Visual Appearance

Visual appearance describes the physical design and visual representation of the agent. While some users favored anthropomorphic agents due to their perceived credibility, others leaned toward cartoon figures for a more "fun" and user-friendly experience [36]. A photo-realistic design, especially one that fits the context, such as a nurse in a health care setting, was reported to make interactions feel more genuine and personal [58]. Ensuring human-like facial expressions and gestures was important for avoiding negative impacts to the user experience [36,46,59]. Sylvia's identity as a woman provoked mixed reactions, with one user calling her a "stupid woman," while another liked her identity as they "hated" listening to men [58]. Only studies using embodied agents contributed evidence on engagement outcomes for the visual appearance domain.

Personality

Personality describes the character and demeanor that the agent embodies. Incorporating human-like mannerisms increased users' engagement with Laura, but her backstory led to frustration for some users, who felt that it was excessive and a waste of time, as Laura was not real [36]. Several users who perceived Laura to be authoritative developed feelings of guilt, leading some to temporarily cease communications and others to consider reporting only their best readings [36]. Whereas users who viewed Laura as friendly and supportive tended to be more engaged during communications [36]. Users explained that because Tanya and Nurse Cora did not say "very drastic things," they felt encouraged to take manageable actions in their daily lives to "do something simple daily" [51,59]. One user expressed a preference for an authoritative agent over a friendly agent, "She could be your girl next door...If I have medical complaints, I prefer an authority to explain what to do or not to do" [58]. Only studies using embodied agents contributed evidence on engagement outcomes for the visual appearance domain.

Proposed Features

Proposed features describe features suggested by users that they felt would enhance their impression of or engagement with the intervention and represent ideas for further exploration. While in-app navigation was intuitive for most users of Nurse Cora, some users indicated that they would have liked instructions on how to navigate the app containing Nurse Cora at the beginning of the trial [59]. Multiple-choice only functionality was frequently a point of frustration for users of conversational agent–enabled interventions, making one participant "consider [them]self a passive participant" in the conversation [35,38,47,54-56,58,60]. Molly users suggested that she omit punctuation when speaking and incorporate voice recognition [49]. Users of Nurse Cora wanted her to emphasize keywords using larger font sizes and to provide the option to repeat dialogues [59]. Vitória users suggested developing a "strategy to remind users to use the app" and offering specialized content such as "recipes for people with diabetes" [47]. Sylvia users desired more follow-up and checks on prior interactions, "Did you read that? Did you do this?" [58]. This sentiment was also expressed by Nurse Cora users who desired more feedback during the quizzes [59].

Research Gaps

Research gaps were found in the way engagement of conversational agent–enabled interventions tended to be reported. Conversational agent–enabled interventions were frequently rated in terms of their engagement, but the rationale behind these ratings was not explored except for the study by Cheng et al [35,38,46,48,50-54,56,58,59,61]. For this study, a natural flow of conversation was credited by most participants, with a favorable view of the app as the reason for its high usability [35]. Additionally, differing levels of engagement, trust, or perceived care based on ethnicity, medication regimes, age, education, and computer literacy were identified but not explained [37,61].

Discussion

Principal Findings

This systematic review synthesized evidence pertaining to conversational agent–enabled intervention design features and their impacts on the engagement of people self-managing CMD. Integrating redundancy and anthropomorphism to increase user autonomy and investment, respectively, emerged as 2 strategies for improving engagement relevant to all 5 emergent domains. However, care must be taken to avoid inundating users with excessive redundancy or anthropomorphism, as these were common frustrations among users across studies. The findings from this review can be applied to optimizing the development and evaluation of conversational agent–enabled interventions, facilitating more engaging and effective strategies for supporting people self-managing CMDs. Additionally, this review establishes a foundation for upcoming research by identifying research gaps and synthesizing an array of innovative design features suggested by users (Textbox 1).

Textbox 1. Design checklist.

- Provide multiple input and output modalities so users can use those that match their preferences or needs. Within each modality, allow users to customize design features, such as increasing text sizes or toggling agent accents.
- Offer a "Skip" button so users can bypass dialogues they perceive as frustrating and time-consuming, such as character backstories.
- Ensure sensitivity to how much time users have for a session and adapt content accordingly.
- Provide expandable dialogue options that users can ignore to determine the pacing of conversations.
- Avatar choices should reflect agent functions, users expect serious activities to be delivered by more realistic avatars, and fun activities to be delivered by more cartoonish avatars.
- Provide multiple options for users to learn how to use agent features, such as in-person, in-app, or helplines.

RenderX

Redundant design features are those that offer additional input options and delivery channels of content. Redundancy is relevant to all 5 emergent domains, as it can be incorporated into modes of communication, offering overlapping functions and inputs and supporting adaptive interaction styles and various other aspects of intervention design. By offering redundant design features, users are empowered to interact with interventions on their own terms, thereby improving sustained engagement. For example, Roca et al [56] reported that one patient was unable to respond to medication reminders, confirming they had taken their medicine because the agent did not understand their messages. In total, the authors recorded 34 such misunderstood interactions between this patient and the agent. Despite this issue, the patient managed to manually log their medication adherence, illustrating the critical role of redundancy within interaction options [56]. A lack of redundancy in accessibility led to problems for Gingele et al [49], who found that despite providing comprehensive outpatient tutorials, users encountered significant challenges when attempting to use conversational agent–enabled interventions independently at home. These challenges could be addressed by offering additional tutorial options like helplines, outpatient sessions, and in-app guides [49]. Despite the benefits of redundancy in promoting user autonomy, empirical evidence identified within this review also underscored the importance of ensuring that users are not inundated with irrelevant content [38,47,58]. For example, Ter Stal et al [58] highlighted instances where participants felt overwhelmed by excessive and inappropriate communication frequency, leading to frustration and disengagement, “When I have to go to work, I do not have time to watch a 15-minute video.” Furthermore, Epalte et al [38] reported a participant complaining of “too much reading,” and Balsa et al [47] reported users identifying information overload and excessive queries as areas for improvement. Similarly, Pop-Eleches et al [63] found that weekly SMS text message reminders significantly improved antiretroviral adherence, whereas daily reminders did not.

The assertion that offering redundant design features improves user engagement by enabling flexibility in interaction aligns with findings grounded in self-determination theory from a tutorial paper by Yardley et al [26]. Self-determination theory posits that engagement can be improved by supporting user autonomy, competence, and relatedness [64]. By providing redundancy in options and content, users are empowered to choose their interaction methods, access alternative options, and find content that feels personally relevant, thereby supporting user autonomy, competence, and relatedness [26]. An alternative explanation for why redundant design features improved user engagement is that they create a more consistent user environment where repeated exposures to similar content can make new information more familiar and accessible [65]. This explanation links into the concept of omnichannel engagement, describing uniformity between content channels, which is elaborated in a viewpoint paper by Blasiak et al [65]. There were several examples where users appreciated interventions providing content, which they could access elsewhere [51,56,57]. For example, Sagstad et al [57] and Guhl et al [51] reported that users appreciated accessing information through the conversational agents within the interventions, which they knew they could access on the web or from their doctor [51,57]. Furthermore, all participants within the study by Roca et al [56] gave an affirmative response to the statement, “From a certain moment, the virtual assistant began to give the weather forecast. Has this helped you to use the virtual assistant more frequently?”

Anthropomorphic design features are those that contribute to users attributing human traits, emotions, or intentions to the intervention. Anthropomorphism is relevant to all 5 emergent domains, as it can be incorporated into the conversational style, personality, visual design, and various other aspects of intervention design. By offering anthropomorphic design features, users can become more invested in interventions, thereby improving sustained engagement. For example, Ter Stal et al [58] reported a participant stating that the realistic depiction of the conversational agent made the interaction more personal. Similarly, Baptista et al [36] reported user preference for Laura’s human character over a cartoon character, “I’m not sure I would have given the same level of credibility to, for example, a dog or a cat or something like that.” Furthermore, a common point of frustration among users across studies was with conversational agents which were “not human enough”; these issues pertained to the speech, mannerisms, gestures, and expressions of conversational agents [36,46,59]. Despite the benefits of anthropomorphism in promoting user investment, empirical evidence identified within this review also identified instances where efforts toward this goal were excessive or came at the expense of other functionalities [36,58]. An example of an excessive pursuit of anthropomorphism was identified by Baptista et al [36], who observed that providing a backstory for their conversational agent led to frustration for some users. Here, a backstory feature in the personality domain, when projected through an anthropomorphized avatar in the visual appearance domain, resulted in this avatar increasing frustration rather than investment with the intervention itself. Furthermore, Ter Stal et al [58] reported that most participants expressed that they were not interested in the small talk from their conversational agent.

The contention that offering anthropomorphic design features improves user engagement by promoting user investment in interactions aligns with the computers are social actors framework. The computers are social actors framework posits that engagement can be improved by supporting user investment by exploiting users’ innate social expectations to make interactions more meaningful [66]. However, the computers are social actors framework fails to explain why excessive anthropomorphism leads to user frustration. Ruslana and Ning [67] identified excessive anthropomorphism as problematic because it caused confusion for users. However, they also suggested an alternative explanation for its positive effect on engagement: anthropomorphic design features may make interventions feel more approachable and less formal. This suggests that developers should carefully consider the function of anthropomorphism and be willing to forego it if simpler methods can achieve more approachable interventions. For example, Baptista et al [36] observed that certain users favored cartoon figures over anthropomorphic agents, as they were more “fun.” Similarly, Thunström et al [68] found that a mental health

XSL•FO
RenderX

chatbot was rated more usable than an anthropomorphic embodied conversational agent, though the usability scale used in this study did not have the fidelity to attribute this to a specific feature differing between the agents.

Limitations

This systematic review faced limitations primarily due to the heterogeneity of included interventions, outcomes, and study types. In terms of interventions, the field of conversational agent–enabled interventions is rapidly evolving, with new technologies and platforms emerging regularly. This resulted in a wide variety of conversational agent–enabled interventions included in the review, ranging from basic chatbots with multiple choice responses to embodied conversational agents. In terms of outcomes, engagement in digital health lacks a standardized definition, leading to different evaluations and operationalizations between studies. For example, some studies equated it directly with use, while others conceptualized it as a composite of behavioral, cognitive, and affective components. The diversity in how engagement was defined and measured across studies limited the synthesis of findings, pointing toward the need for a standardized operationalization of engagement within digital health contexts, to enable more precise and comparable measurements. In terms of study types, papers included in this review were primarily qualitative or quasi-experimental studies, restricting our ability to compare design features with quantitative user engagement metrics through meta-analysis. Together, these heterogeneities limited our ability to compare results across studies and draw definitive conclusions about the impacts of certain design features on engagement, so findings should be interpreted as directional rather than quantitative. Furthermore, studies were conducted in home-based self-management contexts, which are not equally applicable across other health care contexts, such as hospitals and primary care settings. However, the review proceeded with these limitations as more specific inclusion criteria for interventions, outcomes, and study types would have reduced the sensitivity of this systematic review in identifying insights pertaining to design features and their impacts on engagement and in identifying research gaps and opportunities for further research. To address these limitations, we recommend that future systematic reviews focus on specific agent types (eg, embodied agents only) with standardized engagement definitions and conduct individual participant data meta-analyses when sufficient high-quality RCTs become available.

Areas for further research were identified based on the proposed features, research gaps, and limitations identified within this systematic review. A research gap that was consistently identified across studies was that engagement ratings from participants were frequently collected, though the qualitative processes underlying these ratings were rarely explored, hindering a deeper understanding of engagement. For example, Echeazarra et al [48] asked users to rate ease of use and usefulness of their intervention on a Likert scale but did not ask users to explain which features contributed to these ratings. The study by Cheng et al [35] provided a protocol for addressing this research gap, and users were prompted to explain which features contributed to their ratings. Another research gap was that clear and unexplained disparities in how different demographics engage with conversational agent–enabled interventions were identified in multiple studies [37,61]. For example, differing levels of engagement, trust, or perceived care were observed based on ethnicity, medication regimes, age, education, and computer literacy [37,61]. Further research could investigate how design features could be tailored for these different groups, such as using co-design methodologies to explore the role of redundancy in improving engagement of people with poor computer literacy through emphasizing multiple interaction modalities. We recommend factorial RCTs testing specific combinations of design features (eg, 2×2 design testing high or low redundancy×high or low anthropomorphism) across diverse populations, with standardized engagement metrics including both behavioral analytics and qualitative experience measures.

Conclusions

This systematic review provides key insights and rationales for developing conversational agent–enabled interventions for people self-managing CMD. However, because the included studies varied widely in agent modalities and engagement definitions and were largely qualitative, the generalizability of these insights is limited. Designing conversational agent–enabled interventions requires a balance of redundancy and personalization to support user autonomy without overwhelming users. Additionally, a balance between anthropomorphism and functionality is required to support user investment without frustrating users. Maintaining these balances is a key to improving engagement with conversational agent–enabled interventions and supporting people with CMD to self-manage their condition.

Acknowledgments

The authors thank the National Health and Medical Research Council (NHMRC) Centre of Research Excellence in Digital Technology to Transform Chronic Disease Outcomes, which aims to transform Australia’s digital health ecosystem. It is funded by the NHMRC (2020-2024: ID 1170937). NK accepts full responsibility for the work and conduct of this study.

Authors' Contributions

All authors contributed significantly to the research project and manuscript. NK and ATS performed the data collection. NK conducted the data analysis. All authors were involved in writing the manuscript and had final approval of the submitted and published versions.

Abstract

Background: Management of noncommunicable diseases (NCDs) is an increasing challenge for health care systems. Although remote patient monitoring presents a promising solution by utilizing technology to monitor patients outside clinical settings, there is a lack of knowledge about the effect on resource utilization.

Objective: This systematic review aimed to review the effects of remote patient monitoring on health care resource utilization by patients with NCDs.

Methods: Eligible randomized controlled trials (RCTs) involved digital transmission of health data from patients to health care personnel. Outcomes included hospitalizations, length of stay, outpatient visits, and emergency visits. A systematic literature search was performed in Medline, Embase, and Cochrane Central Register of Controlled Trials in June 2024. Titles, abstracts, and full texts were screened individually by 2 authors. Risk of bias was assessed, and data were extracted, analyzed, and pooled in meta-analysis when possible. Confidence in the estimates was assessed using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach.

Results: We included 40 RCTs published between 2017 and 2024. The largest group of NCDs was cardiovascular disease (16 studies). Remote patient monitoring may slightly decrease the proportion of hospitalizations compared with usual care (risk ratio [RR] 0.86, 95% CI 0.77 to 0.95; low certainty). Compared with usual care, remote patient monitoring had fewer or an equal number of hospitalizations (mean difference –0.13, 95% CI –0.29 to 0.03; low certainty). Hospital length of stay may be slightly reduced with remote patient monitoring compared with usual care (mean difference –0.84, 95% CI –1.61 to –0.06 days; low certainty). The proportion of outpatient visits showed probably little to no difference between remote patient monitoring and usual care (RR 0.94, 95% CI 0.87 to 1.02; moderate certainty). Compared with usual care, remote patient monitoring had slightly more outpatient visits, but the CI was wide (mean difference 0.41, 95% CI –0.22 to 1.03; low certainty). The results indicate a small or no difference between remote patient monitoring and usual care regarding proportion of emergency visits (RR 0.91, 95% CI 0.79 to 1.05; low certainty). We are uncertain whether remote patient monitoring increases or decreases the number of emergency visits, as the evidence was of very low certainty.

Conclusions: This systematic review showed that remote patient monitoring possibly led to lower proportions of patients being hospitalized, fewer hospitalizations, and shorter hospital length of stay compared with usual care. Patients undergoing remote monitoring had possibly more outpatient visits compared with usual care. The proportions of patients with outpatient visits or emergency visits were probably similar. Finally, we had very low certainty in the number of emergency visits. The results should be considered with caution as the certainty of evidence was moderate to very low. We did not find results regarding institutional stay.

Introduction

Noncommunicable diseases (NCDs) including diabetes, cardiovascular diseases, chronic respiratory diseases, and mental health conditions lead to widespread human suffering globally and impose a high burden on health care systems, both financially and structurally [1,2]. More than 70% of all deaths globally are caused by NCDs, and cardiovascular disease accounts for most of the deaths [3]. The already substantial societal costs of NCDs are expected to rise even further in the years to come [4]. NCDs contribute to reduced productivity, shortened working lives, and premature mortality, with estimates suggesting a cumulative global loss of between US $30 trillion and US $47 trillion in economic output between 2011 and 2030 [5]. Furthermore, NCDs lead to high treatment costs, imposing a direct economic burden on health systems [1,6].

The follow-up of these individuals is resource-intensive and requires a high degree of interdisciplinary and holistic care over time. This leads to increased demands on both capacity and competence in health care services, as these patients often need both continuous monitoring and acute interventions [1,2]. As a result, there is significant interest in exploring and testing new care models aimed at extending the services to patients' homes through innovative technologies, which may contribute to preventing avoidable use of health care resources [7-9]. Welfare technology is highlighted as an important element in the development of the health and care sector [9].

Among these technologies, remote patient monitoring presents significant opportunities to improve the timeliness of care, enhance health outcomes, and potentially reduce unnecessary use of health care resources [9,10]. Remote patient monitoring utilizes technological tools to track patients' health status outside of typical clinical settings, including patients' homes or other remote locations. This method involves sending health data directly to health care providers via automated electronic systems or web- and phone-based interfaces, facilitating timely interventions if health status deteriorates [11,12].

This process ensures that health care providers can respond rapidly and potentially prevent hospitalizations. Unlike traditional calendar-based hospital follow-up appointments, remote monitoring enables customized treatment plans tailored to each patient's specific needs and disease activity [11,12]. Routine monitoring of patient's health data and receiving alerts when measurements surpass a predetermined threshold can enable health care providers to intervene promptly. This approach offers potential advantages for both individuals and society by lessening the burden on patients and decreasing the need for unnecessary medical visits [10,13].

Moreover, the use of welfare technology hopefully can free up resources within health care services, allowing them to be allocated more effectively to patients with greater needs. However, findings from studies examining patients' utilization of health care services with remote patient monitoring compared with usual care have shown mixed results [14]. Therefore, we lack definitive knowledge about the effect of remote monitoring on resource utilization. [14] The purpose of this systematic review was to examine the effects of remote patient monitoring on health care resource utilization for individuals with NCDs, compared with usual care. The protocol for this review was preregistered in PROSPERO (CRD42023431366) on June 19, 2023. This review is an update of a previous review [15] published in Norwegian with the key messages and executive summary provided in English.

Methods

We conducted a systematic review according to the guidelines described in the Cochrane handbook [16] and the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [17]. The completed PRISMA checklist is provided in Multimedia Appendix 1.

Selection Criteria

Eligible studies were randomized controlled trials investigating the effect of remote monitoring of patients with NCDs (including chronic pulmonary diseases, diabetes, cardiovascular disease, cancer, mental health disorders, and comorbidities) on health care utilization, compared with usual care, published in English or a Scandinavian language.

The interventions had to involve digital transmission of health data from the patient to health care personnel, who would then contact the patient and provide medical support and guidance if the measurements indicated signs of deterioration or fell outside normal values. We also included studies that incorporated additional components alongside remote patient monitoring, such as rehabilitation guidance, exercise prescriptions, and other forms of support.

Studies involving digital follow-up without any element of self-reporting, such as implants that transmit data automatically, were excluded.

Given the rapid advancements in digital health technologies, including remote monitoring tools, software platforms, and communication infrastructure, we prioritized newer studies to ensure the findings reflected current clinical practice and technological capabilities. Older studies may be based on outdated technologies or care models that no longer represent the current standard of care, potentially limiting the applicability and relevance of their results. Hence, only studies published from 2017 and onwards with interventions conducted in 2013 or later (within the last 10 years at the time of our first systematic search) were included.

The studies had to report one or more of the following outcomes: hospitalizations (proportions or numbers), length of hospital stay, outpatient consultations (proportions or numbers), use of emergency services (proportions or numbers), visits to general

XSL•FO
RenderX

practitioners, use of home health care services, and use of institutional stay.

Search Strategy

A librarian developed a search strategy corresponding to the inclusion criteria and searched the following databases: Medline (Ovid), Embase (Ovid) and Cochrane Central Register of Controlled Trials (Wiley). Searches were conducted in 3 rounds: April 2022, May 2023, and June 2024 (Multimedia Appendix 2).

Inclusion Process

The authors independently screened the references identified in the previous review and the updated searches. We utilized the "priority screening" function in EPPI-Reviewer [18] to enhance the efficiency of screening titles and abstracts. This machine learning feature identifies the characteristics of included and excluded studies and predicts the likelihood of relevance for each reference. Priority screening prioritizes relevant records at the beginning of the screening process and relegates irrelevant records toward the end. Two authors (GS and CHH) independently screened the titles and abstracts to determine their eligibility according to our inclusion criteria. Disagreements were solved through discussion. We decided to stop screening after assessing 400 titles and abstracts in a row without including any additional references, as the inclusion rate had plateaued, suggesting that the algorithm had already identified all relevant studies

Subsequently, we obtained the full texts of references deemed relevant. In pairs, the authors (GS, CHH, NØ) then independently reviewed these full texts and made a final assessment to determine which studies to include. Disagreements were solved through consensus.

Risk of Bias

Two authors (CHH and GS) independently assessed risk of bias for each outcome with the Cochrane risk-of-bias tool (RoB 2) for randomized trials [19]. Disagreements were solved through discussion. RoB 2 assesses risk of bias within 5 domains: randomization process, deviations from the intended interventions, missing outcome data, measurement of the outcome, and selection of the reported result. Overall risk of bias for each outcome was classified as low risk, some concerns, or high risk based on the domain with the highest risk of bias.

Data Extraction

One author (GS) extracted data from the included studies, and another (CHH or NØ) checked the data against the publication. We extracted the following data: study and participant characteristics, information about the interventions, observation period, and outcomes related to resource use. These outcomes included hospitalizations (including readmissions), length of hospital stay, and number of outpatient visits (including clinic visits, outpatient visits, and medical consultations with private physicians and general practitioners), and emergency services. In case of missing information, we contacted the study authors.

Statistical Analysis

We conducted meta-analyses combining studies reporting on the same outcome in RevMan Web [20]. Some of the effect sizes were transformed, as the original data were not reported in a format ready for effect size calculation. For dichotomous outcomes (proportion hospitalized, proportion of outpatient visits, proportion with emergency visits) we performed random-effects analyses with the risk ratio (RR) as the measure of relative effect. For continuous outcomes (number of hospitalizations, hospital length of stay, number of outpatient visits, number of emergency visits) we performed random-effects analyses with the mean difference as the measure of relative effect. A decision taken after the protocol was published was to add results of absolute effects on all outcomes to enhance interpretability and clinical relevance. We believe this can reduce the risk of misinterpreting large relative effects with low absolute benefit and facilitate meaningful comparisons and meta-analyses across studies with varying baseline risks

We did not plan any subgroup analyses or meta-regression in the protocol, but we did the following post hoc analyses: If there were 2 or more studies with the same NCD for an outcome, we subgrouped the meta-analysis per disease group. If there were 10 or more studies in a meta-analysis, we performed mixed effects meta-regression using the R-package [metafor] [21]. Explanatory variables were mean age and publication year. In addition, if there were 10 or more studies in a meta-analysis, we produced funnel plots and performed the Egger test in R [metafor].

Grading of Recommendations Assessment, Development, and Evaluation

We used the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) approach [22] to assess our certainty of the effect estimates per outcome within the following 5 domains: risk of bias, inconsistency, indirectness, imprecision, and publication bias. The GRADE approach specifies 4 levels of certainty: high, moderate, low, or very low. Table 1 illustrates how the certainty of the evidence and the importance of the outcome influence the description of the direction and size of an intervention's effect.

XSL•FO
RenderX

Table 1. How certainty of the evidence and importance of the outcome influence the description of an intervention's effect, as described in [23].

Level of certainty	Important benefit or harm	Less important benefit or harm	No important benefit or harm or null effect
High certainty	Increases or decreases	Increases or decreases slightly	Little to no difference
Moderate certainty	Probably increases or decreases	Probably increases or decreases slightly	Probably little to no difference
Low certainty	May increase or decrease	May increase or decrease slightly	May make little to no difference
Very low certainty	Uncertain whether intervention increases or decreases outcome	Uncertain whether intervention increases or decreases outcome	Uncertain whether intervention increases or decreases outcome

Results

Included Studies

We identified 23,562 unique references in the literature search, of which 258 studies were evaluated in full text. In total, 218 of these studies were excluded for the following reasons: wrong study design (n=90), wrong intervention (n=54), wrong outcomes (n=48), observation period before 2013 (n=16), wrong target group (n=8), and wrong language (n=2; Figure 1).

We included 40 studies [24-62] published between 2017 and 2024 (Tables 2 and 3).

The studies were distributed across various countries, mainly representing high-income countries, with the highest number conducted in the United States and Denmark (Table 2).

The most frequently reported outcomes were proportion of hospitalized patients (including readmissions), proportion with emergency visits, and length of hospital stay.

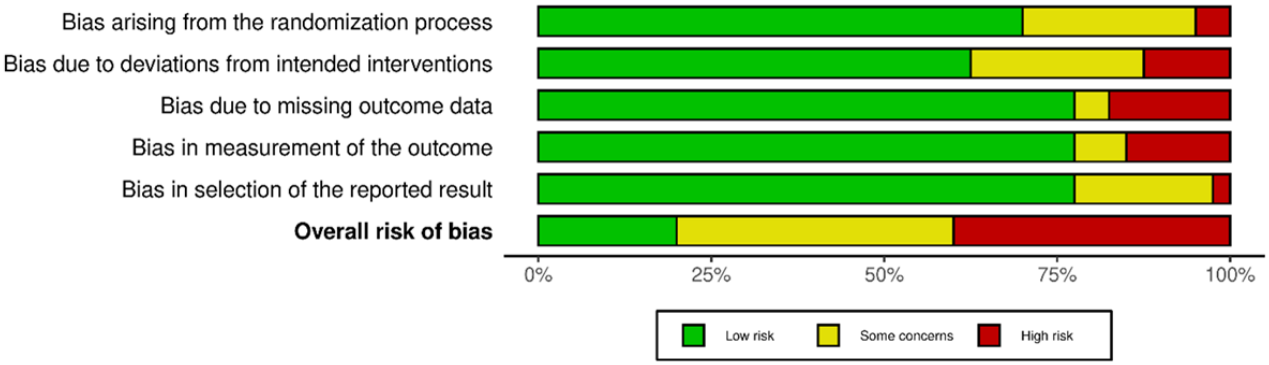
For one study by Abelsen et al [64], we were unable to calculate effect estimates. As a result, the study was not included in the meta-analyses, and we did not assess our confidence in the results. The findings from this study are described narratively. Table 2 shows the main characteristics of the included studies. Some of the trials had specific names, and some utilized a specific app, which are listed in the second column. The interventions were mostly similar, but we provided a detailed description of each. Although the trials had many outcomes, we included only those relevant for this review. Follow-up times ranged from 1 month to 60 months, with 37 studies having follow-up times between 3 months and 12 months (Table 3).

Risk of Bias

Of 40 studies, 8 were assessed as having a low risk of bias, 16 had some concerns, and the remaining 16 were assessed as having a high risk of bias. Figure 2 shows a summary of the risk of bias assessments.

XSL•FO
RenderX

Figure 2. Summary risk of bias assessment.



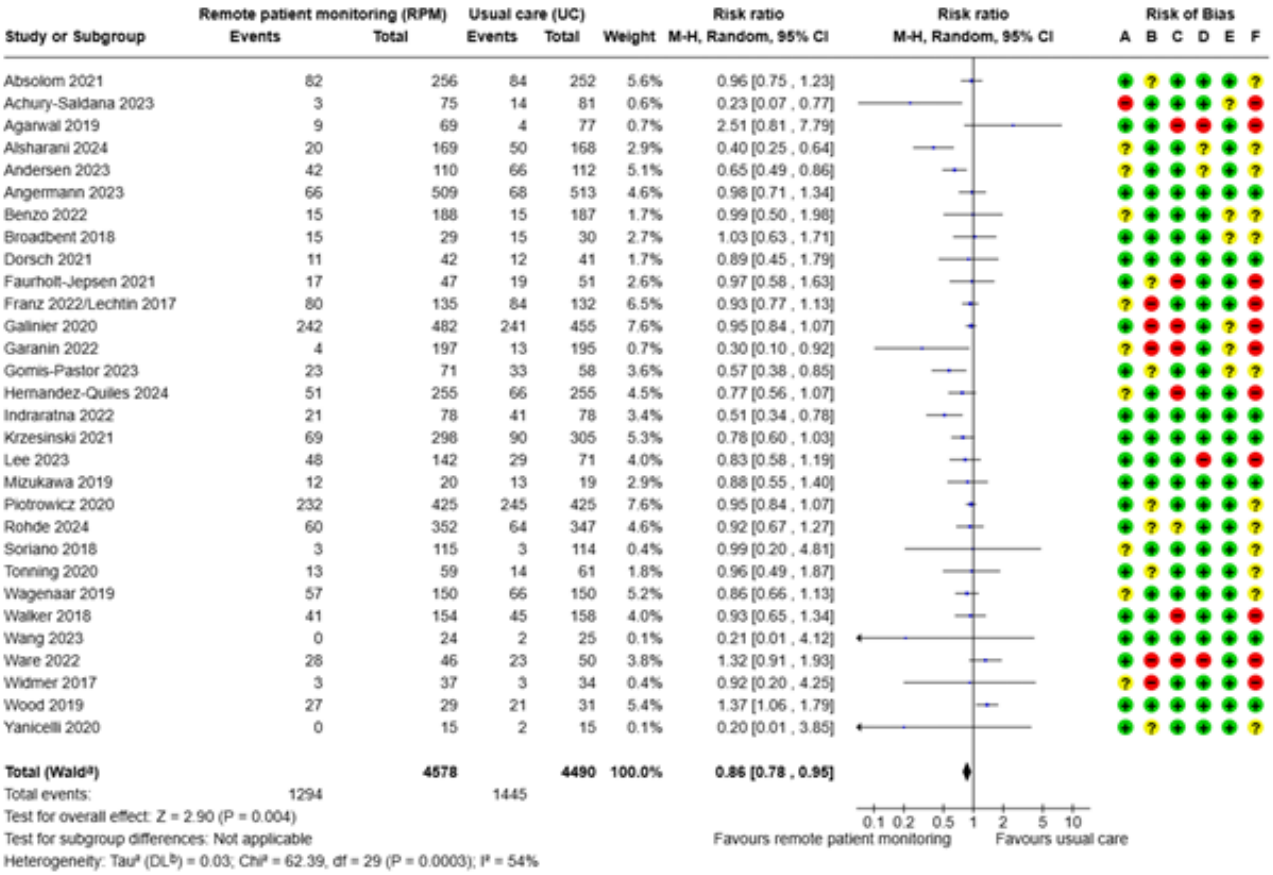
Effects of Interventions

Proportion of Hospitalized Patients

Of the included studies, 30 reported the proportion of hospitalized patients. The RR was 0.86 (95% CI 0.77 to 0.95; low certainty; Figure 3, Multimedia Appendix 2). There was significant heterogeneity (I^2: 55%). Mixed effects meta-regression analysis indicated that newer studies were more in favor of remote patient monitoring (coefficient for publication year: –0.06, *P*=.008; meaning that, for every increase of 1 publication year, the RR decreased by 0.06.) Mean age did not have a significant effect on proportion hospitalized. When both explanatory variables were entered together (full model), publication year was still significant (coefficient: –0.07, *P*=.006). In the full model, I^2 was 46%. Therefore, there was still some unexplained heterogeneity. The Egger test was not significant (*P*=.07), not indicating publication bias. In the subgroup of cardiovascular disease (16 studies), the RR was 0.76 (95% CI 0.65 to 0.88). We did not use GRADE for this subgroup result. The only other diagnostic subgroup with more than 2 studies was chronic obstructive pulmonary disease (COPD; 5 studies). The RR was 0.81 (95% CI 0.66 to 1.00). For the other subgroups, there were no important differences between remote patient monitoring and usual care.

XSL•FO
RenderX

Figure 3. Meta-analysis of the proportion of hospitalized patients in groups randomized to remote patient monitoring or usual care, with the risk of bias assessments for the outcome shown on the right for each study.



Footnotes

[a]CI calculated by Wald-type method.

[b]Tau² calculated by DerSimonian and Laird method.

Risk of bias legend

(A) Bias arising from the randomization process

(B) Bias due to deviations from intended interventions

(C) Bias due to missing outcome data

(D) Bias in measurement of the outcome

(E) Bias in selection of the reported result

(F) Overall bias

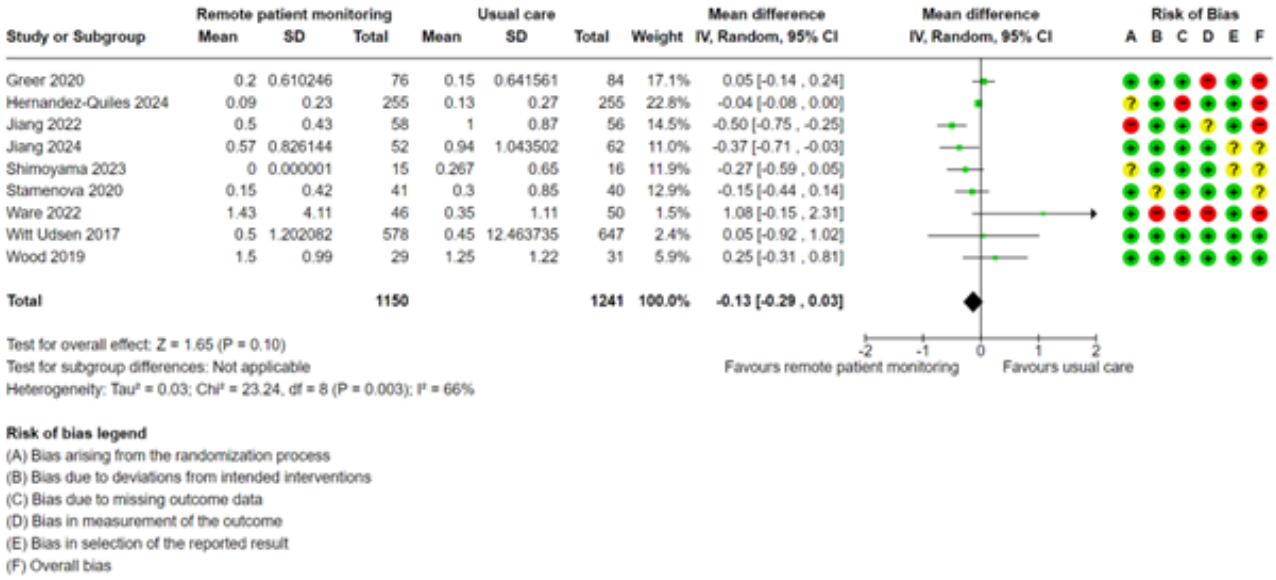
Laursen et al [45] reported the proportion with hospitalizations, but it was only reported as <5. Therefore, this could not be included in the meta-analysis. Jiang et al [43] stated that the 12-month risk of readmission was 34.3% in intervention group compared with 56.0% in the control group, but these numbers could not be included in the meta-analysis.

Number of Hospitalizations

Patients receiving usual care had a mean number of 0.42 hospitalizations. A meta-analysis with 9 studies showed that the group with remote patient monitoring had 0.13 fewer hospitalizations (95% CI –0.29 to 0.03; low certainty; Figure 4, Multimedia Appendix 2). We did not perform mixed effects meta-regression, subgroup, or test for publication bias for this outcome.

XSL•FO
RenderX

Figure 4. Meta-analysis of the number of hospitalizations in groups randomized to remote patient monitoring or usual care, with the risk of bias assessments for the outcome shown on the right for each study.

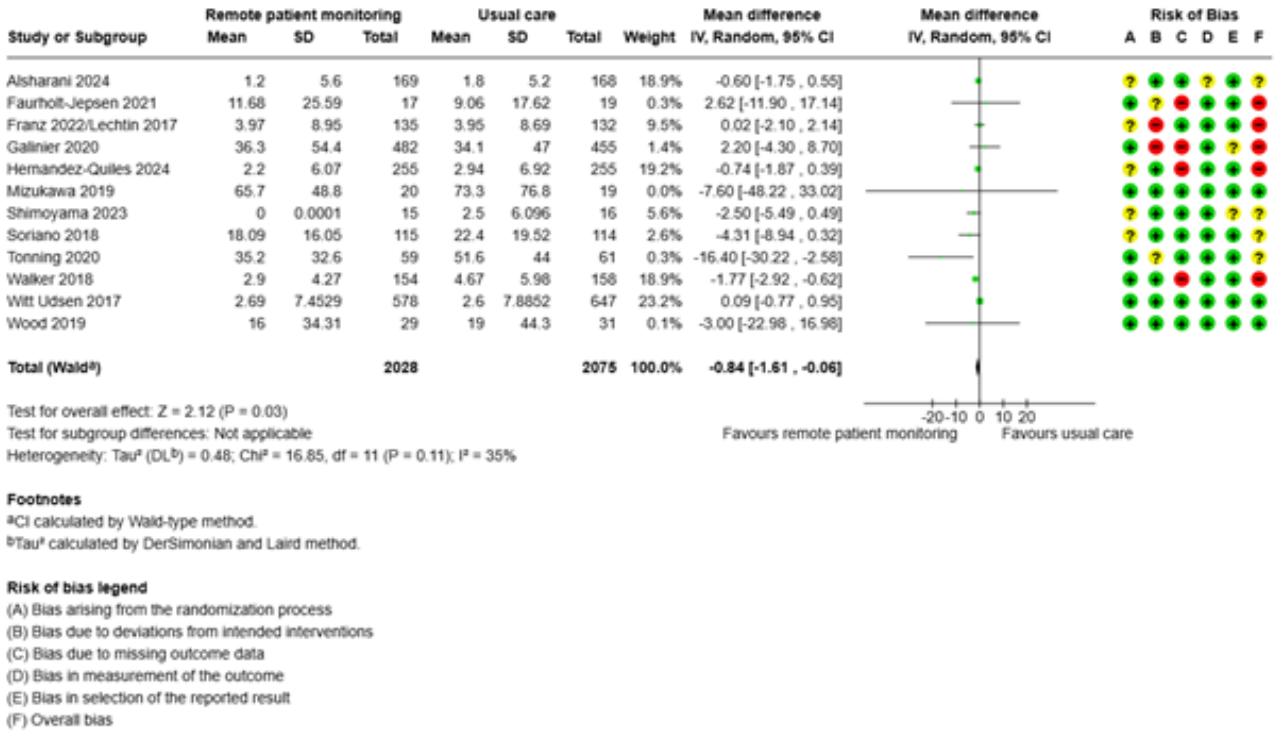


Abelsen et al [64] measured the number of unplanned hospital admissions after 6 months and 12 months and reported no difference between the groups after 6 months. However, they found an increase in the number of admissions in the remote patient monitoring group compared with the usual care group after 12 months.

Length of Hospital Stay

The mean hospital length of stay in the usual care group was 6.82 days. A meta-analysis with 12 studies showed that the length of hospital stay was slightly shorter for the remote patient monitoring group, at 0.84 days shorter (95% CI –1.61 to –0.06; low certainty; Figure 5, Multimedia Appendix 2). None of the explanatory variables had a significant effect on length of hospital stay. The Egger test was not significant (*P*=.08).

Figure 5. Meta-analysis of the length of hospital stay (in days) in groups randomized to remote patient monitoring or usual care, with the risk of bias assessments for the outcome shown on the right for each study.



Abelsen et al [63,64] measured the number of hospital bed days for unplanned admissions after 6 months and 12 months and reported no difference between the groups. Andersen et al [29] reported the median length of stay in the hospital for 0 months through 6 months as 5 days in the telegroup and 7 days in the control group. For a period of 0 months through 24 months,

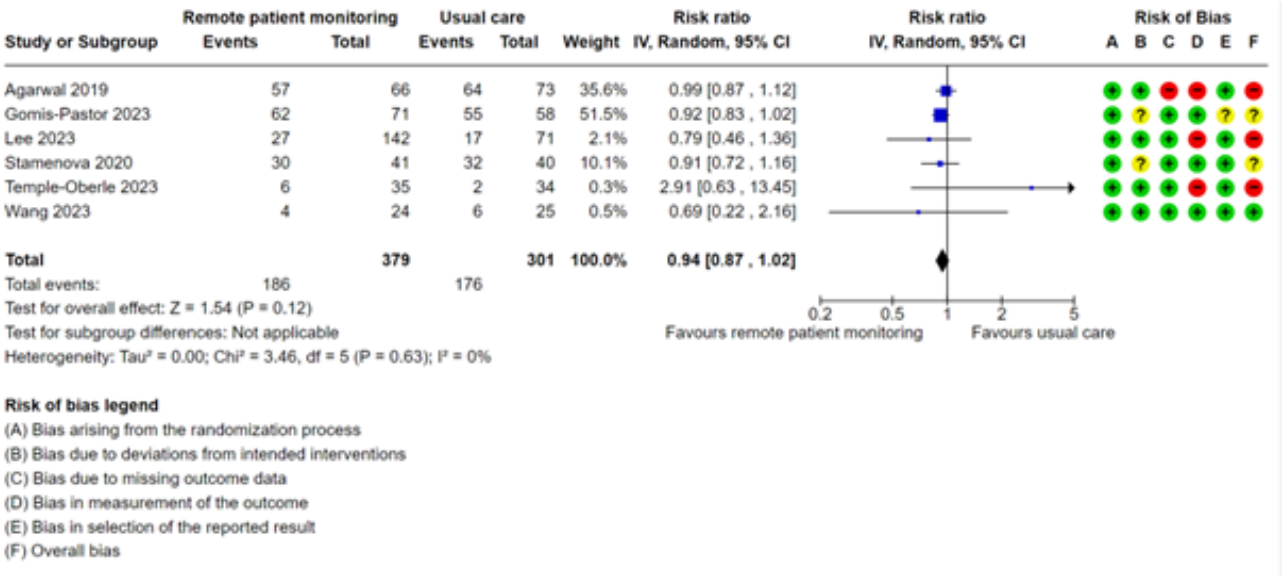
XSL•FO
RenderX

they reported 4 days in both groups. It was not possible to compute an effect size. Broadbent et al [32] reported the total number of days in hospital for respiratory problems in the intervention and control groups. It was not possible to compute an effect size. Garanin et al [37] reported that the intervention group was hospitalized for a mean number of 7.5 days and the usual care group was hospitalized for a mean of 10.2 days. It was not possible to compute an effect size.

Proportion With Outpatient Visits

A meta-analysis with 6 studies showed almost no difference in the proportion of patients with outpatient visits between the 2 groups (RR 0.94, 95% CI 0.87 to 1.02; moderate certainty; Figure 6, Multimedia Appendix 2). We did not perform mixed effects meta-regression, subgroup based on condition, or test for publication bias for this outcome.

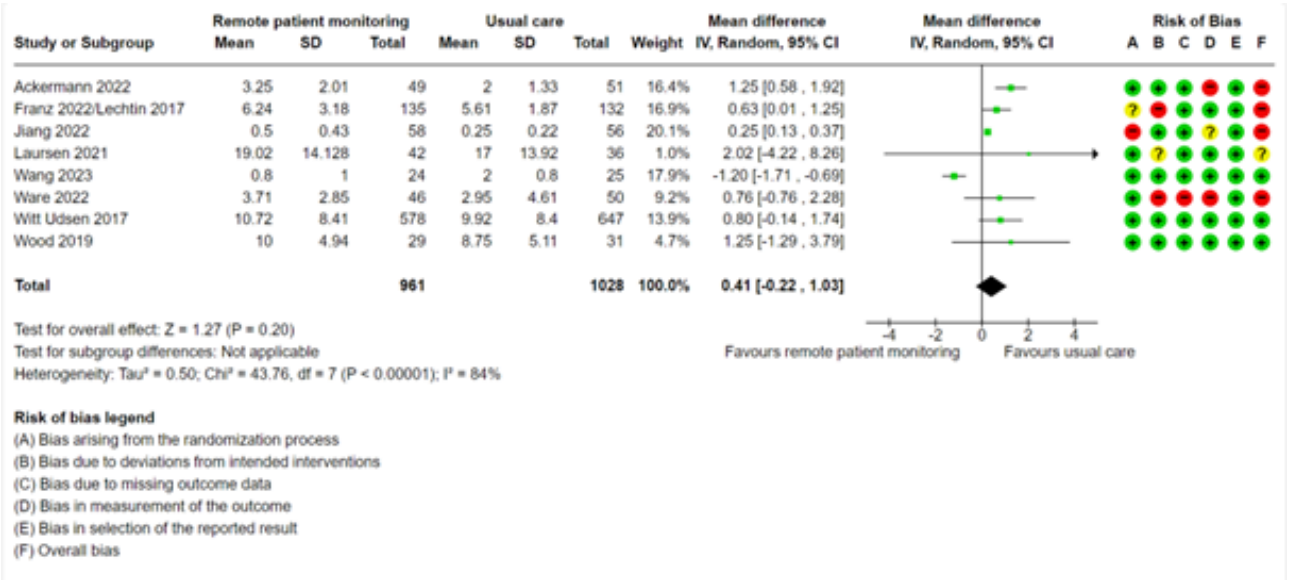
Figure 6. Meta-analysis of the proportion of outpatient visits in groups randomized to remote patient monitoring or usual care, with the risk of bias assessments for the outcome shown on the right for each study.



Mean Number of Outpatient Visits

The studies came from many different countries with diverse health care systems. We decided not to distinguish between private or public clinic visits, medical consultations, private physicians, or general practitioners. Instead, we categorized all these consultations as "outpatient visits." The usual care group had a mean number of 8.13 outpatient visits. A meta-analysis with 8 studies showed that the remote patient monitoring group had slightly more outpatient visits (0.41 more), thus favoring the usual care group, but the 95% CI crossed zero (95% CI –0.22 to 1.03; low certainty; Figure 7, Multimedia Appendix 2). We did not perform mixed effects meta-regression, subgroup based on condition, or test for publication bias for this outcome.

Figure 7. Meta-analysis of the mean number of outpatient visits in groups randomized to remote patient monitoring or usual care, with the risk of bias assessments for the outcome shown on the right for each study.



Abelsen et al [63,64] measured the number of outpatient visits and number of contacts with general practitioners after 6 months and 12 months. They found no difference in the number of outpatient visits and a tendency toward a greater increase in the

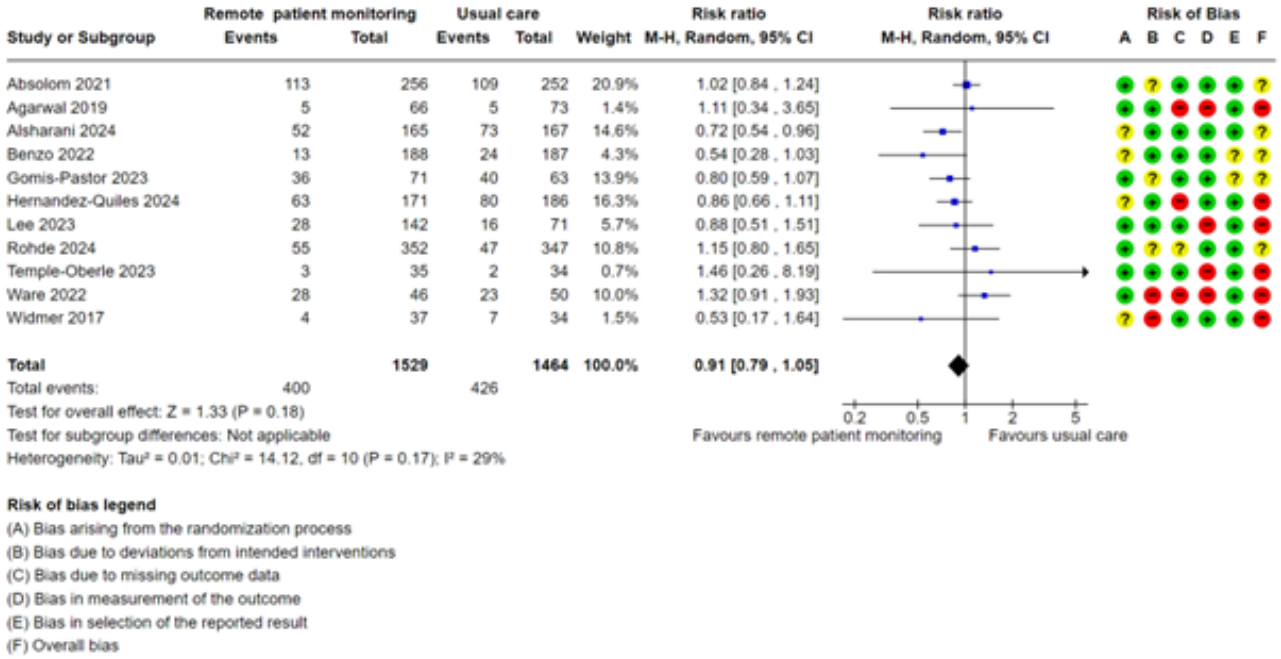
XSL•FO
RenderX

number of general practitioner consultations in the remote patient monitoring group compared with the usual care group after 6 months and 12 months.

