costly ED visits or readmissions. Alternately, this could be due to a patient need for feedback and assurance not received during in-person PT.

To our knowledge, this is the first cost comparison analysis of this care management platform compared with traditional care. There are few studies of other telerehabilitation programs compared with traditional care in this context. One study reported reduced outpatient PT costs with increased use of web-based PT [9] and another reported overall EOC cost savings with telerehabilitation and acknowledged improved outcomes, without attributing costs to the type of event [10].

A key limitation of this analysis is the uncertainty regarding the generalizability of the list price for the sbCMP used in the analysis. Additionally, the cost data may not be generalizable. Postacute care use was not accounted for given it is not expected to differ between treatment modalities.

In conclusion, the sbCMP has a potential for robust cost savings without negatively impacting postsurgical outcomes in patients undergoing knee arthroplasty.

Acknowledgments

The study was funded by Zimmer Biomet.

Conflicts of Interest

JHL receives royalties and research support from Zimmer Biomet and Smith and Nephew and is a paid consultant. JHL also receives stock or stock options and research support from Force Therapeutics and is a paid consultant. ANH, DVA, MBA, RD, and RER are employees of Zimmer Biomet. JF receives stock or stock options from Cast Orthopedics, is on the editorial or governing board of the Journal of Arthroplasty, and is a paid consultant for Zimmer Biomet.