Proportion With Emergency Visits

A meta-analysis with 11 studies showed little or no difference between the groups on proportion of emergency visits (RR 0.91, 95% CI 0.79 to 1.05; low certainty; Figure 8, Multimedia Appendix 2). There was no indication of publication bias (Egger test, *P*=.75). We did not perform mixed effects meta-regression or subgroup analysis based on condition because the heterogeneity was low.

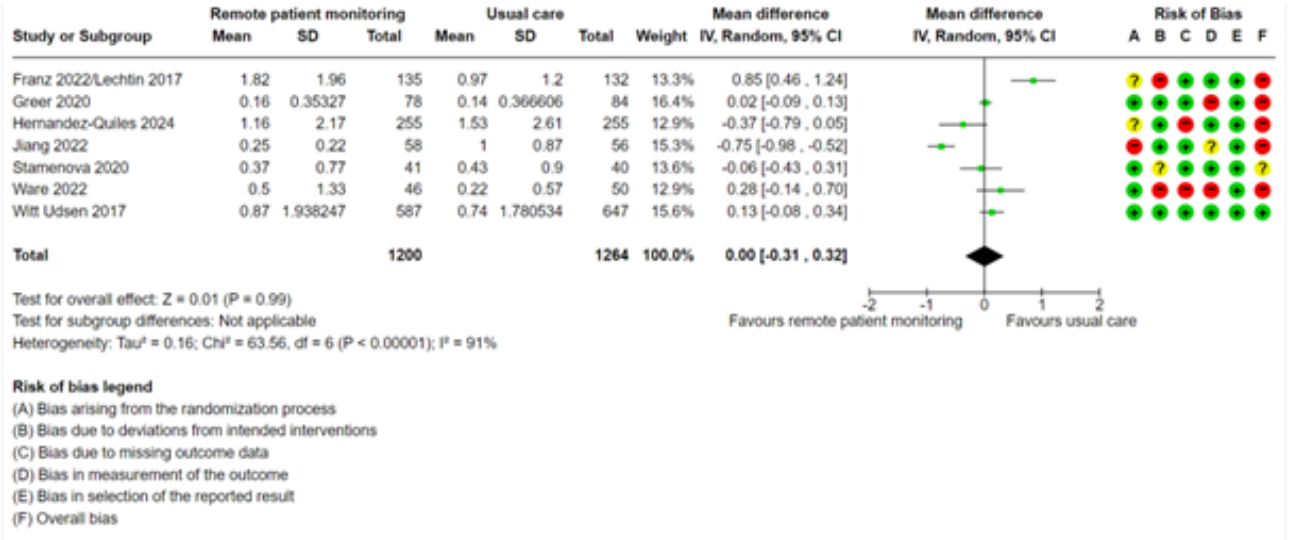
Figure 8. Meta-analysis on the proportion of emergency visits in groups randomized to remote patient monitoring or usual care, with the risk of bias assessments for the outcome shown on the right for each study.



Number of Emergency Visits

The usual care group had a mean number of 0.86 emergency visits. A meta-analysis with 7 studies showed very low certainty evidence for the number of emergency visits (mean difference 0.00, 95% CI –0.31 to 0.32; very low certainty; Figure 9, Multimedia Appendix 2). We did not perform mixed effects meta-regression, perform subgroup analysis based on condition, or test for publication bias.

Figure 9. Meta-analysis on the number of emergency visits in groups randomized to remote patient monitoring or usual care, with the risk of bias assessments for the outcome shown on the right for each study.



Abelsen et al [63,64] examined both the number of stays in municipal acute care and the number of contacts with emergency services after 6 months and 12 months. The study found no differences between the groups for either measure.

XSL•FO
RenderX

Home Care Services

Witt Udsen 2017 [60] measured the average hours spent on health care services at home over a 12- month period, finding that more hours were spent on home health care services in the remote patient monitoring group compared with the usual care group (mean difference 523.2, 95% CI –152.6 to 1199.0 hours).

Similarly, Abelsen et al [63,64] measured the average number of home health care visits after 6 months and 12 months and reported no differences between groups.

Institutional Stay

None of the included studies reported on institutional stay, only hospitalizations.

Absolute Effects

So far, we presented relative effects of remote patient monitoring compared with usual care, reporting RRs and mean differences. However, to fully grasp the impact and understand how many individuals are actually affected, it is important to also consider the absolute numbers. Table 4 shows the proportions of hospitalizations, outpatient visits, and emergency visits for the 2 groups, and Table 5 shows the numbers of hospitalizations, outpatient visits, and emergency visits and length of hospital stay in days.

Table 4. Proportions with hospitalizations, outpatient visits, and emergency visits in remote patient monitoring versus usual care.

Outcomes	Usual care	Remote patient monitoring
Proportion hospitalized	0.32	0.28
Proportion with outpatient visits	0.59	0.55
Proportion with emergency visits	0.29	0.26

Table 5. Absolute numbers of hospitalizations, days in hospital, outpatient visits, and emergency visits in remote patient monitoring versus usual care.

Outcomes	Usual care	Remote patient monitoring
Number of hospitalizations	0.42	0.29
Length of hospital stay	6.82	6.01
Number of outpatient visits	8.13	8.54
Number of emergency visits	0.86	0.86

Discussion

Principal Findings

Remote patient monitoring may slightly reduce the proportion of hospital stays, but it may make little or no difference to the number or length of hospital stays. It likely has little or no effect on the proportion of patients with outpatient visits and may result in little or no difference in the mean number of outpatient visits or the proportion with emergency visits. The evidence is uncertain regarding the effect of remote patient monitoring on the number of emergency visits.

Other systematic reviews have similar findings. Iqbal and colleagues [65], who examined clinical outcomes of digital alerting systems in remote monitoring, also found reductions in hospitalizations and length of stay for certain cohorts. However, they found no important benefit on emergency department or outpatient visits. Similarly, a review by Auener et al [66] on telemonitoring for chronic heart failure patients showed no clear differences in health care utilization between the remote monitoring group and usual care, except for an increase in nonemergency outpatient department visits for the remote monitoring group. These findings suggest that closer monitoring through remote patient monitoring may lead to more frequent health care interactions in an outpatient setting. Improved condition management through continuous monitoring and timely intervention can potentially lower the incidence of critical health episodes, reducing the demand for more costly interventions like hospitalizations. Patients who are remotely monitored may also feel a greater sense of security or may be more inclined to seek medical attention for minor symptoms or concerns that they might otherwise have ignored. This increased health care–seeking behavior could lead to higher health care utilization rates of, for example, outpatient clinical visits and potentially counteract savings from remote monitoring.

Hospitalizations are highly resource-intensive and costly [67]. Although our findings on the absolute reduction in the proportion of hospitalized patients may seem small, with a reduction from 32% to 28%, this modest reduction is expected to result in significant cost savings. Fewer hospitalizations and shorter hospital stays can lead to decreased health care costs per patient and allow for more efficient use of hospital resources, such as freeing up beds and reducing the burden on health care staff. This, in turn, enables hospitals to accommodate more patients and potentially reduces wait times for critical care.

Previous reviews have shown mixed results regarding the cost-effectiveness of remote patient monitoring [68], and remote patient monitoring systems sometimes lead to increased utilization of health care services rather than the anticipated reduction. The effectiveness of remote monitoring in reducing health care resource utilization may vary depending on the specific patient population, disease condition, and health care setting [69]. Thomas et al [14] identified several factors contributing to increased health care utilization. These included recruiting high-risk populations, failure to integrate remote

XSL•FO
RenderX

patient monitoring into workflows, and system measurement errors. Specific issues such as slow responses to alerts and low adherence to the remote follow-up by patients or clinicians were significant contributors to increased acute care use in the remote patient monitoring group. To reduce hospitalizations, it is crucial that remote patient monitoring systems accurately predict disease exacerbations by detecting changes in symptoms related to disease worsening. This can be particularly challenging in populations with unpredictable disease progression [14]. Patients who are more prone to frequent hospitalizations may experience a greater reduction in admissions with timely interventions made possible by remote monitoring. However, in practice, clinicians may hesitate to rely on remote assessments for their most vulnerable and critically ill patients [14]. The subgroup analysis in our review indicated that remote patient monitoring may reduce hospitalizations for patients with heart disease and COPD, but among the other NCDs, there were little or no differences. A systematic review of evaluations of noninvasive remote patient monitoring for chronic diseases [69] found that remote patient monitoring was highly cost-effective for hypertension. However, for COPD and heart failure, the cost-effectiveness varied depending on the severity of the disease. These findings suggest that certain patient populations may benefit more from remote monitoring than others and that variations in outcomes are influenced by factors such as diagnosis severity, health care setting, and the specific design of the remote patient monitoring intervention. Consequently, the impact on health care resource utilization may differ across contexts.

Regarding organizational aspects, remote patient monitoring can potentially streamline care, but it can also introduce complexities that may offset resource savings. For instance, remote patient monitoring generates large volumes of health data, which must be processed, cleaned, analyzed, and managed before it can be reliably used for clinical decision support. This not only requires robust data handling procedures but also the allocation of resources and adaptation of existing health care infrastructure to effectively integrate these systems into routine care [70,71]. Moreover, following up missing data due to lack of patient adherence or problems with devices presents additional, resource-intensive challenges that must be addressed to ensure safe and equitable care [72]. Alignment and adaptation of infrastructure, along with training and upskilling of staff, seem crucial to meet the demands of remote monitoring, ensuring continuity of patient care without creating gaps. Substantial investments in technology, training, and support are required to implement remote patient monitoring, and these costs may not be immediately offset by savings [69]. There is also a rapid advancement in digital solutions, and our results show that newer studies suggest better results in terms of resource utilization than older studies.

Strengths and Limitations

This systematic review's selection of eligible studies relied on a clearly defined and systematic search strategy. Although it is possible that we overlooked studies due to insufficient descriptions of interventions or populations in the title or abstract, we believe it is likely that we identified the most relevant studies. We only included studies in which the intervention was conducted in 2013 or later. This may have excluded valuable research from earlier periods. However, given the significant advancements in technology in recent years, we prioritized newer studies to provide more realistic and up-to-date results. We did not examine health care personnels' resource use related to remote follow-up, though previous studies suggest that handling incoming data from patient-reported outcome measures can be time-consuming for staff and may place a significant burden on health care providers in terms of time and resources [73].

Further, we assessed the risk of bias and certainty of the evidence transparently and systematically. These assessments allow readers to make their own judgments of the strength of the evidence. However, in many of the studies, the settings, interventions, and populations were poorly described, which may introduce limitations when synthesizing results from studies with different populations and intervention types. We attempted to account for this in our GRADE assessments, but due to poor reporting and a lack of detailed information about the settings, there may still be challenges related to heterogeneity. This could affect the overall interpretation of the findings and reduce confidence in the conclusions drawn. Moreover, regarding the outcome of outpatient visits, it is somewhat unclear what specific terms like "outpatient clinic visits," "outpatient visits," "medical consultations," and visits to "private physicians" or "general practitioners" precisely mean in the studies we reviewed. This inconsistency in terminology represents a limitation and should be considered carefully when interpreting this outcome, as it may affect the comparability of health care utilization results across the studies.

The evidence base is heavily skewed toward studies conducted in high-income countries, which limits the applicability of the findings to low- and middle-income settings. Additionally, considerable heterogeneity in patient populations and interventions across studies complicates the ability to draw broader, generalizable conclusions. The lack of economic evaluations in this review also limits our ability to assess cost-effectiveness, which is a critical factor for informing health care policy and implementation decisions.

Implications for Future Research

Future research should explore ways to streamline the processing of data from patient-reported outcomes measures through automated tools and improved system integration to optimize efficiency. Understanding the relationship between remote monitoring and resource utilization—along with identifying barriers and facilitators—is crucial to develop services that can maintain or improve current standards of care while being more resource-efficient. There is also a need for systematic reviews that examine more homogeneous patient groups and forms of digital home follow-up to better understand which groups may benefit from specific treatments. Additionally, a more comprehensive health-economic analysis is needed, considering resource use more holistically, including costs associated with technology acquisition, maintenance, follow-up on incoming data, service usage, and impacts on work absence, among other factors.

Conclusions

This systematic review showed that remote patient monitoring possibly led to lower proportions of patients being hospitalized, fewer hospitalizations, and shorter hospital length of stay compared with usual care. The proportion of patients with outpatient visits was probably similar for remote patient monitoring and usual care. Remote patient monitoring had possibly more outpatient visits compared with usual care. The proportion with emergency visits was possibly similar between the groups. We are uncertain about the effect on number of emergency visits. The results should be considered with caution as the certainty of evidence was moderate to very low. We did not find results regarding institutional stay.

Acknowledgments

We would like to thank Gyri Hval for conducting the literature searches.

Abstract

Background: Cardiovascular diseases remain the leading cause of mortality worldwide, accounting for 18 million deaths annually. Detection and prediction of cardiovascular conditions are essential for timely intervention and improved patient outcomes. Wearable devices offer a promising, noninvasive solution for continuous monitoring of cardiovascular signals, vital signs, and physical activity. However, the large data volumes generated by these devices and the rapid fluctuations in cardiovascular signals necessitate advanced artificial intelligence (AI) techniques for real-time analysis and effective clinical decision-making.

Objective: The objective of this scoping review was to identify the main challenges of AI-driven platforms for real-time cardiovascular condition monitoring with wearable devices and explore potential solutions. In addition, this review aimed to examine how AI algorithms are developed for robust monitoring and how deployment pipelines are optimized to enable real-time cardiovascular condition monitoring.

Methods: A comprehensive search was conducted in the following electronic databases: MEDLINE(R) ALL (Ovid), Embase (Ovid), Cochrane Central Register of Controlled Trials (Ovid), Web of Science Core Collection (Clarivate), IEEE Xplore, and ACM Digital Library, yielding 2385 unique records. Inclusion criteria focused on studies that used wearable devices for participant data collection and applied AI algorithms for real-time analysis to detect or predict cardiovascular events and diseases. After title and abstract screening, 153 papers remained, and following a full-text review, 19 studies met the inclusion criteria.

Results: The findings indicate that despite the promise of AI and wearable devices, research on real-time cardiovascular monitoring remains limited and lacks comprehensive validation. Most studies relied on publicly available wearable datasets rather than real-world validation with recruited participants in community settings. Studies that deployed AI algorithms in real time frequently failed to report operational characteristics and challenges. Electrocardiography-based wearable sensors were the most frequently used devices, primarily in hospital settings. A variety of AI techniques, ranging from traditional machine learning to lightweight deep learning algorithms, were deployed either on wearable devices or via cloud-based processing.

Conclusions: Robust, interdisciplinary research is needed to harness the full potential of AI-driven, real-time cardiovascular health management using wearable devices. This includes the development and validation of scalable solutions for continuous community-based deployment. Furthermore, real-world challenges such as participant compliance, hardware and connectivity constraints, and AI model optimization for real-time continuous monitoring must be carefully addressed.

KEYWORDS

cardiovascular diseases; artificial intelligence; real-time monitoring; continuous monitoring; wearable devices; machine learning; deep learning; smartwatches; electrocardiography (ECG); atrial fibrillation; mobile phone

Introduction

Background

Cardiovascular diseases (CVDs) continue to be the leading cause of mortality worldwide, causing more than 18 million deaths each year [1]. The number of deaths attributed to CVDs has increased significantly over the past decades, rising by 53.7% from 12.1 million in 1990 to 18.6 million in 2019 [2]. This trend is expected to continue, with an estimated 35.6 million cardiovascular deaths by 2050, an increase of 90% compared with 2025 [2]. This escalating trend underscores the urgent need for comprehensive prevention and management strategies to address the global impact of CVDs.

Detection and prediction of CVDs and cardiovascular events are critical for reducing the morbidity and mortality associated with these conditions [3-5]. CVDs, such as coronary artery disease, hypertensive heart disease, and cardiomyopathies, often develop silently over years, with patients exhibiting minimal or no symptoms until a significant event occurs [6]. Identifying risks at an early stage allows for timely intervention, lifestyle modifications, and treatment, which can dramatically reduce the likelihood of severe outcomes [7]. Real-time detection and prediction of cardiovascular events, such as heart attacks, cardiac arrest, and strokes, is particularly essential because it provides actionable insights during critical windows when interventions can have the greatest impact. Delays in recognizing and responding to subtle physiological changes can mean the difference between prevention and a life-threatening event [8,9].

Wearable devices equipped with sensors for continuous monitoring of vital signs such as heart rate, blood pressure, and oxygen saturation offer the potential to identify abnormal patterns indicative of cardiovascular stress or disease [10]. These devices enable remote monitoring for people in the community, allowing health care providers to track patients' health in real time and intervene promptly, even outside of clinical settings. Coupled with artificial intelligence (AI), these devices can analyze large amounts of data in real time, detecting and predicting potential cardiovascular events before they occur [9]. Advanced machine learning and deep learning techniques play a critical role in processing and interpreting the large and complex data captured by wearable devices, identifying subtle patterns and trends that may go unnoticed by human observation. Their ability to learn from historical data and continuously improve predictions ensures timely and accurate alerts, enabling health care providers to intervene before critical events unfold, thereby reducing the risk of adverse outcomes [9].

An AI-driven, wearable sensor-based platform for real-time cardiovascular monitoring can be equipped with single or multimodal sensors to collect various data, including electrocardiography (ECG), photoplethysmography (PPG), heart rate, blood pressure, and mobility indicators. These data are analyzed by AI algorithms, trained on historical datasets, and optimized for real-time inference. Depending on the system's design, these algorithms can run either directly on wearable devices or on cloud servers (requiring data transfer). Analysis results are then communicated to clinicians, participants, or caregivers, enabling timely interventions to prevent or reduce adverse cardiovascular outcomes.

By prioritizing early detection and prediction, health care systems can shift their focus from reactive to proactive care, reducing hospitalizations, improving health outcomes and patients' quality of life, and lowering health care costs [11]. Ultimately, early intervention is the foundation of effective CVD management and a pathway to saving millions of lives annually [3-5].

Related Reviews

Table 1 outlines recent reviews on the applications of wearable devices and AI algorithms for cardiovascular monitoring [10,12-22], as well as relevant reviews in the broader domain of health care monitoring [23-25]. Each review is marked to indicate which of the 4 key concepts (CVD, real-time monitoring, AI, and wearable devices) it covers. While previous reviews on cardiovascular monitoring addressed 1 or 2 concepts, wearable devices [10,12-17,20-22], AI [18,20-22,25], or real-time monitoring [10,23-25], none comprehensively covered all 3. In addition, reviews on real-time monitoring in general health care [23-25] lack a specific focus on the detection and prediction of cardiovascular conditions. Most of these reviews included studies that used precollected public datasets for developing AI algorithms, which do not deal with the real-world challenges of deploying AI for real-time monitoring.

Research Questions

AI [18,20-22,25] plays a crucial role in processing data from wearable devices [10,12-17,20-22] facilitating real-time [10,23-25] detection, prediction, and diagnosis of cardiovascular conditions. This empowers clinicians to intervene swiftly, helping to prevent or mitigate adverse outcomes, reduce hospitalizations and mortality, and improve patient quality of life. In this paper, a scoping review was conducted to systematically map the current body of research on AI-driven platforms using wearable sensors for real-time cardiovascular monitoring and to identify knowledge gaps and associated challenges. The scoping review was guided by the following research questions: (1) What are the primary challenges of AI-driven platforms for real-time cardiovascular condition monitoring with wearable devices, and how are these challenges addressed? (2) How are AI algorithms developed to support robust cardiovascular condition monitoring? (3) How are AI algorithms and deployment pipelines optimized to enable real-time cardiovascular condition monitoring?

While the first research question focuses on platform-level challenges and solutions for real-time cardiovascular condition monitoring, the second and third questions specifically examine AI algorithms, one of the core components of these platforms, in terms of ensuring robustness and enabling real-time deployment.

Methods

Study Design

This study used a scoping review methodology to address the broad scope of the research questions, the diversity of the studies and populations, and the absence of previously conducted comprehensive reviews [26,27]. The scoping review followed the framework outlined by Arksey and O'Malley [26] and was reported in compliance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist (Multimedia Appendix 1) [27].

Eligibility Criteria

Inclusion Criteria

Peer-reviewed journal and conference papers written in English, including quantitative, qualitative, and mixed method studies, were considered for inclusion. To be eligible, studies had to describe either the development of a new platform (research-based or commercial) or the use of an existing platform for AI-driven real-time monitoring of cardiovascular conditions through wearable devices. The platform was required to meet all four criteria: (1) It must collect continuous data from adult participants using wearable sensing devices. (2) It must be AI-driven, incorporating machine learning and deep learning algorithms to analyze wearable data. (3) The AI algorithms must perform data analysis and inference-making in real time or near real time. (4) The inferences made by AI algorithms must

XSL•FO
RenderX

involve the detection or prediction of cardiovascular conditions, diseases, or events. Studies could also look at other comorbidities, such as diabetes, in addition to CVD.

Real-time analysis involves continuous processing with minimal delay, while near–real time refers to intermittent or slightly delayed processing due to computational or design limitations. Although "detection" and "prediction" are often used interchangeably in the literature, this paper distinguishes between them: detection infers current conditions from current wearable data, whereas prediction uses current data to forecast future conditions.

Using the SPICE framework [28], the setting; population; intervention; comparison; and evaluation criteria were identified as participants' homes, nursing homes, or hospitals; adult participants; monitoring (predicting or detecting) any cardiovascular condition; real-time AI algorithms; and the accuracy and latency of real-time AI algorithms, respectively.

Exclusion Criteria

Non–peer-reviewed and non-English publications or resources were excluded. Studies were excluded if they (1) did not use a platform in which wearable sensor devices were used for data collection from adult participants, (2) did not use AI algorithms for wearable sensor data analysis, (3) performed offline data analysis, or (4) evaluated their platform only on wearable sensor datasets already collected, such as publicly available datasets.

If 1 or more of the exclusion criteria were met, studies were excluded.

Information Sources and Search Strategy

To identify relevant studies, a comprehensive literature search was designed in collaboration with an information specialist (CC) and further refined through team discussions. AA and AV initially provided CC with a list of keywords and 20 target papers that needed to be retrieved from the search. Following this, CC, AA, and AV collaboratively refined the keyword list and developed a search strategy using a combination of subject headings and text words for MEDLINE, which was subsequently translated to other databases. The search strategy consisted of 4 concepts: wearable devices, CVDs, AI algorithms, and real-time data analysis. The search was conducted in the following electronic bibliographic databases: MEDLINE(R) ALL (Ovid), Embase (Ovid), Cochrane Central Register of Controlled Trials (Ovid), Web of Science Core Collection (Clarivate), IEEE Xplore, and ACM Digital Library, covering records from inception to July 5, 2024. Search filters were used to remove studies on children and animals when possible. The results were limited to the English language. Table 2 provides a subset of unique search keywords used for database queries. The complete search strategy and associated keywords for databases are detailed in Multimedia Appendix 2. The search results were exported as RIS files, consolidated, imported into the Covidence web application for literature review, and deduplicated. The reference lists of the included studies were also examined to identify any additional relevant studies.

Table 2. A subset of the unique search keywords used to search the databases.

Concept	Sample keywords
Cardiovascular diseases	Cardiovascular Diseases, Heart Diseases, Auriculo-Ventric, Irregular Heart Rate, Small Vessel Disease, Cardiomyopath, Thrombophlebit, High Blood Pressure, Stroke, Heart Attack
Real time	Real-Time, Live, Online, Dynamic, Synchronous, Streaming, Simultaneous, Cloud, Fog, Edge, Continuous
Artificial intelligence	Artificial Intelligence, Pattern Recognition, Decision Trees, Supervised Learning, Natural Language Processing, Large Language Model, ChatGPT, Transformer Architect, Neural Network, Intelligent System, Deep Learning
Wearable devices	Wearable Devices, Remote Sensing Technology, Internet of Things, Wearable, Smart sensor, Garment, Smart eyewear, Smart jewellery, Electronic Textile, Electronic Skin, FitBit

Selection of Sources of Evidence

A group of 4 independent reviewers (AV, DJ, JK, and ZH) conducted the title and abstract screening using the Covidence web application. Each study was independently reviewed by at least 2 of these reviewers. Relevant studies identified during this process underwent full-text review and data charting, performed by at least 2 reviewers from the same group (AV, DJ, JK, and ZH). Any conflicts arising during the title and abstract screening or full-text review were resolved by AA.

Data Charting Process and Data Items

To address the research questions for this scoping review, a data-charting form was designed to extract relevant information from the reviewed studies. The form consisted of five sections: (1) study characteristics, participants, and settings, as well as cardiovascular condition under monitoring; (2) study aims, methodologies, and key findings; (3) characteristics of wearable devices; (4) characteristics of real-time AI algorithms; and (5) robustness analysis of AI algorithms.

Synthesis of Results

To address the research questions, a descriptive analysis was performed, followed by a narrative summary of relevant study characteristics presented using tables. Studies were analyzed based on the data characteristics outlined in the previous subsection. Due to the heterogeneity in populations, CVDs, outcome measurement tools, and measurement times, a meta-analysis was not conducted [29].

Results

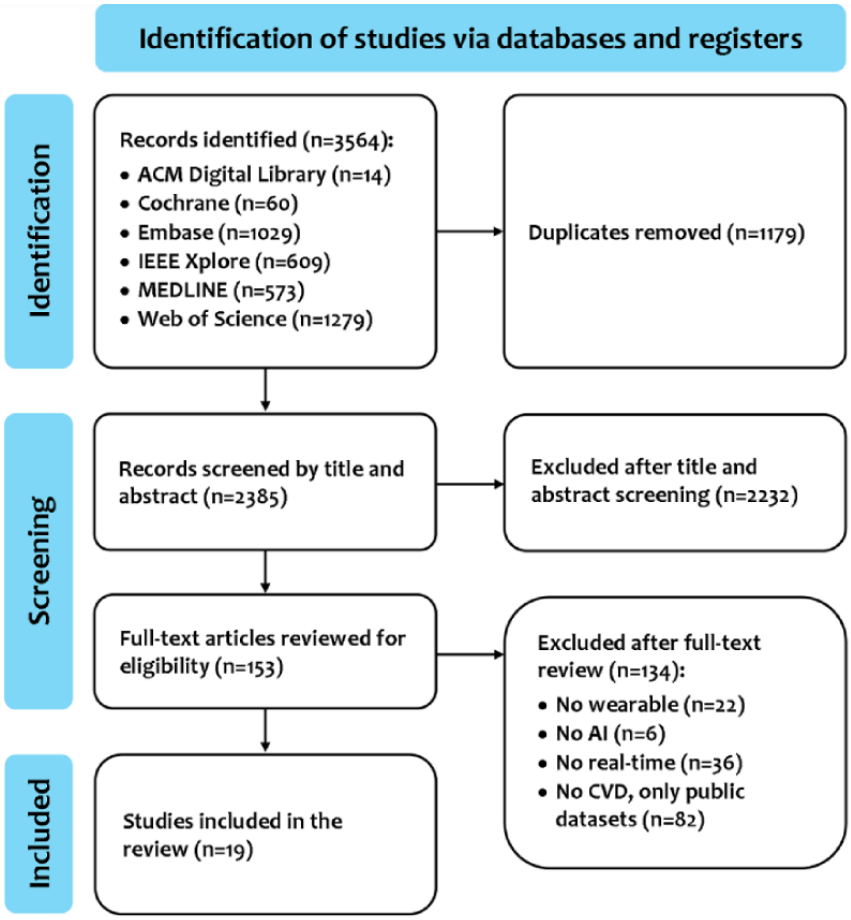
Selection of Sources of Evidence

Figure 1 illustrates the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram, which describes the study selection process. Upon removing duplicates,

XSL•FO
RenderX

a total of 2385 studies were identified through comprehensive literature searches of electronic databases. Following title and abstract screening, 2232 studies were excluded, and 153 full-text studies were retrieved for full-text review. Among these 153 studies, 134 were excluded due to the absence of 1 or more of the 4 aforementioned inclusion criteria. This resulted in the inclusion of 19 studies.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for the scoping review. Of the 2385 unique titles and abstracts initially screened, 153 full-text studies were further evaluated, resulting in 19 studies being included in the scoping review. ACM: Association for Computing Machinery; AI: artificial intelligence; CVD: cardiovascular disease; IEEE: Institute of Electrical and Electronics Engineers.



Characteristics of Sources of Evidence

Multimedia Appendices 3-7 show the 5 aforementioned categories of data items for the studies included in this scoping review. A "—" in the tables indicates that the respective item was not mentioned or discussed in the paper.

Characteristics of Studies

As outlined in Multimedia Appendix 3, the included studies (n=19) were published between 2010 and 2024, with the majority, 17 (89.5%), published between 2019 and 2024 [30-46], highlighting the increasing shift toward real-time AI solutions for monitoring cardiovascular conditions. Among the included studies, 5 (26.3%) were conducted in the United States [32,40,44,45,47], 4 (21.1%) in Taiwan [33,35,36,48], 3 (15.8%) in China [31,34,46], 2 (10.5%) in India [37,43], and 1 (5.3%) each in Japan [30], Turkey [38], Pakistan [39], Bangladesh [41], and Sri Lanka [42]. Of the included studies, 14 (73.7%) were journal papers, while 5 (26.3%) were peer-reviewed conference publications.

Characteristics of Participants

One of the inclusion criteria for this scoping review was that the selected studies must have involved the collection of data from adult participants specifically for monitoring cardiovascular conditions. Consequently, a significant number of studies were excluded during the title and abstract screening, as well as the full-text review (n=82). The majority of these excluded studies focused on the development and evaluation of AI algorithms or AI-driven platforms for cardiovascular condition monitoring using publicly available datasets, such as the Massachusetts Institute of Technology-Beth Israel Hospital (MIT-BIH) Arrhythmia Database [49]. Such studies, while valuable for algorithmic advancements, do not provide insights into the feasibility and practical challenges associated with deploying AI models for real-time cardiovascular condition monitoring in real-world settings.

The included studies generally lacked comprehensive details regarding the demographic information of participants whose data were collected and analyzed for cardiovascular condition monitoring. Notably, as can be seen in Multimedia Appendix 3, 7 out of the 19 included studies did not provide any participant

XSL•FO
RenderX

demographic information [31,33,34,36,39,43,47]. A highly variable number of participants was reported in the 12 studies that disclosed participant counts, ranging from as few as 2 participants [38] to as many as 350 participants [46]. For studies that reported sex distribution, the balance varied. Some studies included more females [30,32,46], while others reported more males [40,44,45]. Age ranges also varied significantly across studies, with the youngest participants reporting having a mean age of 33.2 years [30] and the oldest having a mean age of 72.1 years [45].

Depending on the study design, some studies included only those participants with CVD [31,33-37,40,41,43-47], others involved a mixed population of both healthy individuals and those with CVD [32,38,42,48], and 1 study included only healthy participants [30]. With the exception of Colombage et al [42], who monitored participants with both heart failure and diabetes, all other studies focused exclusively on monitoring 1 or more cardiovascular conditions without accounting for comorbidities beyond CVDs.

Characteristics of Study Settings

Unexpectedly, with the exception of a few studies [32,43-45], which reported study durations of 1, 2, 4, and 16 weeks, the other studies involved data collection lasting only for 1 day [33,46] or a single session [35,40,48]. In addition, while 3 studies were conducted in home settings [30,32,44], all other studies took place in hospital or laboratory environments.

As outlined in Multimedia Appendix 3, in 84.2% (16/19) of the studies, the cardiovascular conditions under monitoring predominantly involved the detection of various types of cardiac arrhythmias, with a primary focus on atrial fibrillation (AF) [30-36,38,41,43-48]. Among these, 2 studies additionally measured the AF burden [32,44], and 1 study aimed to predict AF by detecting early warnings or the onset of AF [46]. One study concentrated on the measurement of left ventricular ejection fraction [40]. In addition, 2 studies focused on detecting heart disease [37] and heart failure [42], while 1 study investigated the prediction of cardiac arrest [39].

Characteristics of Wearable Devices

Depending on the data modalities required for AI-driven cardiovascular condition monitoring, primarily ECG data, a variety of wearable devices were used in the included studies. As outlined in Multimedia Appendix 5, the studies either developed custom hardware sensors or used commercially available wearable devices, such as Polar [30], Samsung [32], Xiaomi [42], Verily [44], and Apple [45] smartwatches. Typically, studies that collected data over extended periods (at least 1 week) relied on commercial smartwatches suitable for everyday use, whereas those conducted in controlled laboratory settings used custom-built hardware wearable sensors [33-40,48].

Seven out of 19 (36.8%) studies used only ECG signals [31,33,34,36,43,46,48], while another 7 (36.8%) studies incorporated ECG signals along with additional physiological or motion signals, such as PPG, acceleration, blood pressure, galvanic skin response, skin temperature, and oxygen saturation [32,39-41,44,45,47]. Other studies exclusively used non-ECG signals, such as PPG [35], heart rate, skin temperature, and acceleration [37], or electrical signals from skin-muscle interfaces [38]. The data collection frequency ranged from every hour [42] to 1200 Hz [33]. Either raw signals or features extracted from signals were input to AI models for analysis.

Of the 19 included studies, 8 (42.1%) deployed AI models directly on wearable devices for data analysis and inference [31,32,35,37,40,44,45,48]. Other studies transferred wearable sensor data to a cloud for AI-based analysis [33,34,39,41-43], while a few used a hybrid approach, deploying AI models on both wearable devices and the cloud [35,44].

Characteristics of AI Algorithms

As outlined in Multimedia Appendix 6, except for 2 studies that performed prediction tasks, one predicting the early warning or onset of AF [46] and another predicting the risk of cardiac arrest [39], all other studies focused on detection. Except for 3 studies using supervised AI models for regression tasks to measure left ventricular ejection fraction [40] and AF burden [32,44], other studies used supervised AI models for classification. These classification tasks varied, including binary classifications (eg, normal vs abnormal cardiovascular conditions) [31,32,35,37,38,43,45] and categorical classifications distinguishing between multiple cardiovascular conditions [30,33,34,36,41,42,44,46-48].

Most of the included studies used preexisting machine learning and deep learning models rather than developing novel AI architectures. The machine learning models applied included rule-based classifiers, logistic regression, decision tree, k-nearest neighbor, random forest, gradient-boosting machines, support vector machine (SVM), feed-forward neural networks, and hidden Markov model [30,32,36,37,39,42,47,48]. The deep learning models primarily comprised low-complexity 1D or 2D Convolutional Neural Networks (CNNs) [31,33-35,38,40,43,45,46], with a few studies incorporating architectures such as residual layers [44] and attention mechanisms [41]. In machine learning models, feature extraction is a separate step where meaningful characteristics are manually engineered from raw wearable data before being input into the model for analysis. In contrast, deep learning models, such as CNNs, take raw data directly as input. These models automatically learn and extract relevant features through their convolutional layers during training, eliminating the need for manual feature engineering. However, deep learning models are typically more complex, with higher computational demands and longer inference times, which is a key consideration for real-time cardiovascular monitoring.

The annotation of wearable sensor data for supervised AI model development was predominantly performed by cardiologists in most studies. However, some studies used public datasets, such as the MIT-BIH Arrhythmia Database [49], for training AI models, which were subsequently tested on data collected from their study participants [30,31,33,37,41,45,47]. Depending on the specific task, a variety of evaluation metrics were used to assess the performance of AI algorithms, with accuracy being the most commonly used.

RenderX

Synthesis of Results

Overview

Research question 1: What are the primary challenges of AI-driven platforms for real-time cardiovascular condition monitoring with wearable devices, and how are these challenges addressed?

Several challenges associated with AI-driven platforms for real-time cardiovascular condition monitoring using wearable devices were identified. This section discusses the identified challenges along with strategies proposed in the reviewed studies that addressed or explored potential solutions to mitigate their impact and improve the performance of cardiovascular condition monitoring.

Latency in Decision-Making

A significant limitation of deploying AI-driven platforms for real-time cardiovascular monitoring is the delay in making inferences about cardiovascular conditions. This delay arises from computational latency, or *inference time*, which refers to the time required for machine learning and deep learning models to extract features and analyze data using pretrained algorithms. In addition, some platforms implement near real-time inference, where data analysis occurs intermittently rather than continuously. Near real-time analysis is often used to balance clinical relevance with computational efficiency, reducing battery consumption and minimizing web-based data usage when data transfer is required for cloud-based processing. This is especially critical for wearable devices, as battery depletion leads to data gaps and interrupted monitoring. For example, the platform developed by Zhu et al [32] processes data in 5-minute intervals to address these trade-offs. However, they noted that such intervals are insufficient to capture brief arrhythmic episodes that occur within shorter time frames, presenting a significant limitation.

As outlined in Multimedia Appendix 6, AI inference times varied widely in the included studies, ranging from milliseconds to several seconds, depending on the platform and implementation. The fastest reported inference time was 100 milliseconds [46], followed by times under a second [30,31,47], 2 seconds [39], less than 5 seconds [33], and under 6 seconds [48]. Inference frequencies, which often correspond to the size of data window lengths, also differed significantly in the included studies. These include processing every second [30,47], every 5 seconds [45], and every 15 seconds [46]. These variations highlight the trade-offs AI platform developers must consider, balancing real-time responsiveness, computational demands, and energy efficiency on wearable and cloud-based platforms.

Motion Artifacts

Motion artifacts are a significant challenge in wearable-based cardiovascular monitoring, particularly for ECG and PPG-based platforms, as they introduce noise that disrupts the detection of true physiological signals. Commonly caused by user movements or improper sensor-skin contact during everyday activities or dynamic conditions such as exercise, these artifacts degrade the signal-to-noise ratio and often overlap with the frequency range of cardiac signals [32]. This overlap complicates the differentiation between true heart rhythms and noise, compromising accurate rhythm detection and increasing the likelihood of missed detections. In addition, preprocessing to filter motion artifacts and noise introduces further latencies, particularly during periods of high physical activity when signal corruption is prevalent.

Hu et al [47] addressed motion artifacts by integrating accelerometer data to classify user activity and differentiate artifacts from true ECG signals. Ye et al [31] optimized motion artifact management by reconstructing multicycle ECG segments to retain correlation features. In the platform developed by Nguyen et al [35], motion artifacts were addressed through a hybrid deep neural network, where a 1D CNN filtered out low-quality PPG signals caused by motion or ambient light interference, ensuring that only reliable data were forwarded to a 2D CNN for the primary task of AF detection.

Participant Compliance

Adherence and participant compliance remain critical challenges in wearable-based cardiovascular monitoring. Participants often face difficulties consistently recharging the device on time, wearing it, and maintaining proper sensor-skin contact, which is essential for obtaining reliable PPG and ECG data. While features such as battery recharge reminders and sensor contact monitors can help notify users of low battery or improper device wear, compliance rates have shown significant variability [32]. Notifications must also be limited to prevent overwhelming participants, which can sometimes delay necessary corrections. In addition, adherence variability has been linked to demographic differences and individual behaviors, underscoring the importance of developing personalized notification systems to improve compliance [32].

Poh et al [44] highlighted participant compliance, reporting a median device wear time of 18.3 hours daily. Compliance was supported by automated notifications prompting users to perform ECG acquisitions when AF was detected through continuous PPG. These notifications encouraged consistent use and improved data quality for continuous monitoring in real-world ambulatory environments.

Internet and Bluetooth Connection

Maintaining reliable internet and Bluetooth connections is a significant challenge for wearable-based monitoring systems, especially for platforms requiring data transfer to the cloud for AI-based analysis or to a base device, such as a smartphone or computer, acting as a hub [30]. Interruptions or instability in these connections can lead to delays, data loss, or incomplete uploads, compromising the system's effectiveness and accuracy.

Battery Life

Battery life is a critical challenge in wearable-based monitoring, as the need for frequent charging directly impacts usability and participant adherence [32]. While notifications can remind users to recharge devices, particularly to ensure the collection of overnight data, maintaining consistent compliance remains difficult. Participants often forget or neglect to charge or wear

XSL•FO
RenderX

the device regularly, resulting in data gaps that undermine the system's ability to provide effective continuous monitoring.

To enhance battery life, the wearable sensor node developed by Hu et al [47] integrated energy-efficient hardware components and low-power Bluetooth communication modules, enabling 24-hour monitoring with a 500-mAh battery. Reliable data transmission was ensured through Bluetooth Low Energy to a smartphone gateway, where AI-based analyses were conducted. Ye et al [31] addressed battery limitations in their wearable cardiac arrhythmia–monitoring processor using an ultra–low-power design.

Research question 2: How are AI algorithms developed to support robust cardiovascular condition monitoring?

Robustness, in the context of AI for cardiovascular monitoring, refers to an algorithm's ability to sustain performance under variable, imperfect, or unforeseen conditions. Balendran et al [50] conducted a scoping review to explore robustness concepts in the application of machine learning models in health care. They identified 8 key robustness concepts, which are detailed in the following subsections and outlined in Multimedia Appendix 7, highlighting whether they were addressed in the reviewed studies. While all 8 concepts are considered in this section, the eighth concept is not included in Multimedia Appendix 7, as none of the included studies addressed it.

Input Perturbations and Alterations

Perturbations such as noise in data collected from wearable devices (eg, ECG and PPG) are often caused by factors such as motion artifacts from body movements. These alterations were addressed in the methodologies of the reviewed studies, including applying signal-processing techniques such as filtering, using acceleration data to compensate for motion, or analyzing ECG and PPG signals only when motion artifacts were absent. However, the extent to which the reviewed studies addressed these artifacts was limited to the methodology level, without comprehensively validating their platforms against the full range of alterations that can occur continuously in everyday life.

Missing Data

Missing input data, such as robustness to random and nonrandom data missingness, is a critical challenge in AI-driven platforms relying on wearable devices. Missing data frequently occurs due to various reasons, including participants not wearing the devices, devices being out of charge, or lack of internet or Bluetooth connectivity [51,52]. However, the reviewed studies did not address this robustness concept on their proposed platforms. To minimize missing data, participant adherence must be improved by encouraging consistent wearing, regular charging, and maintaining internet or Bluetooth connectivity for wearable devices. In addition, when missing data occur, imputation strategies [53] should be used to mitigate their negative impact on the performance of AI algorithms [54].

Label Noise

Label noise refers to the uncertainty or inaccuracies in the labels used to train AI models, such as inconsistencies arising from differing expert opinions [55]. Some of the reviewed studies used publicly available datasets to train their AI models and then applied these trained models for cardiovascular condition monitoring on their recruited participants. However, these studies failed to examine label noise caused by discrepancies between the public datasets and the participant-collected data. For example, Pramukantoro and Gofuku [30] trained their models on the MIT-BIH dataset [49] collected in a hospital setting and deployed them for monitoring participants in home environments. In addition, while some studies reported annotating their datasets with cardiologists, they did not provide detailed information about the annotation protocols [56], such as interrater agreement among annotators, or analyze how annotation variability impacted dataset quality and AI model performance.

Imbalanced Data

Imbalanced data refers to scenarios where samples from 1 or more classes are significantly underrepresented compared with others [57]. This issue is critical when the minority class represents important events, such as the occurrence of cardiac arrest versus nonoccurrence, or in regression problems, where underrepresented values, such as very low heart rates, are of interest. If left unaddressed, AI models trained on such data are prone to overfitting to the majority class, resulting in the failure to detect or predict crucial cardiac events [58]. While some studies acknowledged and addressed this issue using techniques such as the Synthetic Minority Oversampling Technique or weighted loss functions favoring minority classes [30-32,42,47], the majority of the included studies failed to discuss or mitigate this challenge, limiting the robustness of their models. Recent advancements such as contrastive learning [59] and in-context learning [60] offer promising avenues for improving model performance under imbalanced conditions by leveraging richer representations and context-aware adaptation.

In the context of imbalanced datasets, reliance on accuracy alone can be misleading, as it may reflect performance on the majority class while obscuring poor classification of the minority class. Metrics more appropriate for imbalanced scenarios include the area under the precision-recall curve, area under the receiver operating characteristic curve, F_1-score, precision, recall, specificity, true negative rate, and false-negative rate. These metrics provide a more comprehensive assessment of model performance, particularly in high-stakes applications such as cardiovascular monitoring, where failure to identify rare but critical conditions can lead to serious consequences.

Feature Selection

Using feature selection techniques on features extracted from wearable data allows models to focus on the most significant and relevant features for inference in cardiovascular conditions [61]. Selecting the most important features and removing redundant ones enhance model generalizability and reduce overfitting. In addition, reducing the number of features helps avoid the curse of dimensionality, making AI pipelines lighter and more efficient for real-time inference. Among the reviewed studies, none explicitly implemented feature selection techniques; instead, they used either raw sensor data or extracted features directly as input to AI models. One study used attention mechanisms in CNNs [41], enabling the network to focus on

XSL•FO
RenderX

specific portions of input data or features that were more effective at distinguishing between classes.

Model Specification and Learning

It pertains to robustness against variability arising from the selection, parameterization, and training of AI models [62]. A few of the included studies addressed this robustness concept by using various techniques. For instance, some studies used multiple machine learning algorithms or different versions of the same algorithm to enhance platform robustness against model type and parameter variability. Others implemented cross-validation techniques during the development and validation phases of their AI algorithms to ensure stability and reliability in their performance.

External Data and Domain Shift

This robustness concept involves evaluating a model's performance across diverse populations, tasks, and care settings, such as different environments, age groups, sexes, and ethnicities [63,64]. It is linked to bias, as models trained on homogeneous datasets may not generalize well to underrepresented groups [64]. Ensuring robustness helps mitigate bias and improve fairness and reliability in real-world applications. The distribution and diversity of demographics varied across the reviewed studies. Among those that reported demographic information, the data are often imbalanced, introducing bias into AI models that skew inferences toward majority age groups, sexes, ethnicities, or health conditions. It is crucial to include a representative proportion of demographics during the training process, ensuring alignment with the populations where the AI models will be deployed in real-world settings.

Adversarial Attacks

Adversarial attacks involve deliberate alterations to input data to manipulate the predictions of a model [65]. In wearable cardiovascular monitoring, such attacks could subtly distort ECG or PPG signals, leading to misclassification of arrhythmias or missed detection of conditions such as AF. These small changes, invisible to humans, can severely impact model performance. However, none of the reviewed studies addressed or evaluated the potential impact of adversarial attacks on their AI models.

Research question 3: How are AI algorithms and deployment pipelines optimized to enable real-time cardiovascular condition monitoring?

Methods for optimizing AI algorithms and deployment pipelines to enable real-time cardiovascular condition monitoring are examined in this section. Strategies proposed in the reviewed studies, particularly those that explored optimization techniques, are discussed in relation to their effectiveness in improving platform performance, computational efficiency, and real-world applicability.

AI Algorithm Optimization

Zhu et al [32] optimized their AI algorithm for real-time inference through a hybrid decision model that combined machine learning classifiers for clean data with statistical heuristics for noisy data. Advanced signal-preprocessing techniques, including noise filtering and motion artifact detection, enhanced robustness during real-world use. The model processed 5-minute data intervals to balance computational efficiency with accuracy, achieving high AF detection accuracy. Pramukantoro and Gofuku [30] demonstrated the use of lightweight machine learning models, enabling inference times under 1 second for real-time cardiovascular monitoring. Ye et al [31] implemented an event-driven neural network architecture, where data analysis is triggered only when predefined signal thresholds are reached. This selective activation minimizes unnecessary computation, enabling efficient real-time processing. Mary et al [43] used modular linear discriminant analysis for dimensionality reduction in their ECG classification platform. Modular linear discriminant analysis extracted the most relevant shape, texture, and statistical features from ECG signals, reducing dimensionality while retaining critical information. This process enhanced their deep neural network's efficiency and accuracy in real-time analysis.

Backend or Server-Side Processing

Hu et al [47] optimized AI deployment by running arrhythmia classification algorithms on a smartphone gateway rather than a wearable device. The smartphone processed ECG data transmitted via Bluetooth, enabling real-time inference through a layered hidden Markov model, reducing computational demands on the wearable and enhancing overall system efficiency and scalability. Lin et al [33] used a wearable ECG device with Bluetooth Low Energy to transmit real-time data to a smartphone app, which provided immediate classification of ECG signals as normal or abnormal. For detailed analysis, the data were transmitted to a cloud server via Wi-Fi or mobile internet, enabling remote, high-precision classification and storage in a cloud database. This 2-tiered system ensured seamless integration of on-device and cloud-based inference. Nguyen et al [35] used a 1D CNN deployed on the wearable device for quality assessment, which evaluated PPG signals in real time to determine whether they met the required standards for further analysis, while a 2D CNN in the cloud performed the main task of AF detection.

Hardware Efficiency Improvements

Zhu et al [32] designed their system to focus on efficient data handling and real-time inference while minimizing computational and energy demands, enabling seamless monitoring in diverse settings. Ye et al [31] reported that their system achieved a rapid 0.2-second response time and significantly reduced energy consumption to 842 nW in classification mode.

Discussion

Principal Findings

In this scoping review, 19 studies were identified that reported the development or utilization of AI-driven platforms incorporating wearable devices for real-time cardiovascular condition monitoring. These studies leveraged various wearable sensors to acquire multimodal physiological data, which were subsequently processed by AI algorithms to detect or predict cardiovascular events and conditions. Previous reviews have separately demonstrated the feasibility and success of AI-based

XSL•FO
RenderX

[18,20-22,25] wearable [10,12-17,20-22] platforms for cardiovascular monitoring, as well as real-time monitoring [23-25] in general health care applications. Building upon these findings, the current review comprehensively integrates AI, wearable technology, real-time capabilities, and cardiovascular conditions to investigate the state of research in this area. The findings align with earlier literature in supporting the promise of such integrated platforms, while also revealing critical areas that remain underexplored, particularly regarding generalizability, robustness, and real-world deployment.

The included studies were conducted across various countries and study settings, ranging from controlled laboratory environments to real-world clinical and home-based contexts. Participant information varied in completeness, with several studies lacking consistent reporting on age and sex distributions. Most studies focused on detecting AF, suggesting a limited exploration of other cardiovascular conditions. A range of wearable devices was used, including commercial systems and custom-built prototypes, capturing physiological data from modalities such as ECG, PPG, and motion sensors. The AI models used spanned from traditional machine learning techniques, such as SVMs and decision trees, to more complex architectures, such as CNNs equipped with attention mechanisms and hybrid models. While most studies reported favorable performance metrics, such as high accuracy, sensitivity, or specificity, these metrics were not always uniformly provided. Moreover, considerations of robustness were often underrepresented, with only a few studies addressing input noise, missing data, class imbalance, or domain shift through approaches such as data augmentation, weighted loss functions, or external validation. These observations underscore the variability in methodological quality across studies and highlight areas where important limitations and challenges remain to be addressed.

Limitations and Future Recommendations

Platform Validation in Real-World Settings

A wearable sensor platform designed to monitor cardiovascular conditions, particularly those critical enough to risk rehospitalization or death if unmanaged, requires thorough performance evaluation. Furthermore, its validation in real-world settings is essential before being implemented for clinical use with participants. This is especially important when the platform is intended for continuous use in community settings, where it must reliably operate over extended periods. The need for validation becomes even more critical when the platform aims to provide real-time inferences about cardiovascular conditions, as this demands high accuracy, low latency, participant compliance, and reliability under dynamic, real-world conditions. There is a significant gap in the current research literature regarding the validation of proposed platforms in real-world settings, highlighting the need for further studies to assess and improve their performance, reliability, and scalability under practical conditions.

Lack of Evaluation on Real-World Participants

Many studies were excluded during screening because they relied solely on publicly available datasets, such as subsets of the MIT-BIH dataset [49], without recruiting participants for primary data collection. As a result, these evaluations do not assess the platform's usability, comfort, or effectiveness on actual users. For instance, a deep learning model may demonstrate high accuracy for AF detection using benchmark datasets but may not account for variability in signal quality, user behavior, or device adherence observed in real-world participants. Similarly, while custom ECG hardware may perform well in technical terms, it might be unsuitable for continuous wear due to discomfort or practical limitations when tested on real individuals.

Lack of Evaluation in Real-World Environments

Most included studies conducted testing in controlled hospital or laboratory settings, with only a few evaluating their platforms in unsupervised community environments [30,32,44]. However, understanding the effectiveness and usability of AI-driven wearable platforms requires deployment in real-world settings, where participants live independently and are not overseen by researchers or clinicians. Real-world environments introduce critical factors such as motion artifacts, inconsistent device usage, battery constraints, and variable connectivity, all of which affect platform reliability. Importantly, cardiovascular events often occur outside clinical settings [66], reinforcing the need for evaluations that reflect these real-use conditions.

Lack of Platform Usability, Acceptability, and Adherence Validation and Co-Designing

The reviewed studies did not sufficiently evaluate their platforms in terms of usability, acceptability, and adherence from the perspectives of key stakeholders, including patients, caregivers, and clinicians [67,68]. Important factors such as the physical characteristics of the wearable devices (eg, shape, size, and weight), patient adherence to wearing the devices consistently, the frequency and type of alerts (such as cardiac arrest warnings), and the usability of companion smartphone or web apps require co-design with end users to ensure successful deployment and acceptance in real-world settings [69,70]. A major consideration in improving real-world usability is the frequency and reliability of platform-generated alerts, which are closely tied to the robustness of the underlying AI algorithms. High false-positive rates can lead to alert fatigue [71], causing users to lose trust and potentially ignore even critical alarms.

To mitigate these risks, future work should incorporate participatory design approaches and iterative feedback from patients, caregivers, and clinicians [69]. Continuous involvement of stakeholders in the development and postdeployment refinement of platforms can improve usability, foster trust, and increase adherence, thereby supporting successful real-world adoption.

Limitations in the Development and Validation of Real-Time and Robust AI Algorithms

Trade-Offs Between Shallow and Deep Learning Models for Real-Time Cardiovascular Monitoring

Most of the reviewed studies used traditional machine learning models, such as decision trees, SVMs, and lightweight CNNs.

XSL•FO
RenderX

These models were favored due to their lower computational demands and ability to support real-time inference, which is essential for timely cardiovascular condition monitoring. In many cases, shallow models demonstrated comparable performance metrics to deep learning architectures, raising the question of whether increased model complexity is justified. From a deployment perspective, especially on edge devices, simpler models offer advantages in terms of lower latency, reduced power consumption, and ease of integration. Nevertheless, recent advancements in AI research have introduced more sophisticated architectures, such as Transformers [72], which have demonstrated improved performance in analyzing sequential data, such as ECG and PPG signals. These models are capable of capturing long-range temporal dependencies, which can be valuable in detecting subtle patterns in cardiovascular signals. However, their high computational cost often limits their use in real-time or on-device scenarios unless optimization techniques are applied. Approaches such as model pruning, quantization, and knowledge distillation can be used to reduce model size and inference time [73], making these architectures more suitable for deployment in resource-constrained environments.

Edge Versus Cloud Deployment Models for AI-Enabled Cardiovascular Platforms

While edge deployment supports on-device processing with minimal delay, several studies used offloading techniques, sending data to smartphone gateways or cloud servers for analysis [74]. Despite the potential of cloud infrastructure for scalable, low-latency AI deployment, modern cloud-based tools specifically designed for AI, such as Google Cloud Vertex AI, AWS SageMaker, and Azure AI [75], were not used in the reviewed studies. These platforms provide capabilities for efficient training, deployment, and maintenance of AI models, including support for real-time inference and compliance with health care data standards. Their use could significantly enhance the flexibility, performance, and maintainability of AI-enabled cardiovascular monitoring systems. Future studies should consider the trade-offs between edge and cloud deployment models when designing AI-driven platforms. While edge computing ensures privacy and immediate feedback, cloud deployment enables more complex models and centralizes updates and maintenance. Both deployment strategies involve specific considerations around latency, energy consumption, data privacy, and reliability, which must be evaluated based on the target application and environment.

Robustness and Ethical Considerations in AI Algorithms for Cardiovascular Monitoring

The robustness of the included studies was examined under research question 3, based on the 8 robustness dimensions defined by Balendran et al [50]. Input perturbations, such as motion artifacts or physiological noise in ECG and PPG signals, were minimally addressed. Some studies applied basic signal filtering, but few used advanced noise mitigation strategies. Missing data, often resulting from sensor detachment or transmission issues, were rarely discussed. Models that ignore such gaps risk biased outputs. Incorporating imputation methods or continuity-aware algorithms could improve resilience. Data imbalance was common, with normal cardiovascular states vastly outnumbering abnormal ones. Many studies reported only accuracy, which is insufficient for imbalanced datasets. Metrics such as precision, recall, specificity, F_1-score, and area under the precision-recall curve provide a more comprehensive view. External validation was often absent, raising concerns about generalizability and algorithmic bias when models are applied across diverse populations or devices.

Adversarial robustness, although critical, was not explicitly explored. Wearable data can be susceptible to manipulation or distortion. To mitigate such vulnerabilities, techniques such as adversarial training or input preprocessing can be used [76]. Cloud-deployed models were typically supported by encrypted data transfer and Health Insurance Portability and Accountability Act–compliant storage. However, more advanced privacy-preserving strategies, such as federated learning and split learning with differential privacy, offer better protection by avoiding transmission of raw data [77]. These approaches enable collaborative model training across devices, sharing only model parameters or components.

Interpretability was another underaddressed dimension. Machine learning and deep learning models, including CNNs and Transformers, are often treated as black boxes. To promote clinical adoption, interpretability techniques should be applied. Tools such as attention mechanisms [72], Grad-CAM [78], and SHAP [79] can help identify critical signal segments or features contributing to a prediction. This allows clinicians not only to detect cardiovascular conditions but also to understand potential underlying causes, supporting more informed decision-making.

Together, these observations highlight the need for more robust, transparent, and ethically aware AI systems. Addressing these robustness dimensions is essential for advancing AI-driven cardiovascular monitoring platforms that are safe, reliable, and applicable in real-world health care settings.

Other Methodological and Reporting Limitations

Among all cardiovascular conditions requiring real-time monitoring, the included studies addressed only a limited subset, with most focusing on AF detection. Critical conditions, such as stroke, remain unexamined. Many studies also lacked essential methodological details, including complete demographic information [31,33-39,41,43,47], study duration [30,31,34,36-39,41,42,47], and data collection frequency [36,38,39]. These omissions limit the interpretability and reproducibility of findings.

There is also inconsistency in how AI algorithms are applied to wearable data for cardiovascular monitoring. Although continuous data collection and inference are desirable, practical constraints such as battery life, network reliability, and participant adherence often necessitate compromises. To determine appropriate monitoring frequency and system design, collaboration between platform engineers and cardiovascular clinicians is essential, as requirements vary across conditions, such as AF detection, cardiac arrest detection, and early warning applications.

XSL•FO
RenderX

Methodological Limitations and Scope of the Review

This review used a systematic and reproducible approach, guided by a well-established scoping review framework. The search strategy was developed in collaboration with a Library Sciences Expert to ensure comprehensive coverage of relevant literature from the inception of the technology to the present. However, some methodological limitations should be acknowledged. The exclusion of non–English language papers may have led to the omission of relevant studies published in other languages. Gray literature and preprints were also excluded, potentially contributing to selection bias. Although multiple databases were searched, some degree of publication bias or incomplete database coverage cannot be ruled out. In addition, the generalizability of findings may be limited due to the predominant focus on AF in the included studies and the underrepresentation of diverse cardiovascular conditions and populations.

Conclusions

AI-powered platforms integrated with wearable devices show strong potential for transforming real-time cardiovascular condition monitoring in community settings. By leveraging AI algorithms to analyze data from wearable sensors, these systems enable early detection of conditions such as AF and cardiac arrest, allowing timely intervention by clinicians or caregivers. However, most studies reviewed were limited to short-term evaluations in hospital environments, with minimal validation in unsupervised, real-world contexts. Key challenges include inconsistencies in data collection and inference frequency, lack of model robustness evaluation, and limited coverage of ethical considerations such as privacy, interpretability, and algorithmic bias. Few studies addressed robustness dimensions such as resilience to input noise, dataset imbalance, or domain shift, which are critical for safe deployment. Usability and adherence validation across diverse populations remain underexplored, as do issues related to participant compliance, battery constraints, and user-centered design. To advance this field, future research should (1) validate platforms in diverse, community-based settings with long-term use; (2) optimize and test robust AI models under real-world constraints; (3) address usability, acceptability, and co-design with stakeholders; (4) evaluate privacy-preserving techniques and interpretability tools to foster trust; and (5) develop standardized protocols for data collection and model evaluation.

Interdisciplinary collaboration will be essential to enhance the practicality, equity, and reliability of AI-enabled cardiovascular monitoring systems for real-world use.

Acknowledgments

The authors extend their sincere thanks and appreciation to the Natural Sciences and Engineering Research Council of Canada for providing funding for this research. Special gratitude is also due to Zara Hasan and Sahail Barakzi for their invaluable support during the title and abstract screening and full-text phases of this review.

Authors' Contributions

AA and SSK developed the research questions. AA designed the review framework and protocol, building on an initial version conceived by SSK and ML. CC conducted the systematic database search. AA led the review process, including title and abstract screening, full-text review, and data extraction, and also refined the data extraction tables and drafted all manuscript sections. AV contributed to developing the review protocol. AV, DJ, and JK participated in title and abstract screening, full-text review, and data extraction. In addition, they helped prepare the data extraction tables included in the manuscript. All authors reviewed the manuscript.

Abstract

Background: Work engagement is an important determinant of workers' well-being. According to the job demands–resources model, personal resources are one of the key antecedents of work engagement. Enhancing personal resources leads to improved work engagement. Furthermore, reflecting positively on one's achievements at work may enhance personal resources. Hence, there is a need for a simple, self-guided tool such as a smartphone app that can be used by employees to record and reflect on their work accomplishments.

Objective: This study aimed to evaluate the effect of a smartphone-based diary (ie, Work Engagement Diary) that promotes positive reflection in daily working life on work engagement among Japanese workers in a randomized controlled trial.

Methods: Six hundred Japanese workers who met the inclusion criteria were randomly allocated to either the intervention group or the wait-list control group (300 participants each) via a web survey company. Participants in the intervention group kept the Work Engagement Diary for 2 weeks, whereby they were required to set a weekly goal at the beginning of the week and fill in their work achievements at the end of the day. Those in the waitlist control group did not receive any interventions until they completed a follow-up survey. Work engagement was assessed at preintervention (T1), postintervention (T2), and 3 weeks after intervention (T3) in both groups.

Results: A mixed model for repeated measures conditional growth model analysis using intention-to-treat revealed a significant improvement in work engagement for the intervention group compared to the wait-list control group throughout the study period (P=.04). Effect sizes were small in work engagement for T1 versus T2 (Cohen d=0.11 [95% CI −0.06 to 0.28]) and for T1 versus T3 (Cohen d=0.12 [95% CI −0.06 to 0.28]).

Conclusions: This randomized controlled trial demonstrated that our newly developed smartphone-based positive reflection diary at work effectively improved work engagement among Japanese workers. Future research needs to clarify longer-term intervention effects and detailed mechanisms of the intervention effects.

Introduction

Work Engagement

Work engagement is beneficial for employees and organizations alike [1,2] and is associated with work- and health-related positive outcomes. Work engagement refers to employees' strength and optimal functioning and positive work-related states characterized by vigor, dedication, and absorption in their work [3]. Vigor is defined as high levels of energy and mental resilience in one's work. Dedication is a strong involvement in one's work combined with a sense of significance, enthusiasm, and challenge. Absorption is defined as having higher concentration and being happily engrossed in one's work. It is viewed as a psychological state in which time seems to pass quickly and it is difficult to leave work [1]. A recent meta-analysis [4] reported that work engagement was positively related to job performance, job satisfaction, and organizational commitment and negatively related to turnover intention. Furthermore, work engagement as an antecedent of health- and work-related outcomes is positively associated with variables such as job performance and job satisfaction and negatively associated with variables such as work withdrawal behavior and physical and mental ill health [5,6].

Job Demands–Resources Model

According to the job demands–resources (JD-R) model [1,7], job resources foster work engagement in a positive motivational process wherein an increase in job resources leads to an increase in work engagement and positive health and organizational outcomes. On the contrary, job demands cause exhaustion in an energy-sapping process [8,9] wherein an increase in job demands (such as stressors) leads to an increase in burnout and negative health and organizational outcomes. Personal resources (such as positive emotions, vitality, and mental acuity) as antecedents have been included in the extension of the JD-R model and may be directly or indirectly related to work engagement [10-12]. Positive work reflection is considered a personal resource in the JD-R model and plays a key role in enhancing work engagement [4]. Research suggests that when employees reflect on their work achievements and growth, their personal resources increase, leading to higher work engagement [13]. Furthermore, positive reflection helps sustain work engagement—even under high job demand—highlighting its importance in promoting work engagement [14]. Therefore, interventions that focus on increasing personal resources, such as focusing on what workers have achieved rather than what they have not achieved, may improve work engagement.

Positive Reflection

Increasing awareness of one's own achievements at work leads to positive health outcomes among workers [12]. Reflecting positively on one's work, which focuses on achievement at work, leads to a reevaluation of potentially stressful work situations [15]. Positive work reflection refers to thinking about the positive aspects of one's job and includes thoughts about pleasurable events such as successful task performance and supportive work relationships [16]. A recent meta-analysis [17] reported that off-job positive work-related thoughts had a positive relationship with work engagement (ρ=0.493, 95% CI 0.407-0.579). Thus, positive reflection about one's achievement at work during off-job time can lead to improved work engagement. Furthermore, self-monitoring may be helpful for reflecting positively on one's work. Keeping a diary of positive work achievements, including increasing access to positive emotions, and positive work-related thoughts can be a strategy for self-monitoring. According to social cognitive theory, self-monitoring influences people's motivation and behavior by increasing their interest in their actions and their occurrence and effects [18,19].

Smartphone-Based Apps

There are two types of smartphone apps: those that run on a web browser (web apps) and those that run as native apps. In general, native apps are considered to have an advantage over web apps in terms of CPU and memory usage [20]. However, few health-related native apps are supported by evidence [21]. Paganin and Simbula [22] reviewed 31 studies that examined the impact of workplace smartphone-based apps on improving employees' physical health, targeted symptoms (eg, depressive symptoms), and well-being. Of the eight interventions specifically designed to improve worker well-being, only four—namely, Headspace, Hello Mindcare, Viary, and Smartphone Resiliency Training—were strictly native smartphone apps. The other four were intervention programs accessible via web browsers compatible with smartphones. These findings suggest that native smartphone apps explicitly designed to improve worker well-being are limited.

In a meta-analysis of intervention studies designed to improve work engagement among employees published between 2009 and 2017 [23], 15 online (web-based or web apps) intervention studies were included, yielding an effect size of 0.14 (P<.05). Furthermore, while app stores offer numerous health-related apps claiming to improve well-being, only a small proportion of them have undergone rigorous scientific evaluation. According to Lau et al [24], of the 1009 psychosocial wellness and stress management smartphone apps available for self-help, only 21 (2.08%) were supported by peer-reviewed evidence regarding feasibility or effectiveness. Thus, the intervention proposed in the present study represents a significant advancement as it is both a native smartphone app and has undergone scientific validation, which distinguishes it as a robust tool for improving worker well-being.

According to a meta-analysis of work engagement interventions [12], most personal resource-building interventions were delivered in group or face-to-face sessions (eg, [25-27]), which had a significant effect compared to online sessions [22] and the advantage of direct instruction and interaction with others. However, they also have the disadvantage of requiring coordination of time and place and trained staff. One way to overcome these disadvantages is to use smartphone apps. Smartphone apps offer several advantages, such as being easy to start and complete in a short time, being intuitive with minimal explanation, and being ubiquitous without worrying about time and place, offering just‐in‐time interventions [28]. Bartels et al [29] found that mobile technologies are suitable for flexible self-monitoring in everyday life. However, while there are numerous smartphone apps designed to enhance

XSL•FO
RenderX

occupational health, safety, and well-being in workplaces, only a limited number of them have been scientifically evaluated [30]. Therefore, it is worthwhile to conduct an evaluation of the effects of a newly developed smartphone-based app.

Aim

The present study aimed to evaluate the effect of a newly developed smartphone-based positive reflection diary, the Work Engagement Diary (WEDiary), to improve work engagement as a primary outcome among Japanese workers using a randomized controlled design.

Methods

Recruitment

Participants were recruited from those registered with a web survey company (Macromill Inc., Tokyo, Japan). Target participants were workers who met the following four inclusion criteria: (1) aged from 20 to 59 years, (2) had two consecutive days off in a week, (3) were not going to quit or change jobs within the next 3 months, and (4) used iOS 10.0 or later or Android 5.1 or later smartphones. First, candidates who were registered with the web survey company received an email invitation from the survey company that included study information and an informed consent form. Respondents read the research explanation, and those who agreed to participate in the study clicked on the "Agree" button on the webpage to indicate their consent. Subsequently, candidates who met the inclusion criteria and agreed to participate in the study were asked to complete a web-based baseline survey. This survey was continued until the number of participants reached 600. The baseline survey began on October 31, 2019, and ended on November 5, 2019. After completing the baseline survey, participants received an email informing them of their allocation group: the intervention group or the wait-list control group. At the end of the study period, participants received redeemable points from the web survey company that could be used for shopping as a reward for participating in the study.

Sample Size

A sample size of 394 participants per group was calculated, entering α error probability of .05, power (1–β) of 0.80, and small effect size of 0.20 [12,31] using G*Power 3.1 [32]. However, funding constraints led to a sample size of 300 per group.

Trial Design and Randomization

We conducted a two-group parallel-group, nonblinded, randomized controlled trial (RCT). The study protocol was registered at the University Hospital Medical Information Network Clinical Trials Registry (UMIN000038430). After the baseline survey, participants were randomly allocated to either the intervention group or the wait-list control group at a 1:1 ratio at the individual level by the survey company. The survey company was asked to generate the allocation table and register and assign participants. The researchers were not involved in any of the following activities undertaken by the survey company: random allocation sequence generation and implementation and allocation concealment. The log data of the WEDiary were managed by NT, which were subsequently passed on to MT without being processed. In addition, NT did not have access to the questionnaire data at any of the three time points. Therefore, they were unable to link the log data to the questionnaire data at any of these time points. The study protocol was written according to the Consolidated Standards of Reporting Trials checklist [33].

Development of Smartphone-Based App

Overview

We developed a smartphone-based positive reflection diary app (the WEDiary) for both Android and iOS. Figure 1 shows screenshots of the WEDiary. The intervention period was 2 weeks from November 11 to 24, 2019. We determined the intervention and follow-up periods based on a meta-analysis conducted by Vîrgă et al [23] who found a larger effect size for a 2-week intervention (d=0.55, P<.05) compared to those of other durations. The meta-analysis also revealed that follow-ups within 1 month postintervention showed a larger effect size (d=0.34, P<.05) than those conducted at longer intervals. The WEDiary is designed to incorporate a post-work prompt, "Please write about what you were able to do at work today," aimed at fostering positive reflection on daily work activities. Through consistent engagement with this reflective practice, participants are expected to cultivate and accumulate positive emotions over time. According to the Broaden-and-Build theory, positive emotions expand individuals' attention and cognitive flexibility, thereby facilitating the generation of diverse ideas and the development of critical personal resources [34]. However, the transient experience of isolated positive emotions alone is insufficient for resource building; instead, sustained accumulation of such emotions is essential [35,36].

Figure 1. Screenshots of the Work Engagement Diary (WEDiary).

A. Setting a goal, daily achievement, and answering four questions on daily work engagement.

B. Clicking the "Graph" button (dotted square) opens a graph of the daily values.

C. Clicking the "List" button (dotted square) opens the "Daily achievement" screen once a day to upload the data.

On the morning of the first day, participants in the intervention group were required to set a goal for that week by filling in the relevant box in the WEDiary (Figure 1A). At the end of the working day, they filled in "Daily achievement" (serving as a daily reflective diary) and rated the following four questions on daily work engagement, using a 7-point scale ranging from 1 (not at all) to 7 (very well): (1) "I felt energetic at work today (for vigor)," (2) "I felt like going to work (for vigor)," (3) "I was inspired by my work today (for dedication)," and (4) "I am proud of the things I did at work today (for dedication)" (Figure 1). These four questions were adopted to measure daily work engagement based on previous diary studies [10,36,37]. Vîrgă et al.'s [23] meta-analysis of the effects of controlled interventions on work engagement found that the effect size for absorption was small (d=0.21, P<.01) as opposed to those for vigor (d=0.36, P<.01) and dedication (d=0.35, P<.01). Thus, we adopted two items each for "vigor" and "dedication" but none for "absorption." A line graph of the daily values was available when users clicked the button with the graph icon (Figure 1B). The line graph helped participants enhance positive reflections from their visual perspective. On the last day of the 5 working days, they filled in their weekly reflections and goals for the next week in the relevant box. Finally, they pressed the "List" button on the home screen to open the "Daily achievement" screen once a day (Figure 1C) to check their use of the WEDiary and to upload the data to the server. Empirical evidence supporting this notion includes a study employing the experience sampling method, which demonstrated that positive emotional experiences are associated with enhanced hope and increased work engagement [36]. The WEDiary allows users to record, accumulate, visualize, and reinforce these positive emotional experiences. Complementary findings from a meta-analysis [17] highlight the positive association between post-work positive thoughts and work engagement (ρ=0.493, 95% CI 0.407-0.579) as well as between positive reflection and engagement (ρ=0.482, 95% CI 0.390-0.573). Additionally, positive rumination about work was found to significantly contribute to the accumulation of positive emotions (ρ=0.610, 95% CI 0.51-0.709). The WEDiary's ability to graphically track work engagement is aimed to further reinforce the accumulation of positive emotional experiences. However, the act of responding to the prompt "What did you do well at work today?" could potentially introduce stress for some users. To tackle this, the WEDiary emphasizes cultivating a habitual focus on positive recollection rather than limiting reflection to specific daily achievements. The tool encourages users to acknowledge progress even if predetermined goals are not fully attained. Additionally, guidance provided within the WEDiary directs users to concentrate on the positive aspects of their experiences, with the option to discontinue its use at any time. Its comprehensive design aims to support the sustainable enhancement of positive emotional states and work engagement, contributing to long-term personal resource development.

Intervention Group

A few days before starting the program, participants in the intervention group received an email including the URL/QR code of the WEDiary download website/app store and were required to install the app on their smartphones. Furthermore, on the morning of the first day of the intervention period, they received an email to start the program with user IDs and authentication codes for activating the WEDiary. User

XSL•FO
RenderX

registration consisted of three steps. First, participants entered their user IDs, gender, year of birth, and authentication code. Subsequently, they were asked to read and agree with the privacy policy. Finally, they were asked to enter their starting and ending business days for a week. Participants received emails requesting them to download, install, and activate the WEDiary if activation of the WEDiary was not confirmed. Participants in the intervention group received email reminders to use the app every day during the intervention period.

Wait-List Control Group

Participants in the wait-list control group were requested to be as usual until the completion of the survey 3 weeks after the intervention. They could use the WEDiary after the 3-week follow-up survey period had concluded, that is, on December 23, 2019, or later.

Measures

Data Collection

The intervention period was from November 11 to 24, 2019. All participants in both groups were asked to complete web-based self-report surveys thrice to measure the effects of the 2-week intervention. The preintervention survey period was from October 31 to November 5, 2019 (T1); the postintervention survey period after the intervention was from November 25 to December 5, 2019 (T2); and the 3-week follow-up survey period was from December 16 to 22, 2019 (T3). Participants were not allowed to proceed to the next question unless they answered the previous question.

Primary Outcome

As the primary outcome, work engagement was measured using the Japanese version of the Utrecht Work Engagement Scale (UWES-J), which was reported to be reliable and valid [38]. The UWES-J consists of three subscales of three items each (eg, vigor: “At my work, I feel bursting with energy;” dedication: “My job inspires me;” and absorption: “I get carried away when I am working”). Each item was assessed on a 7-point Likert scale ranging from 0 (never) to 6 (always). The scale score was calculated by adding all the scores and dividing them by the number of items, ranging from 0 to 6. A higher UWES-J score indicated a higher degree of work engagement.

Demographic Characteristics

Gender, age, marital status, education, job, employment status, working hours per week during the past month, and years of employment tenure were collected at T1. Only education was collected at T2 because we missed out on collecting it at T1.

Statistical Analysis

Descriptive statistics for participants’ characteristics at T1 were calculated to identify the differences between the intervention and wait-list control groups. *T*-tests were conducted for continuous variables such as age, working hours per week, and years of employment tenure. χ^2 tests were conducted for categorical variables such as gender, marital status, education, and job. The mean scores and SDs of work engagement at the three time points were calculated.

We conducted intention-to-treat (ITT) and per-protocol analyses (not adjusted) to evaluate the effect of the WEDiary using a mixed model for repeated measures conditional growth model analyses with unstructured covariance and full information maximum likelihood estimation for the data with missing values, respectively. A group (intervention and wait-list control)×time (T1, T2, and T3) interaction was analyzed as an indicator of the intervention effect. Since some participants did not consistently use the WEDiary at the three time points, only those who used it every working day during the intervention period (2 weeks), excluding weekends, and responded to all three surveys were analyzed for per-protocol analysis. In addition, a mixed model for repeated measures conditional growth model analysis was conducted for subgroup analyses, dividing each of the following into two groups: work engagement, age, and working hours (divided into two groups based on their median values); gender (male/female); educational background (university graduate or higher/high school graduate or lower); white-collar/non-white-collar; and employment status (regular employees/nonregular employees).

The effect sizes (95% CIs) were calculated using Cohen *d* only among the participants for per-protocol analysis, although the effect sizes may be biased due to dropouts. Values of 0.2, 0.5, and 0.8 are generally interpreted as small, medium, and large effects, respectively [39].

To evaluate the process evaluation, the number and percentage of those who installed the WEDiary and active users of the WEDiary were calculated. Active users were defined as those who clicked the “List” button to upload the diary data, such as “Daily achievement,” and rated the four questions on daily work engagement. However, those who clicked the “List” button without uploading the diary data or did not rate the four questions were excluded.

To evaluate the trajectories of the four questions in the WEDiary for 10 days (excluding weekends), a mixed model analysis was conducted using the total score of the four questions as the dependent variable and time as the independent variable.

Two-tailed test with a *P* value set to .05 was used in all statistical analyses. All statistical analyses were performed using the Statistical Package for Social Sciences for Mac version 27 (IBM Corp., Armonk, NY, USA).

Ethical Considerations

This study was reviewed and approved by the Research Ethics Review Board of the Faculty of Policy Management and the Faculty of Environment and Information Studies at Keio University (approval no.: 265), in accordance with the Declaration of Helsinki and relevant ethical guidelines. All participants were provided with detailed information about the study on a designated web page, including its purpose, procedures, potential benefits, and their rights. Informed consent was obtained electronically from those who agreed to participate. Participation was entirely voluntary, and participants were free to withdraw from the study at any time without penalty. To ensure privacy and confidentiality, all questionnaire data were collected by a survey company, anonymized (decoded), and subsequently provided to the researchers. Personally identifiable

XSL•FO
RenderX

information was retained solely by the survey company and was not accessible to the research team. Participants had the opportunity to benefit directly, as the intervention had the potential to improve work engagement. In addition, participants received a reward of points equivalent to 1000 yen (approximately US $9 at the time of the study), which could be used for shopping upon completion of the study.

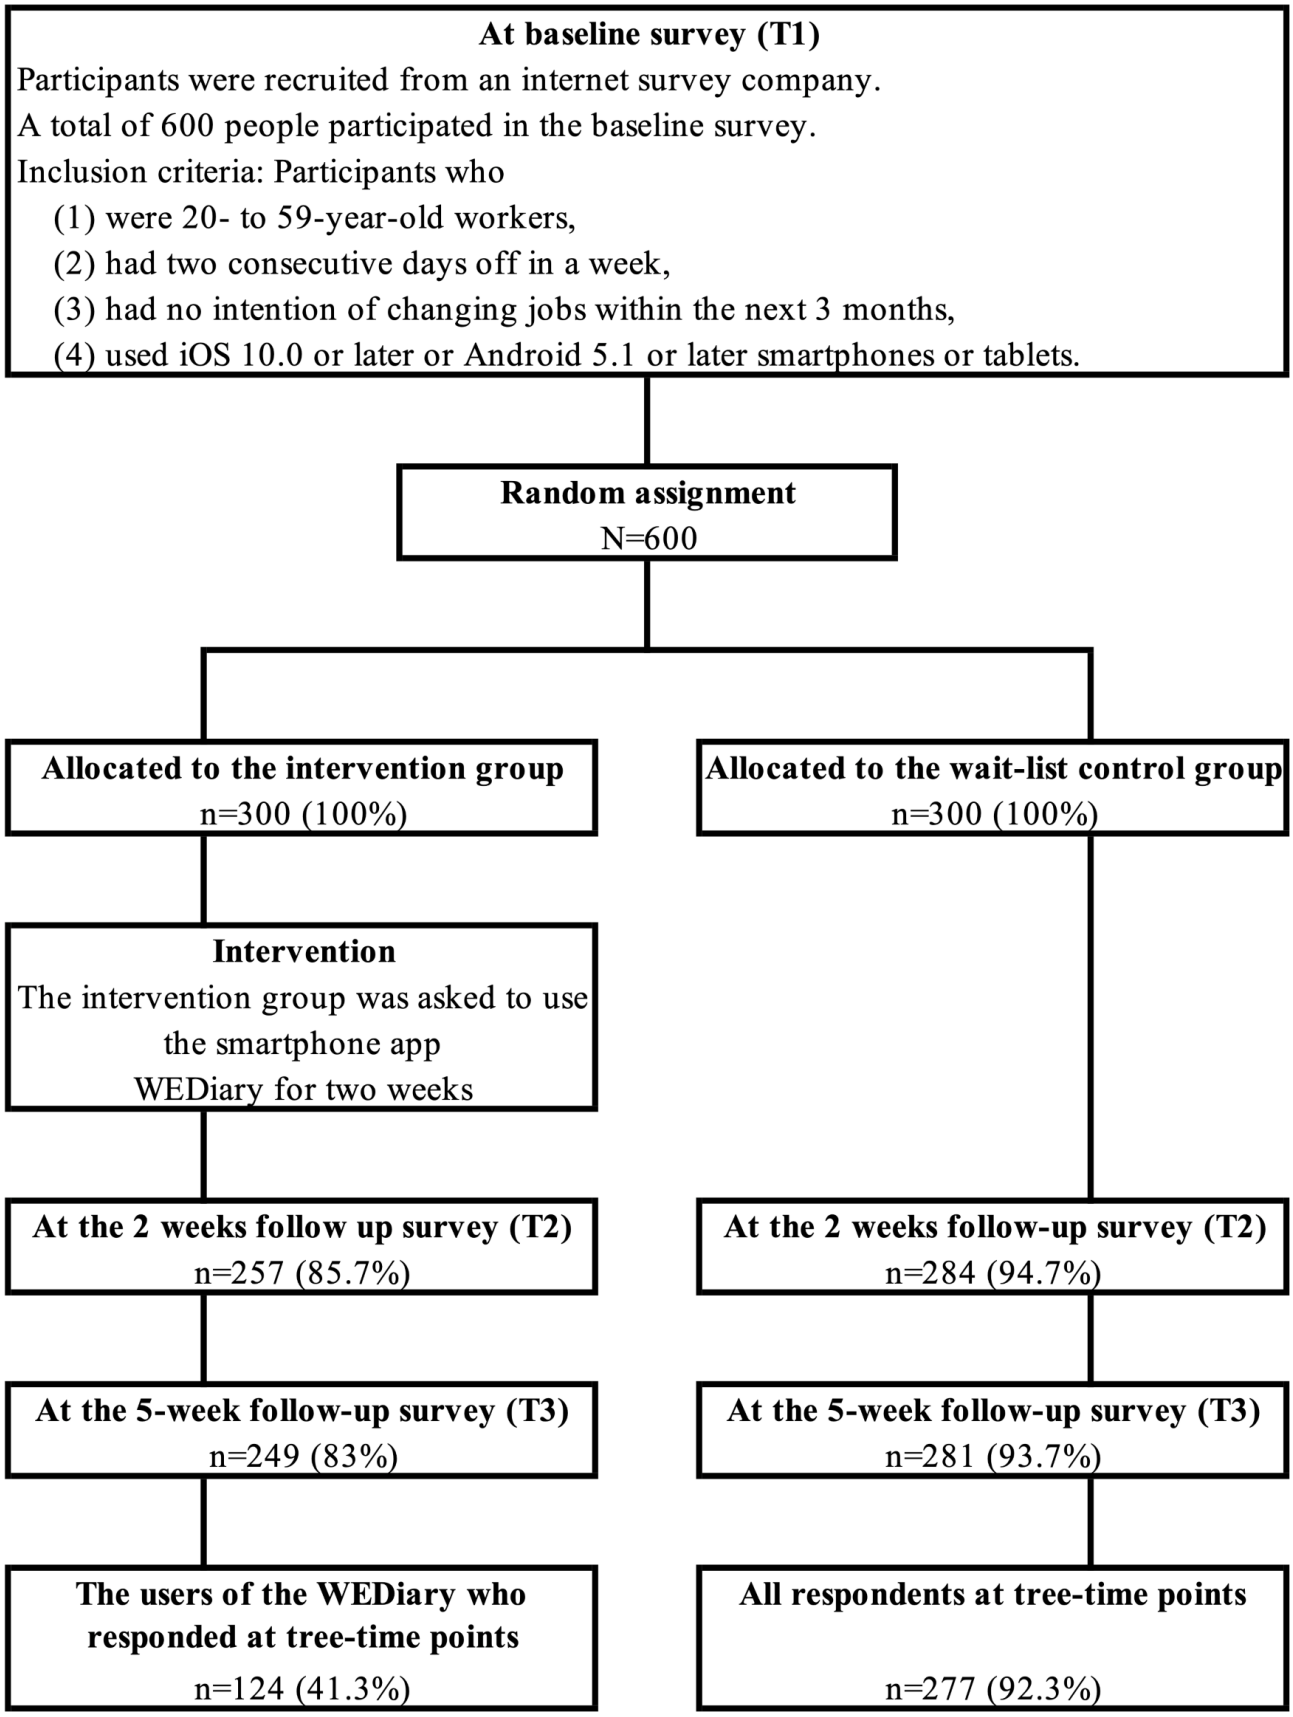
Results

Participants, Randomization, and Attrition

Figure 2 presents the flowchart and randomization of the participants. After the baseline survey, 600 participants were randomly allocated to either the intervention group or the wait-list control group (300 participants per group). After the 2-week intervention period, participants answered the questionnaires again at T2 and at T3. The number of respondents in the intervention group was 257 (85.7%) at T2 and 249 (83%) at T3, while that in the wait-list control group was 284 (94.7%) at T2 and 281 (93.7%) at T3.

XSL•FO
RenderX

Figure 2. Participant flowchart.



Demographic Characteristics

Table 1 presents participants' demographic characteristics at T1. There were no significant differences in characteristics between the intervention and wait-list control groups, except for education. Most participants were male (the intervention group: 68.3%; the control group: 67%) and married (intervention group: 62%; control group: 65.7%). Education was significantly

XSL•FO
RenderX

different between the intervention and wait-list control groups (P<.001). More participants in the intervention group, as opposed to the wait-list control group, had completed high school or less (19.7% for the intervention group and 15.7% for the control group) and graduate school (8.3% for the intervention group and 7.7% for the control group).

Outcome Mean Scores and SDs

Table 2 shows the means and SDs of the outcome variables at T1, T2, and T3 in the intervention and wait-list control groups. The means (SDs) for the intervention group were 2.6 (1.1) at T1, 2.7 (1.1) at T2, and 2.7 (1.2) at T3. The means (SDs) for the wait-list control group were 2.6 (1.1) at T1, 2.6 (1.1) at T2, and 2.5 (1.2) at T3. The reliability estimated by Cronbach α was .93 at T1, .95 at T2, and .95 at T3 for this study.

Table . Means (SDs) of outcome variables at T1, T2, and T3 in the intervention and wait-list control groups for the whole sample.

	Intervention group		Wait-list control group	
	Participants, n	Mean (SD)	Participants, n	Mean (SD)
T1	300	2.6 (1.1)	300	2.6 (1.1)
T2	257	2.7 (1.1)	284	2.6 (1.1)
T3	249	2.7 (1.2)	281	2.5 (1.2)

Effects of the WEDiary

Intention-to-Treat Analyses

Table 3 shows the estimated effect of the WEDiary on work engagement based on the mixed model analyses for the ITT analyses. There was a significant effect on work engagement between the two groups (t=2.03, P=.04). For the subscales, significant effects on vigor (t=2.30, P=.02) and dedication (t=2.78, P=.01) were found, although no significant difference on absorption (t=0.35, P=.73) was found between the two groups.

Table . Result of mixed model for repeated measures conditional growth model analyses for the whole sample throughout the study period.

	Effect	SE	*df*	*t*	*P* value	95% CI (lower to upper)
Work engagement	0.07	0.03	545	2.03	.04	0.00 to 0.13
Vigor	0.08	0.04	549	2.30	.02	0.01 to 0.16
Dedication	0.11	0.04	546	2.78	.01	0.03 to 0.18
Absorption	0.01	0.04	546	0.35	.73	–0.06 to 0.09

Per-Protocol Analyses

In per-protocol analyses, the number of participants was 124 for the intervention group and 277 for the wait-list control group. A significant effect on work engagement (t=2.61, P=.01) was found between the two groups. For subscales, significant effects on vigor (t=2.32, P=.02) and dedication (t=3.26, P=.001), but not on absorption (t=1.22, P=.22), were found between the two groups (Table 4).

Table . Effect of the Work Engagement Diary (WEDiary) on work engagement between the intervention group using the WEDiary for every working day (n=124) and the wait-list control group (n=277).

	Effect	SE	*df*	*t*	*P* value	95% CI (lower to upper)
Work engagement	0.11	0.04	399	2.61	.01	0.03 to 0.19
Vigor	0.11	0.05	399	2.32	.02	0.02 to 0.20
Dedication	0.15	0.05	399	3.26	.001	0.06 to 0.24
Absorption	0.06	0.05	399	1.22	.22	–0.04 to 0.16

Subgroup Analyses

A mixed model analysis was conducted on work engagement as the dependent variable, dividing each of the following into two groups: work engagement, gender, age, working hours, educational background, white-collar/non-white-collar, and employment status. The results showed that work engagement significantly improved among females, university graduates or higher, white-collar workers, and regular employees (t=2.85, P=.005; t=2.37, P=.02; t=2.37, P=.02; t=2.37, P=.02, respectively).

Effect Size

The effect size was small at each time point (T1 vs T2 and T1 vs T3; Table 5). The number of questionnaire respondents at both T1 and T2 was 257 for the intervention group and 284 for the wait-list control group, respectively, whereas that at both T1 and T3 was 249 for the intervention group and 281 for the wait-list control group, respectively.

XSL•FO
RenderX

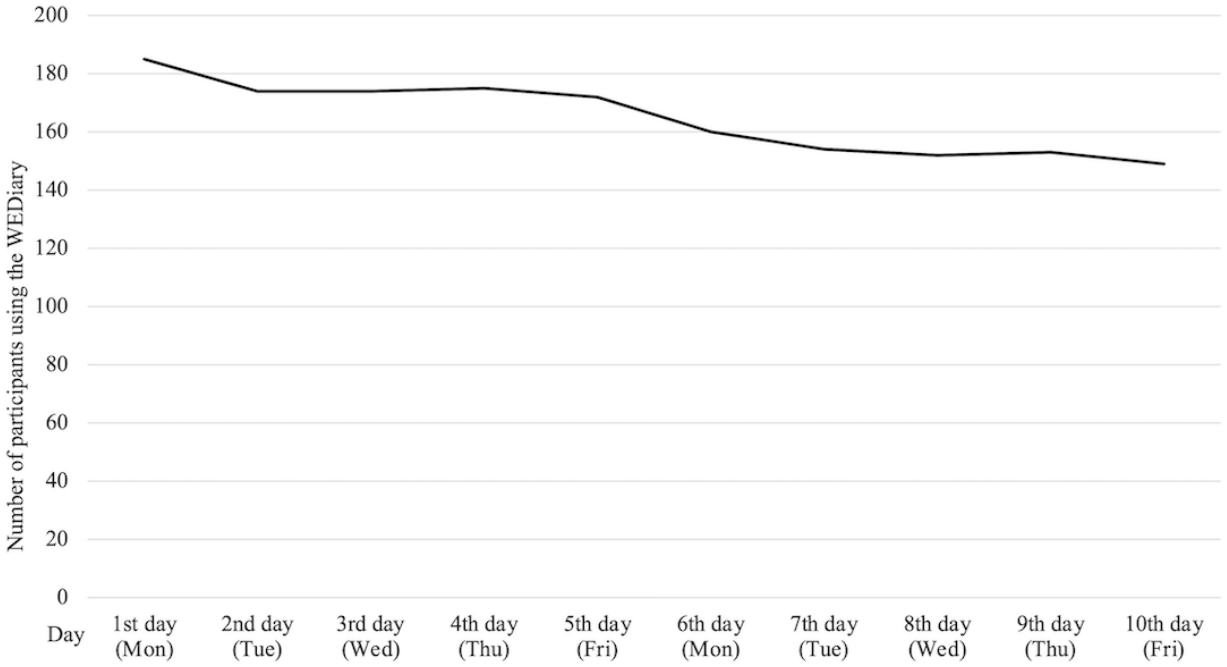
Table . The effect sizes of the Work Engagement Diary (WEDiary).

	T1 versus T2	T1 versus T3
	Cohen *d* (95% CI [lower to upper])	Cohen *d* (95% CI [lower to upper])
Work engagement	0.11 (−0.06 to 0.28)	0.12 (−0.06 to 0.28)
Vigor	0.06 (−0.11 to 0.23)	0.14 (−0.03 to 0.31)
Dedication	0.16 (−0.02 to 0.32)	0.17 (−0.002 to 0.34)
Absorption	0.06 (−0.11 to 0.23)	0.01 (−0.16 to 0.18)

Process Evaluation

Of the 241 (80.3%) participants in the intervention group (n=300) who installed the WEDiary on their smartphones, 191 (63.7%) used it at least once. The number of daily users gradually decreased during the intervention period. The first day of the intervention period had 185 users (61.7%), which was the highest number. In contrast, the number of users on the last day of the intervention period was 149 (49.7%), which was the lowest (Figure 3).

Figure 3. The number of daily WEDiary users.



Trajectories of the Four WEDiary Questions

The total scores of the four questions included in the WEDiary were analyzed using a mixed model (linear regression model), with the total score as the dependent variable and the time point as the independent variable. The intercept (mean value) at the 10 time points was 3.58, and the slope was 0.035 (P<.01), showing a significant increase over time. Each of the four items also had a significant positive slope; however, the slope parameters were small.

Discussion

Effect on Work Engagement

The present study showed that our newly developed smartphone-based positive diary app for enhancing work engagement (WEDiary) among Japanese workers had a significantly favorable effect on work engagement in the intervention group compared to the wait-list control group during the study period. Thus, the WEDiary was effective in improving work engagement among participants. Subgroup analysis showed that work engagement significantly improved among females, university graduates or higher, white-collar workers, and regular employees. This suggests that providing the WEDiary to specific target groups is effective. Females tend to ruminate more than males in response to stress [40]. WEDiary may have guided female participants toward positive rumination (ie, positive reflection). This result can also be explained by the Broaden-and-Build theory, which posits that positive emotions expand individuals' attention and cognitive flexibility, thereby facilitating the generation of diverse ideas and the development of critical personal resources [34]. Participants with a university degree or higher are likely to be self-regulated learners and tend to be highly capable of utilizing self-efficacy [41]. As a result of using WEDiary and enhancing self-efficacy as a personal resource, work engagement may have increased. The JD-R model is a valid theoretical framework regardless of job type; however, the importance of specific demands and resources

XSL•FO
RenderX

may vary depending on the job type [42]. In this study, in terms of enhancing personal resources, white-collar workers may have benefited more from using WEDiary compared to non-white-collar workers. Future research should examine job types rather than the two categories of white-collar and non-white-collar workers to potentially refine the WEDiary. Furthermore, in the JD-R model, nonregular employees may represent a vulnerable group with fewer job resources [43], while regular employees, who typically possess relatively higher job resources, may experience greater enhancement of personal resources through using WEDiary. Thus, the WEDiary, which focuses on one's strengths and positive experiences at work, is likely to be particularly effective for females with a high tendency to ruminate, highly educated individuals with self-control, white-collar workers, and regular employees possessing high job resources.

Effect on Vigor and Dedication

The WEDiary might have facilitated participants to gain a greater sense of achievement, such as through "Daily achievement" (serving as a daily reflective diary) or the visualized line graph, leading to enhanced work engagement. Participants set a weekly goal at work, filled in one daily achievement at work, and answered four questions about work engagement. A text box was provided to indicate daily achievement in one short sentence. Answering the four questions about work engagement and the text input of what was accomplished provided an opportunity to reflect on the day's work. Through this process, participants may gain a greater sense of achievement at work, leading to improved work engagement [17]. In other words, this process may enhance the levels of energy and mental resilience in one's work (vigor) and strong involvement in one's work combined with a sense of significance, enthusiasm, and challenge (dedication).

On the other hand, absorption (ie, having higher concentration, being happily engrossed in one's work, and being in a state of mind in which time seems to pass quickly and in which it is difficult to leave work) may have had delayed effects. The fact that the WEDiary was used at the end of the working day may be why the effect on absorption was not immediately evident. Future research with a longer study period than that of the current study may have more success in observing the effect on absorption. Continuous use of the WEDiary may improve work engagement and, in the long run, absorption. Another possibility is that the WEDiary may have a low effect on absorption. Prior meta-analyses of studies on work engagement improvement also found absorption to be lower than vigor and dedication [23,44]. It may therefore be necessary to consider an improved version of the WEDiary that takes absorption improvement into account.

Comparison With Prior Work

In comparison to prior interventions focusing on building personal resources, the strength of our study lies in targeting diverse workers (hotel employees [45], caregivers [45]), with work engagement (exhaustion [45,46]) as its outcome. Hence, the generalizability of the WEDiary may be higher compared to prior interventions focusing on building personal resources. Vîrgă et al's [23] meta-analysis on the effectiveness of interventions intended to improve work engagement found a modest but significant overall improvement in work engagement (d=0.21, P<.01), with notable gains in vigor (d=0.36, P<.05) and dedication (d=0.35, P<.05), though absorption showed a smaller effect (d=0.16, P<.05). In addition, it was found that intervention effects peaked within the first month (d=0.34, P<.05) but declined over time, becoming negligible by 6 - 12 months. Interventions of up to 2 weeks (d=0.55, P<.05) or those between 12 and 16 weeks (d=0.46, P<.05) were deemed most effective, while very short or extended interventions were less impactful. The WEDiary, a smartphone app based on positive psychology, aims to improve work engagement through a 2-week intervention and a 3-week follow-up, suggesting potential effectiveness based on these findings.

Time of Appearance of the Effect

Effect sizes were relatively larger for T1 versus T3 than for T1 versus T2 (except for absorption). This could be a delayed effect, which may be a sleeper effect [47]. It occurs when an intervention does not have an immediate effect and requires incubation time to produce its effect [47]. It may take time for work engagement to improve through the use of the WEDiary. Regarding previous studies on improving work engagement by focusing on personal resources, those with an intervention period of 30 days [48] and 8 weeks [49] significantly improved work engagement at postintervention, while those with an intervention period of 2 weeks [25] from baseline to follow-up survey and half a day [50] from baseline to 1-month follow-up showed no statistically significant effects. On the contrary, a meta-analysis of intervention studies aimed at improving work engagement [23] reported that the effect size for a 2-week intervention period was relatively high at d=0.55 (P<.05) compared to other intervention periods and that the effect size for a follow-up period of less than 1 month was relatively higher (d=0.034, P<.05) than those for other periods (1 - 3 months: d=0.28; 3 - 6 months: d=0.07; 6 - 12 months: d=0.03; all P<.05). The strength of the present study is that the WEDiary with a 2-week intervention period showed a sustained significant effect throughout the study period of 4 weeks. The intervention and follow-up periods of the WEDiary may have been suitable for evaluating the effect. However, while the intervention aimed at encouraging work engagement improved two of the three subdimensions of work engagement (ie, vigor and dedication), improvements in the third subdimension (ie, absorption) remained limited. This result is in line with recent research that has reported a similar trend. There are several possible reasons for the limited improvement observed in absorption, including work environment characteristics [51] and individual intrinsic motivation [52]. Therefore, it is suggested that the approach to improving immersion should be based not only on psychological intervention but also on a thorough review of work design and the interests and concerns of individual employees.

Small Effect Size

Unfortunately, the effect size was small in this study. However, despite this, effect sizes were relatively larger for T1 versus T3 (Cohen d=0.12) than for T1 versus T2 (Cohen d=0.11). This may be because it takes time to accumulate positive emotions. A prior meta-analysis of interventions aimed at improving work

XSL•FO
RenderX

engagement [23] reported effect sizes of *d*=0.14 (95% CI 0.05-0.22) and *d*=0.29 (95% CI 0.16-0.41) for online and face-to-face interventions, respectively. Considering that the WEDiary is a self-learning program with no feedback function and that the intervention period was 2 weeks long, an effect size of 0.11 immediately after the intervention and 0.12 at follow-up is in line with previous studies and suggests the possibility of participants being in the middle of accumulating positive emotions. This could be because the WEDiary usage rate gradually decreased during the intervention period (2 weeks); users who used the app infrequently or not at all may have weakened the effect of the intervention. Allocated interventions such as the RCT have a smaller effect than volunteered interventions [11]. This speculation could be supported by the fact that the intervention effect improved in the per-protocol analyses compared to ITT analyses. In the future, we need to investigate how to enhance the installation and use of an app, such as using push notifications or messages. However, the significance level was set at α=.05 in this study, and there is a possibility that the statistical power (1–β) may be low, necessitating caution when interpreting the results. A low power increases the risk of Type II errors, potentially leading to false-negative conclusions. Additionally, it is essential to assess whether the effect size used in the sample size calculation (Cohen *d*=0.20) was appropriate, particularly when comparing conditions such as face-to-face versus online formats or the presence versus absence of support. An underestimated or overestimated effect size could impact the validity of the findings and the robustness of the statistical conclusions. Increasing sample sizes has recently become a critical concern in online psychological interventions aimed at behavior change. Previous studies have identified several effective strategies for expanding participant pools. Utilizing digital platforms, such as chatbots, has significantly enhanced sample sizes by improving accessibility and user engagement [53]. Additionally, large-scale online recruitment methods, including the use of social media and targeted advertising, have proven effective in reaching diverse populations and increasing the number of participants [54].

User Attrition

Process evaluation clearly showed user attrition. Positive psychology interventions such as the one used in our study, in particular, often have low participation rates and high attrition [11]. In a positive psychology study involving workers similar to those in the present study, attrition may have been due to participants perceiving the required time commitment as burdensome and to the absence of face-to-face interactions, as WEDiary was self-learning [55]. The following solutions to user attrition have been examined: self‐selection [56], participant autonomy [57], and belief [58]. To apply our results to different work settings, the WEDiary with the addition of the above strategies may have the potential to increase the promotion of use. This study did not include a qualitative survey on user experience such as satisfaction. Further detailed qualitative surveys on user experience are needed in the future. This may contribute to future app updates.

Questionnaire Response Rate

The questionnaire response rate was higher in the wait-list control group than in the intervention group (85.7% vs 94.7% at T2, 83% vs 93.7% at T3). This may be because the expectation of using the WEDiary in the wait-list control group may have encouraged the participants to respond to the questionnaires. In this study, data from the wait-list control group were not collected. However, including a plan to collect and analyze data from the wait-list control group after using the app in such intervention studies may help clarify the mechanisms of improvement in outcomes such as work engagement in more detail.

Limitations

The present study has several limitations. First, the participants were all registered members of the online research company, which requires caution regarding the generalizability of our findings. Second, internet users' socioeconomic and educational status is usually high on average, compared to that of the general population [59,60]. Indeed, participants in the present study had a higher educational status than those completing nationwide paper-and-pencil surveys in Japan [61]. Third, the small sample size compared to the calculated sample size might have lowered statistical power compared to expectations. The sample size of the study was 300 participants per group compared to the estimated number of 394 participants per group needed to detect an effect size of 0.20 for work engagement. Thus, this study had a lower statistical power. Fourth, the low adherence rate to the study protocol may have weakened the effect of this study. Of the 300 participants, 241 (80.3%) installed the app but only 191 (63.7%) used the WEDiary. Previous studies on smartphone-based interventions did not indicate the installation rate because it was required that the smartphone app be installed in advance [62-64]. To evaluate the effects of the intervention, it may be necessary to require participants to download and install the WEDiary prior to the presurvey. Alternatively, we may need to develop strategies to encourage participants to download and install the WEDiary actively. Further research is required to increase the installation rate. Fifth, participants with social desirability or the dropout of nonresponders might cause a biased estimate. Sixth, this study employed a nonblinded RCT design, which may introduce potential bias in both the intervention and wait-list control groups. Seventh, it is possible that work engagement measured using the UWES-J at the three time points correlates with the four questions included in the WEDiary (modified UWES-J). In other words, responding to the UWES-J at T2 and T3 may lead to improving positive emotions in the participants. However, UWES-J items use the present tense to measure the present state, with no items reflecting on the state of only the day. The UWES-J may be unlikely to improve work engagement. Furthermore, of the four WEDiary questions, three include the word "today;" hence, each of these three questions asks for an evaluation of today. Eighth, this study analyzed the positive motivational process of the two processes of the JD-R model. The analysis did not control for factors such as the job demands and job resources of the JD-R model. No control for factors could limit the accurate determination of the effectiveness of the intervention and the potential buffering or mediating effects of these

XSL•FO
RenderX

variables; hence, further research is needed to clarify the mechanisms.

Finally, there are limitations in the generalizability of the results because the present study was conducted for Japanese workers. It is unclear whether similar results can be obtained for non-Japanese workers. Further research is needed for a variety of workers.

Conclusions

This RCT demonstrated that our newly developed smartphone-based positive reflection diary (WEDiary) was effective throughout the three time points in improving work engagement among Japanese workers. Effect sizes were relatively larger for T1 versus T3 than for T1 versus T2. Future research needs to clarify longer-term intervention effects and detailed mechanisms of the intervention effects.

Acknowledgments

This research was funded by a grant from the Japan Productivity Center. The sponsor had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication.

Authors' Contributions

MT, SK, KT, and AS developed the study design and collected data. MT, SK, and AS drafted the manuscript. MT, SK, and DM performed the statistical analyses. NT and HN managed the WEDiary. All authors reviewed and approved the final manuscript.

Conflicts of Interest

The authors declare that this research was funded by a grant from the Japan Productivity Center, to which the co-authors NT and HN belong, which could be construed as a potential conflict of interest. Co-author DM manages Better Options, Inc., which did not fund this research. The remaining authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Abstract

Background: Advances in artificial intelligence technology have raised new possibilities for the effective evaluation of daily dietary intake, but more empirical study is needed for the use of such technologies under realistic meal scenarios. This study developed an automated food recognition technology, which was then integrated into its previous design to improve usability for meal reporting. The newly developed app allowed for the automatic detection and recognition of multiple dishes within a single real-time food image as input. App performance was tested using young adults in authentic dining conditions.

Objective: A 2-group comparative study was conducted to assess app performance using metrics including accuracy, efficiency, and user perception. The experimental group, named the automatic image-based reporting (AIR) group, was compared against a control group using the previous version, named the voice input reporting (VIR) group. Each application is primarily designed to facilitate a distinct method of food intake reporting. AIR users capture and upload images of their selected dishes, supplemented with voice commands where appropriate. VIR users supplement the uploaded image with verbal inputs for food names and attributes.

Methods: The 2 mobile apps were subjected to a head-to-head parallel randomized evaluation. A cohort of 42 young adults aged 20 - 25 years (9 male and 33 female participants) was recruited from a university in Taiwan and randomly assigned to 2 groups, that is, AIR (n=22) and VIR (n=20). Both groups were assessed using the same menu of 17 dishes. Each meal was designed to represent a typical lunch or dinner setting, with 1 staple, 1 main course, and 3 side dishes. All participants used the app on the same type of smartphone, with the interfaces of both using uniform user interactions, icons, and layouts. Analysis of the gathered data focused on assessing reporting accuracy, time efficiency, and user perception.

Results: For the AIR group, 86% (189/220) of dishes were correctly identified, whereas 68% (136/200) of dishes were accurately reported. The AIR group exhibited a significantly higher degree of identification accuracy compared to the VIR group (P<.001). The AIR group also required significantly less time to complete food reporting (P<.001). System usability scale scores showed both apps were perceived as having high usability and learnability (P=.20).

Conclusions: The AIR group outperformed the VIR group concerning accuracy and time efficiency for overall dish reporting within the meal testing scenario. While further technological enhancement may be required, artificial intelligence vision technology integration into existing mobile apps holds promise. Our results provide evidence-based contributions to the integration of automatic image recognition technology into existing apps in terms of user interaction efficacy and overall ease of use. Further empirical work is required, including full-scale randomized controlled trials and assessments of user perception under various conditions.

Introduction

Background

In 2022, the World Health Organization [1,2] classified 2.5 billion adults (aged 18 years and older) as overweight and thus susceptible to chronic diseases associated with obesity. Failure to maintain appropriate nutrition among young people leads to a range of health issues later in life [3,4]. Young people also increasingly integrate smartphones into their daily lives, raising a growing interest in using this technology platform to deliver health-improving behavioral interventions, including healthy eating among young adults [5,6]. Such mobile health (mHealth) interventions are increasingly used to encourage healthy eating behaviors [7-10] and are increasingly popular among young users [11,12]. mHealth technologies already play a significant role in reshaping health care access [13,14] and allow for broad access to scalable and cost-effective solutions [8].

Artificial intelligence (AI)-based services are an emerging trend [15,16], with an increasingly substantial impact on various health care domains, providing enhanced accuracy, improved outcomes, and cost-effectiveness [17-19], and health care professionals have been found to hold favorable views toward AI [20,21]. Machine learning, an increasingly mature AI application, has the potential to revolutionize the mHealth domain [11,14].

Challenges in Dietary Intake Input

An ideal mHealth app should prioritize ease of use, reliability, and long-term engagement [13,22,23]. However, manually entering dietary intake information poses significant usability challenges for mHealth app users [24], potentially resulting in inaccurate or incomplete reporting, and thus undermining the efficacy of managing healthy eating habits [16]. This raises an urgent need to minimize the operational loading of users [25,26], as the ease and effectiveness of food data entry methods have a direct and significant impact on the usability of dietary tracking applications [23]. Recent advancements in computer vision and deep learning show potential for replacing traditional input methods [27,28]. This study integrates automatic image recognition technology [29-31] into an mHealth app, which originally used voice-based inputs, seeking to improve accuracy and time efficiency in meal reporting.

Objectives

This study assesses a parallel 2-group randomized trial designed to evaluate the relative effectiveness of a new automatic image-based reporting (AIR) app compared to the existing voice input reporting (VIR) app [32], in terms of reporting accuracy, time efficiency, and user perception. The key technological components use newly developed AI features to integrate a set of food images representing both single and mixed dishes [31].

Methods

General Overview of the Approach

The original app was designed to aid individuals in improving their dietary habits [33]. The previous iteration included voice inputs to enhance meal reporting, using AI services, specifically Google AI, to transcribe speech into text [32]. Users could use this feature to vocally report food ingredients, portion sizes, cooking methods, and other attributes for individual dishes. While the existing design was shown to be positive in terms of accuracy and was generally well received by users, there were concerns regarding the accuracy and time-consuming nature of completing meal reporting for an entire meal. Furthermore, in authentic dietary intake scenarios, voice reporting during meal consumption was not always convenient. Consequently, we developed the latest version to enhance the existing design.

The iterative development process was rooted in a user-centered design model [34] and included research, ideation, and implementation stages. We reviewed the relevant literature and commercially available apps, along with extensive brainstorming sessions among team members to generate diverse design ideas. AI techniques have been increasingly applied to food identification and nutrition-related applications; thus, one idea raised in the ideation stage was to allow users to take a single photo of an entire meal for analysis using AI-based recognition, rather than to process individual dishes in sequence. The initial automated meal recognition system was developed and validated using our developed AI recognition model, extracting features from convolutional neural networks [31], and tested under a laboratory setting. The results offered relatively high mean average precision for a range of dish types. The newly developed feature allowed users to upload a meal image for automatic recognition using the AI engine located on a remote server. This functionality was then integrated into the previous app version to improve convenience, accuracy, and time efficiency for meal reporting. The previous version, the voice-only reporting app, allowed users to simultaneously use verbal reporting of food names and attributes [32].

App Implementation

The 2 apps were implemented in a 6.8-inch smartphone using the Android (Google, Inc) operating system. The AI server used in our previous research was improved to simultaneously recognize a set of multiple dishes and achieve a relatively high accuracy of food-image recognition under a laboratory setting [31]. Both apps used the Google Speech Cloud service for continuous speech recognition. The developed interfaces included user-friendly design elements, such as large-sized buttons and text, a simple layout, and high-contrast colors. Based on recommended design guidelines [32], the 2 apps shared a common interface design including the placement of buttons, text, and icons. Clear and intuitive visual cues were used to facilitate user interaction.

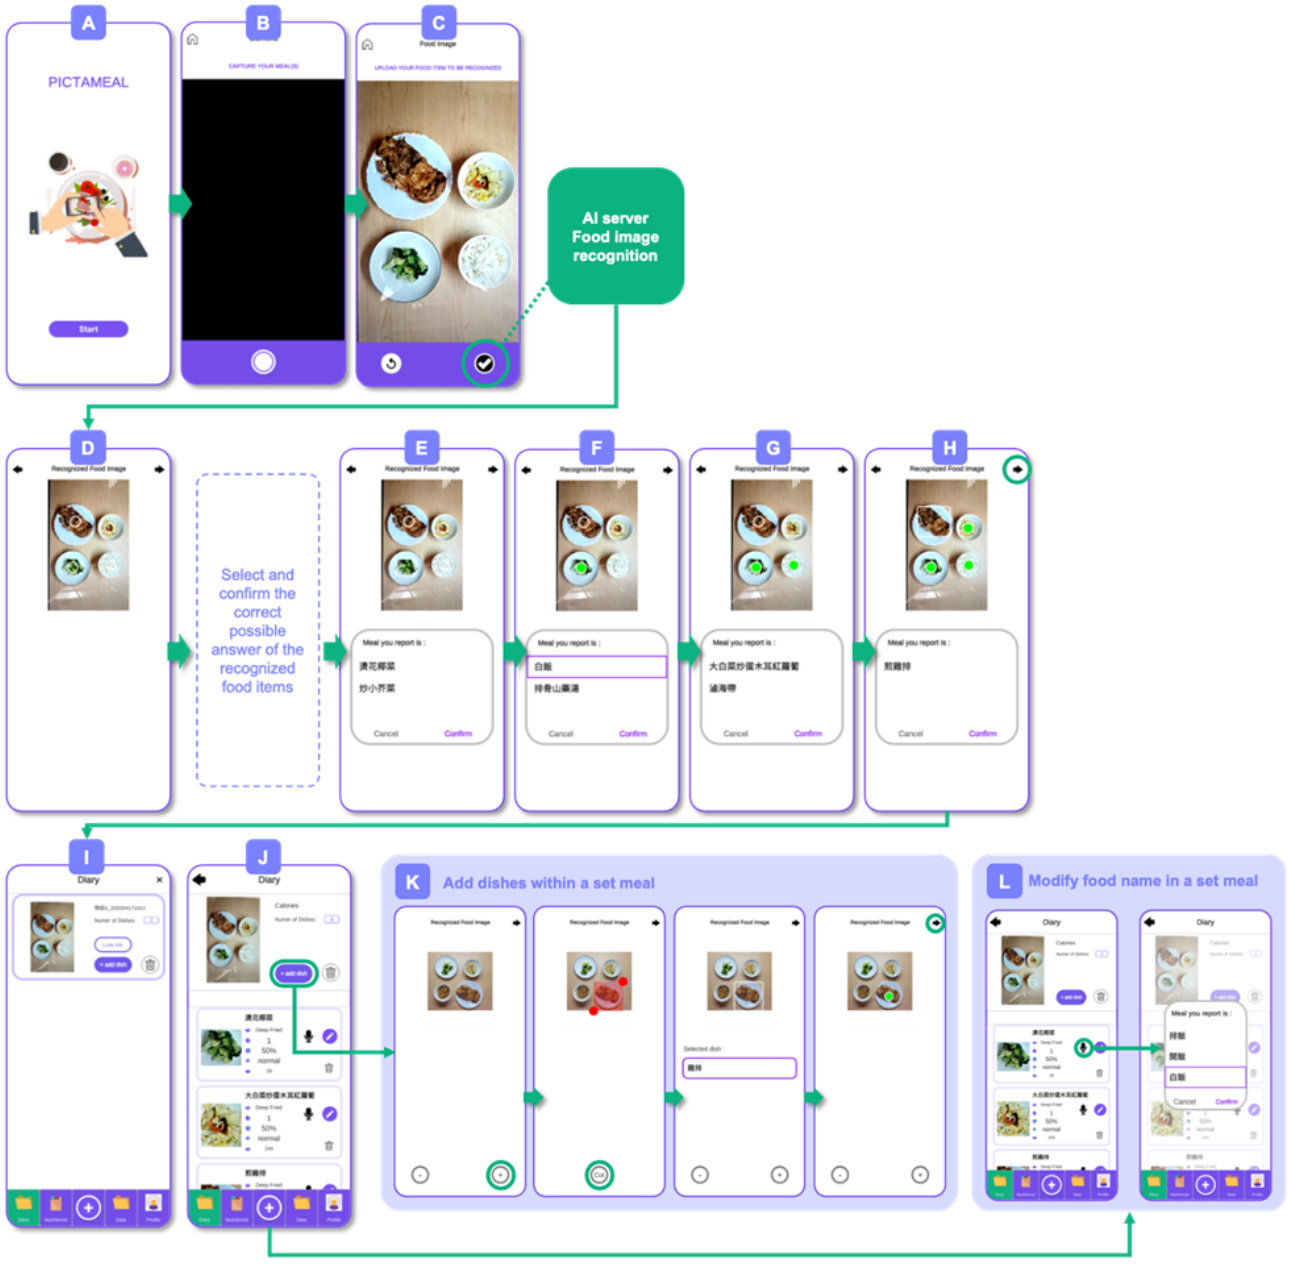
RenderX

App Operation

Overview

Figure 1 summarizes the 4 major stages in user interaction for the AIR design. In the first stage, users take and upload a photo of a meal (Figure 1A-C), followed by modification of the food ingredients and cooking method for each of the dishes and the provision of additional information, for example, portion size (Figure 1I,J). Users reviewed, revised, and confirmed the image, calorie content, and macronutrient information for each dish (Figure 1J,K) and were given the opportunity to add missing dishes (Figure 1J,L).

Figure 1. Workflow of the automatic image-based reporting (AIR) app: the user captures a food image, and the app automatically detects and works to recognize the dish (illustrated here with steamed rice as an example).



About AIR

To activate the app, users click the "start" button (Figure 1A) and then activate the smartphone's built-in camera (Figure 1B). To capture the meal photo, the user clicks the icon in the lower-right corner (Figure 1C) and can retake the photo using the icon on the lower-left. Once confirmed by the user using the upload button (lower-right in Figure 1D), the meal photo is uploaded to the remote AI server for analysis. Analysis results are then sent to the app, with white dots appearing above each dish that was successfully recognized. In Figure 1, four dishes were successfully recognized (Figure 1D). Figures 1E-1H illustrate the steps by which users select the correct dish name.

For each recognized dish, up to 3 possible names with the highest confidence scores are provided (see Figure 1E). The user then selects the correct name. Upon confirmation, the color of the small circle switches from white to green, indicating that the dish entry has been completed (Figure 1E-H).

If the dish item is not recognized, or if the selection provided does not include an appropriate answer, the user resorts to an alternative input method, that is, voice input. To use the voice

XSL•FO
RenderX

input method, the user drags a boundary square to surround a specific dish, then clicks the "voice" button and recites the dish name aloud (Figure 1I-K). For example, Figure 1J shows an unrecognized dish with 1 to 3 possible answers, prompting the user to respond by selecting an option using the "check" button or to return to the previous step using the "undo" button. Once all the dishes are reported, the user proceeds to the Food Diary Page to input related information such as portion size and cooking method (Figure 1J). Once dish reporting is complete, detailed information is provided for the entire meal (Figure 1L top) and for each individual item (Figure 1L bottom), including calorie count, food item name, and food attributes.

About VIR

The VIR process initially follows the procedure depicted in Figure 1A-C. However, rather than uploading the image to the server for automatic recognition (as depicted in Figure 1E-H), users manually manipulate the cursor (depicted as a red square in Figure 1K) to scroll down and adjust the size of the area displaying the dish image. The scrolled image is then stored for later visualization on the subsequent page (Figure 1H). Once the desired dish is identified, the user clicks the microphone icon and records the dish name. Then the user uses the voice input function to report the dish ingredients and cooking method, prompting the system to provide up to 3 options for selection and confirmation by clicking the check button, thereby concluding the reporting process. If none of the supplied answers are correct, the user clicks the microphone icon and repeats the process until the correct answer is determined. Once each dish reporting is finalized, a green circle appears above the dish. Once all dish reporting is complete, the user proceeds to the Food Diary Page to input related food information using the voice reporting process previously discussed.

Ethical Considerations

The study protocol was reviewed by the ethics committee of Chang Gung Memorial Hospital and received institutional review board approval (202101985B0C501). A total of 42 young adults were recruited and provided informed consent. Participants received a small incentive (ie, New Taiwanese $150, roughly US $5) upon completing the study sessions. All data were handled in deidentified form to ensure participant privacy.

Study Design and Participant Recruitment

We conducted a parallel 2-group randomized trial to compare the performance of the AIR app against the VIR app in terms of accuracy, time efficiency, and user perception. Study participant recruitment was conducted through notices placed on bulletin boards in Chang Gung University in Taoyuan City, Taiwan. Registration, schedule arrangement, and collection of background information were conducted through a web-based form. Biographic data were used to allocate participants into the AIR and VIR groups. Self-reported baseline information included gender, age, BMI, experience in nutrition education, use of nutrition-related apps, cooking experience, and experience using mobile phones or tablets. Eligible participants were (1) aged from 20 to 25 years and (2) capable of operating the app on their mobile phones. Participants currently under any form of dietary control, currently engaged in deliberate weight loss, or following a vegetarian diet were excluded. The assessment was conducted in a cafeteria at Chang Gung University.

Dishes for the experiment were selected under the supervision of a senior nutritionist (HYC) and consisted of typical local foods familiar to study participants. Foods were presented in terms of set meals involving 17 food items that were used to represent lunch and dinner. Each set meal contained 5 food items (ie, a staple food; a main course; a dish with 1 ingredient, such as stir-fried broccoli; a dish with 2 ingredients, such as stir-fried egg with tomato; and a dish with 3 ingredients).

Sample Size Estimation

Drawing from our prior experience evaluating the young population [35], mobile app usage within this demographic exhibited nearly perfect accuracy. Consequently, in addition to assessing accuracy, we aimed to explore potential differences in time efficiency when young individuals used the newly designed app. Our previous study of customized dietary recording among young participants [35] found that the mean duration difference for the assessment of a fried pork chop was 0.7464 (2.60 vs 3.34 seconds) with SD=0.93. The sample size of that study provided a statistical power of 80% and a 2-tailed alpha level of 5%, indicating the minimum sample size required was 26 participants each for the AIR and VIR groups.

Randomization

SAS software (SAS Institute) was used to generate randomized lists of equal size with a 1:1 ratio for the 2 studies, with 22 and 20 participants, respectively, assigned to the AIR and VIR groups.

Evaluation Outcomes

Three outcome measures were evaluated to assess the respective performance of the 2 mobile apps. Data were collected automatically from each participant's interaction, including the tapping of function buttons, and each interaction was logged with a timestamp. In addition, all suggested results were recorded, along with the user's subsequent actions.

Accuracy

Accuracy was defined as the degree to which the response provided by the participant during app operation matched the predefined answer. Conversely, an incorrect response occurred if the app output did not match the predefined answer. The accuracy rate for a certain dish, for example, fried rice, was calculated as the overall number of correct responses divided by the total number. Furthermore, following our previous study [32], four error types were defined as follows: (1) "missing cooking method," where the app provided an incorrect answer due to the absence of a cooking method (eg, "stir-fry"); (2) "incorrect cooking method," where the app provided an incorrect answer due to the use of the wrong cooking method; (3) "irrelevant food name," where the incorrect answer was due to a food name not matching the desired one; and (4) "missing food ingredients," defined as when essential food ingredients (eg, rice) were not included in the reported answer.

XSL•FO
RenderX

Task Duration

The operating duration began when the participant started to report a food dish until the reporting task was completed. For the AIR group, having uploaded the image, the task duration was calculated from the time the participant clicked on the dish displayed on the screen to when the participant clicked the "complete" button. For the VIR group, the task duration was calculated from the time the participant clicked the "voice" button to begin recording to when the participant clicked the "complete" button.

Perception

Brooke's system usability scale (SUS) [36] measures participant perception using a questionnaire comprising 10 items on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree). Consistent with the approach outlined by Bangor et al [37], the mean SUS score was used alongside an adjective rating scale in which mean scores of 35.7, 50.9, 71.4, and 85.5, respectively, corresponded to the adjective scales "poor," "ok," "good," and "excellent." There is no fifth adjective category, and scores above 85.5 are generally considered "excellent."

Assessment Procedures

The experiment was conducted by 2 research assistants (DI and MS) who obtained informed consent from all participants. All participants used an identical 6.8-inch Android smartphone, and all trials took place in the same university cafeteria, with individual participant sessions scheduled by appointment. Before the experiment, each participant underwent training by watching an instructional video illustrating how to use the food reporting app. Each participant was allowed to interact with the app for several minutes to ensure familiarity before the trial and was informed that task completion time was included as a performance metric.

Each individual trial included 2 consecutive sessions, each requiring the reporting of a set meal. Each set meal included a staple food, a main course, a dish with 1 ingredient, a dish with 2 ingredients, and a dish with 3 ingredients. Participants were allowed to rest for up to 3 minutes between each test. The total test duration for each participant was approximately 1 hour, and all participants successfully completed the assessment.

Statistical Analysis

Chi-square and *t* tests were applied to examine the baseline characteristics of participants for categorical and continuous variables, respectively. The accuracy between different groups was reported as the proportion of error, calculated as the number of errors or total answer items. The time duration for operating assessment was also used to evaluate efficiency. As the time duration is a continuous variable, a *t* test was used to assess and compare the difference between the 2 groups. This comparison was also applied to dishes with different ingredients. SAS (version 9.1.4) was used to conduct all statistical analyses. In all 2-tailed statistical tests, $P<.05$ was considered statistically significant.

Results

Participant Characteristics

Following the assessment procedures shown in Figure 2, all 42 participants completed the experiment, including 9 male and 33 female participants, with a mean age of 21.21 (SD 1.39) years. As shown in Table 1, 22 and 20 respondents were randomly assigned to the AIR and VIR groups.

[a]AIR: automatic image-based reporting.

[b]VIR: voice input reporting.

[c]Age and BMI data were analyzed with ANOVA.

Overall Accuracy

The AIR and VIR groups achieved respective overall accuracy levels of 86% (189/220) and 68% (136/200) for all 17 food dishes (Table 2). Within the food categories, the AIR group was significantly more accurate than the VIR group for the staple food (P<.05), main course (P<.05), and side dish with 3 ingredients (P<.05). No significant differences were found for the other food categories (ie, side dishes with 1 or 2 ingredients).

[a]AIR: automatic image-based reporting.

[b]VIR: voice input reporting.

[c]N/A: not applicable.

The AIR group achieved accuracy rates exceeding 95% for individual dishes, including stir-fried noodle, steamed rice, fried rice, stir-fried bitter melon, stir-fried bitter melon with carrot, and stir-fried bean sprout with carrot and black fungus. The VIR group achieved accuracy rates exceeding 95% for stir-fried noodle, steamed rice, fried rice, and stir-fried bitter melon with carrot. The lowest accuracy for both groups was for stir-fried broccoli (less than 30% accuracy).

XSL•FO
RenderX

Time Efficiency

Compared to the VIR group, the AIR group required significantly less time for task completion (P<.001), requiring around 2-25 seconds per task, with “steamed rice” being the fastest (mean 2.05, SD 1.43 seconds) and “stir-fried cauliflower with carrot and black fungus” the slowest (mean 24.90, SD 20.60 seconds; Table 3). In the VIR group, the operation time ranged from around 12 to 22 seconds per task, with “stir-fried kelp” being the fastest (mean 12.76, SD 4.12 seconds) and “stir-fried cauliflower with carrot and black fungus” the slowest (mean 21.65, SD 5.25 seconds).

Table . Dish reporting time in the AIR[a] and VIR[b] groups.

Dish	Reporting time (seconds)				*P* value

RenderX

In the 3 food categories, that is, the staple food, main course, and dishes with 1 ingredient, the AIR group required significantly less time than the VIR group. Reporting performance for the 2 food categories did not differ significantly for dishes with 2 or 3 ingredients.

Within the 6 dishes in the categories of staple food and main course, except for "braised pork chop," the other 5 dishes in the AIR required significantly less time than the VIR group. Within the five 1-ingredient dishes, the AIR group required significantly less time to report "stir-fried cauliflower" ($P<.001$) and was faster for "stir-fried bitter melon" ($P<.05$). For dishes with 2 ingredients, the AIR group required significantly less time in "stir-fried egg with tomato" ($P<.05$). For 3 dishes with 3 ingredients, the 2 groups did not reveal significant differences.

SUS and Subjective Perception

Table 4 summarizes the SUS score and its 2 divisions in terms of usability and learnability. Overall scores showed no significant differences between the AIR and VIR groups, but both groups had the overall score at 84.72 and 83, respectively, indicating that the participants in both groups considered the app to be generally easy-to-use and easy-to-learn.

Table . System usability scale of the AIR[a] and VIR[b] groups.

Score[c,d,e]	Assessment score, mean (SD)		*P* value
	AIR (n=22)	VIR (n=20)	
Overall score	84.72 (12.66)	83.00 (11.95)	.66
Usability score	84.43 (11.34)	83.50 (9.30)	.77
Learnability score	85.00 (15.66)	82.50 (16.18)	.61

[a]AIR: automatic image-based reporting.

[b]VIR: voice input reporting.

[c] The questionnaire was presented in Chinese.

[d]Mean scores for system usability with adjective ratings are as follows: 35.7 (poor), 50.9 (ok), 71.4 (good), and 85.5 (excellent).

[e]The questionnaire's Cronbach α for AIR (α=0.91) and VIR (α=0.89) exceeded 0.70, indicating good internal consistency.

Discussion

Principal Findings

While automatic image recognition is increasingly integrated into mobile meal reporting [28,38,39], few comparative studies have examined how this technology creates additional value for existing apps. Unlike previous studies, such as MyDietCam [26] and other existing apps [40], which primarily assessed usability through user-reported opinions or heuristic evaluation methods without using comparative experimental designs, our study used a randomized controlled trial to quantitatively evaluate differences in accuracy and time efficiency between automatic image recognition combined with voice input and voice-only reporting methods. Additional image capture techniques include wearable sensors. For example, Hussain et al [38] developed a system using a wearable camera and convolutional neural networks for food recognition.

In this study, we included VIR as the control condition because it represented the previous version of our app and served as the existing standard for comparison. At the time the study was designed, it was not known how VIR would perform relative to the newly developed AIR version. Our goal was to quantify the added value of the image recognition feature by comparing AIR against a practical and relevant baseline, namely, VIR. The results of this study indicate that combining automatic image and voice recognition is not only feasible but also provides improvements over voice-only versions in terms of accuracy and time efficiency. Our evidence-based findings provide insight for researchers or practitioners developing the next generation of dietary intake reporting applications, with implications as follows.

Accuracy in AIR Versus VIR

Correctly identifying and reporting the dish names and cooking methods is crucial for accurate daily intake management. Table 2 shows that user performance with AIR is significantly more accurate than with VIR due to the integration of automatic image recognition. However, in the AIR group, the dishes that had been correctly recognized remain limited. Furthermore, the recognition accuracy rate of each dish for the 5 food categories fluctuated significantly within the AIR group. Image recognition errors in the trial may have resulted from the AI server failing to adequately recognize the dish or providing incorrect possible answers. In addition, errors could occur when participants were required to use voice input to complete the reporting task when the image recognition did not work properly for some dishes. Failed image recognition could also occur due to poor image quality in the uploaded file, inappropriate lighting, the technical algorithm, food recognition technologies [31,41], limited food datasets [25,26], and the contexts of use [42].

Time Efficiency in AIR Versus VIR

Task completion for the AIR group was significantly faster than for the VIR group, suggesting that the integration of automatic image recognition can effectively reduce reporting time, though such performance improvements were inconsistent across food categories, and further enhancements are needed.

Participant Perception

Overall, SUS results indicated participants found both apps to be easy to use. Regardless of the differences in accuracy rate and time difference achieved by the 2 groups, the app in each of the groups demonstrated high overall SUS scores.

RenderX

Limitations and Future Research

The study design assumed that users would take a photo, upload it, and report the meal in order to complete the meal reporting task. However, there are potentially other reporting scenarios to be considered in future research. For example, users may forget to take a photo before eating, or they may consume meals that are the same as or similar to previous ones. Another scenario could involve users completing the report at a later time. Adding features to the app—such as allowing users to select a previously recorded meal—could enhance flexibility and support these situations. These cases could affect the performance of automatic image recognition and warrant further investigation.

Regarding the sample size, this study was conducted during a period of severe COVID-19 restrictions, and the university was under semilockdown, making it challenging to recruit additional participants. Based on the same parameters used for the original sample size calculation, the final sample of 42 young participants yielded an estimated statistical power of 72%, which is slightly below the conventional threshold of 80%. Even in this context, the primary outcomes—accuracy and time—still showed statistically significant differences. However, these results should be interpreted with caution, as the study may have been underpowered for these measures. To generalize the findings, further confirmation with a larger and more diverse participant sample is recommended. Future research should also include a broader range of authentic dishes and longer reporting periods.

Conclusions

Integrating AI image recognition in a voice-based meal reporting application was found to significantly improve reporting accuracy and time efficiency among young adult users. Further design improvements are required, as is testing in a broader range of authentic dining environments and a more varied array of food items.

Abstract

Background: Today, most smartphones provide a digital voice assistant (DVA) for their user, and it is estimated that about 91% of adults report owning and operating a smartphone. A DVA is an automated system preinstalled on technological devices, such as smartphones, computers, tablets, and speakers, which serves to aid users in performing tasks like answering questions, managing smart devices at home, playing music, managing schedules, sending messages, and more. Research with DVA is emerging, and its applicability to health and health care needs to be elucidated.

Objective: The objective of this study was to describe the use of DVAs among primary care patients, as well as purposely sampled clinics including patients with visual and physical disabilities.

Methods: A convenience sample of adult participants was recruited to complete a needs assessment survey to ascertain the interest and possible utility of DVAs to promote and enhance health from among three populations at an academic medical center: (1) general primary care patients recruited from a primary care clinic, (2) patients with visual disabilities recruited from a low vision clinic, and (3) patients with physical disabilities recruited from a physical medicine and rehabilitation clinic. The survey used in this study was a 46-item investigator-developed instrument administered to participants assessing knowledge, use, and perceptions of DVAs, participant interest to participate in related future studies, and demographics.

Results: The results of the survey showed that the majority of participants have used a DVA before (69.7%, 152/218) and were or might be willing to use them in the future (84.0%, 178/212). Participants reported moderate to high concern about the privacy (47.8%, 97/203), security (54.5%, 110/202), and confidentiality (51.7%, 105/203) of DVAs. A greater proportion of those with visual disabilities reported having never used DVA than those without visual disabilities (39.0% vs 24.6%, *P*=.03). There was no significant difference in reliance on DVAs for participants with and those without physical disabilities (45.0% vs 34.9%, *P*=.31), indicating that they do not require it for everyday needs.

Conclusions: DVA use remains low among the surveyed participants with physical and visual disabilities. For those with visual disabilities, DVA use was seen to be advantageous in everyday life for tasks such as answering questions and seeking information, but not for those with physical disabilities. However, further research should be conducted that focuses on the use of DVAs by accessing data that represent an individual's DVA use without being biased by knowledge of a research study. In addition, research is needed on DVA use that includes diverse samples of participants with physical and visual disabilities, which address the barriers to using DVAs for these adult populations.

Introduction

Currently, about 91% of American adults report owning and operating a smartphone [1] and the overwhelming majority of those smartphones provide users with a digital voice assistant (DVA). DVAs are software that comes preinstalled on many different mobile devices, such as smartphones, computers, tablets, and laptops, or that operates as a stand-alone device such as a smart speaker. DVAs aid users in performing tasks like answering questions, managing smart devices in the home, playing music, managing schedules, sending messages, and more. To recognize and execute these tasks, DVAs communicate with the user in their natural language by using voice recognition while using either native or third-party services to obtain the requested information or perform the task at hand. The first DVA, Siri, was invented in 2011 by Apple and additional companies brought their own DVAs to market in the following years. DVAs not only exist on smartphones, but also within other smart devices such as speakers, TVs, and other various automated home control systems [2]. Studies investigating the use and quality of these smart home devices have shown that they increase convenience, reduce loneliness, and improve quality of life in older adults and adults with disabilities [3]. However, barriers exist in installing, troubleshooting, and updating these technologies for long term use [4]. The most prevalent examples of DVAs in the United States across smartphones and home devices include Siri by Apple, Alexa by Amazon, and Google Assistant [5]. DVAs have experienced explosive growth within the past few years, with recent estimates indicating 62% of American adults having used one on a device [6].

In the past, most research involving DVAs has been narrowly focused and limited to economic analyses focused on potential market value [5], as well as consumer perceptions of privacy and security in regards to DVAs [7]. DVA applications within health care are becoming more widely commercially available and have been primarily focused on demonstrative projects for memory support in patients with dementia [8], older adults with diabetes [9], and communicative apps and technologies for individuals with intellectual and developmental disability or autism spectrum disorder [10]. DVAs are ripe for study within health care contexts, and they pose a particularly exciting innovation in the realm of assistive technologies for older populations, as well as those with various disabilities. Indeed, the potential for DVAs to aid older adults is becoming more clear and emerging research, especially during the COVID-19 pandemic, has investigated the ability of DVAs to reduce loneliness and social isolation of older adults [11].

Aside from assisting with disabilities, older populations engage with DVAs in more relational ways, such as through asking the DVA "personal questions" to get to know them, asking for advice, and engaging with the DVA to alleviate stress [12]. Indeed, as DVAs are typically controlled with voice activation and voice prompts, they may be more easily used by populations who have physical or visual disabilities that result in difficulties manipulating or navigating their mobile devices. DVAs have the potential to deliver interventions specifically for patient populations with a broad range of physical and visual disabilities, both of which can make using mobile devices challenging. For individuals whose physical disabilities affect their endurance, mobility, or dexterity, DVAs could enhance their ability to complete daily tasks and acquire information by mitigating detrimental exertion. Likewise, those with visual disabilities may benefit from DVAs ability to read information out loud instead of being required to visually read online information.

DVAs have great potential for use in health care and could potentially facilitate clearer communication between patients and providers through language translation capabilities, hands-free calling and messaging, and reminders for medications and rehabilitation exercises [13]. For those with visual disabilities, as well as physical disabilities that prevent one from holding a device, DVAs could be transformative in bridging their connection to online health information, family members, and health care providers [14]. The technology can provide greater independence and manage safety risks for those who fall under these specific populations [15]. Given the widespread penetration of DVAs, coupled with their potential for use among populations who may struggle with traditional mobile devices, research to explore potential applications for use within these contexts is needed. In addition, recent and ongoing research exists to evaluate the accuracy and quality of health information that DVAs provide to users [16]. As a first step at understanding the potential for greater use within health care settings, it is integral to investigate the behaviors and opinions on DVAs and barriers to access and use of this technology.

To better understand the potential for use in various health care settings and populations, we sought to describe general DVA use among a broad range of adult patients including primary care patients, as well as those seeking care from specialty clinics where there are high concentrations of patients with either visual or physical disabilities. The results of this study carry importance to inform the future innovations in DVA technology. Depending on the use type, or lack thereof, these tools can be better designed to address the needs of these populations and aid them in their daily functioning.

Methods

Participants and Setting

A cross-sectional study using a convenience sample of adult participants was used to survey the use and perceptions of DVAs from patients at Michigan Medicine, the academic medical center affiliated with the University of Michigan. Patients from 3 purposely sampled clinics in a single city were recruited. The clinics included a family medicine (Briarwood Family Medicine Center), low vision (Kellogg Eye Center Low Vision and Rehabilitation Clinic), and physical medicine & rehabilitation (PM&R) clinic at Michigan Medicine. The family medicine clinic was selected to reflect a typical primary care setting with a range of patients. The low vision clinic was selected for its access to patients with visual disabilities. Finally, the PM&R clinic was selected to enrich the sample for individuals who had physical-related disabilities. Potential participants younger than 18 years were excluded from participation.

XSL•FO
RenderX

Participant Recruitment

Potential participants at the Kellogg and PM&R clinics were informed of the study by clinic staff members during check in. If interested, participants were given a paper survey to complete. Completed surveys were returned to clinic staff members. In addition, participants were recruited at the monthly low-vision support group offered at the Kellogg Eye Center. At the family medicine clinic, study staff members were posted in the lobby and informed potential participants of the study. Those interested in participating were handed a survey, which was returned to study staff at completion. Recruitment occurred over 19 months from September 2019 to March 2021, with recruitment delays experienced due to the COVID-19 pandemic.

Procedures

At each of the 3 clinic sites, an information sheet explaining the purpose of the survey, as well as a self-administered paper copy of the survey, were given to potential participants by clinic or study staff members. Participants then had the option to fill out the survey at any point during their clinic visit and return the paper survey to the clinic or study staff members upon completion. The assessment survey was self-administered by the respondent; however, in cases where assistance was needed for survey completion, participants could select a friend or caregiver accompanying them for assistance. In the case of participants recruited from the low vision clinic, clinic staff members were available to help respondents complete the survey.

Survey Instrument

The study survey used was a 46-item investigator-developed paper-based instrument that surveyed participants about their knowledge, use, and perceptions of DVAs, their interest to participate in related future studies, and demographic questions (Multimedia Appendix 1). Questions regarding knowledge and use of DVAs were presented in 6 closed, multiple-choice format questions with some including an “other” option for further elaboration. There was one additional open-ended question that asked participants to give examples of potential use cases of DVAs that aligned with their interests. Participants were also asked to rate their concerns about 5 specific issues related to the use of DVAs, and one opportunity to voice their own concern. These ratings used a 5-point Likert scale (0=not concerned at all; 4=highly concerned) and were used to measure concerns relating to privacy, security, confidentiality, accuracy, and reliability of the DVAs. The questions about privacy, security, and confidentiality included definitions of the respective terms to clearly define the specific concern. “Privacy” referred to freedom to opt out of monitoring and to determine how personal data is used. “Security” referred to protection of personal data from loss or theft. “Confidentiality” was defined as the obligation of trusted persons to keep data safe and held in confidence. To assess participants’ interest in participating in future studies relating to DVAs, 3 closed multiple choice questions were asked.

The next set of questions presented assessed whether participants had a visual disability. If participants endorsed having a visual disability, 9 additional questions were presented asking about the nature of their disability, access to care, and access to resources. These questions were presented in mixed format. Participants who did not have visual disabilities were asked to skip to the next section, which was focused on physical disability.

The physical disability portion of the survey asked questions generically about disability, which allowed participants to self-identify and describe the nature of their disability. Those endorsing no physical disability were asked to skip to the final set of questions on demographics; whereas those who did endorse a physical disability were asked mixed format questions about the nature of their disability, access to care, and access to resources. As participants were allowed to self-identify with having a physical disability, this study included a wide range of physical disabilities and documented disability within the electronic health record was not required by any participants; rather, participants were asked to endorse whether they had any kind of physical disability and if so, questions probed into the nature of their self-reported disability.

Given that participants with visual disabilities were expected to have more difficulty taking the survey and would require assistance, a shortened 34-item survey presented in large print was administered to participants recruited from the Kellogg low vision clinic (Multimedia Appendix 2). The 34-item survey contained the same questions as the aforementioned 46-item instrument, except it excluded the question set focused on physical disabilities. Both versions of the survey were designed to be completely anonymous, with no protected health information or HIPAA (Health Insurance Portability and Accountability Act)-protected data collected. See Multimedia Appendices 1 and 2 for the survey instrument.

Participants gave their completed surveys to study or clinic staff members, who then placed the surveys into a box clearly labeled with the study title. After the collection of the completed surveys, the data were entered into a secure web application REDCap (Research Electronic Data Capture; Vanderbilt University) by approved study personnel. The entered data were verified through a 10% random sampling for entry errors. Incomplete survey responses were also retained and collected during this study.

Statistical Analysis

The survey data were analyzed using descriptive statistics including frequencies, means, and SD. To determine differences in responses between subgroups, bivariate associations between subgroups and demographics, DVA use, and DVA concerns were performed using chi-square tests or Fisher exact tests as appropriate depending on the numbers in each group. Differences were examined by previous DVA use, clinic site, visual disability status, physical disability status, and willingness to participate in future research studies. All analyses were performed using SAS Software (version 9.4; SAS Institute Inc).

Ethical Considerations

Our study was registered under a self-exemption process at the University of Michigan, classified under EXEMPTION 2 (i) and 2 (ii) as described in 45 CFR 46.104(d)(IRBMED HUM00156811). Participants were handed an information sheet

XSL•FO
RenderX

outlining the risks and benefits of the study before completing the survey. All study materials were stored in locked file cabinets in the locked office of the principal investigator. All data were collected anonymously and reported in the aggregate, and participant responses cannot be linked to individual participants. No financial or nonfinancial incentives were offered for study participation.

Results

Demographics

A total of 218 eligible participants completed the survey. The majority of the sample was White (71.6%, 156/218) and female (61.7%, 124/201) with an average age of 52.6 (SD 18.9) years. The education levels of the participants varied, with the largest portion having a graduate degree (35.0%, 71/203), followed by a split between those who have completed a bachelor's degree (20.2%, 41/203) and those who have completed some college education (19.7%, 40/203). Participants' employment status was primarily full-time (40.8%, 82/201) followed by retired (29.9%, 60/201). Roughly half of the participant population earned an annual income of US $75,000 or higher (46.3%, 88/190) and was insured through their employer (54.1%, 118/218). Almost half of the participant population (49.5%, 101/204) indicated interest in participating in an additional research study that provides DVAs for use (Table 1).

[b]DVA: digital voice assistant.

[c]Questions about physical difficulties were not asked at the Kellogg site. Number missing reflects this.

General Use of DVAs

The results of the survey showed that DVAs are being used for various tasks and there is a willingness to use them in the future. The majority of all participants had previously used a DVA (69.7%, 152/218) and were or might be willing to use DVAs in the future (84.0%, 178/212) including 57.1% (36/63) of participants who had never used a DVA before (Table 1). Among the 152 participants who had used a DVA, Siri was the most highly used DVA (67.8%, 103/152). Other commonly used DVAs were Alexa and Google Assistant which were both used similarly by about nearly half (70/152 and 71/152, respectively) of participants. Of those who did report DVA use, the majority accessed the tool from their personal cell phone (88.8%, 135/152), and the main task was to answer questions (75.0% 114/152), with entertainment (57.2%, 87/152), accessing information online (55.9%, 85/152), and setting timers (51.3%, 78/152) also being frequent tasks done with a DVA. While many of the participants have used DVAs, the frequency of this use was split between those who use it rarely or sometimes

XSL•FO
RenderX

(57.4%, 85/148) and those who use it often or always (42.6%, 63/148). Although the participants use DVAs, the majority did not rely on the DVA for everyday needs (57.0%, 85/149; Table 2).

[a]DVA: digital voice assistant; participants could select multiple categories in these questions resulting in percentages that may add to more than 100%.

DVA Use and Visual Disabilities

Among respondents, 36.5% (77/211) reported having visual disabilities. Of the participants who reported having any visual disability, 81.6% (62/76) found it mildly to extremely difficult to perform activities because of their vision impairment and 41.9% (31/74) reported having vision-related needs not being met. Only 38.2% (26/68) of participants with visual disabilities indicated being very or highly satisfied with current services and devices, revealing a crucial need for improvement.

XSL•FO
RenderX

A greater proportion of participants with visual disabilities reported having never used DVA (39.0%, 30/77) than those without visual disabilities (24.6%, 33/134; *P*=.03). Most participants with visual disabilities who had used a DVA did so on their personal cell phone (53.2%, 41/77) but this was significantly less than the proportion of those without visual disabilities who use DVAs on cell phones (68.7%, 92/134) (*P*=.03). As in the entire sample, the most common DVA task was answering questions regardless of visual disability status, but this task was done by fewer people with visual disabilities (40.3%, 31/77) than those without visual disabilities (60.4%, 81/134; *P*=.005). Those with visual disabilities indicated relying on DVA sometimes or always (63.8%, 30/47), more often than those without visual disabilities (32.7%, 33/101; *P*=.001). In addition, participants with visual disabilities were equally as willing to potentially use DVAs in the future (85.3%, 64/75) as those without visual disabilities (85.0%, 113/133; *P*=.78). Within the group of participants who had never used a DVA, those with and those without visual disabilities had similar willingness to potentially use DVAs in the future (62.1%, 18/29 vs 56.3%, 18/32, respectively; *P*=.64). Those with visual disabilities were also more willing to grant access to past data for DVA studies than those without visual disabilities (22.5%, 16/71 vs 13.1%, 17/130; *P*=.01; Table 3).

[c]N/A: not applicable.

[d]These values were excluded from the chi-square tests, as well as the % calculations.

DVA Use and Physical Disabilities

Among respondents, 47 (30.1%, 47/156) reported having a physical disability. Those with physical disabilities were more likely to report also having visual disabilities (29.8%, 14/47) than those who did not report having any physical disabilities (9.2%, 10/109, respectively; *P*=.001). Among the participants who possessed physical disabilities, 63.0% (29/46) found it moderately, very, or extremely difficult to perform everyday activities. The most common activities affected by the physical disability were walking or climbing stairs (87.2%, 41/47) and holding objects in one's hands (31.9%, 15/47). Most participants (80.4%, 37/46) reported that their physical needs are being met. Still, only 55.6% (10/18) of participants with physical disabilities report being very or highly satisfied with the services or devices meeting their needs.

Participants with physical disabilities reported having never used DVA (34.0%, 16/47) more often than those without a physical disability (21.1%, 23/109), although the difference is not statistically significant (*P*=.09). The proportion of participants that used DVAs for certain tasks tended to be lower for those with physical disabilities than those without physical disabilities but again these differences were not statistically significant. There was a statistically significant difference (*P*=.01) in the use of Alexa or Amazon Echo for those with physical disabilities vs those without physical disabilities (21.3%, 10/47 vs 42.2%, 46/109, respectively). Similarly to those with visual disabilities, the most common task participants with physical disabilities used DVAs for was answering questions (59.6%, 28/47). There was no significant difference in the participants' reliance on DVA for everyday needs by physical disability status. Most participants with physical disabilities were willing, or possibly willing, to use DVA in the future (86.7%, 39/45). There is a significant difference of reliance on DVA with those without either disability being less reliant and those with visual or both visual and physical disabilities being more reliant (*P*=.01; Table 3).

Concerns With DVAs

Overall, a large proportion of participants had at least a slight concern about privacy (86.2%, 175/203), security (89.1%, 180/202), confidentiality (86.7% 176/203), accuracy of information (81.7%, 165/202), and reliability of information (85.1%, 171/201). More specifically, roughly half of the participants had moderate to high concerns about the privacy (47.8%, 97/203), security (54.5%, 110/202), and confidentiality (51.7%, 105/203) of DVAs. The degree of concern about privacy, security, and confidentiality had no significant differences between the participants with and those without visual disabilities. We found a significant difference between concerns about accuracy (*P*=.04) and reliability (*P*=.048) of information from DVAs based on visual disability status with participants with visual disabilities tending to be moderately or highly concerned more often. The degree of concern about privacy, security, confidentiality, accuracy, and reliability had

XSL•FO
RenderX

no significant differences between the participants with and those without physical disabilities. Despite these concerns, we generally did not see a significant decrease in DVA use, frequency, or reliance for those with higher levels of concern. The one exception was in those with high levels of concern about security who tended to use DVAs less frequently than those with slight or no concern about security (P=.04; Table 4).

[a]Participants recruited from Kellogg Eye Center were not asked questions pertaining to physical disabilities, so the total number of people reporting physical disability status is a subset of the total sample.

[b]These values were excluded from the chi-square tests, as well as the % calculations.

Discussion

Principal Findings

In this study, we found the majority of participants had previous experience with DVAs and that there was interest in using them in the future. Looking specifically at those with self-reported disabilities, many adults with physical disabilities and visual disabilities do not regularly use DVAs, however, those with visual disabilities have a greater reliance on the technology. Overall, participants were moderately concerned with the issues of privacy, security, confidentiality, accuracy, and reliability of DVAs. Roughly half of those with visual disabilities had moderate or high concern for privacy, security, and confidentiality, but these numbers do not drastically differ from those without visual disabilities, or with or without physical disabilities, nor does it seem to affect their use and reliance on the technology. Previous literature has discussed smartphone-based low vision aids where DVAs are briefly examined among other smartphone tools for low vision usability [17,18]. The use of DVAs for people with disabilities, especially for the purposes of living independently, is a rapidly expanding field of study [15]. Many recent studies have focused on the accessibility, perceptions, and feasibility of the applications of DVAs, but few have evaluated the actual use cases and frequency of DVA use among individuals with visual or physical disabilities. This is an important step toward understanding and developing technology that better meets the needs of these individuals to improve health outcomes and quality of life.

Regularity of DVA Use

Overall, it was observed that more than half of the participants used DVAs only “sometimes” or “rarely.” Despite the lack of current use when the survey instrument was completed, more than half of the participants were willing to use DVAs in the future. This was perhaps a function of age, seeing that the average age of participants was older at 52.6 years old. From the survey, it was observed that the dominant use of DVAs was found in smartphones. Smartphone use among older age groups differs from those younger as a 2024 study from the Pew Research Center reported that 91% of adults aged between 50 - 64 years and 79% of adults aged 65 years and older own smartphones in the United States, compared with 99% of adults aged 18 - 29 years [1]. Using smart speakers as DVAs in populations of older adults in low socioeconomic positions has also proved to be promising, though more research should be conducted to promote the answering of health-related questions [19]. The additional smartphone functions and tools available for consumers are not necessarily used by older populations. While lower DVA use is more common among older adults, this could be related to a number of factors including lesser comfort with the technology, lower digital literacy, usability factors, technology learning curves, and other personal hesitations.

Perceptions of DVAs

The perceptions of DVAs were quite similar across those with and those without physical and visual disabilities. Overall, about half of participants expressed a moderate to high concern with the security and reliability of DVAs. It was interesting to note that those with visual disabilities were less concerned with privacy and confidentiality issues than those without visual disabilities. Concerns regarding online data privacy, security, and reliability are not novel, as literature spanning decades has documented these concerns. With specific regards to data privacy, DVAs represent an interesting use case as large data giants such as Facebook (Meta) and Amazon are increasing their use of personal user data for advertising, as well as individual targeting and tailoring of products and services. DVA companies have a reputation for lacking transparency with users about privacy protection which can lead to a lack of trust among users [20]. Many DVAs rely on the “activation keyword approach,” where devices listen for a specific keyword before they start recording, which means that these technologies are always listening, unless muted. It also means that DVAs are susceptible to false activation, which means that recording could be unintentionally turned on at a time when users are not aware. Overall, there needs to be improved transparency and additional user controls for personal recording for DVAs and their devices. However, despite the concern over data privacy, 23% of participants reporting visual disabilities and 15% of participants reporting physical disabilities in our study were willing to grant access to their past existing data or share future data for future DVA studies.

The landscape of DVAs along with the integration of generative artificial intelligence (AI) is everchanging, which could lead to evolving data privacy and data quality concerns regarding DVAs. Since the release of ChatGPT by OpenAI in 2022, the interest and number of publications regarding “trust” in conversational agents has risen rapidly. Before 2024, computer science held the vast majority of publications regarding trust in conversational agents; however, the field of medicine has shown

XSL•FO
RenderX

greater growth in interdisciplinary research with conversational agents over the last 8 years [21]. Applications of AI in health systems will require close monitoring and transparency for patients to feel comfortable granting access [22]. Recent research has shown that many individuals feel relatively comfortable sharing their data with national health organizations and universities, but much less willing to share with private commercial organizations such as insurance and technological companies [23]. This further emphasizes the importance of exploring utility and applications of DVAs and AI in health care and research contexts.

Reliance on DVAs by Those With Visual Disabilities

The survey showed that those with visual disabilities had a greater reliance on DVAs than those without visual disabilities. This is likely due to those with visual disabilities relying on voice commands to read and assist them with tasks they otherwise would not be able to do. In terms of specific activities, participants with visual disabilities reported using DVAs more frequently for answering questions than those without visual disabilities.

DVA Use by Those With Physical Disabilities

The survey showed that the DVA use cases of those with physical disabilities did not differ significantly from those without physical disabilities. Due to the nature of the relatively small convenience sample, there was not a large degree of heterogeneity in terms of types of physical disabilities. Those with physical disabilities were shown to rely more on DVAs than those without. The finding of increased reliance is supported by previous interview-based research that noted DVAs promote autonomy by increasing the ability to perform daily activities and tasks that were normally obstructed by mobility or other barriers [24].

Strengths and Limitations

To our knowledge, this is one of the first studies to assess the utility and perceptions of DVAs for adults with specific focus on those with visual and physical disabilities. Despite the novelty of the study, there are multiple limitations to consider that can guide future exploration. It is crucial to note that due to the COVID-19 pandemic, data collection was disrupted with delays in analysis. Despite the lag experienced, the study begins to fill a literature gap on the use of DVAs, particularly from the perspective of those living with visual and physical disabilities.

This study is not without limitations. The study findings relied on participant self-reported information, which may introduce response or recall bias, such as participants not remembering, or choosing not to share information related to disabilities or DVA use. Moreover, this study used a convenience sample, which is a limitation to our approach. In addition, participants were recruited from one health system, so results may not be generalizable to other populations. To reduce participant burden among those with visual disabilities, the survey was shortened. This may have overlooked potential dual disability concerns (physical disabilities among those with visual disabilities). In addition, the study survey did not capture the specifics related to the reported disability, such as etiology, onset, severity and overall quality of life. In addition, the survey instrument used was created specifically for this study and not validated. Despite these limitations, our study was intended to be exploratory in nature and serve as a foundation for future work in this field.

Future Perspectives

Future work should examine DVA use through device use data recordings and compare this across different disabilities and functional levels. Additional areas of investigation should incorporate qualitative approaches to more fully elucidate the ways that DVAs have been used, or could be used, to support the health of older adults and those individuals living with disabilities. Not only does this have great implications for the more than 25% of individuals in the United States living with a disability [25], but it also has great implications for the number of aging individuals who may benefit from DVA use (eg, social isolation and improved independence).

Conclusions

Self-reported use of DVA varied across the surveyed participants. Tasks such as answering questions and seeking more information were the most used functions of DVAs by individuals with physical and visual disabilities. Participant perceptions of DVAs, regardless of disability status, suggest that concerns with data privacy, security, confidentiality, reliability, and accuracy exist.

Acknowledgments

The authors of this study wish to thank Sherry Day and Ebony Parker-Featherstone for their assistance with recruitment for this study, as well as Melanie Herschel, Kelley Wyse, and Katie Grode for administrative support. Additional thanks to the University of Michigan Briarwood Family Medicine Clinic, the Kellogg Low Vision Clinic, and the Department of Physical Medicine & Rehabilitation for supporting recruitment for this study. This research was unfunded. Generative artificial intelligence was not used in the production of this manuscript.

Abstract

Background: The association between physical activity (PA) behavior and cardiometabolic risk factors has depended largely on questionnaire-based reporting. More studies are turning to mobile health (mHealth) device solutions to measure PA. While there are differences between self-reported activity levels and objectively measured accelerometer-based activity, how these differences manifest in disease risk is unknown.

Objective: Here, we sought to evaluate these differences between self-reported and mHealth-based PA and to model the impact on their association with cardiometabolic factors. Our study provides a framework to assess the quality of relationships measured by mHealth technologies, which is generalizable to other sensors or activity-measuring devices.

Methods: We assessed PA using both wrist-worn accelerometer data and self-reported questionnaires in 16,000 participants of the UK Biobank (UKB) between 2013 and 2015, focusing on walking, sleeping, sedentary, and moderate-to-vigorous physical activity (MVPA). We compared the concordance between self-reported and objective measures of PA. We also compared the association between objectively measured or self-reported PA and future clinical biomarker levels (eg, BMI, pulse rate, glucose control, and cholesterol).

Results: Participants underestimated their weekly sedentary duration on average of 2.86 hours, and the coefficient of correlation (r) between subjective and objective activity was 0.12 for sedentary time, 0.16 for MVPA, 0.18 for walking, and 0.13 for sleeping. We found an inverse association between objectively measured MVPA and cardiometabolic biomarkers such as BMI and pulse rate, but found no association between subjectively reported activity and cardiometabolic biomarkers. We estimated that there is a 6% larger association between subjectively measured MVPA and BMI in healthy adults (vs the objective counterpart). We also estimated a 2%-3% difference on a healthy adult heartbeat (healthy range: 60-100 bpm) if relying on subjectively reported observations instead of measured PA.

Conclusions: These findings suggest that the association based on self-reported activity is likely overestimated and biased compared with objectively measured PA. Therefore, care should be taken when assessing the effects of self-reported PA on key cardiometabolic factors, such as BMI and pulse rate. We emphasize that while the associations are biased when comparing PA modalities, we cannot conclude which method more closely reflects the daily activity load.

Introduction

It is well established that physical activity (PA) is paramount in the maintenance of health and reduction of risk of chronic disease [1]. PA, whether self-reported or measured by mobile health (mHealth) devices, is consistently associated with higher risks of cardiovascular diseases, type 2 diabetes, low life satisfaction, and general worse health [2-5]. A better understanding of the relationship between specific PA behaviors and health is critical for disease prevention, but efforts are hindered by the complexity of PA assessment.

XSL•FO
RenderX

PA is characterized by 4 dimensions (type, frequency, duration, and intensity), is carried out in at least 4 different contexts (home activities, leisure, transport, and occupational), and can be reported in at least 3 different manners (using energy expenditure in kilocalories, categorizing time spent in different types of activities over a period of time, or using the metabolic equivalent [MET] of a task) [6]. The heterogeneity in reported PA contributes to the conflicting results in this field and adds to the difficulty of discerning a clear link between PA and diseases or biomarkers predictors of diseases. For instance, in the US Centers for Disease Control and Prevention National Health and Nutrition Examination Survey (NHANES), Troiano et al [7] found that less than 5% of US adults met PA directives when relying on accelerometer-measured PA, but more than 51% did when basing on self-reported questionnaire data. Using the same survey, Atienza et al [8] found that physiological and anthropometric biomarkers associated more strongly with accelerometer-derived moderate-to-vigorous physical activity (MVPA) measurements than self-reported PA. Other meta-analyses also reported systematic underestimations of measured sedentary time (as much as 1.74 hours per day) when using self-reported measures [9,10]. As a result, there is conflicting evidence for the validity of relying on self-reported PA.

Sensors and wearable devices (mHealth devices), including accelerometric devices, have progressively integrated into cohort studies, allowing an increasingly diversified field of participants and an easier framework to collect measured data. While these wearable devices can measure PA, they cannot determine disease risk outcomes directly from measured PA. Instead, physiologically relevant metrics modulating diseases must be measured.

Then, a relationship between measured (mHealth) and self-reported PA levels and disease can be quantitatively compared. If these are assessed in the same cohort study, then it is possible to determine whether mHealth devices allow obtaining additional signals with lower error in comparison to traditional self-reporting PA. Furthermore, it is also possible to demonstrate the added value of mHealth-like devices for research through such quantitative comparisons.

In this study, we evaluated the concordance between objectively-measured (via mHealth devices) and subjectively-reported PA in their association with biomarkers (eg, BMI, pulse rate) of cardiometabolic disease in the UK Biobank (UKB) cohort for a quantitative comparison of these measurement techniques in a research setting. We examined the differences between objective and subjective activity population means at an individualized level. Finally, we compared the different types of activities in the cohort, highlighting the discrepancies found when predicting cardiometabolic biomarker levels from activity levels. We anticipate that the approaches developed here to systematically study associations between PA data modalities and clinical outcomes will be generalizable to new approaches and sensors that measure activity. Thematically, these findings demonstrate addressing key themes in mHealth, including mHealth for Data Collection and Research, Evaluation and Research Methodology for mHealth, and Fitness Trackers.

Methods

Physical Activity Measurements

Measured Activity Derived From an Accelerometer

It is hypothesized that weekend and weekday patterns of MVPA are different [5]. Therefore, we sought to analyze the population on both weekends and weekdays separately. Hourly proportion of time spent in weekly and weekend activity was extracted and preprocessed by Le Goallec et al [11] from the publicly available software [12,13] and converted to weekly minutes of types of activity. The weekly total activity of the 4 types of activity—walking, sleeping, sedentary, and MVPA—was obtained by summing all the hourly proportion of weekday and weekend separately, weighting by 5 and 2, respectively, and converted to weekly minutes by multiplying by 60. Following the filtering out of missing or unusable accelerometer-derived data, the number of participants was 16,467. For sensitivity analysis, we also subdivided the study population to only retain individuals who had a nonwear time of zero days, meaning that all the included participants wore the accelerometer device for an uninterrupted period of 7 days. This allowed for a quality assessment of the objective PA in 5587 individuals.

Self-Reported Activity Derived From the Physical Activity Questionnaire

Weekly minutes of activity estimated by questionnaires were obtained by multiplying the weekly frequency by the daily amount (see Table S1 in Multimedia Appendix 1 for all the questions) only if participants had answered both questions. The questionnaire answers were part of a short-form International Physical Activity Questionnaire (IPAQ) filled out at every visit. If a participant did not recall the duration of an activity but had at least practiced it for 10 minutes, the participant's average was substituted. Any participant with an incomplete answer was dropped. To compare to the measured MVPA, weekly minutes of moderate activity were added to vigorous physical activity (VPA) reported by participants. Weekly minutes of sleep were calculated by converting the reported daily hours of sleep to daily minutes and multiplying by 7. Self-reported time spent watching television, on the computer, and driving was added and capped at 7560 weekly minutes (corresponding to 18 daily hours) as other studies have reported doing [3] to obtain weekly sedentary minutes. If participants reported spending less than 1 hour in either category, the total for that category was encoded as 0 minutes.

Anthropometric and Biomarker Data

Response Variable Encoding

We chose "response" variables, or dependent clinical variables that include anthropometrics and plasma biomarkers, such as BMI and pulse rate [3,14,15]. We also chose "negative controls," such as sunscreen use. Blood pressure readings were averaged for the visit. Answers containing "prefer not to answer" were excluded, and those that answered "do not know" were replaced with the average of the population to maximize the study population size.

XSL•FO
RenderX

Covariate Selection to Adjust for Lifestyle and Comorbidities

Dietary factors were included as covariates in regression models incorporated as 6 separate regression terms in the final model, each accounting for weekly intakes of vegetables, fruits, poultry, fish, meat, and bread-type. We included a variable for red meat (eg, pork, beef, lamb/mutton) and another for poultry. Bread type was encoded as a binary indicator of nonwhite or white bread.

We used a modified version of the Charlson Comorbidity Index (CCI), which measures the total comorbidities for a participant, to account for frailty and disease. We also included in the modified CCI any self-reported diabetes diagnosed by a practitioner or a medical record for type I or type II diabetes, any self-reported cancer diagnosed, any *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) record for Chronic Obstructive Pulmonary Disease, and any record of major cardiovascular diseases.

Statistical Analysis

Study Population Statistics

We reported the mean and SD for all measures where possible. For proportions, we provided a percentage and the nonsimplified fraction.

Quantifying the Measured/Self-Reported Relationship

The median and IQR of each activity, for both self-reported and measured, were calculated. Pearson correlation *r* was reported between measured/self-reported pairs of each activity type.

Estimating Associations Between Biomarker Levels and PA in 2 Separate Models for Measured and Self-Reported Activity

Models predicting individual biomarker levels from self-reported PA only (MVPA and sedentary time) were fit and adjusted for self-reported dietary intake, modified CCI, and smoking status. Separately, we modeled individual biomarker levels from measured PA, for both MVPA and sedentary time, adjusting for dietary intake, adapted CCI, and smoking status. The models using only measured PA values weighted each observation by a decay function that mapped individuals' time interval between their measurement and the subsequent date at which the biomarker was recorded. This mitigated crosstalk from other factors prone to vary as time passes and affect biomarker levels, such as medication use, by upweighting individuals with biomarker measurements closer to the date of activity measurement. The decay function, fΔdays=12πe-Δdays22(2*365)2+0.5, is a Gaussian with a SD of 2 years, translated vertically by 0.5 units and normalized.

We extracted the β coefficients and their 95% CI of respectively measured and self-reported PA to compare effect sizes for every permutation of biomarker/activity combination, stratifying the results by sex and age. To calculate the average effect size difference between subjectively and objectively reported categories of PA, we simply multiplied the effect sizes by, respectively, the subjective and objective population means of MVPA and sedentary time.

Quantifying the Independent Contribution of Objective PA Versus Self-Reported PA

To compare the effect size and the independent contribution of objective versus self-reported PA, we estimated the 95% CI of measured and self-reported estimates. Specifically, we fit a model predicting the biomarker level ("response" variable) as a function of measured PA or self-reported PA, and other adjusting variables. In summary, if the CI of the PA estimate after adjusting for lifestyle and the CCI variables did not contain 0 (was *P* value significant), we concluded that measured PA added additional signal independent of self-reported PA. The impact of PA on selected biomarkers was ranked based on the estimates' magnitudes.

All statistical analyses were carried out on software R version 4.2.1 (R Core Team) with RStudio 2022.02.1+461 "Prairie Trillium" (Posit, PBC) release for Chrome (Google LLC)/111.0.0.0.

Ethical Considerations

- We applied for internal review board (IRB) approval to the Harvard University IRB. The Harvard University IRB approved of this study (IRB: IRB16-245). The project number for this manuscript is 22881. The UKB investigative team had informed consent, and individuals who have opted out of the study have been removed from the analysis. The consent form is provided on the web [16]. The UKB data are deidentified data. UKB recipients were not directly compensated for participation; however, participants were reimbursed for time and travel. More information can be found here [17].

The UKB is a prospective cohort study of 502,507 recruited between 2007 and 2010 [18]. Participants were asked to participate in follow-up studies (at random). Between 2013 and 2015, a total of 103,661 participants consented to wear a wrist accelerometer for 7 consecutive days [19]. The study participants all took part in subsequent visits between 2013 and 2015, following their participation in the accelerometer measurement.

Results

Study Population Description

Of the 502,507 participants included in the UKB, 103,661 had accelerometer records available. Of those, 16,467 had valid accelerometric data and had anthropometric and biomarker data available following the accelerometer measurement visit (see Figure 1 for the flowchart of the study). The study cohort was comparable to the whole UKB population, in that it was primarily white (97% vs 95%), had similar measured anthropometrics such as BMI (26.29 [4.39] kgm2 vs 27.43 [4.8] kgm2) and similar proportions of males and females (53% females vs 54%). However, the study population was more educated (56% in the highest education category vs 33%), had higher income (31.5% in the top 2 income categories vs 25.4%), and healthier lifestyle habits in that the majority had never smoked (63% vs 55%). The studied cohort was also on average 4 years older than the whole UKB population at baseline, even after accounting for the time elapsed between initial recruitment

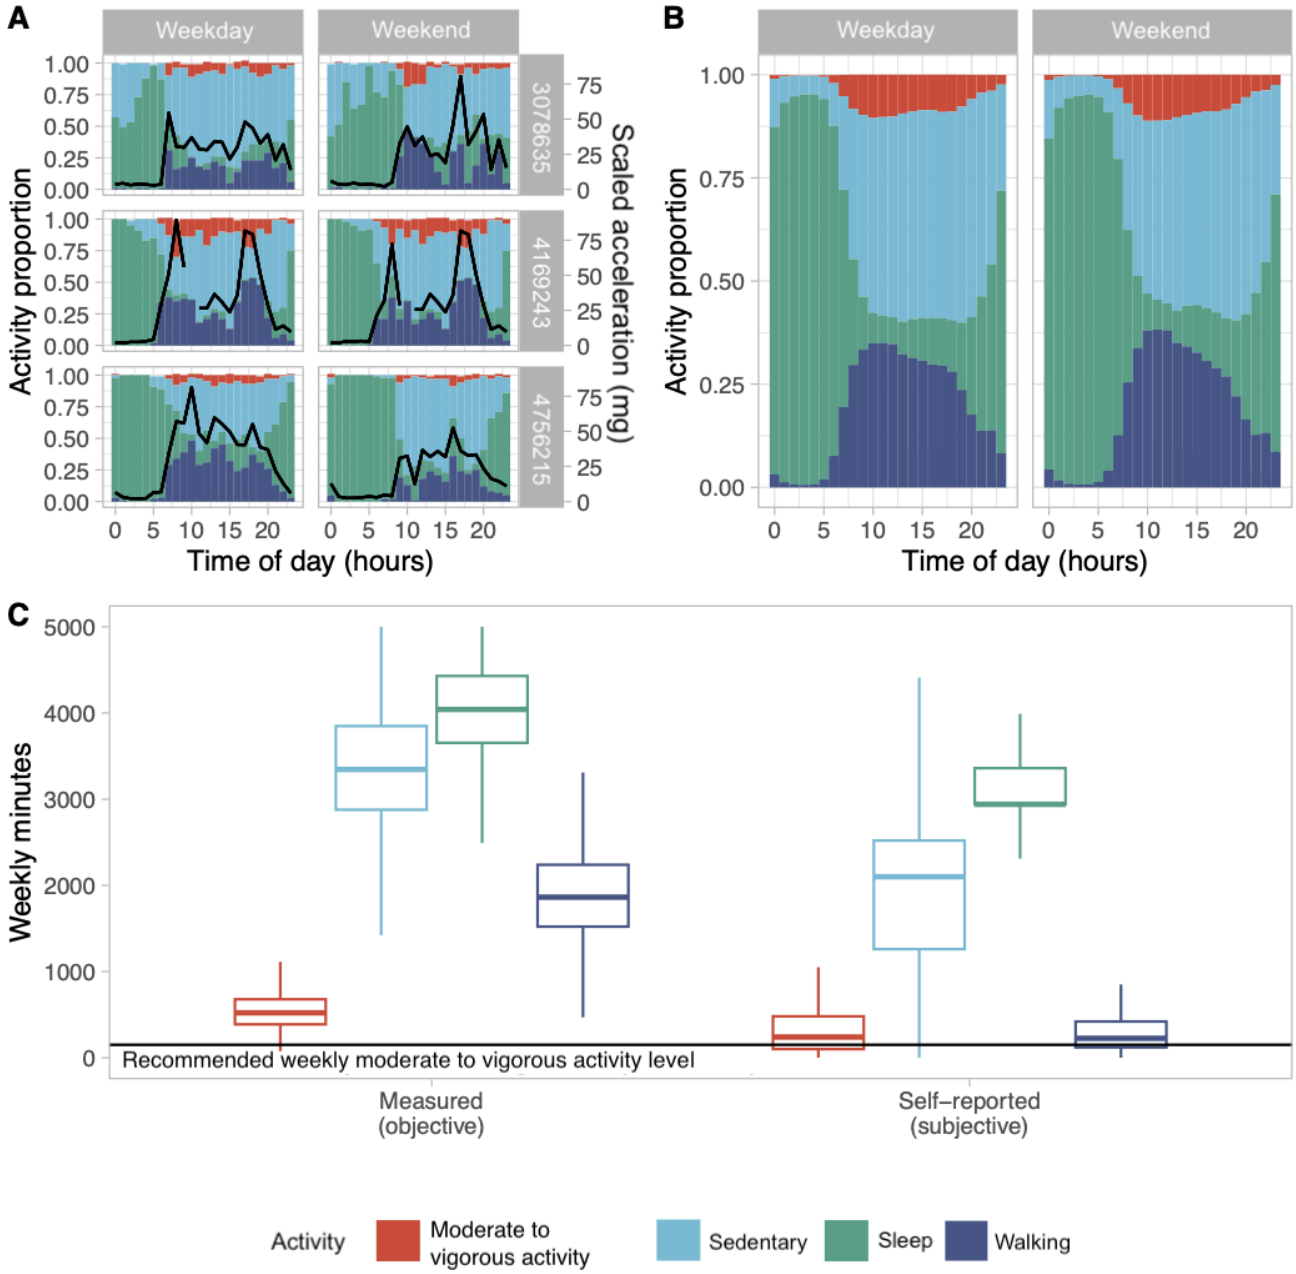
Relationship Between Measured and Self-Reported PA

Measured or objective PA was assessed at both the individual level (Figure 2A). We observed concordance between 3 random participants' hourly classified activities and the averaged triaxial acceleration, and at the population level in Figure 2B. At the population level, and even at the individuals' level, we found that a little proportion of time was spent in MVPA. Throughout the day, individuals spent at most 12.5% of an hour engaged in MVPA, whereas 50% of their time was spent in sedentary status outside of their sleep. The weekly median number of minutes spent in sedentary time was 3200 minutes (7.62 daily hours), 2000 minutes (4.76 daily hours) in walking, and 500 minutes (1.19 daily hours) in MVPA (Figure 2C). Participants averaged 24-hour period habits during the weekday did not differ from habits during the weekend.

The self-reported levels of sedentary time were not concordant with the objectively measured sedentary time. Participants reported 2000 weekly minutes (4.76 daily hours) of sedentary time, or about 1200 weekly minutes (2.85 daily hours) less than the measured level. The population mean of self-reported walking was similar to the self-reported MVPA population mean, each averaging 250 weekly minutes (0.6 daily hours). However, these self-reported values deviated from their measured counterparts by 1750 minutes for walking (4.17 daily hours) and 250 minutes for MVPA (0.60 daily hours; Figure 2C).

XSL•FO
RenderX

Figure 2. (A) Three individuals' average measured hourly activity over the course of a day overlaid with their scaled averaged recorded triaxial acceleration (black line) separated by weekday/weekend (black line discontinuities correspond to values in excess of the figure window), (B) the averaged (mean) classified measured hourly activity of the study cohort over a 24-hour period separated by weekday/weekend, and (C) the cohort's weekly measured and self-reported physical activity, stratified by activity type.

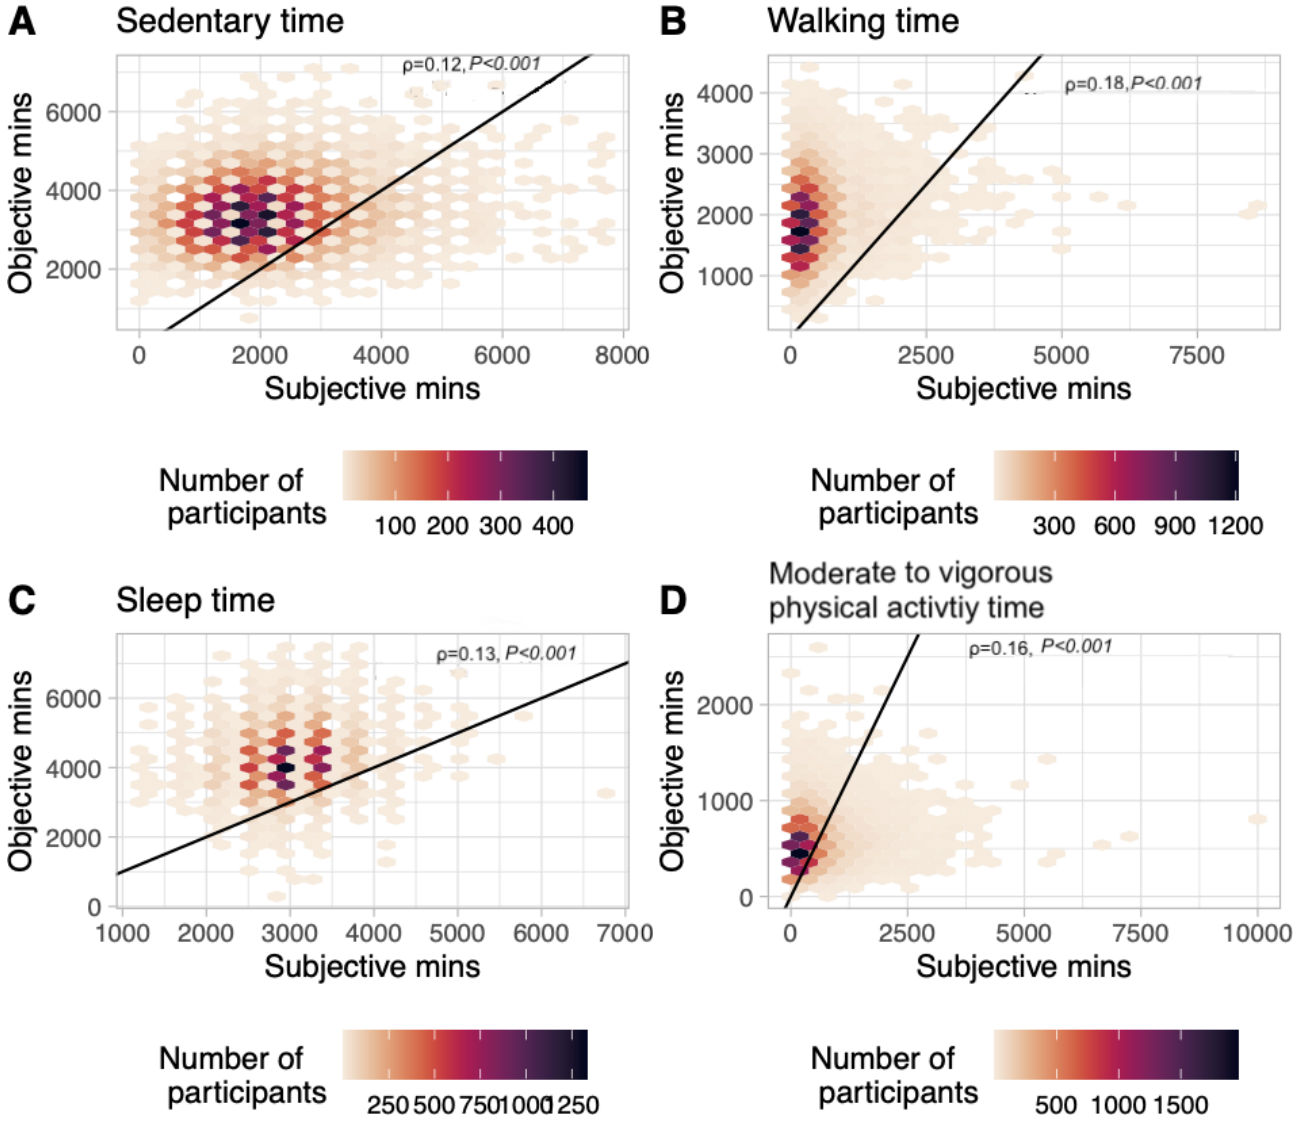


Quantifying the Measured/Self-Reported PA Relationship

Objective PA was modestly associated with subjective PA in Figure 3A-D (r=0.12; P<.001 for sedentary; r=0.18; P<.001 for walking; r=0.16; P<.001 for MVPA; and r=0.13; P<.001 for sleeping). Interestingly, the correlation was higher for walking and MVPA activities than for sedentary time and sleeping. We found the same correlations for the subpopulation that had noninterrupted accelerometer wear time during the study period (figures not included).

XSL•FO
RenderX

Figure 3. Scatter plots of the study population comparing the reported subjective minutes to the objectively measured minutes in each type of physical activity. The correlation coefficient (*rho*) is reported in each grid. The black line is the identity line (y=x), corresponding to a perfect one-to-one match. Hexagons are color-coded by their density: (A) weekly minutes of sedentary time, (B) weekly minutes of walking, (C) weekly minutes of sleeping, and (D) weekly minutes of moderate to vigorous activity.

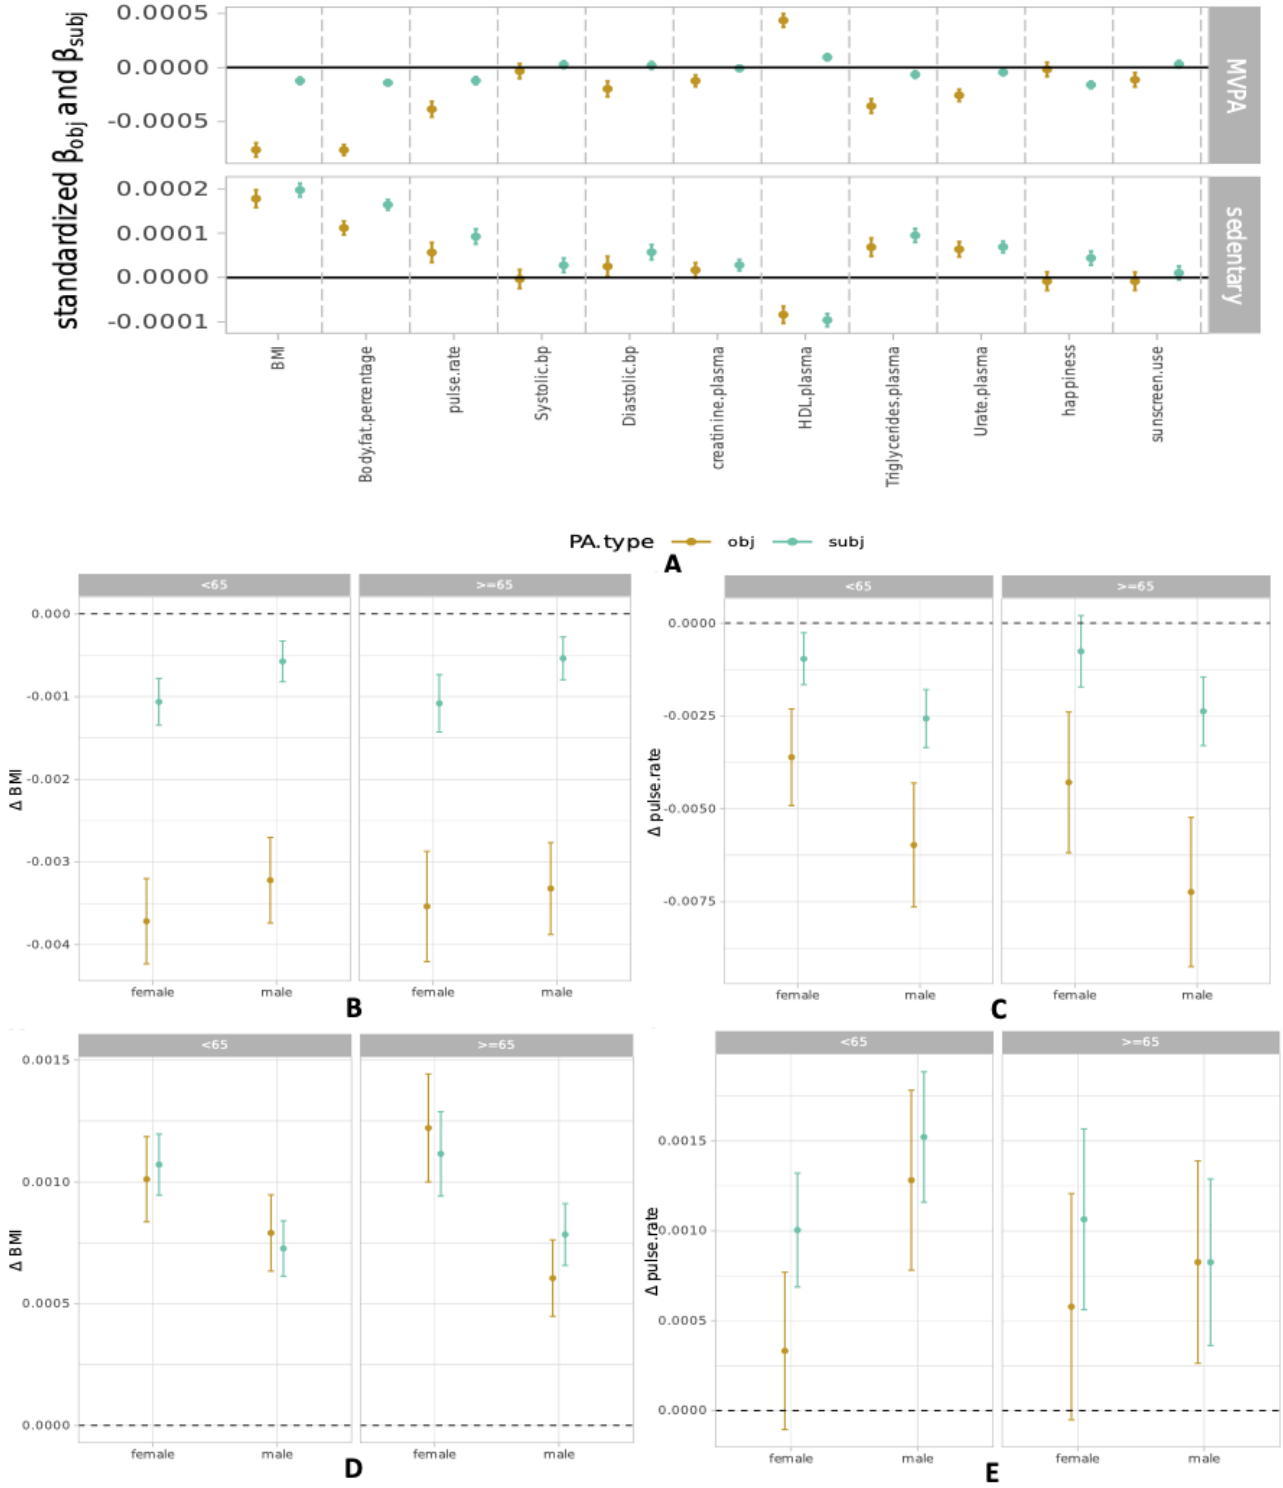


Effect of PA on Cardiometabolic Biomarkers

Figure 4A depicts the standardized effect size of measured and self-reported MVPA and sedentary time on selected cardiometabolic-related biomarker or "response" levels (see Figure S1 in Multimedia Appendix 1). The subjective and objective PA are modeled jointly, such that each measurement's effect estimate assumes the other is held constant; in other words, the coefficients measure the effect of one PA measure independent of the other. The objective PA association sizes were greatest for anthropometric markers (BMI, waist circumference, body fat mass), certain physiological markers such as pulse rate, and certain plasma biomarkers such as high-density lipoprotein and triglycerides. As a negative control, objective sedentary time did not predict other biomarkers presumably unrelated to physical fitness, such as sunscreen usage (β=−8.42e-6; 95% CI −2.89e to 5,1.20e0; *P*=.42); however, objective MVPA was nominally significant (β=−1.13e−4; 95% CI −1.79e−4 to 4.72e−5; *P*=.009). Also, BMI and pulse rate levels had an inverse association with MVPA (eg, lower BMI and pulse rate for higher levels of MVPA) and a positive association with sedentary time. Further, subjective MVPA estimates were null across all biomarkers, but subjective sedentary time estimates were similar to the estimates predicted by objective sedentary time.

XSL•FO
RenderX

Figure 4. (A) Standardized effect sizes of objective physical activity adjusted for dietary intake, adapted CCI, and subjective physical activity on selected biomarkers. The subjective physical activity coefficients are plotted as a comparison; (B-E) effect sizes of PA on selected biomarkers issued from two separate models of objective and subjective physical activity, stratified by age group: (B) moderate-to-vigorous physical activity BMI, (C) moderate-to-vigorous physical activity pulse rate, (D) sedentary BMI, (E) and sedentary pulse rate.



The association sizes of objective MVPA were directionally consistent and stronger in magnitude than those of subjective MVPA in all groups (above/below 65, males/females; Figures 4B and C, Figure S2 in Multimedia Appendix 1). There was also no substantial difference in effect size between the age groups.

In contrast to MVPA, objective and subjective effect sizes for sedentary time coincided almost perfectly for all anthropometric and physiological measurements (see Figure S3 in Multimedia Appendix 1 for all tested biomarkers). Sedentary time was associated with an increase in BMI and pulse rate (Figures 4D and E). We also replicated these tests in the subpopulation that

XSL•FO
RenderX

wore the accelerometer without interruption and found the same results (figures not included).

Finally, we calculated the differences of biomarker effect sizes between each subjective/objective PA pair stratified by sex and age (above/below 65 years old) in original and nonstandardized units (eg, beats per minute for pulse rate and kgm2 for BMI). For BMI estimations from weekly MVPA, we found that subjective MVPA was associated with an increase of 1.5 kgm2 more than objective MVPA (1.59kgm2 [1.41, 1.78] for females <65, 1.47kgm2 [1.27, 1.67] for males <65, 1.5 kgm2[1.25, 1.75] for females >=65, and 1.53kgm2 [1.31,1.74] for males >=65). We also found that subjective MVPA was associated with an increase of approximately 2 bpm more than objective MVPA (1.56 bpm [1.09, 2.04] for females <65, 2.34 bpm [1.71, 2.98] for males <65, 1.95 bpm [1.25, 2.66] for females >=65, and 3.03 bpm [2.25, 3.8] for males >=65). For BMI predicted by sedentary time, we found that subjective estimates were lower than objective measurements by, on average, 1kgm2 for all subsets. See Figure S4 in Multimedia Appendix 1 for all tested biomarkers.

Discussion

Principal Findings

Here, we quantified the relationship between objective and subjective PA in two ways: (1) in a direct, one-to-one comparison and (2) in their association with cardiometabolic biomarkers. The former yielded similar results to previously reported studies assessing the differences between measured PA assessed with wearable devices and questionnaires [7,10,20,21].

First, the reported low Pearson correlations between objective and subjective PA measures were unsurprising given other reported levels below r=0.30 [7,21,22]. A European cohort reported a Pearson correlation of r=0.28 [21] while a Norwegian study reported correlations of r=0.46 for sedentary time and r=0.20 for MVPA [20]. Our results were lower. Further, participants underestimated their sedentary durations by almost 1200 weekly minutes (2.86 hours per day), a larger difference than what Prince et al [10] reported in their systematic meta-study review, where an underestimation of 731 weekly minutes (1.74 hours per day) was reported.

We found great mismatches when matching each individual's subjective/objective measurements. In particular, we found that the mismatch was greatest in those who self-reported higher values of MVPA. This may have indicated that either participants with high activity levels over-reported their MVPA workout activity, either because (1) the accelerometers were less adapted to validate highly-active participants' levels, or (2) that other factors like education level, age, or physical ability [20], affected participants' self-reporting values. A reasonable explanation is probably a combination of these hypotheses. For example, at the population level, measured activity medians of all types were higher than the questionnaire-based ones. In fine, discrepancies in perceived PA durations are sure to vary between individuals given their different mobility abilities, which were not assessed in the cohort.

The way that we assess PA has a large influence on the size and robustness of the association with clinical biomarkers of disease. Our findings are in agreement with other studies that describe the inverse association between increased MVPA and BMI and heart rate (respectively, the regular association between sedentary time and BMI and heart rate) [3,14]. However, we observed that objective measurements were more strongly associated with cardiometabolic biomarkers than has been previously appreciated. In the case of increased MVPA, the negative association of measured PA was of a larger magnitude than that of subjective PA by 4e-3 standard units on anthropometric markers and on the order of 1e-3 standard units in the case of plasma biomarkers and pulse rate. In the case of increased sedentary PA, the magnitudes of objective and subjective associations were largely invariant to age and sex/gender.

Moreover, we found discrepancies between levels of BMI and pulse rate estimated with subjective and objective MVPA. Subjective weekly MVPA was estimated on average, in the different population subsets, 1.5 kgm2 and 2 bpm more than objective MVPA. Contextualized in healthy adults, these numbers reflect a 6% overestimation of MVPA association on BMI, if relying on subjectively-reported observations rather than measured MVPA. The MVPA impact on pulse rate differences was less, varying between 2% and 3% difference on an adult heart beating 60-100 bpm. Though small, these variations may present key influences on clinical biomarkers.

Comparison With Previous Work

Due in part to the ease of implementation of IPAQ (long or short form) or equivalent questionnaires such as 7-day Physical Activity Recall [23], and in part by the relatively new widespread use of wearable devices, most cohort studies still rely on only subjective PA measurements to assess physical fitness. For instance, a recent study using the UKB found that participants adhering to frequent MVPA patterns based on subjective PA were associated with reduced risk of dementia [24]. Given the discrepancies between subjective and objective PA quantified in this study, however, it is questionable whether the reported effect is discernible in objectively measured PA in the UKB cohort.

PA investigation on cardiometabolic disease may benefit from increased power and precision from the use of accelerometer data. These findings support the hypothesis that the difference observed between subjective and objective MVPA measurements was more likely due to misjudging MVPA duration according to fitness levels and not age. Indeed, we did not observe any objective MVPA activity difference between the 2 age groups but found diluted pulse rate associations with increased MVPA activity in both groups (similarly, increased pulse rate with increased sedentary time). Given that the objectively reported effect sizes had greater magnitudes (and perhaps less error) than the subjective ones, greater power may be found with accelerometer-based measurements.

The measured PA data values were extracted and categorized from the freely available software [12,13,19]. Although measured PA was shown to strongly correlate with daily observed and reported behavior, the PA categorizations are only

XSL•FO
RenderX

approximations of MET, which is defined as using 3.5 mL of oxygen per minute per kilogram of body weight. By definition, a participant is classified as doing MVPA if the activity duration intensity is greater than or equal to 3 METs. While gold-standard methods such as doubly labeled water [25] exist and result in precise, individual-based calibrations, the method used to process accelerometric data did not benefit from an individual-centric calibration. This, therefore, is one source of the discrepancies between PA classifications.

We hypothesize that individuals with different baseline cardiometabolic health may perceive their PA differently, and this will bias associations between reported activity and cardiometabolic biomarkers. We describe a plausible scenario: for instance, if 2 individuals of different baseline metabolic capacities are carrying out the same activity intensity, such as running a certain distance at a certain pace for a certain time, an individual-centric method would result in different MVPA duration classifications for each individual. Equivalently, an individual with a healthier baseline metabolic capacity would have less MVPA duration than an individual with a lower metabolic capacity. Hence, in a scenario where both individuals run the same distance at the same pace, the accelerometer reading will be identical. However, the self-reported perception of PA may differ; the individual with better cardiometabolic fitness may have perceived and reported doing less MVPA than the other individual. This could translate to the reported discrepancy observed in the study participants and therefore influence the magnitude of the coefficients of the biomarkers studied.

Unlike MVPA, we observed concordant associations between sedentary activity (measured by both accelerometer and self-reported) on biomarker levels. We hypothesize that measurement "error" in the aggregate may be lower for activities related to inactivity, which sum over behaviors such as watching television and using a computer versus reporting one MVPA-related activity carried out weekly [9,20].

With the new generation of mHealth devices that have been developed since the study's conception, which incorporate personalized thresholds to categorize activity intensities [5]. There is evidence that activity intensity is assessed more objectively and therefore reflects more precise metabolic exertion. Leveraging these threshold personalization allows us to distinguish new behavioral patterns. For instance, McConnell et al [5] identified a cluster of adults who were more active during the weekend (called weekend warriors) in comparison to weekdays. Implementing studies with such devices is, however, expensive, but given the discrepancies highlighted in this study between self-reported and measured PA and predicting cardiometabolic biomarker levels, it may be crucial to re-evaluate PA assessments, especially when these are translated to prevent disease outcomes, such as in guidelines [26]. While we acknowledge the development of new technologies for measuring PA, the core contribution of our paper lies in the method we present to quantify the quality of relationships produced by mHealth technologies. This approach is not limited by specific devices or data sources and, importantly, should generalize to newer technologies as they emerge.

It may be possible, in the future, to create a calibration between self-reported and objective PA to reanalyze results from studies that have one measure and not the other. Many studies rely on self-reported measures. In this study, we are primarily focused on how the discrepancies between self-reported and objective measures impact associations with clinical outcomes, rather than directly translating between the two measures. As we show in Figure 3, the correlation between self-reported and objectively measured PA is very modest, below 0.1, highlighting the challenges inherent in creating such a mapping. This low correlation, in itself, demonstrates that providing a simple or reliable translation will require a formal study and potentially more data.

Use of self-reported versus accelerometer-based approaches for measuring PA has implications in biobank-scale genetic studies, such as "genome-wide association studies" (GWASs) [27]. GWASs are a discovery-based approach to broadly uncover inherited genetic loci, or places along the genome that predispose individuals to perform PA. However, we hypothesize that the scale of genetic discovery (the number of loci found) and their association sizes are influenced by the type of PA being interrogated. A number of papers have begun to interrogate the genetic contributions, via GWAS, in PA using both self-reported [28] and/or objective/accelerometer-based modalities.

For example, Klimentidis et al [29] conducted a GWAS of habitual PA of both self-reported PA and accelerometry data in the same participants analyzed in our study, individuals from the UKB. Briefly, they associated genetic loci with self-reported MVPA and VPA. They also associated genetic loci with average acceleration and fraction of time with higher accelerations as proxies of vigorous activity. In brief, while the sample sizes from each of the GWASs were different, they found different numbers and genetic loci from GWASs of self-reported and accelerometer-based measurement of PA. Specifically, the self-reported and objective indicators had an overlap in some loci found (particularly near gene *Cell Adhesion Molecule 2*), but the concordance was not consistent across all assessments of self-reported and accelerometer-based modalities. At a relaxed genome-wide *P* value threshold, the authors observed 4 genetic loci in common between self-reported MVPA and accelerometer and 3 loci in common between vigorous activity and accelerometer GWASs. Studying the difference in the genetic "architecture," or the number and biological implications of genetic loci, is an aim for a future study.

Limitations

Some caution should be used when interpreting these results. First, objective and subjective measurements were not collected at the same time. Participants of the UKB were invited to fill out IPAQ forms during their medical appointments independently of their participation in the accelerometer study. Furthermore, participants in the accelerometer study were not required to schedule a medical appointment during the week of their participation. Thus, self-reported PA was not collected simultaneously with the measured PA. While most participants had self-reported PA measures within weeks of their measured PA recording, some had at most 2 years between the measures.

XSL•FO
RenderX

Though we applied a weight correction accounting for time elapsed between the measures (self-reported PA and measured PA) and considered additional lifestyle factors, there were other factors that could not be captured, which may have influenced the observed differences between objective and subjective MVPA.

Conclusions

In sum, by associating both objective and subjective PA with health indicators and clinical risk variables, we quantified the epidemiological implications of the relationship between subjective and objective PA versus just studying the concordance between objective and subjective PA. We found that BMI and pulse rate followed a positive relation with MVPA and a negative association in the case of increased MVPA. Further, we showed that objective MVPA measurements, even in the presence of subjective MVPA, captured more robust signals than subjective MVPA. Importantly, the framework we presented here allows us to quantify the quality of relationships produced by mHealth versus self-reported approaches. We showed that our comparison should be carried out to evaluate the degree of bias of self-reported versus mHealth devices in large cohort studies. This has implications beyond the accelerometer devices used in this study and is generalizable to other mHealth devices. Thematically, these findings demonstrate addressing key themes in mHealth, including mHealth for Data Collection and Research, Evaluation and Research Methodology for mHealth, and Fitness Trackers.

Abstract

Background: Consumer-grade wearables allow researchers to capture a representative picture of human behavior in the real world over extended periods. However, maintaining users' engagement remains a challenge and can lead to a decrease in compliance (eg, wear time in the context of wearable sensors) over time (eg, "wearables' abandonment").

Objective: In this work, we analyzed datasets from diverse populations (eg, caregivers for various health issues, college students, and pediatric oncology patients) to quantify the impact that wear time requirements can have on study results. We found evidence that emphasizes the need to account for participants' wear time in the analysis of consumer-grade wearables data. In Aim 1, we demonstrate the sensitivity of parameter estimates to different data processing methods with respect to wear time. In Aim 2, we demonstrate that not all research questions necessitate the same wear time requirements; some parameter estimates are not sensitive to wear time.

Methods: We analyzed 3 Fitbit datasets comprising 6 different clinical and healthy population samples. For Aim 1, we analyzed the sensitivity of average daily step count and average daily heart rate at the population sample and individual levels to different methods of defining "valid" days using wear time. For Aim 2, we evaluated whether some research questions can be answered with data from lower compliance population samples. We explored (1) the estimation of the average daily step count and (2) the estimation of the average heart rate while walking.

Results: For Aim 1, we found that the changes in the population sample average daily step count could reach 2000 steps for different methods of analysis and were dependent on the wear time compliance of the sample. As expected, population samples with a low daily wear time (less than 15 hours of wear time per day) showed the most sensitivity to changes in methods of analysis. On the individual level, we observed that around 15% of individuals had a difference in step count higher than 1000 steps for 4 of the 6 population samples analyzed when using different data processing methods. Those individual differences were higher than 3000 steps for close to 5% of individuals across all population samples. Average daily heart rate appeared to be robust to changes in wear time. For Aim 2, we found that, for 5 population samples out of 6, around 11% of individuals had enough data for the estimation of average heart rate while walking but not for the estimation of their average daily step count.

Conclusions: We leveraged datasets from diverse populations to demonstrate the direct relationship between parameter estimates from consumer-grade wearable devices and participants' wear time. Our findings highlighted the importance of a thorough analysis of wear time when processing data from consumer-grade wearables to ensure the relevance and reliability of the associated findings.

Introduction

Physical activity can be used to prevent and treat multifarious health issues. In the clinical setting and in research studies, the assessment of physical activity level is often carried out using self-report questionnaires. However, because self-reports are low in resolution, subjective, and often limited in scope, researchers have been looking for solutions to objectively quantify physical activity [1,2]. In the early 21st century, smartwatches and fitness trackers entered the consumer market [3]. These consumer-grade devices integrate a combination of sensors to measure key health metrics such as step count or heart rate. With the realization that fitness trackers can motivate users to exercise by providing them with real-time feedback, researchers and clinicians are now increasingly using these devices to monitor individuals [4-7]. In particular, Fitbit (Google Inc) smartwatches have imposed themselves in the clinical world due to their low price, high battery life, user-friendliness, and compatibility with most smartphones on the market. However, useful data can only be collected if participants are compliant and wear the watch.

With longitudinal studies, it can be challenging to maintain users' engagement and compliance. It is common to observe what is called "wearables' abandonment"; as the excitement from having a new gadget wears off, people start to wear the sensors less and less [8]. In the accelerometer research—where accelerometers are commonly used to monitor physical activity—researchers have established different methods to account for wear time in the data processing pipeline [9-12]. In both the Fitbit and the accelerometer literature, when wear time is considered, researchers use different thresholds on daily wear time or on step count to preprocess their data and extract valid days [13-16]. However, as wear time and activity levels vary for each study population, those thresholds might not always be generalizable or may be overly strict for some research questions. For instance, a very active population might need a higher step count threshold compared to a sedentary population. This suggests that researchers should evaluate whether their selected wear time requirements are appropriate for their study population and research question to ensure the validity of their data processing [17]. Researchers should also present a justification for their wear time requirements. Furthermore, as different research questions might require a different amount of data, the required amount of data will need to be adapted.

In this work, we aimed to further the understanding of the effects of compliance on parameter estimates. Our objective was to (Aim 1) quantify the sensitivity of calculations to different wear time requirements between and within different population samples and (Aim 2) demonstrate that not all research questions may require identical wear time requirements. We leveraged three Fitbit datasets from six different populations to illustrate this work: the estimation of the average (1) daily step count, (2) daily heart rate, and (3) average heart rate while walking. As the use of consumer-grade wearables is rapidly increasing, this work provides a thorough demonstration of the potential impact of wear time on essential parameter estimates in a diversity of populations (clinical and nonclinical) with varying degrees of compliance. This work provides quantitative evidence of the need to use wear time requirements in data analyses, specifically for study population samples with low compliance.

Methods

Description of Datasets

For this study, 3 Fitbit datasets from 6 different populations were used (Table 1).

Table . Dataset details.

Dataset	Caregivers			Students	Pediatric oncology	
	Hematopoietic cell transplantation	Huntington disease	Spinal cord injury		Caregivers	Patients
Sample size, n	30	21	19	2107	49	44
Study length, days	90	90	90	90	120	120
Fitbit type	Fitbit Inspire 2	Fitbit Inspire 2	Fitbit Inspire 2	Fitbit Charge	Fitbit Charge	Fitbit Charge
Fitbit wear instructions	Wear as much as possible	Wear as much as possible	Wear as much as possible	40 h/wk	Wear as much as possible	Wear as much as possible
Fitbit wear incentives	Fitbit given + US $1/day if some Fitbit OR survey data	Fitbit given + US $1/day if some Fitbit OR survey data	Fitbit given + US $1/day if some Fitbit OR survey data	Fitbit given	Fitbit given	Fitbit given

Three Different Caregiver Groups

The details of this study protocol can be found in Carlozzi et al [18]. Briefly, caregivers for persons with Huntington disease (HD), spinal cord injury (SCI), and hematopoietic cell transplantation (HCT) from different clinics at the University of Michigan were recruited between November 2020 and June 2021. This study's objective was to evaluate a just-in-time adaptive intervention to promote caregivers' self-care. This intervention leveraged the combination of Fitbit and survey data collected using an app (TBI-CareQOL). It is important to note

XSL•FO
RenderX

that participants were reminded to sync their Fitbit data every Monday and Friday if they had not already done so.

College Students

The details of this study protocol can be found in Cislo et al [19]. Briefly, graduate and undergraduate students at the University of Michigan were recruited between September 2020 and December 2020 to study students' mental health and physical activity during the COVID-19 pandemic. Different measures were collected using surveys, a smartphone app (Roadmap 2.0), and a Fitbit smartwatch.

Pediatric Oncology Caregivers and Patients

This dataset was collected in a study evaluating the use of a mobile health app (Roadmap 2.0) intervention for cancer caregivers and their patients [20]. Participants were recruited between September 2020 and September 2021 from the Adult and Pediatric Hematology and Oncology Units of Mott Children's Hospital in Ann Arbor, MI.

Data Analysis and Statistics

Compliance Levels for Each Population

We first compared the level of compliance and wear time for each population. To calculate wear time, we used the heart rate data from the Fitbit watch [13]. A heart rate value was registered by the watch every minute if the watch was worn. Thus, wear time was calculated as follows:

(1)Wear time=# Minutes of registered heart rateTotal minutes

Total minutes depended on the time frame of interest. For instance, if we wanted to calculate wear time over 24 hours, the total number of minutes was 1440 minutes. Because our groups did not have a similar variance, and the sample sizes were largely different, the difference in wear time between groups was evaluated using a Kruskal-Wallis test [21]. If the omnibus test was significant, the Dunn test was used to evaluate pairwise differences [22]. Significance was evaluated at the .05 level.

Aim 1: Sensitivity of Parameter Estimates to Different Wear Time Requirements

For Aim 1, three different definitions of compliance were used to evaluate the impact on the evaluation of the average daily step count and average daily heart rate for the population and the individual. Both of these measures have been used to determine fitness levels in multifarious populations [20-22]. Compliance was expressed in the form of valid days, where a valid day corresponded to a day that met a certain criterion and was kept for analysis. The 3 different definitions of a valid day were as follows: (*None*) all days were considered valid, (*StepCount1000*) a day was valid if the step count registered for that day was greater than 1000, and (*WearTime80*) a day was valid if the wear time that day (24 hours) was greater than 80% (19.2 hours). For that last definition, wear time was calculated using equation (1). The definitions of a valid day *StepCount1000* and *WearTime80* were based on studies found in the literature [13,14]. These 2 definitions also offer different perspectives on wear time by leveraging 2 distinct data types (step count vs wear time, defined here using heart rate). We also added the definition *None* to demonstrate the impact of not including wear time in analyses, which is the case in a large number of studies that use consumer-grade wearables [17]. The average daily step count and heart rate were calculated for the population and each individual using these 3 different definitions. The code to extract participants' wear time using Fitbit heart rate data and evaluate effects on step count is available on GitHub [23]. This repository includes the data preprocessing scripts and analysis code using an open-source Fitbit dataset.

Aim 2: Effect of Compliance on the Research Objective

For Aim 2, we examined the effect of compliance on the ability to address different research questions. We wanted to investigate whether some research questions can be answered, even when subject compliance is poor. Two research objectives were compared for this aim: (1) the evaluation of average daily step count and (2) the evaluation of average heart rate while walking. Heart rate while walking can be an indicator of cardiac health and exercise intensity [24-26]. To obtain heart rate while walking, we used Fitbit's number of steps taken in a minute and isolated instances where that value was above 80 steps taken in a minute. That indicated a high likelihood for an individual to be on a walk [27]. Then, we isolated the values of heart rate corresponding to those instances that we named walking heart rate. To determine the minimal number of samples of walking heart rate (eg, the number of data points of heart rate corresponding to our definition of walking heart rate) needed to converge to a confident average, the standard error was calculated for an increasing random number of samples. A threshold of 1 bpm (beats per minute) was set for convergence (Figure 1). Once the minimum number of samples necessary for each individual was found, the number of days needed to get this amount of samples was extracted.

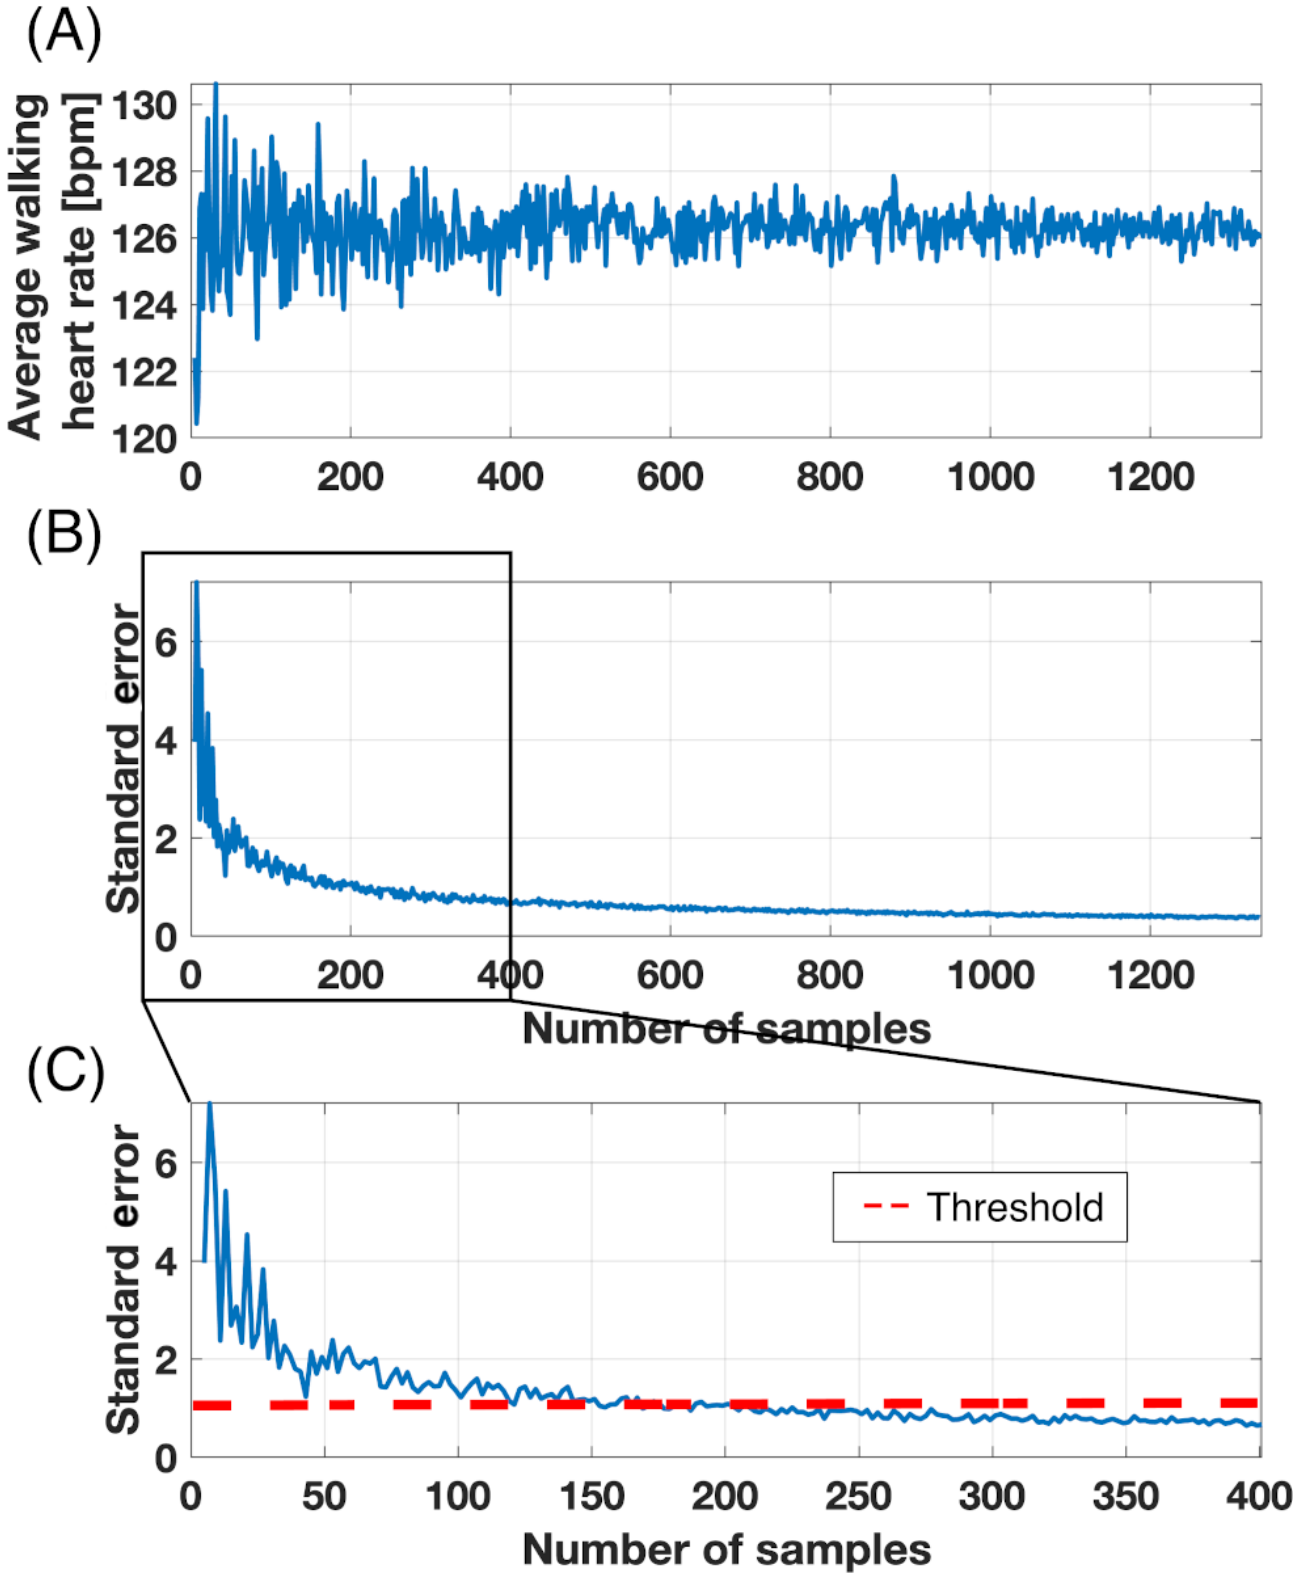
RenderX

Figure 1. Evolution of average steps taken in a minute (A) and standard error (in steps) (B and C) with an increase in the number of samples for a representative subject. (C) is the expansion of (B) to visualize the number of samples necessary for this individual to obtain a standard error below 2. bpm: beats per minute.



Ethical Considerations

All datasets were generated by teams at Michigan Medicine at the University of Michigan, and the different data collection protocols were each approved by the University of Michigan institutional review board, under the review numbers HUM00186436, HUM00176584, HUM00184455, and HUM00185391. All participants provided informed consent prior to their participation in the study. The details of the compensation for each study are provided in Table 1.

Results

Wear Time

The average wear time of the device varied by population (Figure 2). The most compliant sample was the HCT caregivers with an average daily wear time of 20.8 hours. The least compliant sample was the pediatric oncology patients with an average daily wear time of 9.8 hours. Differences were also observed in the spread of the data. For the pediatric oncology patients and caregivers and the student sample, the distribution went from 0% to above 90% of wear time. A 0% wear time indicated that participants received the Fitbit but never wore it.

There were significant differences in the average wear time between populations (Table 2). Notably, the pediatric oncology patients had significantly lower wear time than all other studied samples except for the pediatric oncology caregivers. The HCT caregivers also had significantly higher wear time than the other groups, except for the SCI and HD caregivers.

A decrease was observed in monthly wear time for all recruited groups. The average decrease was a little more than 10%, with the highest decrease recorded for the pediatric oncology patients (−19%) and the lowest decrease recorded for the HCT caregivers (−8%).

Figure 2. Distribution of average daily wear time in percentages (left) and hours (right) for each recruited sample. The pediatric oncology patients and caregivers population, as well as the student population, had participants that were given a Fitbit and never wore it. As such, there are instances with 0 hours of daily wear time in the distributions. HCT: hematopoietic cell transplantation; HD: Huntington disease; SCI: spinal cord injury.

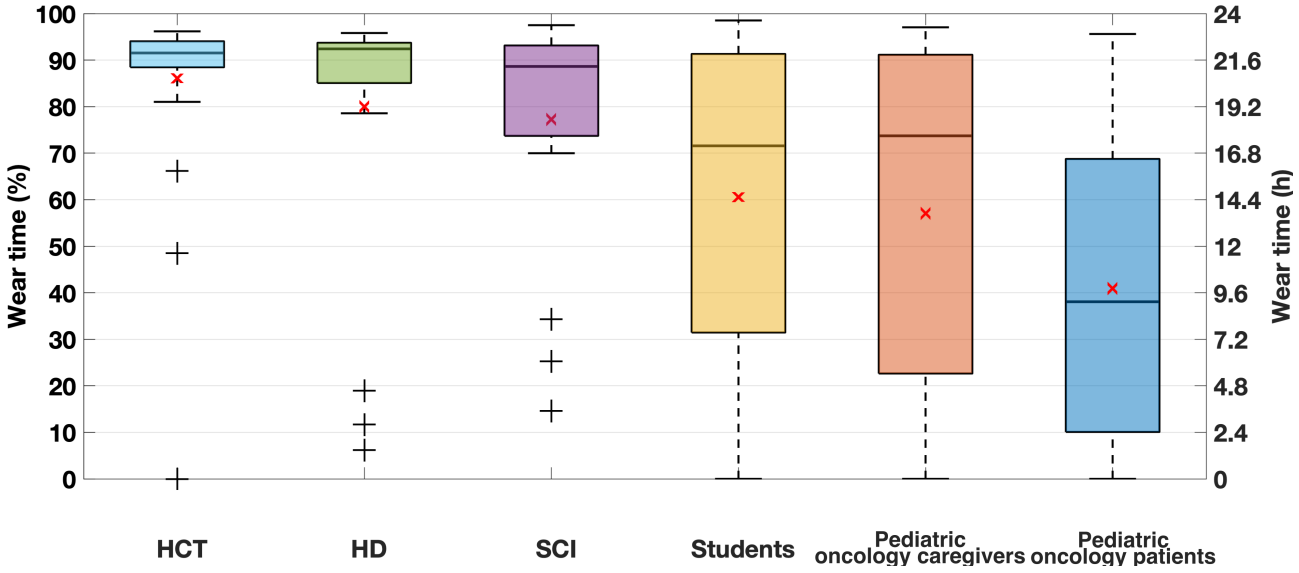

Table . Model coefficients and significance from post hoc test evaluating the difference in wear time between samples.

	HCT[a]	HD[b]	SCI[c]	Students	Pediatric oncology caregivers

Aim 1

Population Level

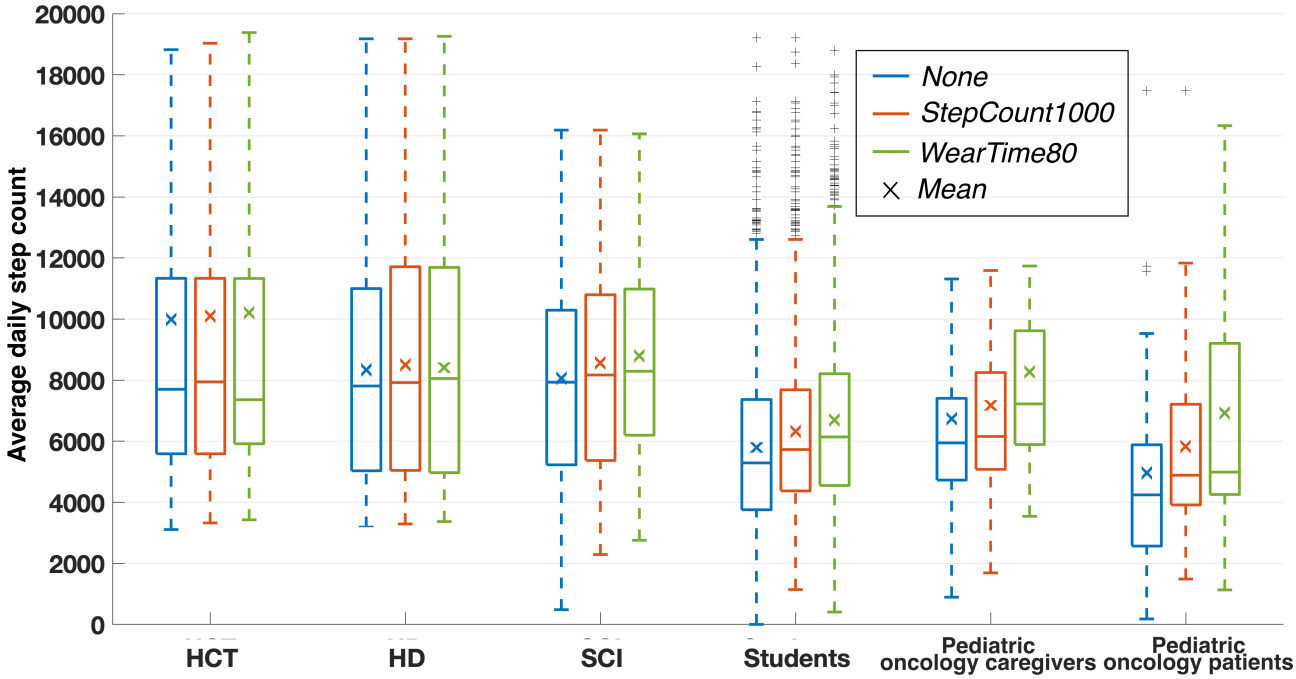
First, we observed the changes in the sample average daily step count for the 3 chosen definitions of a valid day (Figure 3). The average number of valid days decreased between 15% and 33% from the definition *None* to *WearTime80*. The decrease from *None* to *StepCount1000* was around 12% for the SCI caregivers and the pediatric oncology patients and close to 0% for the other samples. There was also a decrease from *StepCount1000* to *WearTime80* from 12% to 21%. The change in average daily

XSL•FO
RenderX

step count was dependent on the sample. HCT and HD caregivers both showed a difference smaller than 15 steps between *None* and *WearTime80*. On the other hand, the pediatric oncology patients showed a difference of almost 2000 steps between *None* and *WearTime80*. The sample sizes decreased from *None* to *WearTime80* for the pediatric oncology patients, caregivers, and students (n=6, −14%; n=10, −20%; and n=7, −8%; respectively).

We also analyzed changes in the sample average daily heart rate for the 3 definitions. We found only small differences in average daily heart rate for all samples. The student sample showed the largest difference of 3 bpm between *None* and *WearTime80*.

Figure 3. Average daily step count across samples for the different definitions of a valid day. The effect of these different definitions was dependent on the sample, going from less than 80 steps for the HD sample to almost 2000 steps for the pediatric oncology patients. HCT: hematopoietic cell transplantation; HD: Huntington disease; SCI: spinal cord injury.



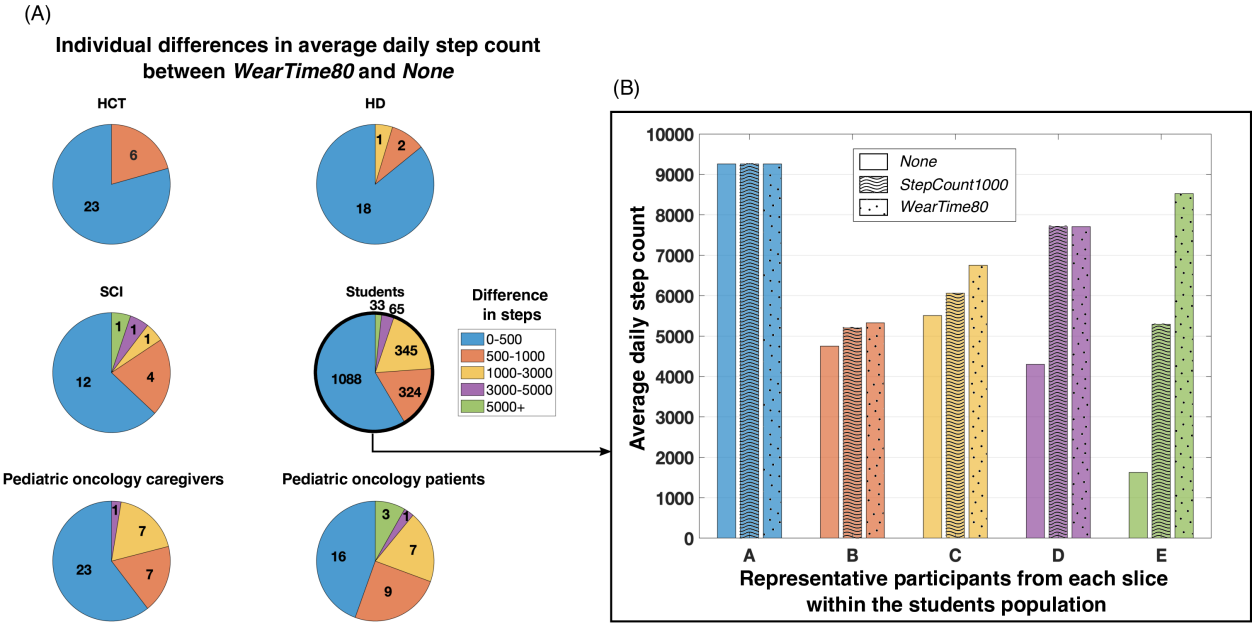
Individual Level

We assessed the changes in each individual's average daily step count (Figure 4). We binned individuals based on the average daily step count difference between *None* and *WearTime80*, since those definitions were the least and most stringent, respectively (Figure 4A). For all samples, the majority of individuals had a difference in average daily step count between 0 and 500 steps. The HCT caregivers had the least differences in individual steps, followed by the HD caregivers. Approximately, a quarter of the SCI caregivers, pediatric oncology patients and caregivers, and students had a step count difference higher than 1000. By taking a closer look at the individuals in each bin for a group (Figure 4B), we saw that participants like participant A did not display any difference in average daily step count between each definition. However, participants like participant E showed a difference higher than 3000 steps between each definition, with that difference reaching almost 7000 steps between *None* and *WearTime80*.

Little to no variation was observed within participants for the average daily heart rate between *None* and *WearTime80*. Only 3% (n=1) of the pediatric oncology patient participants had a difference between 5 and 10 bpm, and less than 1% (n=21) of students had a difference between 10 and 15 bpm.

XSL•FO
RenderX

Figure 4. (A) Individual differences in average daily step count calculated using *None* versus *WearTime80*. For example, 21% (n=6) of the HCT sample had a difference in average daily step count between 500 and 999 steps when calculations were made using *WearTime80* versus *None*. The grouping of the step differences was inspired by the physical activity level categories presented by Tudor-Locke and Bassett [28]. (B) Five representative participants' average daily step count from the different slices of difference in step count, using the 3 definitions of a valid day. For example, participant E was representative of students who had a difference in average daily step count larger than 5000 when calculated with *WearTime80* compared to *None*. HCT: hematopoietic cell transplantation; HD: Huntington disease; SCI: spinal cord injury.

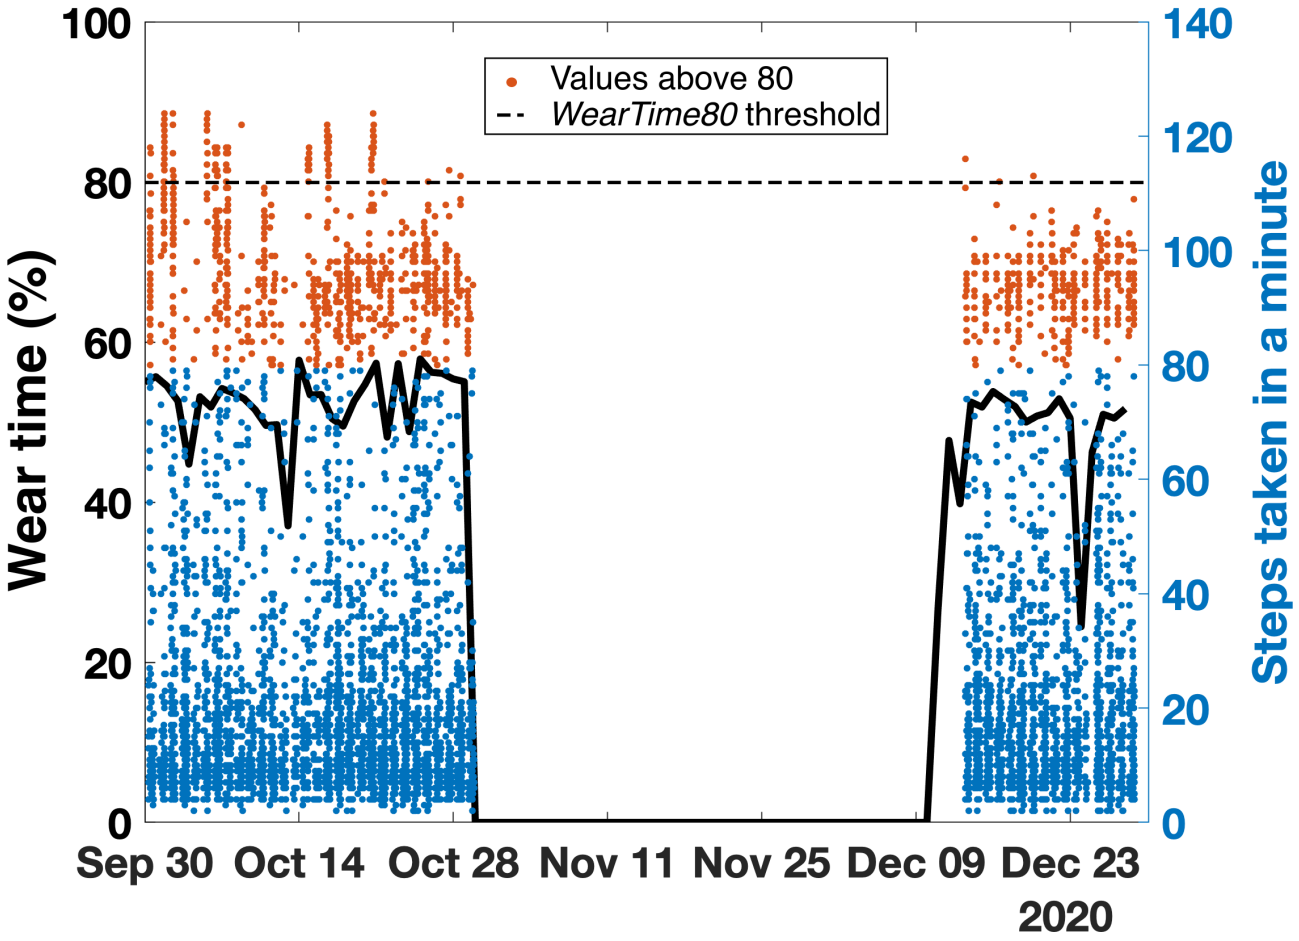


Aim 2

On average, across all population samples, 304 samples (minutes of walking) were needed to obtain an estimate of the walking heart rate with a standard error of 1 bpm. For most individuals, the minimal number of samples was reached in under 26 days of data collection. For the pediatric oncology caregivers, 1 participant did not have enough samples to obtain a confident estimate of the walking heart rate, but an estimate of that caregiver's average daily step count using *WearTime80* was obtained. On the other hand, 5 (17%) HCT, 3 (14%) HD, 2 (11%) SCI, 186 (10%) students, and 3 (7%) of the pediatric oncology patients did not have any valid days to calculate their average daily step count but presented enough samples to confidently obtain their walking heart rate. Figure 5 illustrates an individual's data from the student sample within that 10%. That individual wore the Fitbit at the beginning and the end of the study for around 50% of the day. That student had 1314 samples of steps taken in a minute—enough to estimate walking heart rate—while presenting no days with a wear time higher than 80%.

XSL•FO
RenderX

Figure 5. Wear time (black line, left axis) and steps taken in a minute (blue and orange dots, right axis) over time for an individual from the student sample. Average daily step count using *WearTime80* with this participant was not possible as no days presented a wear time larger than 80%. However, there was a sufficient number of samples to confidently estimate walking heart rate based on the number of samples of steps taken in a minute that was above 80.



Discussion

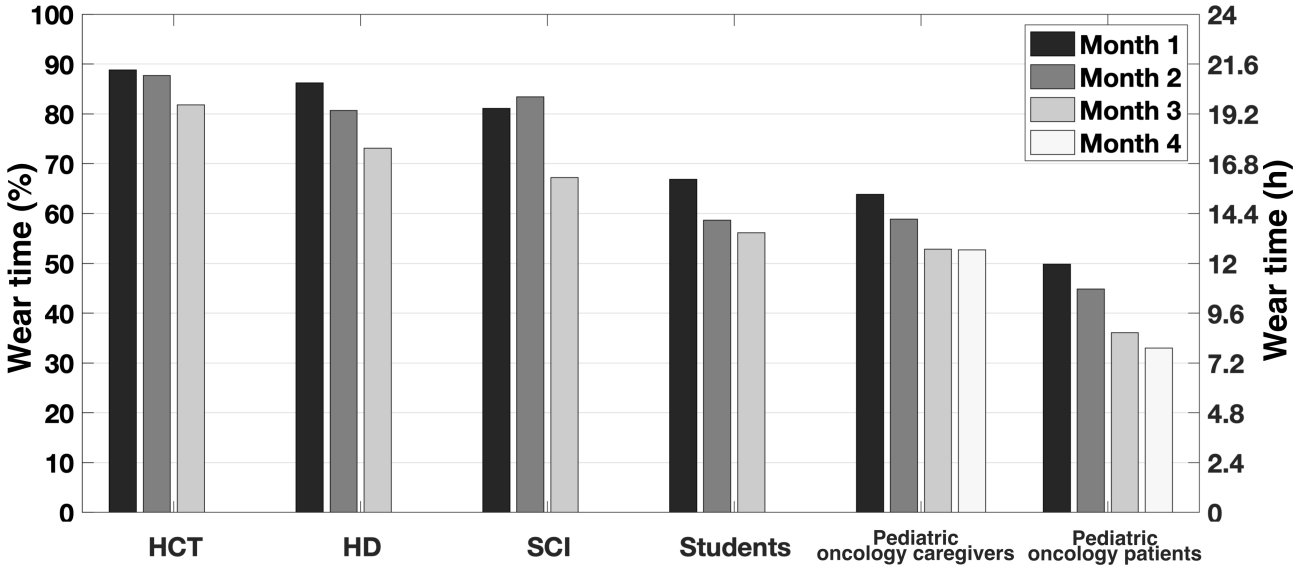
Principal Results

The purpose of this study was to quantify how wear time could impact parameter estimates in studies using consumer-grade wearables by using real-world samples with varying participant compliance. This work is distinguished from the literature by demonstrating the conditional nature of wear time's influence in consumer-grade wearables' data, which varies significantly across research samples and research questions. By leveraging a broad array of datasets, including vulnerable patient populations, we showed evidence of the nuanced effect of wear time, highlighting its critical role in research using wearables, especially in samples with inconsistent wear patterns such as the pediatric oncology caregiver and patient participants used in this study. It is important to note that the pediatric oncology patients' ages ranged from 5 to 20 years, with a mean of 11.9 years. The young age combined with illness for these subjects likely explained this population sample's low level of wear time with large variability.

Unsurprisingly, implementing different wear time requirements to define a valid day can significantly impact parameter estimates, especially in samples with low compliance. Wear time compliance for the HD and HCT caregivers was high (Figure 6); therefore, the estimates of the samples' average daily step counts were minimally affected by different definitions of a valid day (Figure 3). In comparison, the pediatric oncology patient sample had low wear time compliance (Figure 6); therefore, the estimate of the sample average daily step count was significantly impacted by different definitions of a valid day (Figure 3). Importantly, our analysis quantifies these differences so that other researchers can better understand the potential implications of different valid day definitions. The definition of a valid day had almost no impact on estimates of the average daily heart rate across samples. This also is not surprising as heart rate is a more stable measure that does not necessarily correlate with wear time; any biases from missing data are averaged out.

XSL•FO
RenderX

Figure 6. Monthly average daily wear time in percentages (left) and hours (right). We observed a monthly decrease in wear time for all groups symptomatic of the phenomenon of wearables' abandonment. The pediatric oncology dataset was collected over 120 days versus 90 days for the other datasets. HCT: hematopoietic cell transplantation; HD: Huntington disease; SCI: spinal cord injury.



A significant novelty in this work is demonstrating the flexibility of data usage in real-world settings (ie, outside of the hospital). In fact, we showed that even if an individual's data were not sufficient to answer a specific research question, those data could potentially still be leveraged toward a different analysis (eg, for the estimate of walking heart rate as shown in this study). In particular, the variations in the research question time frame (eg, daily, nighttime, and weekly) can lead to different levels of required compliance. For example, to accurately estimate the average number of steps per day, we need a sufficient number of days with high wear time. However, for the example we used in Aim 2—the estimation of walking heart rate—we need a sufficient number of steps taken in a bout of walking by an individual. As such, we show in our example how an individual can have a large amount of walking data throughout an entire study while not having enough individual days with high wear time (Figure 5). These findings suggest that even samples with low compliance may still be useful for answering research questions. In this case, even a day with low wear time (ie, not a valid day) may contain several valid walks useful for estimating average walking heart rate.

Secondary Findings

We also found that depending on whether one is interested in studying a population as a whole or the individuals within a population, the impact of wear time differed. For instance, in the student population, we observed only a small change in the estimated average daily step count in the population with the different methods of analysis (Figure 3). Depending on the objective of a study, that change could be negligible. However, if research is conducted to design a physical activity intervention or to evaluate the efficacy of an intervention, for example, the processing of an individual's data without the inclusion of wear time could lead to critical errors (Figure 4). In particular, if one considers the standard classification of participants into levels of physical activity (0 - 5000 daily steps: sedentary; 5000 - 7500: low active; 7500 - 10,000: somewhat active; 10,000+: highly active) [28], those errors can induce a misclassification. Ultimately, the intervention design or the evaluation of the intervention could be erroneous.

We quantified the phenomenon of wearables' abandonment within our different populations (Figure 6). That phenomenon can potentially create a bias in results over time. For example, a monthly decrease in the population sample level of physical activity can be explained by an actual decline in people's movements or by the fact that participants were not wearing their sensors as much. An appropriate quantification of wear time in the analysis can potentially remove that bias.

Comparison With Prior Work

While the literature on accelerometer usage presents various methodologies for accounting for wear time, it is essential to acknowledge that raw acceleration data or activity counts, typical outputs from accelerometers, are not available from consumer-grade wearables. Therefore, the strategies for considering wear time in the context of these devices necessitate their own approach. Consumer-grade wearables often offer summarized or processed data, which requires tailored methods for wear time analysis to ensure accurate and meaningful interpretation in research contexts. In general, research data on the analysis of wear time and compliance with consumer-grade wearables are sparse in the literature. Often, studies using consumer-grade wearables, such as smartwatches, rely on threshold-based methodologies for processing wear time [13-16]. However, these thresholds are often implemented without sufficient justification based on the specific dataset being analyzed and the research objectives.

Claudel et al [17] developed a novel method to calculate wear time and determine a valid assessment day. Their proposed method calculated wear time using heart rate detection, step count, and the range of heart rate values. A valid day was defined as a day with more than 10 hours of wear time, with the removal of sleeping hours (from 11 PM to 5 AM). Claudel and colleagues present a structured and detailed methodology that can potentially be replicated for other studies. It highlights

XSL•FO
RenderX

the importance of nighttime in wear time calculations and how researchers can conduct a sensitivity analysis to determine the impact of different nighttime limits on the outcome variables. Our study also demonstrates the potential impact of different calculations of wear time on parameter estimates. Both studies illustrate the importance of considering how the definition of a valid day may impact sample parameter estimates.

Studies have explored the factors that are related to compliance levels [13]. The NetHealth study [13] collected data from a student population using Fitbit devices and showed that some personality traits (eg, extraversion and openness) and Fitbit metrics (eg, minutes asleep and sedentary minutes) were related to compliance levels. Understanding the underlying reasons that may lead an individual to be more or less compliant can be useful in improving the overall wear time levels in these types of studies.

Another, perhaps more, direct way to increase compliance is through the use of incentives. There is a range of incentive models one can use to maintain compliance in longitudinal studies [29]. Although improving compliance allows for parameter estimates to be less sensitive to wear time, it is difficult to imagine a "one size fits all" incentive model that would work on every single participant of a study. Thus, the analysis of wear time is likely to remain a crucial step in the analysis of consumer-grade wearables data to ensure accurate parameter estimates.

Limitations

In the accelerometer literature, raw outputs from the sensors are most often used to determine wear time [10,11], which removes a layer of potential error. The outputs provided by Fitbit are processed (as opposed to raw) with unknown algorithms. Here, we assumed those outputs, and in particular minute-by-minute heart rate, were reliable and could be used to accurately estimate wear time. Claudel et al [17] formulated a more complex wear time calculation algorithm fusing both heart rate detection and heart rate values revealing a potential overestimation of wear time when using heart rate detection only. Determining the most accurate estimate of wear time was beyond the scope of this study. However, further research should be conducted to validate methods for the calculation of wear time using the processed outputs of consumer-grade wearables as it may influence parameter estimates.

We assumed in Aim 2 that wear time was random. In other words, we assumed that participants did not choose a particular moment in their day to wear the device, which would bias the estimates of walking heart rate. However, this does not influence the conclusion of Aim 2, as we primarily focused on the amount of data needed to estimate a parameter with confidence, and not whether we could accurately estimate true walking heart rate.

It is important to note that the different datasets we used came from 2 different Fitbit devices (Fitbit Charge and Fitbit Inspire 2). It is possible that the versions of software and hardware are different between these 2 devices. Since the software information is proprietary information, we do not know whether the model differences impacted the used outputs. However, we expect and assume that the measurements between the 2 models are comparable and did not have a significant impact on our analysis.

Additionally, although we analyzed samples from different populations, our results may not translate to similar populations. First, each population sample was given a different set of instructions, which influenced their wear time. Second, Fitbit data syncing can be difficult and depends on the software used as well as the Fitbit model itself. Thus, the amount of data retrieved for the same population sample can be variable from one study to another. Finally, the different datasets used in this study were all collected during the COVID-19 pandemic, which may have affected the health-related behaviors of participants. We recommend that researchers conduct an analysis of wear time systematically when using sensing technologies to derive conclusions.

Conclusions

One of the major benefits of leveraging fitness trackers is the potential to gain a unique and objective insight into an individual's natural behavior. However, if the analysis of wear time is not appropriately integrated into the data processing pipeline, that purported insight can become biased and imprecise, driving the results away from reality. Herein, we presented evidence of the critical impact of wear time on parameter estimates and how that impact may vary depending on the population sample, research question, study design (ie, incentives), and participant compliance. Future research could significantly benefit from our findings and methodological examples to incorporate the following recommendations: first, it is essential to conduct a thorough analysis of the wear time of the population in any given study that uses wearables, with particular attention to the data available when using consumer-grade wearables; second, it is equally important to systematically document and provide comprehensive details on that analysis. Our work provides quantitative data on the impact that different valid day definitions can have on sample parameter estimates in samples with varying wear time compliance.

Acknowledgments

The Roadmap projects that leveraged the Fitbit wearable sensors across the pediatric oncology and college student populations were supported by the National Institute of Health and National Heart, Lung, and Blood Institute (grants 1R01HL146354 and K24HL156HL156896), the Edith S Briskin and Shirley K Schlafer Foundation, the University of Michigan Taubman Institute (Taubman Institute Innovation Project), and by a Scientific Research Initiative grant from the Biosciences Initiative of the University of Michigan Biosciences Initiative. The CareQOL JITAI project that used Fitbit wearable sensors across hematopoietic cell transplantation, spinal cord injury, and traumatic brain injury populations was supported by the following grants: R01NR013658 from the National Institutes of Health (NIH)/National Institute of Nursing Research; R01HL146354 and K24HL156896 from the

Abstract

Background: Chronic heart failure (CHF) has become a serious threat to the health of the global population. Self-management is the key to treating CHF, and the emergence of mobile health (mHealth) has provided new ideas for the self-management of CHF. Despite the many potential benefits of mHealth, public utilization of mHealth apps is low, and poor health literacy (HL) is a key barrier to mHealth use. However, the mechanism of the influence is unclear.

Objective: The aim of this study is to explore the dyadic associations between HL and mHealth usage intentions in dyads of patients with CHF and their caregivers, and the mediating role of mHealth perceived usefulness and perceived ease of use in these associations.

Methods: This study had a cross-sectional research design, with a sample of 312 dyads of patients with CHF who had been hospitalized in the cardiology departments of 2 tertiary care hospitals in China from March to October 2023 and their caregivers. A general information questionnaire, the Chinese version of the Heart Failure-Specific Health Literacy Scale, and the mHealth Intention to Use Scale were used to conduct the survey; the data were analyzed using the actor-partner interdependence mediation model.

Results: The results of the actor-partner interdependent mediation analysis of HL, perceived usefulness of mHealth, and mHealth use intention among patients with CHF and their caregivers showed that all of the model's actor effects were valid (β=.26 - 0.45; *P*<.001), the partner effects were partially valid (β=.08 - 0.20; *P*<.05), and the mediation effects were valid (β=.002 - 0.242, 95% CI 0.003 - 0.321; *P*<.05). Actor-partner interdependent mediation analyses of HL, perceived ease of use of mHealth, and mHealth use intention among patients with CHF and caregivers showed that the model's actor effect partially held (β=.17 - 0.71; *P*<.01), the partner effect partially held (β=.15; *P*<.01), and the mediation effect partially held (β=.355 - 0.584, 95% CI 0.234 - 0.764; *P*<.001).

Conclusions: Our study proposes that the HL of patients with CHF and their caregivers positively contributes to their own intention to use mHealth, suggesting that the use of mHealth by patients with CHF can be promoted by improving the HL of patients and caregivers. Our findings also suggest that the perceived usefulness of patients with CHF and caregivers affects patients' mHealth use intention, and therefore patients with CHF and their caregivers should be involved throughout the mHealth development process to improve the usability of mHealth for both patients and caregivers. This study emphasizes the key role of patients' perception that mHealth is easy to use in facilitating their use of mHealth. Therefore, it is recommended that the development of mHealth should focus on simplifying operational procedures and providing relevant operational training according to the needs of the patients when necessary.

KEYWORDS

chronic heart failure; caregivers; health literacy; mHealth; actor-partner interdependence mediation model; mobile health

Introduction

Heart failure is a condition of signs and symptoms triggered by structural or functional abnormalities of the heart, as evidenced by elevated natriuretic peptide levels and cardiogenic, pulmonary, or systemic congestion [1]. Chronic heart failure (CHF) manifests as a persistent state of heart failure that may be stable, worsening, or decompensated [2]. As a severe or advanced manifestation of a wide range of cardiovascular diseases, CHF is known for its high morbidity and mortality and has become an important public health problem threatening the health and lives of the global population [3]. According to the Global Heart Failure Survey, the average incidence of CHF reaches 460/100,000 persons/year, while the 5- and 10-year survival rates of patients after diagnosis are only 57% and 35%, respectively [4,5]. More worryingly, approximately 60% of patients with CHF die within 5 years of diagnosis [6,7].

Studies have shown that self-management is important for patients with CHF to improve cardiac function, improve disease prognosis, and reduce mortality [8]. With the increasing popularity of smartphones and wearable devices, mobile health (mHealth) has gradually become a new means to support self-management in patients with CHF [9]. mHealth refers to the integrated application of mobile phones and other wireless technologies in medical practice, and its functions cover a wide range of aspects such as booking appointments, health information inquiry, and vital signs monitoring [9]. Although the role of mHealth in facilitating self-management in patients with CHF has been widely recognized, the actual usage of mHealth by patients is generally low [10,11].

Health literacy (HL) refers to an individual's ability to access, understand, process, and utilize health information to promote one's health [12]. As information largely moves to a digital medium, HL takes on an added dimension in supporting the skills needed to understand online health information, which makes digital health a significant component of HL [13-15]. It has been evidenced that digital HL is an important indicator of mHealth use intention, indicating that HL is an important factor influencing mHealth use intention [16]. On the other hand, mHealth use intention would reinforce individual motivation and confidence to broadly develop their literacy about digital health and HL as well [17]. Additionally, the study indicates that individuals who intend to seek health-related information or advice on the internet exhibit higher digital HL levels, suggesting that mHealth use intention could contribute to an increase in HL [18]. Existing studies have shown that HL is positively associated with mHealth use intention and behavior. Specifically, the higher the level of HL of patients, the more likely they are to adopt and use mHealth technologies, and vice versa [19,20]. Although the association between HL and willingness to use mHealth has been reported several times, the exact mechanism remains to be further explored. According to the Technology Acceptance Model (TAM) theory, users' actual adoption or rejection of a technology such as mHealth is primarily affected by 2 factors, namely perceived usefulness and perceived ease of use [21]. The same researchers determined that perceived ease of use and perceived usefulness of telemedicine services have a substantial effect on the telemedicine behavioral intention of older patients [21]. Additionally, it has been evidenced that HL can influence the perceived usefulness and perceived ease of use of mHealth [22,23]. Hence, perceived usefulness and perceived ease of use of mHealth might act as mediators of HL and mHealth use intention.

In addition, previous studies have pointed out that caregivers play an integral role in the self-management of patients with CHF [24,25]. Cheng et al suggested that caregivers bear 70% of the responsibility for chronic disease management [26]. According to Interdependence Theory, in a dyadic relationship, each person has the ability to influence the outcomes of the other, suggesting partners affect each other's motives, preferences, behaviors, and health outcomes [27,28]. Patients with CHF and their caregivers constitute a dyad, and the attributes of one dyad member can influence the motive and behavior of the other [26], hence, patients' and caregivers' HL might influence the partners' mHealth use intentions. The social influence variable in the Unified Theory of Acceptance and Use of Technology model also suggests that a patient's willingness to adopt a technology may be influenced by the perceptions of important people around them, such as caregivers [29,30]. However, current research has mostly explored mHealth use intentions from the single perspective of either the patient or the caregiver, ignoring the interactions between the two.

Therefore, this study explored in depth the underlying mechanism linking HL and mHealth use intention of patients with CHF and their caregivers from a dyad perspective, which can help provide targeted intervention for future mHealth use intention studies, thus promoting the use of mHealth among patients with CHF.

Methods

Design and Sample

This study adopted a cross-sectional research design with a convenience sampling method. Patients with CHF admitted to the cardiology departments of 2 tertiary care hospitals in Yunnan Province, China, from March to October 2023 and their caregivers were selected for the study. The inclusion criteria for patients with CHF were as follows: (1) age ≥18 years old; (2) compliance with the 2022 AHA/ACC/HFSA Guidelines for the Management of Heart Failure [2] diagnostic criteria for CHF; (3) meeting New York Heart Association (NYHA) cardiac function class I-III; (4) at least one caregiver; (5) being able to complete the questionnaire independently or under the guidance of the researchers; and (6) voluntarily participating in this study. The exclusion criteria for patients with CHF were as follows: (1) acute myocardial infarction or acute pulmonary embolism in the past month; (2) with other critical diseases, such as malignant tumor, renal failure, respiratory failure; (3) not using smartphones; (4) cognitive disorders or psychiatric disorders;

XSL•FO
RenderX

and (5) being involved in other research projects. Caregiver inclusion criteria were as follows: (1) informal caregivers who are the primary caregiver and provide care and support to the patient without compensation [26,31]; (2) age ≥18 years old; (3) being able to complete the questionnaire independently or under the guidance of the researchers; and (4) voluntarily participating in the study. Caregiver exclusion criteria were as follows: (1) cognitive impairment or mental illness; (2) serious physical disease, such as cancer or vital organ failure; (3) not using smartphones; and (4) participating in other studies. According to Ledermann et al [32], in the actor-partner interdependence model (APIM), a sample size of approximately 93 to 241 dichotomies is recommended, while for the actor-partner interdependence mediation model (APIMeM), a sample size of approximately 120 dichotomies is required for good mediation. Of 367 eligible patient-caregiver dyads, 31 were excluded from enrollment because one member of the dyad refused to participate, and 24 were excluded from the analysis because of missing data. Thus, 312 dyads were included in the final data analysis. This sample size met the requirement for structural equation modeling and APIMeM.

Data Collection

Before the survey, all of the researchers received unified training to familiarize themselves with the content of the questionnaire scale and to master the way of filling it out and the precautions to be taken. Data collection was carried out by patients with CHF and their caregivers alone, with the researcher providing guidance but not interfering with the study subjects. After the survey was completed, researchers checked the data on the spot; if they found any missing or wrongly filled items, they verified the data with the research subjects immediately and assisted them in completing the data.

Measures

Demographic and Clinical Characteristics

A questionnaire, which was designed by the researchers based on a large amount of literature, was used in the survey, and it included patients' information such as gender, age, literacy level, marital status, smoking history, drinking history, duration of heart failure, number of hospitalizations, NYHA cardiac function classification, previous history of cardiovascular disease, left ventricular ejection fraction, and BMI, as well as the caregiver's information such as gender, age, relationship with the patient, education level, occupation, marital status, monthly income, total caregiving time, caregiving time per day, and illness.

Health Literacy

The Heart Failure–Specific Health Literacy Scale (HF-SHLS) was used to measure HL; it was initially developed by Matsuoka et al [33] and Chineseized by Yue Meng et al [34] in 2016. The HF-SHLS consists of 3 dimensions with 12 entries, namely functional HL, interactive HL, and critical HL; each entry ranks from "not applicable" (score of 1) to "very applicable" (score of 4), and the total score ranges between 12 - 48, with a higher score representing a higher level of HL. The Cronbach values of the overall scale and 3 dimensions were 0.87, 0.84, 0.72, and 0.69, respectively [33,34], with acceptable internal consistency, and the scale was used with permission from the original authors.

mHealth Use Intention

In this study, "mHealth" refers to the integrated application of smartphones in medical practice, including activities such as booking appointments and inquiring about health information. The mHealth Service Use Intention Questionnaire, which was prepared by Shi Lin [35] was used to measure the perceived usefulness of mHealth, perceived ease of use of mHealth, and mHealth use intentions, which consists of 7 dimensions and 26 entries. Cronbach values for each dimension ranged from 0.822 - 0.968. In this study, the 3 dimensions measuring the perceived usefulness of mHealth, perceived ease of use of mHealth, and mHealth use intentions were used, with Cronbach values of each dimension being 0.904, 0.846, and 0.968, respectively. The indicators in the questionnaire are scored on a 5-point Likert scale, with scores of 1 - 5 representing strongly disagree, disagree, undecided, agree, and strongly agree; a higher score in the related dimension means a higher level of perceived usefulness of mHealth, perceived ease of use of mHealth, and mHealth use intentions. The scale was used with permission from the original authors. For the detailed items and response options of this questionnaire, please refer to Multimedia Appendix 1.

Statistical Analyses

SPSS (version 26.0; IBM Corp) and AMOS (version 26.0; IBM Corp) were used for data analysis. A value of $P<.05$ based on a 2-tailed test was considered statistically significant. Data were tested for normality (results are detailed in Multimedia Appendix 2), which was based on the Kolmogorov-Smirnov test when the sample size was greater than 50, and when $P<.05$, it was considered as not conforming to normal distribution [36]. The results showed that the data in this study did not conform to normal distribution. Thus, we used median and interquartile spacing to describe the skewed distribution. The Wilcoxon signed-rank sum test was used to detect differences in scores for HL, perceived usefulness of mHealth, perceived ease of use of mHealth, and mHealth use intention among patients with CHF and their caregivers. Spearman correlation analysis was used to test the relationship between HL, mHealth perceived usefulness, and perceived ease of mHealth in the patient-caregiver dyad in the context of CHF. APIMeM was used to construct the APIMeM of HL-perceived usefulness of mHealth-intention to use mHealth in patients with CHF and their caregivers and the APIMeM of HL-perceived ease of use of mHealth-mHealth use intention in patients with CHF and their caregivers. The nonnormal distributions were calculated using the bootstrap method. The fit of each model was assessed using X^2/df (<3), root mean square error of approximation (RMSEA; ≤0.08), comparative fit index (CFI; ≥0.90), and Tucker-Lewis index (TLI; ≥0.90). The mediating effects in APIMeM were tested using bootstrap analyses, with a sample size of 5000 and a confidence interval of 95%. Furthermore, we conducted multigroup APIMeM to analyze whether age and relationship with the patient moderated the dyadic effects. We used a *t* test, Mann-Whitney test, or Kruskal-Wallis test to determine whether there was a significant difference in the path

XSL•FO
RenderX

coefficients between groups based on the normality of the path coefficients of each group; significance tests were set at a 2-sided, $P \leq .05$.

Ethical Considerations

The study was approved by the Ethics Committees of the First Affiliated Hospital of Kunming Medical University (2022-L-304) and Fuwai Cardiovascular Disease Hospital of Yunnan Province (2023-033-01) and was conducted in accordance with the principles of the Declaration of Helsinki. Informed consent was obtained from all participants before the investigation. Participation in the study was entirely voluntary, and no compensation was provided for their involvement. Participant data were deidentified and stored on a local secure server. Further, the participants had the right to withdraw from the study at any time, without giving any reasons. In addition, no identification of individual participants or users in any images occurred in the manuscript or supplementary material.

Results

Characteristics of the Patient-Caregiver Dyads

A total of 312 dyads of patients with CHF and their caregivers were included in the final analysis. The age of patients with CHF ranged from 18 to 89 years old; most of them were male (65.7%), their education level was primary school or below (32%), their NYHA classification was mostly grade II (46.8%), 130 of them had a left ventricular ejection fraction of more than 50% (41.7%), and almost half of the patients' BMIs were in the range of 18.5 - 23.9 (49%). The age of caregivers ranged from 18 to 84 years old; most of them were female (62.2%), their education level was mainly junior high school (25.6%) and bachelor's degree (27.6%), and most of them were the children of patients (46.6%); for 41.35% of the caregivers, the average per capita monthly income was 2000 - 4999 yuan (US $274-$686), and for most caregivers, the total time of caregiving was less than 1 year (76%). Detailed information is shown in Table 1.

The Scores and Differences in the Study Variables in the Dyadic Group

The median HL score of patients with CHF was 34.00 (IQR27.00-40.00), which was lower than that of their caregivers (median 37.00, IQR 31.00-42.00), with a statistically significant difference between them (*P*<.001). The median (IQR) scores of perceived usefulness, perceived ease of use, and mHealth use intention in patients with CHF were 20.00 (17.00-23.00), 12.00 (6.00-15.00), and 14.00 (11.00-15.00), respectively; the median (IQR) perceived usefulness, perceived ease of use, and mHealth use intention in caregivers were 21.00 (19.00-25.00), 15.00 (12.00-15.00), and 15.00 (14.00-15.00), respectively. The patients' scores were lower than those of carers, with statistically significant differences between them (*P*<.001), as shown in Table 2.

Table . Scores and differences in variables among patients with chronic heart failure and their caregivers.

Dimension	Patients with chronic heart failure (N=312), median (IQR)	Caregivers (N=312), median (IQR)	*Z*-score	*P* value
Health literacy	34.00 (27.00-40.00)	37.00 (31.00-42.00）	4.90	<.001
Perceived usefulness	20.00 (17.00-23.00)	21.00 (19.00-25.00）	4.38	<.001
Perceived ease of use	12.00 (6.00-15.00)	15.00 (12.00-15.00）	7.88	<.001
Mobile health use intentions	14.00 (11.00-15.00)	15.00 (14.00-15.00）	6.86	<.001

Correlation Coefficients of Study Variables

Among patients with CHF, mHealth use intention was positively correlated with their own HL, mHealth perceived usefulness, and perceived ease of use (*r*=0.512 - 0.682, *P*<.05), and positively correlated with the caregiver's mHealth perceived usefulness and mHealth use intention (*r*=0.222 - 0.310, *P*<.05); caregiver's mHealth use intention was positively correlated with their own HL, mHealth perceived usefulness, and perceived ease of use (*r*=0.393 - 0.572, *P*<.01), and positively correlated with patients' HL, mHealth perceived usefulness, perceived ease of use, and mHealth use intention (*r*=0.170 - 0.310, *P*<.01). The results of the correlation analyses are detailed in Table 3.

The APIMeM of HL-Perceived Usefulness of mHealth-mHealth Use Intention in Patients With CHF and Caregivers

In this study, the model fit index values were X^2 (*df*)=1.175 (<3), RMSEA=0.024 (≤0.08), CFI=0.992 (≥0.90), TLI=0.995 (≥0.90), which indicated that the model was well fitted.

Direct Effect Analysis

The results showed that (1) patients' and caregivers' HL was a positive predictor of their own perceived usefulness of mHealth (β=.38 - 0.39; *P*<.001); (2) patients' and caregivers' perceived usefulness of mHealth was a positive predictor of their own mHealth use intention (β=.42 - 0.45; *P*<.001); (3) patients' and caregivers' HL had a positive predictive effect on their own mHealth use intention (β=.26 - 0.27; *P*<.001), that is, the subject effects of the model all held; (4) HL of patients and caregivers had a positive predictive effect on each other's perceived usefulness of mHealth (β=.08 - 0.09; *P*<.05); (5) perceived usefulness of mHealth of patients and caregivers had a positive predictive effect on each other's mHealth use intention (β=.16 - 0.20; *P*<.001); (6) patients' and caregivers' HL had a nonsignificant effect on each other's mHealth use intention, that is, the object effect was partially established (see Figure 1 for details).

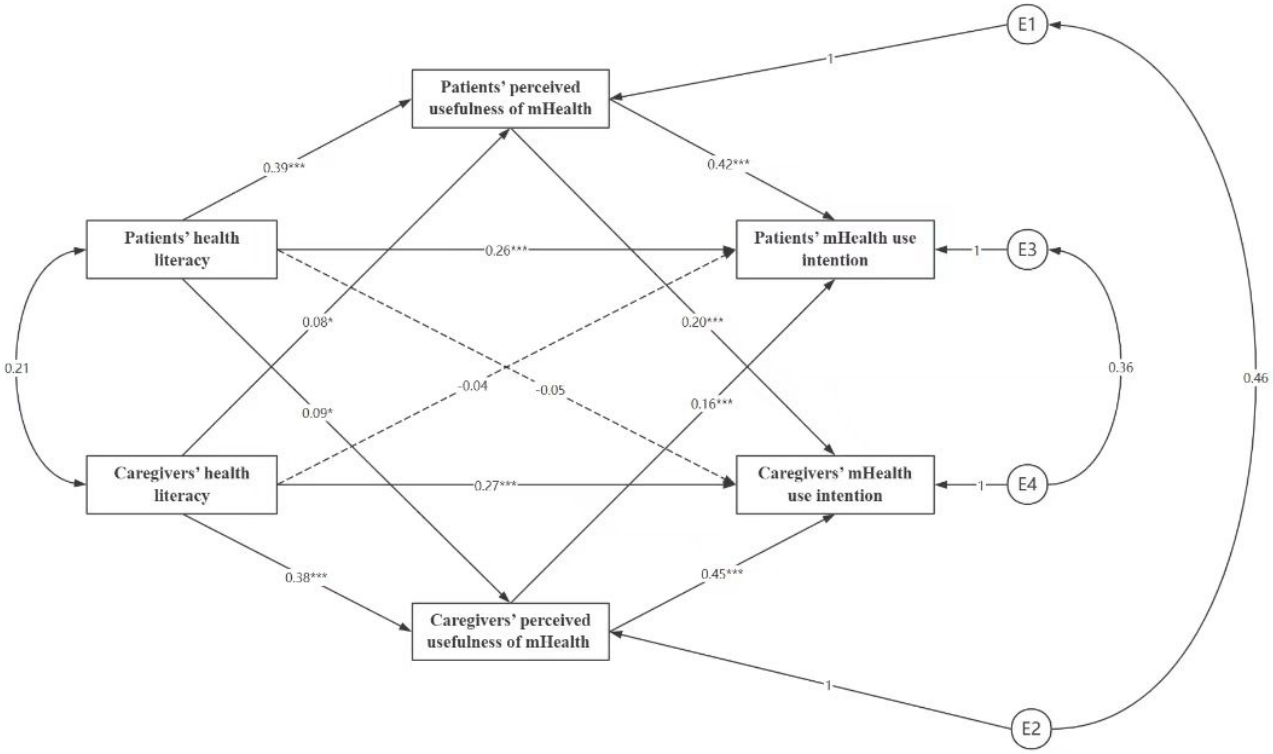
APIMeM: actor-partner interdependence mediation model; mHealth: mobile health.



Mediation Analysis

Bootstrap tests for mediating effects showed the patients' and caregivers' HL directly positively predicted their own mHealth use intention (β=.381, 95% CI 0.279 - 0.495; P<.001) and also positively predicted both their own (β=.242, 95% CI 0.171 - 0.321; P<.001) and their counterpart's mHealth perceived usefulness (β=.022, 95% CI 0.003 - 0.052; P=.02), which meant that the perceived usefulness of mHealth for patients with CHF and caregivers played a partial mediating role between their own and their counterpart's HL and mHealth use intention. In addition, patients' and caregivers' HL did not directly predict their counterpart's mHealth use intention (β=−.068, 95% CI −0.168 - 0.038; P=.21), but it could be positively predicting own perceived usefulness (β=.102, 95% CI 0.049 - 0.167; P<.001) and their counterpart's perceived usefulness (β=.053, 95% CI 0.006 - 0.107; P=.02), further positively predicting their own intention to use mHealth and their counterpart's intention to use mHealth, which meant that mHealth perceived usefulness of patients with CHF and caregivers played a fully mediating role in the relationship between their own HL and their counterpart's mHealth use intention (see Table 4 for details).

The APIMeM of HL-Perceived Ease of Use of mHealth-mHealth Use Intention in Patients With CHF and Caregivers

The model was a saturated model with 0 degrees of freedom [37], so its fit indices would no longer be estimated and only its path coefficients would be of interest [38].

The results showed that (1) patients' and caregivers' HL was a positive predictor of their own perceived ease of use (β=.53 - 0.71; *P*<.001); (2) patients' and caregivers' perceived ease of use was a positive predictor of their own mHealth use intention (β=.48 - 0.54; *P*<.001); (3) caregivers' HL had a positive predictive effect on their own mHealth use intention (β=.17; *P*<.01), that is, the main effect of the model was partially established; and (4) perceived ease of use in patients had a positive predictive effect on the caregiver's mHealth use intention (β=.15; *P*<.01); the rest of the object effects were not significant (see Figure 2 for details).

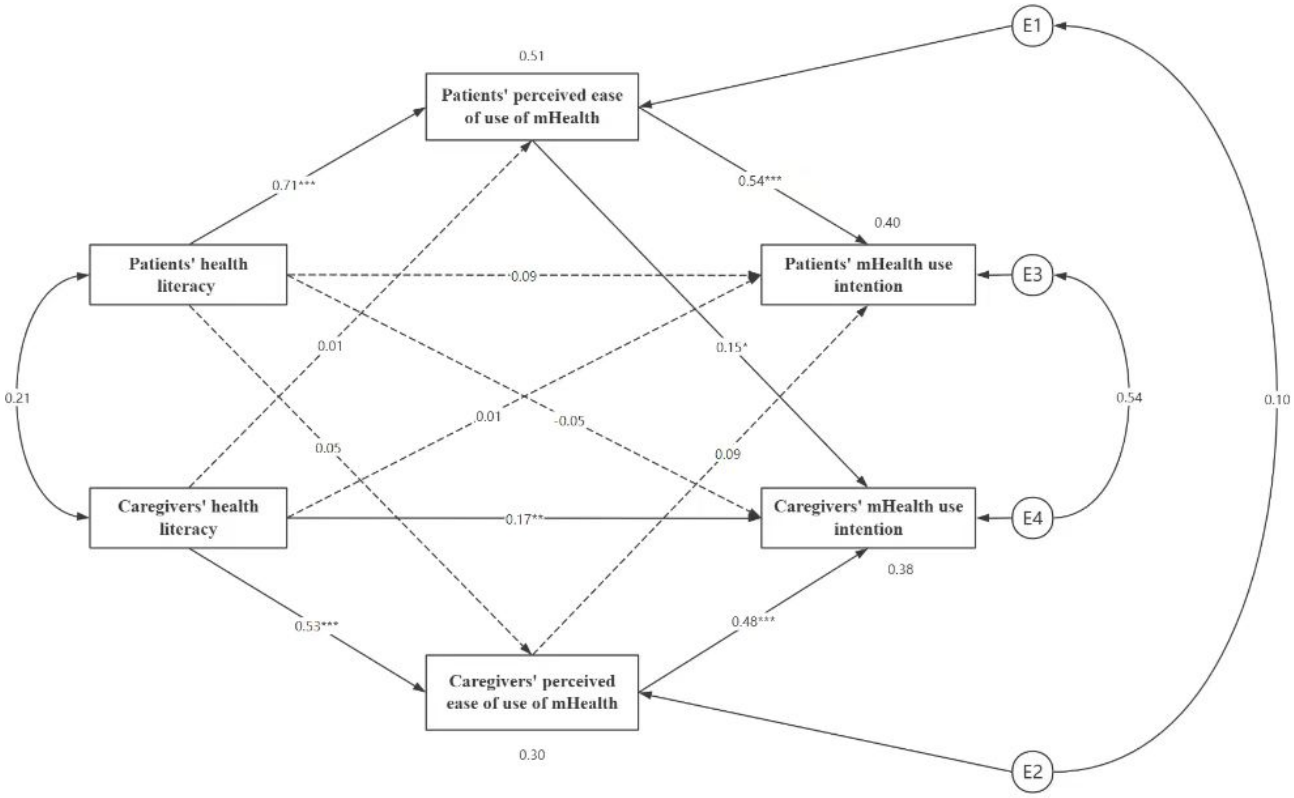
Figure 2. APIMeM results of health literacy and perceived ease of use on mHealth use intention in patient-caregiver dyads. Dashed lines indicate insignificant path coefficients and solid lines indicate significant path coefficients (*P<.05, **P<.01, ***P<.001). APIMeM: actor-partner interdependence mediation model; mHealth: mobile health.



Mediation Analysis

Bootstrap tests of mediating effects were conducted, and the results showed that patients' HL positively predicted their own perceived ease of use, which then positively predicted their own mHealth use intention (β=.584, 95% CI 0.443 - 0.764; P<.001), with perceived ease of use playing a fully mediating role. Caregivers' HL directly positively predicted their own mHealth use intention (β=.235, 95% CI 0.079 - 0.402; P=.003), as well as positively predicting their own perceived ease of use, which predicted their mHealth use intention (β=.355, 95% CI 0.234 - 0.504; P<.001), and perceived ease of use played a partial mediating role. In addition, patients' HL positively predicted their own perceived ease of use, which positively predicted their counterpart's mHealth use intention (β=.128, 95% CI 0.012 - 0.281; P=.02; see Table 5 for details).

Moderated Effects of Age and Patient-Caregiver Relationship on Dyadic Effects

We regrouped the data into older and younger groups based on patient and caregiver age, and into spouse, child, and other groups based on patient-caregiver relationship, and used multigroup APIMeM to explore further whether the dichotomous effects of HL, perceived usefulness of mHealth, and perceived ease of use on mHealth use intention were moderated by patient and caregiver age and relationship. The results showed that the path coefficients of the APIMeM were not significantly different across groups (P>.05), meaning that no moderate influence of patient and caregiver age and relationship on the dichotomous effects of HL and mHealth perceived usefulness and perceived ease of use on mHealth use intention was observed. The details are shown in Multimedia Appendix 3.

Discussion

Principal Findings

The study took place during the heart of the COVID-19 pandemic, which forced much of the world to rely on eHealth and mHealth during this time. Some studies have reported an increase in internet dependence as a result of the COVID-19 pandemic, which has led to an increase in digital connectivity among older adults, thereby increasing the feasibility of their use of mHealth services [39]. Our study showed that the HL, perceived usefulness, perceived ease of use, and mHealth use intention of patients with CHF were significantly lower than caregivers' scores, which might be due to the following reasons. First, most of the caregivers in the study were the children of the patients and were therefore younger. It has been evidenced that bodily functions and cognitive capacities deteriorate with age, resulting in decreased vision flexibility and memory loss,

XSL•FO
RenderX

among other effects [40,41]. In addition, the younger generation, called "digital natives," had earlier and more frequent access to the internet, whereas the ability of older adults to adapt to modern digital life wanes over time, and this "digital divide" of older adults means that they face greater difficulties and obstacles in the process of using mHealth [42]. Furthermore, previous studies have pointed out that HL declines with age [43]. Therefore, compared with younger caregivers, patients with CHF have more difficulties grasping and using mHealth, and they may show lower perceived usefulness, perceived ease of use, mHealth use intention, and HL as well. Second, research has shown that [44] physical limitations associated with illness might impede an individual's ability to use technology, making it more arduous and challenging to use mHealth. The more severe the condition, the more likely the individual is to perceive more impediments to the use of mHealth [45]; therefore, compared with caregivers, people with CHF might exhibit lower levels of perceived usefulness, perceived ease of use, and mHealth use intention.

Our study showed that the HL of patients with CHF and their caregivers positively contributed to their own mHealth use intention. HL has emerged as a powerful predictor of self-care behaviors including mHealth use in the context of chronic illness, which can empower individuals to navigate the adoption of mHealth use [46]. HL entails people's motivation to understand and apply health information in order to make decisions in everyday life to maintain or improve quality of life [47]; therefore, people with higher HL might be more motivated to use mHealth to manage disease. Evidence also suggests that individuals with low HL face greater challenges in computer use and reading, manipulating, and assessing health information [48], whereas individuals with higher levels of HL are more likely to comprehend and use mHealth [49], leading to a high level of mHealth use intention. Our study also found that the HL of patients with CHF and their caregivers positively influenced their counterparts' mHealth use intention by the fully mediating role of perceived usefulness. Therefore, to improve patients' mHealth use, not only is the improvement of their HL necessary but their caregivers' enhanced HL is also highlighted.

Perceived usefulness was identified as a partial mediator of HL and mHealth use intention in patients with chronic heart disease and their caregivers in our study. This aligns with the broader literature emphasizing the importance of perceived usefulness in shaping mHealth adoption intention. As an important attribute of HL, reading skills entail a multitude of complex cognitive processes that require the ability to obtain meaning from the text being read. Additionally, HL lies in being able to use the information to make appropriate health care decisions [50]. All of the above suggests that higher HL might facilitate the understanding of mHealth, including the design, purpose, precautions, and adoption, leading to a higher level of perceived usefulness. It has also been evidenced by Wu et al [22,23] that HL positively affects the perceived usefulness of mHealth. Furthermore, usability issues, such as lack of an easy overview and nonintuitive app design, text, buttons, and icon elements, have been reported to be negatively correlated with mHealth utilization [51,52]. In addition, TAM theory also supports the positive relationship between perceived usefulness and mHealth use intention [53]. It was also suggested by the study of Dunn Lopez et al that mHealth apps must be readable, provide useful functions, and be based on evidence to improve patients' intention to use mHealth [54]. We also identified that the perceived usefulness of patients acted as the full mediator of patients' HL and caregivers' mHealth use intention, and the perceived usefulness of caregivers acted as the full mediator of caregivers' HL and patients' mHealth use intention. The findings suggest that the perceived usefulness of the patients and caregivers can both influence the mHealth use intention of patients, highlighting that patients and caregivers should be involved during the redevelopment process of mHealth to improve its usability from the perspectives of patients and caregivers. The app content must be readable, provide useful functions, and be based on evidence.

In our study, perceived ease of use was identified as a partial mediator of HL and mHealth use intention in patients with chronic heart disease, and it was a full mediator of HL and mHealth use intention in caregivers. HL includes individuals' capabilities to access and use available resources within the health care system, which allows individuals to increase their abilities to use preventive health services including mHealth to manage their health [55]. Thus, people with higher HL will show increased perceived ease of use of mHealth. In addition, perceived ease of use influencing individuals' mHealth use intention is also attested by other researchers and is supported by TAM theory. Patients' and caregivers' concerns about mHealth apps being difficult and time-consuming to use, along with being not easy to access through the use of complex keywords, led to their unwillingness to use mHealth [56]. The actor-partner analysis showed that perceived ease of use of the patients was a full mediator of patients' HL and their caregivers' mHealth use intention; however, perceived ease of use of the caregivers was not a mediator of caregivers' or patients' HL and patients' mHealth use intention. Therefore, caregivers' perceived ease of use of mHealth will not induce patients' willingness to adopt mHealth, and patients will choose to use it based on their own experience, highlighting the key role of perceived ease of use of the patients in facilitating their mHealth use. Nevertheless, some patients with CHF have expressed difficulty in downloading electronic health–related equipment and procedures and in operating health-monitoring equipment due to their complexity, which has increased their anxiety about its use [57]. Other research has also pointed out that the target population of mHealth expressed the desire for a simple and intuitive-to-use mobile app with nonmedical language and easy-to-understand material [58]. Therefore, it is recommended that the development of mHealth should focus on simplifying operational procedures and providing relevant operational training when necessary based on the needs of patients.

Limitations

This study also has limitations. First, it was not possible to infer a causal relationship between the variables as this was a cross-sectional study. Second, this study only focused on the mediating effects of 2 variables, perceived usefulness and perceived ease of use of mHealth, and the mediation of the relationship between HL and mHealth use intention, ignoring other possible variables. To better explain how HL affects

XSL•FO
RenderX

mHealth use intentions in the patient-caregiver dyad, future research should focus on other possible mediating or moderating variables. In addition, the increase in internet and digital technology use spurred on by the pandemic might have impacted the findings; therefore, our study findings should be considered with caution. Third, participants were from only 2 tertiary hospitals in Kunming, Yunnan Province, China, and most of the patient-caregiver relationships were between parents and children, who had a certain age gap. Therefore, the population characteristics and cultural differences between countries and regions may limit the generalizability of our findings.

Conclusions

Our study proposes that patients with CHF will exhibit lower HL, perceived usefulness, perceived ease of use, and intention to use mHealth compared to their caregivers. Furthermore, the HL of patients with CHF and their caregivers positively contributes to their own mHealth use intention, with the full mediating effect of perceived usefulness. Therefore, mHealth utilization among patients with CHF could be promoted by improving their own HL and that of their caregivers as well. The findings suggest that both patients' and caregivers' perceived usefulness affects patients' mHealth use intention, and therefore patients and caregivers should be involved in the entire mHealth development process in order to improve the usability of mHealth for patients and caregivers. The study highlights the key role of patients' perception of mHealth as easy to use in facilitating their use of mHealth. Therefore, it is recommended that the development of mHealth should focus on simplifying operational procedures and providing relevant training about operations according to the needs of the patients when necessary.

Acknowledgments

The authors would like to express their heartfelt gratitude to all persons who participated in this study as well as the members of the research team. This study was supported by the Yunnan Provincial Department of Education Science Research Fund Project, China (number 2023Y0749).

Data Availability

The full interview transcripts and audio files are not available to the public due to data protection reasons. However, transcripts and findings are available on request from the corresponding author.

Authors' Contributions

XJ (first author) participated in study design, data collection and analysis, and manuscript writing. YZ and MZ participated in data collection and data analysis. QM, YB, QH, and WW participated in reviewing the research design manuscript. XZ participated in data analysis. Abstract

Background: Maintaining accurate medication records in clinical trials is essential to ensure data validity. Traditional methods such as direct observation, self-reporting, and pill counts have shown limitations that make them inaccurate or impractical. Video-based monitoring systems, available as commercial or proprietary mobile applications for smartphones and tablets, offer a promising solution to these traditional limitations. In Korea, a system applicable to the clinical trial context has been developed and used.

Objective: This study aimed to evaluate the usefulness of an asynchronous video-based self-administration of the investigational medicinal product (SAI) monitoring system (VSMS) in ensuring accurate dosing and validating participant adherence to planned dosing times in repeated-dose clinical trials.

Methods: A retrospective analysis was conducted using data from 17,619 SAI events in repeated-dose clinical trials using the VSMS between February 2020 and March 2023. The SAI events were classified into four categories: (1) Verified on-time dosing, (2) Verified deviated dosing, (3) Unverified dosing, and (4) Missed dosing. Analysis methods included calculating the success rate for verified SAI events and analyzing trends in difference between planned and actual dosing times (PADEV) over the dosing period and by push notification type. The mean PADEV for each subsequent dosing period was compared with the initial period using either a paired *t* test or a Wilcoxon signed-rank test to assess any differences.

Results: A comprehensive analysis of 17,619 scheduled SAI events across 14 cohorts demonstrated a high success rate of 97% (17,151/17,619), with only 3% (468/17,619) unsuccessful due to issues like unclear video recordings or technical difficulties. Of the successful events, 99% (16,975/17,151) were verified as on-time dosing, confirming that the dosing occurred within the designated SAI time window with appropriate recorded behavior. In addition, over 90% (367/407) of participants consistently reported dosing videos on all analyzed SAI days, with most days showing over 90% objective dosing data, underscoring the system's effectiveness in supporting accurate SAI. There were cohort differences in the tendency to dose earlier or later, but no associated cohort characteristics were identified. The initial SAI behaviors were generally sustained during the whole period of participation, with only 16% (13/79) of study days showing significant shifts in actual dosing times. Earlier deviations in SAI times were observed when only dosing notifications were used, compared with using reminders together or no notifications.

XSL•FO
RenderX

Conclusions: VSMS has proven to be an effective tool for obtaining dosing information with accuracy comparable to direct observation, even in remote settings. The use of various alarm features and appropriate intervention by the investigator or observer was identified as a way to minimize adherence deterioration. It is expected that the usage and usefulness of VSMS will be continuously improved through the accumulation of experience in various medical fields.

KEYWORDS

adherence; mobile health; self-administration; repeated-dose clinical trials; video-based monitoring; mobile phone

Introduction

Repeated dose studies in healthy volunteers are essential for obtaining basic information about the pharmacokinetics of a drug. These studies are performed during the development of a specific investigational medicinal product (IMP) for which the dose of the active ingredient, formulation and route of administration has been determined. They include repeated dose escalation studies, drug-drug interaction studies, and some bioequivalence studies [1-3]. The changes in drug concentration that occur when an active ingredient is administered using a specific IMP are usually described in terms of the time elapsed after administration, from which various pharmacokinetics relationships are defined. Therefore, whether the IMP was actually administered and the time of administration are considered pivotal information to be obtained in such studies [4].

Historically, a variety of techniques have been used to ensure precise dosing information in clinical trials. These include direct observation by investigators, self-reporting through diaries or questionnaires, and pill counts [4,5]. Although direct observation is the most reliable method, it may be impractical and burdensome due to the necessity of frequent hospital visits, which increases costs and inconveniences participants [4,6-10]. Self-reporting methods are susceptible to biases such as recall and social desirability biases, which can lead to inaccuracies [5,6,11-15]. While pill counts are a straightforward approach, they cannot confirm actual administration, making them less reliable for studies requiring precise dosing records [12]. The inherent limitations of existing methodologies have consistently underscored the necessity for novel approaches capable of addressing the demands of repeated-dose studies.

The advent of mobile technologies has brought about innovative methodologies for the monitoring of the IMP administration in clinical trials [4,16]. One such advancement is the use of video-based observation, which permits the remote assessment of self-administration of the investigational medicinal product (SAI) [4]. Video-based observation uses either synchronous or asynchronous methodologies. In the former, the investigator observes the SAI in real-time [6,16-21], whereas in the latter, the participant uploads a video of the SAI for subsequent review [4,6,16,17,22-25]. This technology offers a degree of verification that is comparable to that of direct observation while reducing the necessity for frequent hospital visits, thus enhancing the convenience of participants and reducing the costs associated with the trial [4].

This study was to assess the usefulness of an asynchronous video-based SAI monitoring system (VSMS) through a simple and straightforward outcome measure: “Was the investigator able to reliably verify SAI using the videos uploaded by the participant?” This outcome measure is ultimately a direct indicator of whether the system performed as targeted, and was considered to be a composite of technical influences such as system reliability and sociodemographic influences such as digital literacy. In addition, if the results showed that the VSMS was sufficient to verify SAIs, it was planned to explore participants’ adherence to planned SAI times when using these systems. These evaluations will enhance our understanding of the validity and reliability of asynchronous VSMS in a range of repeated-dose trial settings.

Methods

The System Overview

The VSMS used in this study comprises a web-based system for investigators and a mobile app for participants. The web-based system allows investigators to (1) search for a QR code to match a participant to a specific participant number in the study; (2) view the SAI schedule, which should be assessed by calendar date; (3) view SAI-related videos uploaded by the participant; (4) determine if a valid administration is made and enter corresponding data; and (5) send the participant feedback on the SAI.

The system is designed to allow the investigator to make the final confirmation about the SAI results, with outcomes recorded in one of four categories (1)-(4):

(1) **Verified on-time dosing**

- The actual dosing time Provided by the system is within the allowed SAI time window and the dosing behavior recorded in the video is appropriate.
- The actual dosing time Provided by the system is outside the limits of the allowed SAI time window, but based on the video, it is verified that the appropriate dosing behavior occurred within the window (eg, video recording started before the time window range, but the actual dosing occurs within the window). In this case, the investigator manually corrected the actual dosing time.

(2) **Verified deviated dosing**

The actual dosing time provided by the system is outside the limits of the allowed SAI time window, and the appropriate SAI behavior is verified based on the video, but the timing is outside the window.

XSL•FO
RenderX

(3) **Unverified dosing**

SAI cannot be verified via video due to technical issues, participant nonadherence to recording procedures (eg, too dark recording environment, skipping oral cavity disclosure), and so on, but there is evidence to believe the participant performed the SAI (eg, the participant's statement from a phone call with the reason of inappropriate video recording)

(4) **Missed dosing**

SAI cannot be verified via video and no evidence that the participants performed SAI can be obtained.

The mobile app is designed with a simple and user-friendly interface. The system may provide push notifications to participants before or after the scheduled dosing time, as specified in the protocol. Upon opening the application, the participant is immediately instructed to start the video recording and proceed with the SAI. The server connection time, recording start time, and recording end time were always captured based on the participants' mobile device time to ensure that the data remained accurate even in situations such as slow internet speeds or transmission failures. In these cases, the recorded video was sent to the server as soon as mobile network conditions improved. Of the stored time data, the recording start time was displayed on the investigator's web system as the default value for the actual dosing time. The recorded video was temporarily cached on the participants' mobile device and deleted once the transfer to the server was confirmed. The behavior of the system according to the SAI schedule and procedures, storage and management of SAI data, and processing of other communication-related information was handled through servers operated by the service provider, which complied with all applicable quality and regulatory standards (encrypting network communications, ensuring physical security, and restricting video access only to authorized users).

Clinical Trials and Cohorts

The data presented in this study were derived from repeated-dose clinical trials in healthy volunteers who used DoseEase. These trials were conducted between February 2020 and March 2023 and the IMPs were all self-administrable formulations (oral or ophthalmic). Trials that included groups with 2 or more different SAI schedules were also included in the analysis, and each group was treated as a separate Cohort. The eligibility criteria for participants across all trials were consistent and included the following: age between 19 years and 55 years, a minimum weight of 50 kg for men and 45 kg for women, with a BMI between 18.5 and 24.9, and confirmation of healthy condition in a comprehensive medical examination, which included an assessment of medical history, physical examination, and laboratory tests. Participants were excluded if they exhibited significant active disease at the screening stage or a history of previous disease that could affect the administration and absorption of the IMP.

Before enrollment began for the clinical trial, the service provider received a protocol from the research staff members to set up the system that specified the following;

- The number of participants and the principle of participant numbering.
- Cohort categorization according to the dosing schedule.
- SAI schedules by cohort and overall dosing schedule.
- Allowable time deviations per SAI event.
- Plan to deliver push notifications per SAI event.

The finalized system was piloted and validated by the investigators before the start of the trial.

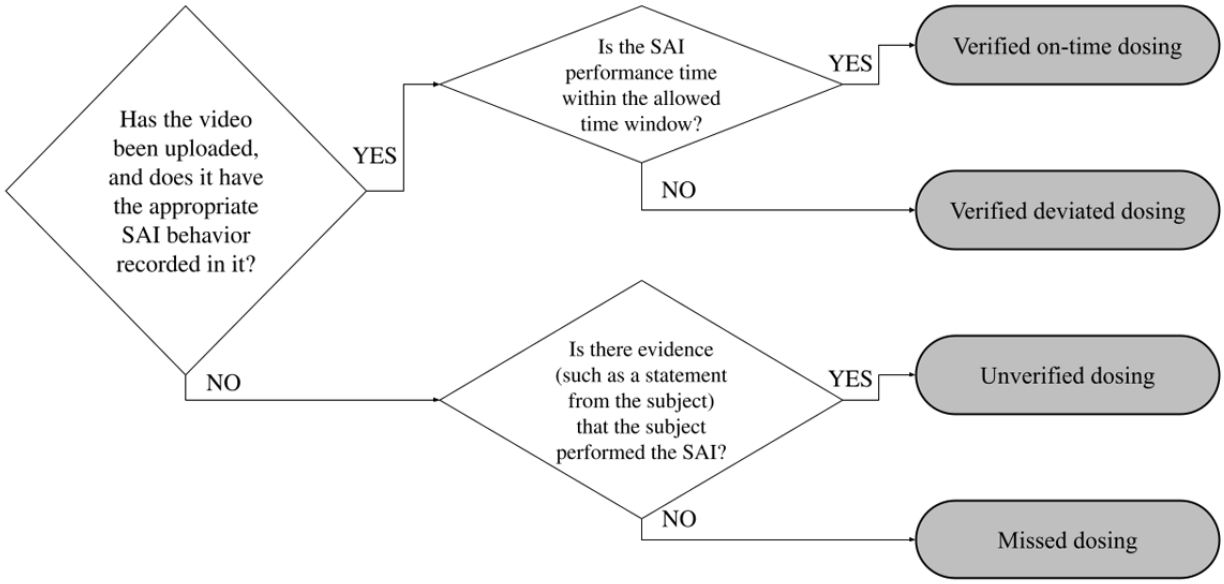
At the first participant visit, the investigator accessed the VSMS web, retrieved and printed a QR code for each participant number, which was then scanned by the participant with that number using his or her mobile device (this was a key procedure to ensure that each participant was correctly identified without obtaining additional sensitive personal information). This registered the participants device in the system at the same time as the VSMS application was installed on the participants mobile device. This procedure was followed by training, which included 1-2 mock SAIs to familiarize the participant with the system. The mock SAI underscored the significance of securely positioning the mobile device and executing all procedures associated with the SAI (eg, the IMP preparation with a specified volume of water, the oral administration, and the disclosure of the oral cavity after dosing for oral administration) within the boundaries of the recording screen. Participants were also instructed to protect their privacy by wearing appropriate clothing and recording the video in a place where their home environment was not visible. At the visit immediately before the scheduled SAI, the participant received the IMP for the number of scheduled SAIs before the next visit, after which the IMP was managed by the participant at a location other than the hospital.

On days when SAI was scheduled, participants were either alerted via push notification on the mobile application or not, as specified in the protocol. The timing (before the planned dosing time [dosing notification], after the planned dosing time [dosing reminder], or both) and frequency of these alerts varied by cohort. As trained in advance, at their own available time (preferably within the allowable SAI time window specified in the protocol), participants performed the SAI while recording a video. If mobile network conditions were adequate, the video was sent to the server as soon as it was recorded, at which point it was made available to the investigator. If the video was not uploaded after the planned dosing time, investigators were able to contact participants by phone to remind them to perform SAI or to check for any technical issues.

For each SAI event, investigators evaluated the uploaded videos to assess whether the SAI was appropriate for each participant. A decision tree was provided to help the investigator confirm SAI videos and related records into the appropriate category (Figure 1). For cases other than verified on-time dosing, investigators were able to send proper feedback to the participant to improve adherence.

XSL•FO
RenderX

Figure 1. Investigator's outcome decision-tree based on self-administered videos. SAI: self-administration of the investigational medicinal product.



Dataset for Statistical Analysis

Each SAI record included the planned Study Day (with the first dose day equal to 1), the Planned Dosing Time, the time the video recording started, and the investigator-confirmed actual dosing time. The difference between planned dosing time and actual dosing time (PADEV) was defined as the dosing time deviation. Study day values of 15 or more were recorded as "≥15" since the typical dosing duration was under 2 weeks. The investigator's final decision on SAI (categorized as verified on-time dosing, verified deviated dosing, unverified dosing, or missed dosing) and the type of push notification delivery (categorized as none, dosing notification, dosing reminder, or both) were also included. All available data from participants who dropped out before completing all study procedures were included in the analysis. Dataset handling and statistical analyses were performed using R software (version 4.2.2; R Foundation for Statistical Computing). The significance level was set at .05, and all tests were 2-tailed.

Fundamental Evaluation of Usefulness-Success Rate of the SAI Events

The primary goal of a VSMS is to ensure that the participant's video-recorded SAI behavior is successfully transmitted to the investigator, who can then determine the SAI outcome. This goal cannot be achieved if the participant or investigator is unskilled in using the system, or if the data is incomplete due to technical problems with the system. Therefore, a VSMS may be considered "useful" when it adequately fulfills its intention of use. In this study, cases where the investigator's final decision for the SAI is either verified on-time dosing or verified deviated dosing are collectively referred to as validated dosing. The percentage of validated dosing among all SAI records (referred to as the success rate, %) is evaluated as a measure of usefulness. The success rate was determined for each study day in which SAIs were performed in each cohort (considered separate cohorts if the same study included arms with 2 or more different dosing schedules). The success rate for each study day in the overall cohort and across all study days in each cohort were also calculated.

Trends in Dosing Time Deviations by Cohort

VSMS allows investigators to view SAI records in real-time, unlike other existing methods. This means that investigator-participant interaction is possible in real time throughout the study period, with features such as push notifications (dosing notification or dosing reminder) and appropriate participant management to provide input on adherence. To assess the usefulness of this aspect, the trend of PADEV per study day was analyzed for each cohort. Only validated dosing data records from cohorts with the success rate of 90% or higher were used in this analysis (even verified on-time dosing records may have deviations between planned dosing time and actual dosing time). In the first analysis, a paired *t* test or a Wilcoxon signed-rank test (depending on the sample size) was performed on the difference between the mean of PADEV in the reference study days (the first 3 study days in which SAIs were performed) and the mean of PADEV in each subsequent study day to assess whether the dosing trend identified early in the dosing period was maintained thereafter. In the second analysis, we performed a descriptive statistical analysis of the trend in dosing deviations over the entire SAI period according to the type of push notification (type 1 [dosing notification only], type 2 [both dosing notification and dosing reminder], and type 3 [no push notifications]) provided, followed by *t* tests of means between groups.

Ethical Considerations

This study used a retrospective SAI dataset gathered through the use of DoseEase (CareSquare, Inc), the inaugural

XSL•FO
RenderX

asynchronous VSMS developed in Korea. Each individual clinical trial that provided data for this study was approved by the hospital's institutional review board (IRB) before conduct and documented informed consent was obtained from all participants; however, this study is a secondary analysis of anonymized data already available. The dataset for this study included only SAI results interpreted by the investigators in each trial, and no personally identifiable information, including videos, was accessed or analyzed. We used the trial protocol number as the study identifier and the participant number assigned per protocol as the participant identifier. Due to the nature of this study, no additional consent was required for the individual participants who provided data in each trial, and the overall study design, including the consent waiver, was reviewed and approved by The Catholic University of Korea Songeui Campus IRB (MC23EASI0052, approval date: July 11, 2023).

Results

Cohort Characteristics

There were 10 trials included in the analysis based on the selection criteria, resulting in 14 unique cohort datasets. The Cohort characteristics could be summarized based on IMP characteristics, enrollment and completion rates, SAI schedule, push notification settings, and allowed time window for SAI. The route of administration was oral in 12 cohorts (86%, 12/14) and ophthalmic in 2 cohorts (14%, 2/14). The IMPs were formulated in various forms, including tablets, capsules, and powders. High completion rates were observed in 13 cohorts (93%, 13/14), with more than 80% of participants completing the study, and some cohorts achieving 100% completion (Table 1).

Table 1. Investigational medicinal product types and participant disposition of each Cohort.

Cohort	Dosing route	Formulation	Number of participants		
			Enrolled, n	Dropout, n	Completed n/N (%)
1	Oral	Tablet	90	8	82/90 (91)
2	Oral	Tablet	15	3	12/15 (80)
3	Oral	Tablet	23	4	19/23 (83)
4	Oral	Capsule or tablet	36	5	31/36 (86)
5	Oral	Tablet	40	9	31/40 (78)
6	Oral	powder	44	1	43/44 (98)
7	Oral	Capsule	8	1	7/8 (88)
8	Oral	Powder	45	0	45/45 (100)
9	Oral	Tablet	15	0	15/15 (100)
10	Oral	Tablet	15	2	13/15 (87)
11	Oral	Tablet	15	1	14/15 (93)
12	Ophthalmic	Eye drops	16	2	14/16 (88)
13	Ophthalmic	Eye drops	16	2	14/16 (88)
14	Oral	Tablet	29	2	27/29 (93)

The SAI schedules varied widely, ranging from 5 to 94 days, with daily frequencies varying from 1 to 4 times. In some cohorts, interinstitutional administration and SAIs were performed at different times on the same day. The planned dosing time was centered around a reference point (eg, 9 AM) for each cohort, with only minor variability in minutes across participants (eg, 9:02, 9:04, 9:06, etc). Push notifications were used in 11 cohorts (79%, 11/14), with the majority (73%, 8/11) using both dosing notifications and dosing reminders (Table 2).

[a]SAI: self-administration of the investigational medicinal product.

[b]The presented data refers to the reference point for the planned dosing time (eg, 9:00 AM) in each cohort, with minor variability across participants (eg, 9:02, 9:04, 9:06, etc).

[c]N/A: not applicable.

[d]The planned dosing times vary across participants, and no common reference point can be provided.

[e]SAI event and dosing by investigator performed on the same day.

Fundamental Evaluation of the Usefulness-Success Rate of the SAI Events

A comprehensive analysis was conducted on 17,619 scheduled SAI events across the 14 cohorts to evaluate the system's ability to fulfill its intended use. The analysis revealed a high success rate of 97% (17,151/17,619), while 3% (468/17,619) were unsuccessful due to issues such as unclear video recordings or technical difficulties. Among the successful events, 99% (16,975/17,151) were validated by investigators as verified on-time dosing, indicating that the actual dosing time was within the allowed SAI time window and the dosing behavior recorded in the video was appropriate.

A total of 127 SAI days were analyzed, with over 90% (367/407) of participants consistently reporting dosing videos on all SAI days. The majority of SAI days (95%, 121/127) had more than 90% objective dosing data, with some days requiring additional verification via phone to ensure accurate data capture. This high rate of validated dosing (verified on-time dosing and verified deviated dosing) indicates that the system effectively supported the accurate SAI (Table 3 and Multimedia Appendix 1).

[b]N/A (not applicable) indicates SAI was not performed on the study day.

[c]Success rate is less than 90%.

Trends in Dosing Time Deviations by Cohort

The pattern of PADEV by cohort appeared to be random and did not show any consistent trend depending on the characteristics of the IMP or the scheme of the SAI. For almost all SAI events, the SD of PADEV was greater than the mean, showing that dosing deviations per participant were highly variable around the planned dosing time. Cohort 10 had the earliest mean PADEV during the initial period at –29.6 (SD 65.8) minutes, and this trend remained consistent in subsequent periods, with a mean deviation of –27.2 (SD 65.9) minutes. Similarly, cohort 8 had the latest mean PADEV of 24.0 (SD 50.5) minutes during the initial period and maintained a similar pattern thereafter with a deviation of 27.6 (SD 53.1) minutes.

A trend toward delayed dosing was observed in cohorts 1, 2, 6, 8, 12, and 14, especially during the initial period. For example, cohort 1 had a mean deviation of 5.0 (SD 44) minutes in the initial period, with subsequent deviations ranging from 1.9 (SD 38.9) minutes to 14.8 (SD 39.5) minutes. Cohort 6 had an initial mean deviation of 11.3 (SD 49.9) minutes, which increased to 21.5 (SD 54.5) minutes in the second half. Conversely, cohorts 3, 4, 5, 7, 9, 10, 11, and 13 tended to dose earlier than the planned time, and this trend was maintained over time. For example, cohort 3 had an initial mean deviation of –6.3 (SD 27.8) minutes, which was followed by a deviation of –2.7 (SD 27.5) minutes. Cohort 7 had an initial deviation of –14.3 (SD 30.9) minutes and remained at the same deviation of –8.3 (SD 32.4) minutes afterward (Figure 2 and Multimedia Appendix 2). While some SAIs were conducted at times that may be outside of the participants' daily routine (after 10 PM and before 7 AM), the overall SAI pattern was not significantly different from the typical time of day.

Tests of comparison between reference (the first 3 study days in which SAIs were performed) and subsequent study days showed no significant differences in dosing time deviations for most cohorts. However, significant differences (P<.05) were observed on 13 of 79 (16%) days, indicating occasional deviations from the initial trend (Table 4). For example, cohort 12 had a significant difference on day 8 with a mean deviation of –13.3 (SD 17.1) minutes compared with 1.8 (SD 23.0) minutes in the initial period. The detailed results of the analysis are presented in Multimedia Appendix 2.

11	0 (0/1)
12	13 (1/8)
13	25 (3/12)
14	0 (0/4)
Total	16 (13/79)

[a]Proportion (number of study days with a significant mean PADEV [difference between planned and actual dosing time] difference from the reference period/total study days with SAI excluding the reference period).

For type 1 cohorts, which included Cohorts 9, 10, and 11 with a total of 525 SAI data points, the average PADEV was –24.9 (SD 63) minutes. This indicates a tendency to administer doses earlier than planned when only notifications were used. type 2 cohorts included cohorts 1, 5, 7, 12, 13, and 14; cohorts 6 and 8 were excluded due to potential bias in PADEV due to formulation differences (powder). The mean and SD of the PADEV was –3.5 (SD 31.3) minutes, and it should be noted that this type contained significantly more SAI events than the other types. This suggests that the SD of other types is likely overestimated compared to this type. In a mean difference test performed to account for this possibility (without the equal variance assumption), this type was significantly different from type 1, but not from type 3. The cohorts with no push notifications (type 3), including cohorts 2, 3, and 4 with 639 SAI data points, showed an average PADEV of –1.3 (SD 32.2) minutes. Despite the lack of notifications, these cohorts also maintained relatively small mean deviation, similar to type 2 (Table 5 and Figure 3).

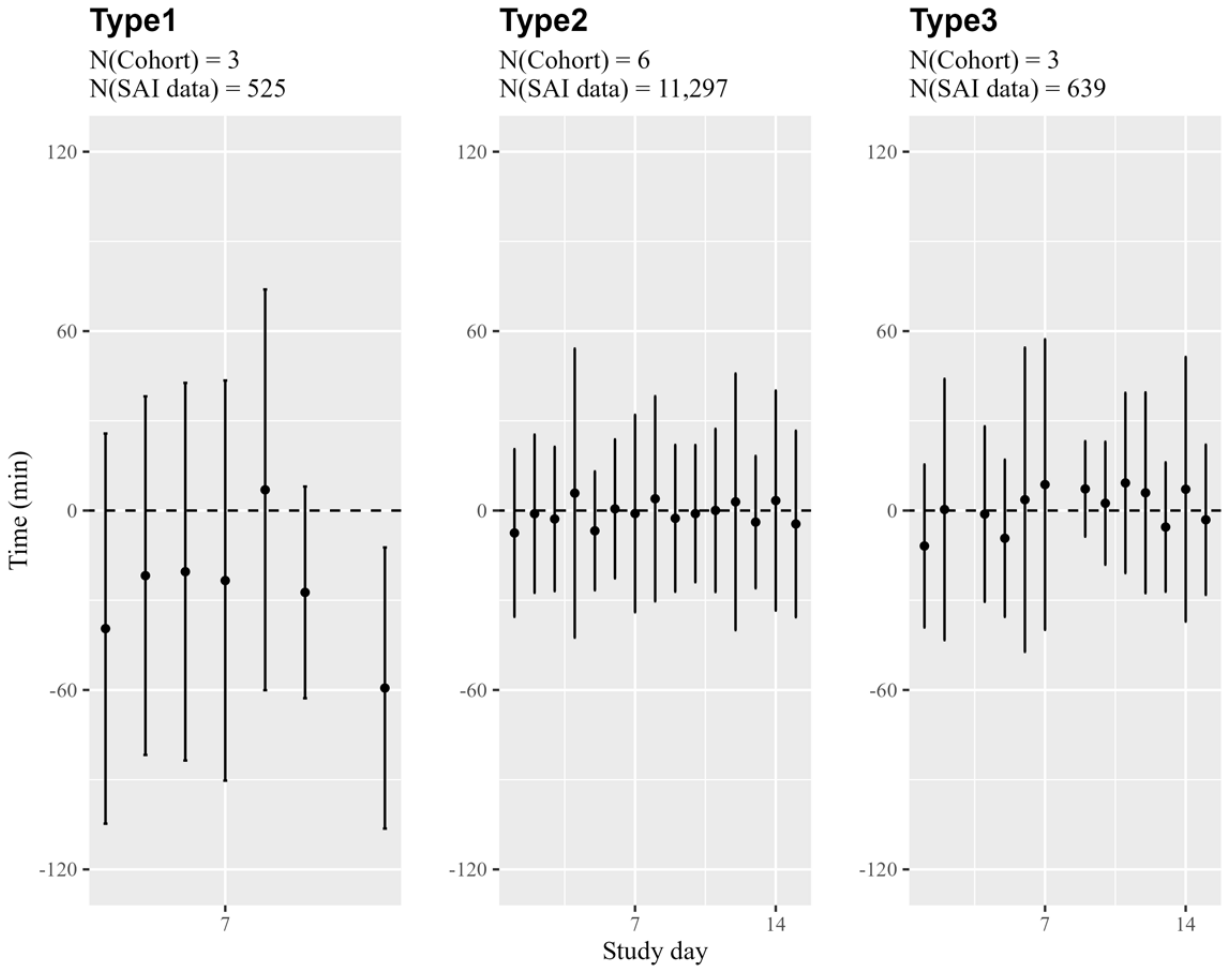
Figure 3. Trends in the dosing time deviation by push notification type. SAI: self-administration of the investigational medicinal product. Push notification types are as follows: type 1 (dosing notification only), type 2 (both dosing notification and dosing reminder), and type 3 (no push notifications). The distribution illustrates the trends in self-administration times for each type based on the push notifications sent through the VSMS. VSMS: video-based self-administration of the investigational medicinal product monitoring system.



Discussion

Principal Findings

The cohort characteristics of this study highlight key considerations for the implementation and scalability of VSMS. In all cohorts, high adherence was mandatory to achieve the study objectives, and participants provided informed consent before participation. This is likely the primary reason for the relatively high adherence observed across cohorts compared with that observed in later clinical trials or real-world settings [5,26]. Nevertheless, the clear benefits of using a VSMS were consistent with previous studies of similar systems [16-18,20-25,27-30]. By providing visual evidence of SAI, the VSMS enabled SAI instead of direct observation, and the video-based, real-time management allowed investigators to monitor adherence during the dosing period and intervene in a timely manner to minimize noncompliance [17,23-25,31]. In this study, additional measures to improve the reliability of the data were proposed by clarifying the outcome categorization system of verified on-time dosing, verified deviated dosing, unverified dosing, and missed dosing. While VSMS increases the participant's performance burden for the SAI itself, it reduces the inconvenience of site visits for dosing and minimizes the potential for participant dropout due to nonadherence [6,27,32], expanding the feasibility of a variety of clinical studies that require full adherence and its evidence. Conversely, the use of VSMS in studies that only investigate the percentage of planned doses actually taken and do not require thorough evidence of adherence will need to be determined on a cost-benefit basis.

Adherence in cohorts with SAI using VSMS was similar to that observed in repeated-dose early-phase clinical trials based on direct observation (where almost 100% adherence is required for participants). Furthermore, the concept of adherence extends not only to the performance of SAIs, but also to the use of the provided system to record SAI behavior and transmit it to the researcher. Therefore, high adherence in studies using VSMS indicates that the essential requirements of the system have been met, which (1) technical reliability: the system operated without significant technical errors, ensuring that data capture and processing was accurate and reliable; (2) participant acceptability: participants were able to use the mobile-based application without difficulty, which is critical to maintaining high levels of compliance in clinical trials; and (3)

XSL•FO
RenderX

comprehensiveness for investigators: the system provided sufficient information in an appropriate manner to enable investigators to make informed decisions regarding the validation of SAI. Along with the intuitive user interface, user acceptability can be attributed in part to the initial training during the first visit, including a mock SAI session.

The study observed that SAI behaviors established early in the trial were generally maintained throughout the study period. Only 16% (13/79) of events showed statistically significant differences in dosing times compared with the initial SAI events. When using dosing notifications alone, a deviation toward faster SAI times was observed compared with using dosing reminders together or no push notifications at all. The use of dosing notification alone was associated with a faster deviation to SAI time compared with the use of dosing reminder or no push notification at all. Even accounting for the difference in the number of events in each group, the variability in deviation was greatest for dosing notification alone. The fact that the distribution of deviations was similar between no push notification group and both dosing notification and reminder group suggests that participants were highly motivated to adhere to their planned dosing times. In this situation, using only the dosing notification would have resulted in participants choosing to perform SAI before they forgot to do it, and there would have been significant interparticipant variation in this choice. Although push notifications were preset and remained constant throughout the study period in the cohorts included in these studies, given the nature of SAI behavior and the impact of push notifications, it is possible that better compliance could be achieved by adjusting push notifications based on the initial SAI pattern of the cohort. Particularly, it is considered necessary to modify the strategy of push notifications by identifying the tendencies of the participants at the beginning of the SAI period when only dosing notification is planned.

The VSMS used in this study is compatible with any type of mobile device with video recording and wireless transmission capabilities. As an alternative to installing the VSMS application on a participant's smartphone, a separate mobile device capable of performing VSMS could be provided for the entire study period to conduct the SAI. Some participants in the cohort included in this study participated in this manner. This fact means that the participant or patient does not necessarily need to own a smartphone and agree to install the VSMS application in order to use VSMS. In other words, the usefulness of VSMS depends on the participant's willingness to perform the SAI and the appropriate use of the VSMS application, rather than the ownership of a mobile device.

Limitations

The findings were derived from a population with limited demographic characteristics. The usefulness of VSMS is likely to be contingent upon the participant's or patient's capability to use mobile apps and the mobile environment in which they reside. It is expected that prospective evaluations in larger and more diverse populations, including different participant characteristics in terms of age, dosing regimens, or indications, will provide even more reliable evidence.

Conclusions

VSMS proved to be an effective tool for obtaining dosing information with accuracy comparable to direct observation, even in remote situations. The potential to minimize adherence deterioration through various alarm features and appropriate investigator or observer intervention was also identified. In many research or clinical situations where participant adherence is essential, but direct observation is difficult, VSMS may be a key element in obtaining dosing information. Proper usage of participants' smartphones or other mobile devices and previous training of participants and observers may improve the accuracy of SAI recording via VSMS. It is expected that the usage and usefulness of VSMS will be continuously improved through the accumulation of experience in various medical fields.

Abstract

Background: Sudden cardiac arrest is a major cause of mortality, necessitating immediate and high-quality cardiopulmonary resuscitation (CPR) for improved survival rates. High-quality CPR is defined by chest compressions at a rate of 100-120 per minute and a depth of 50-60 mm. Monitoring and maintaining these parameters in real time during emergencies remain a challenge.

Objective: This study introduces a neural network model designed to predict and assess CPR quality using accelerometer data from a smartwatch.

Methods: The study involved 83 participants performing CPR on mannequins, with accelerometer data collected via smartwatches worn by the participants. These data were aligned with gold-standard data from the mannequins. The accelerometer-derived compression data were segmented into 5-second intervals for training the neural network models. A total of 1226 neural network models were developed, incorporating variations in hyperparameters and dataset configurations to optimize performance.

Results: The optimal model demonstrated the capability to accurately predict the number of compressions and the average compression depth within a 5-second interval. The model achieved an accuracy of ±3.8 mm for compression depth and an average deviation of 0.8 compressions. The results indicated that the neural network model could accurately assess CPR quality metrics, surpassing other models discussed in the literature. The large and diverse dataset used in this study contributed to the robustness and reliability of the model.

Conclusions: This study validates the efficacy of a neural network model in accurately predicting CPR metrics using smartwatch accelerometer data. The model outperforms previous methods and shows promise for real-time feedback during CPR. Future work involves deploying the model directly on smartwatches for real-time application, potentially improving sudden cardiac arrest survival rates through immediate and accurate feedback on CPR quality.

Introduction

Sudden cardiac arrest (SCA) is identified as a principal cause of mortality in North America, particularly among young athletes [1-4]. It can affect individuals irrespective of their lifestyle or health status, leading to either irregular or nonexistent heart rhythms [5,6]. As a consequence, the flow of blood to major organs is halted, depriving them of essential oxygen, resulting in tissue damage and potentially culminating in organ failure. The probability of survival decreases by about 10% with each passing minute without intervention; therefore, immediate and effective treatment is crucial to enhance survival rates by minimizing damage to tissues and organs [7,8].

Efforts to deliver prompt care to SCA victims continue, with emergency medical services (EMS) prioritizing SCAs to expedite emergency responses [9,10]. Public data indicate that the target for EMS response time to an SCA event is within 8-10 minutes [5,11-14]. The initial treatment involves performing cardiopulmonary resuscitation (CPR) and using an automated external defibrillator (AED) to assist in heart pumping and maintain blood flow to the brain and other vital organs. In certain instances, an AED can also restore the heart's electrical activity [6,15].

Organizations such as the American Heart Association (AHA) and the Red Cross play a pivotal role in providing CPR and AED training to the public, empowering bystanders to administer early care to SCA victims until EMS arrives. Studies indicate that bystander-administered CPR significantly improves survival rates compared with scenarios where CPR is not administered [16-18]. The quality of CPR is critical, as high-quality CPR is associated with increased chances of survival. The AHA defines high-quality CPR as having a compression depth of 5-6 cm and a rate of 100-120 compressions per minute, standards that are also supported by the European Resuscitation Council [19,20].

Training the general public in CPR administration has emerged as a key objective for numerous organizations aiming to improve survival rates for SCA patients [21,22]. If a significant portion of the populace receives training in CPR, SCA victims stand a higher chance of receiving necessary immediate care until EMS arrive, thereby enhancing their survival prospects. Public training programs instruct participants on identifying SCA victims and initiating high-quality CPR. In these sessions, participants engage in CPR practice on mannequins while trainers offer real-time feedback on their performance, ensuring proficiency [23-25]. With advancements in technology, CPR performance can now be quantified, allowing feedback to be grounded in these measurements. Technologies used in training encompass sensor-equipped mannequins and CPR feedback devices.

Mannequins equipped with sensors accurately assess compression depth and frequency, providing trainers with metrics to deliver precise feedback to trainees. Beyond training devices, the industry also offers devices that can be placed on the chest of a mannequin or patient. These devices are equipped with accelerometers and pressure sensors to accurately assess CPR performance and transmit the information to another device for providing real-time feedback. The Laerdal CPRMeter2 is an example of such a device [26].

For SCA incidents, emergency call operators use technologies like tele CPR and video CPR to assist individuals in achieving high-quality CPR [27-29]. Upon identifying an SCA situation, EMS is dispatched, and the caller is guided over the phone on performing CPR. Nevertheless, the operator cannot gauge the quality of compressions administered, providing only verbal instructions to help the caller maintain an appropriate pace, which leaves compression depth uncertain. Video CPR, as an advanced approach, transitions communication from audio to video, allowing the operator to observe the CPR performance and offer real-time feedback. This technology requires advancements in emergency response systems to support video calling capabilities and necessitates video capability on the caller's part. A limitation is its dependency on 2 bystanders—one to execute CPR and another to capture it.

Researchers have delved into next-generation CPR feedback technologies, including virtual reality and augmented reality–based devices [30-33]. These devices employ integrated cameras to capture and analyze compression depth and rate, displaying real-time statistics on the device screen to aid users in enhancing their CPR performance [34,35]. However, the widespread adoption of such advanced technologies encounters obstacles: they are not always accessible to those who do use them.

Therefore, the challenge lies in identifying a device suitable for real-world emergencies that can precisely measure CPR performance and provide appropriate feedback without the necessity for specialized hardware. The literature identifies smartphones and smartwatches as 2 potential solutions [36-38]. Both types of devices are equipped with sensors capable of evaluating CPR performance. Song et al [39] introduced a mobile app that leverages accelerometer data from smartphones to assess compression quality and provide feedback via screen displays and audio cues. Nonetheless, this approach faces limitations; it necessitates attaching the smartphone to the user's arm, lacks details on data cleaning and noise removal, and does not consider variations in device orientation [40]. Similar challenges are evident in other algorithms designed for mobile CPR apps [41-43], with many focusing solely on training scenarios rather than real emergencies.

Gruenerbl et al [44] proposed a smartwatch app capable of measuring CPR parameters and offering visual feedback. This app analyzes accelerometer data to evaluate compression quality, identifying each positive peak on the y-axis as a compression and calculating the differences in y-axis peaks to determine compression depth. However, the study does not provide detailed algorithmic and data-cleaning methodologies for replication and comparison.

Lu et al [45] also proposed a smartwatch app alongside an algorithm for evaluating compression metrics. They tested using a Resusci Anne QCPR training manikin (Laerdal) and an android ASUS ZenWatch 2 (model WI501Q; ASUSTeK Computer Inc). The developed polynomial model predicts compression depth and rate from smartwatch accelerometer data. Although data were collected, its limited variability—compression counts

XSL•FO
RenderX

between 80-140 and depths of 4-7 cm—fails to cover the wider range expected in real-world scenarios, nor does it elaborate on data cleaning or handling irregularities.

Using smartwatch accelerometer data presents several challenges, such as sensor white noise, gravitational effects, hand movements, and shifts in the watch's position due to a loose fit. Filtering such noise from sensor data remains a significant challenge [46]. Employing noisy datasets can result in substantial variations in output results over time. To tackle noise filtration, we propose a neural network model trained on noisy data to predict compression performance, as detailed in the Methods section.

Methods

Overview

This section presents the technology and equipment used during the data collection, cleaning, and processing phases. A total of 83 participants from Thunder Bay Regional Health Sciences Centre (TBRHSC) took part in the data collection by performing CPR in a controlled simulation setting, using an Apple Watch, Apple iPhone, and a Laerdal mannequin for data capture [26,47].

Equipment and Hardware

Participants collected accelerometer data with an Apple Watch Series 7 while performing CPR, which was then stored on an Apple iPhone 14. These devices, chosen for their significant presence in the wearable segment, were equipped with specially developed apps for data collection and analysis [48,49]. This study differs from previous ones by focusing on the potential of the Apple ecosystem for health care apps, rather than on Android devices. The apps were designed for compatibility with Apple iPhone 10 and newer, as well as Apple Watch Series 3 and later models.

CPR performance practice occurred on the Laerdal SimMan 3G mannequin, which is outfitted with sensors that record and provide feedback on key compression quality metrics such as depth, rate, and recoil. This aids in improving CPR quality [50]. Laerdal mannequins were chosen, as in other studies, for their precise data capture capabilities [39,40,44].

Data analysis was performed using a laptop with an i7 Intel processor, 32 GB RAM, and a 1TB hard drive, using Microsoft Excel and Python for data cleaning, processing, model training, and evaluation. Final analyses were done on a cloud server (Amazon Web Services) equipped with an NVIDIA A10G GPU (24 GB GPU Memory), 32 GB RAM, and 8 vCPUs [51].

Data Collection

A convenience sampling method was used in this study. A notice was sent around the hospital and health care providers including doctors, nurses, respiratory therapists, and paramedics were recruited to participate. Data for this study were collected from 83 individuals over a 3-month period. Staff members from TBRHSC were invited to participate in the research, with their CPR experience ranging from none to more than 30 instances. Initially, participants received a brief orientation on CPR techniques and the benchmarks for high-quality CPR performance.

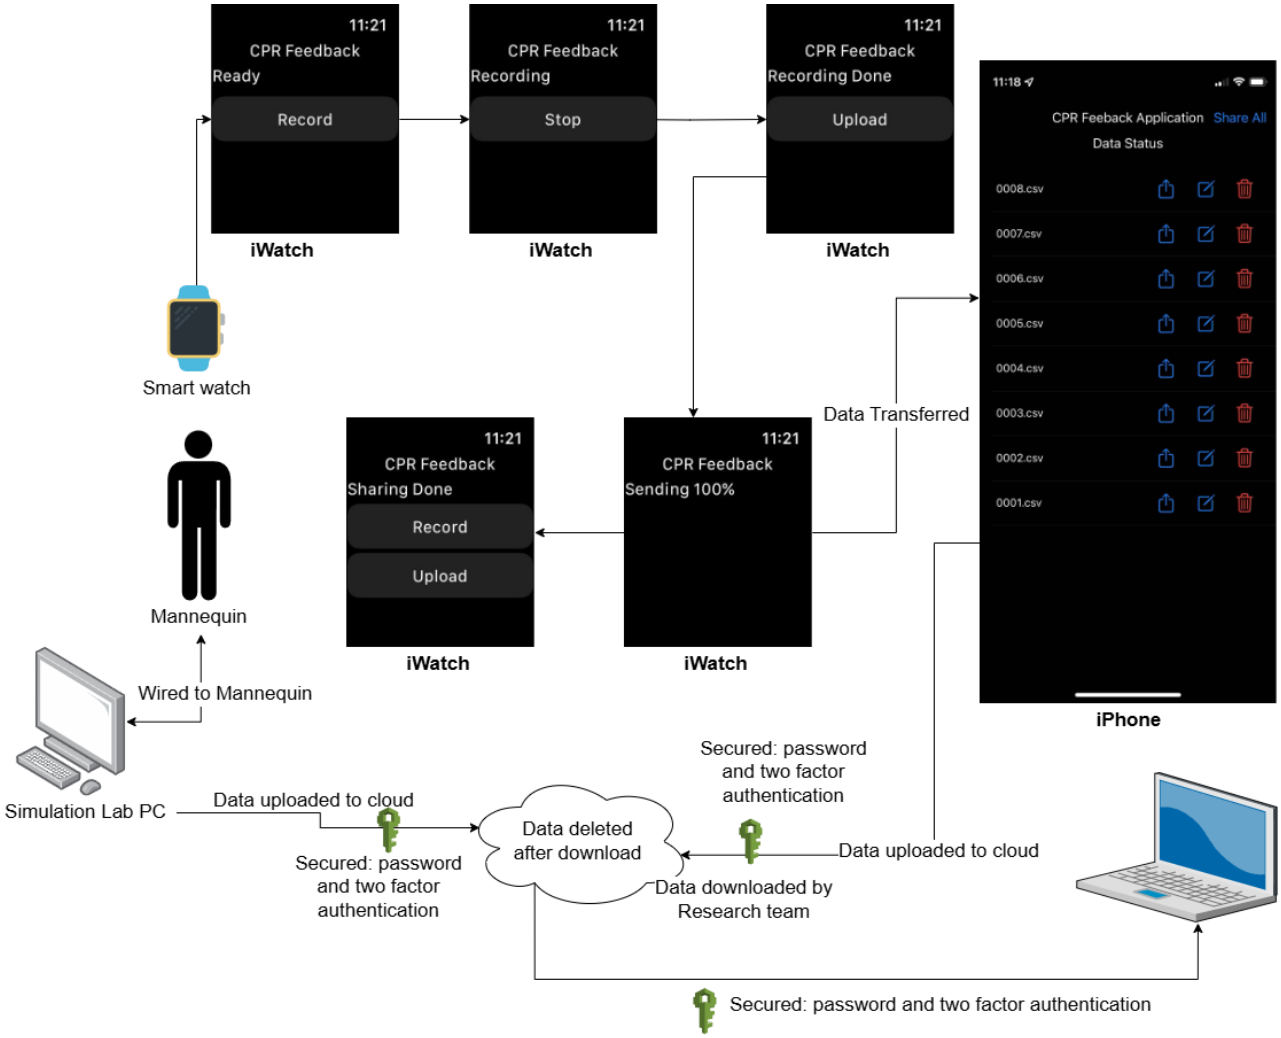
The simulation laboratory at TBRHSC, equipped with a Laerdal SimMan 3G mannequin capable of measuring compression depth, rate, and recoil, served as the setting for data collection. Upon arriving at the laboratory, participants received an Apple Watch containing the necessary data collection application. The participants were given training on how to perform high-quality CPR. After training, the participants were asked to perform CPR for 2 minutes, during which the data would be recorded. During these 2 minutes, participants were not provided with any feedback on their performance. A limited number of participants (n=41) performed another round of 2 minutes of CPR after taking a short 10-minute break.

When participants were ready to perform CPR after training, they were positioned correctly beside the mannequin, placing their hands on its chest, and initiated CPR compressions upon commencing data collection via the Apple Watch and mannequin. This procedure was carried out for 2 minutes, after which participants were advised to keep their hands in place on the mannequin to mitigate the potential introduction of noise in the data caused by removing their hands. The protocol was approved by TBRHSC and is attached as a Multimedia Appendix 1.

Subsequently, data from the Apple Watch and the mannequin were exported with a unique anonymous identifier to link the datasets without disclosing the identities of the participants. The process of data collection and the following data transmission is delineated in Figure 1. The data were securely transferred daily to the lead author's workstation. The app on the Apple Watch recorded accelerometer data, including timestamps at a 50 Hz frequency. The mannequin's data yielded detailed insights into each compression, providing metrics on depth, recoil completeness, start and end times of compression, and the peak time of compression. It is important to note that the mannequin's time stamps were relative to the onset of the data collection period rather than an absolute start time.

XSL•FO
RenderX

Figure 1. The flow diagram shows the screenshots of iPhone and Apple Watch apps, and the data flow used to collect the data during the study. CPR: cardiopulmonary resuscitation.



In aggregate, the study compiled 256 minutes of CPR data, which included 27,844 compressions with an average depth of 44 (SD 4) mm. Of the 83 contributing participants, 27 were male, and 56 were female; 48 of these individuals had previously performed CPR on more than 10 occasions.

The sample size was determined by the number of eligible participants available during the data collection period, using a convenience sampling approach. While no formal power analysis was conducted, the sample size of 83 participants was considered sufficient to meet the study's objectives. Notably, previous studies in similar domains have used smaller sample sizes—Gruenerbl et al [44] included 50 participants, and Lu et al [45] conducted their study with just 8 participants. In addition, some participants in our study performed CPR twice, resulting in 124 distinct datasets, further enhancing the dataset's richness and utility for training and evaluation.

Data Cleaning and Preparation for Model Training

Overview

This study used data from 2 sources—an Apple Watch app and exported data from a mannequin. Each source's data were recorded in separate files, but a unique identifier linked them for consistency throughout the data cleaning and preprocessing stages. Figure 2 illustrates the process of preparing the raw data for model training and the collected sample files.

The mannequin's data, exported as a comprehensive list of compressions during each session, served as the gold standard due to the sensors' precise compression depth, rate, and recoil measurements. Meanwhile, the Apple Watch provided time-stamped accelerometer data across the x-, y-, and z-axes, formatted as comma-separated values (CSVs). Both datasets included detailed compression information, enabling analysis of 2-minute CPR sessions.

For each session involving a pair of mannequin and smartwatch datasets, a 2-minute duration was recorded. The data were segmented into smaller portions to facilitate prompt feedback, potentially enabling real-time feedback. This segmentation process involved two critical steps: (1) aligning the datasets from the mannequin and the smartwatch to ensure their data corresponded accurately for analysis, detailed in subsection “Data Matching (Process 1)”; and (2) executing the chunking algorithm, detailed in the subsection “Data Chunking (Process 2).”

While real time user feedback was beyond this project’s scope, the data were examined to assess future applicability for this purpose. A 5-second analysis window was selected for potential feedback, where high-quality CPR—defined by approximately 10 compressions within this period—was used as the feedback standard. After receiving feedback, users would need time to comprehend and adjust their technique before the next feedback prompt.

Data Matching (Process 1)

The 2 data sources have different structures: the mannequin (XML file) records a sequence of compression events and their properties, while the smartwatch logs (CSV file) contain time-series accelerometer data. Because of this difference, synchronization cannot be based on time stamps. Instead, the datasets are aligned based on compression events, as the focus is on analyzing compression depth and frequency. The first step is to identify when compressions occurred using the accelerometer data, as explained further in this study. Once these events are detected, they can be matched with the corresponding compression depth and other properties from the XML file.

A chest compression pattern typically indicates a peak in acceleration when the CPR performer compresses the chest, as shown in Figure 3. Due to sensor noise and the performer’s hand movement vibrations, various peaks can appear in the data; however, only a few of these should be considered valid compressions. The XML file from the mannequin specifies the number of compressions performed, which serves as the gold standard for creating an algorithm to identify compression peaks in the CSV file.

After analyzing the accelerometer data from the compressions, 3 variables were identified to help determine if a peak is a valid compression peak. First, the acceleration difference: the change in acceleration at the compression peak should be significant.

XSL•FO
RenderX

Second, the window size is the time frame within which a peak can occur; for example, 2 compressions cannot happen within 5 microseconds. Third, the minimum acceleration peak helps filter out recoil peaks or peaks caused by vibrations or sensor noise. These values may vary from one compression to another, even if performed by the same person, due to factors such as user fatigue, incomplete recoil, changes in compression rate, or varying compression force.

To handle variability, algorithm 1 (Figure 4) was designed to match the "peaksFoundInCSV" with the peaks recorded in the XML file. The authors used SciPy's *find_peaks* function to detect peaks in the CSV file based on 3 key variables—acceleration difference, window size, and minimum acceleration peak. Since these values varied across files, a script iterated through a range of values—acceleration difference (0.01-2), window size (1-40), and minimum acceleration peak (–1 to 2)—with step sizes of 0.2, 3.9, and 0.3, respectively, until the detected peaks matched those in the XML file. To verify accuracy, random manual checks were performed by generating graphs, similar to Figure 3, to ensure the peaks were correctly identified and aligned.

Figure 3. Process 1: The diagram illustrates a representative output showing the mapping of compressions in the XML data (mannequin data) with the compressions detected in the accelerometer data (smartwatch data).

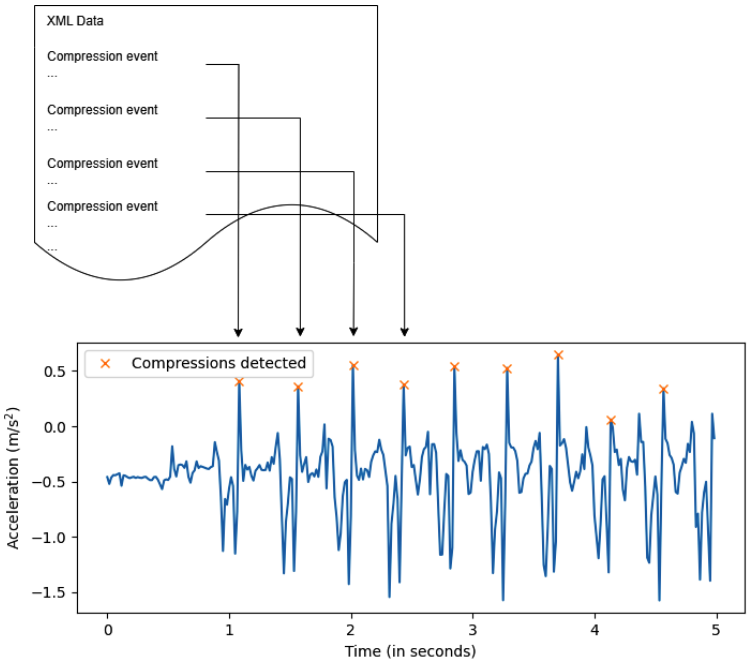

Figure 4. Pseudocode to generate matches between compressions in mannequin and accelerometer data files (algorithm 1).

Input: AccelerometerFile (C); MannequinFile (X); AccelerationDifferenceRange (AD), MinimumAccelerationPeakRange (MAD), WindowSizeRange (WS)

Output: Dictionary (CompressionMatching) mapping compression peaks in accelerometer data to corresponding Records in mannequin data

```
PeaksInMannequin = findCompressionsCountInMannequin(X)        ▷ Collecting Mannequin data

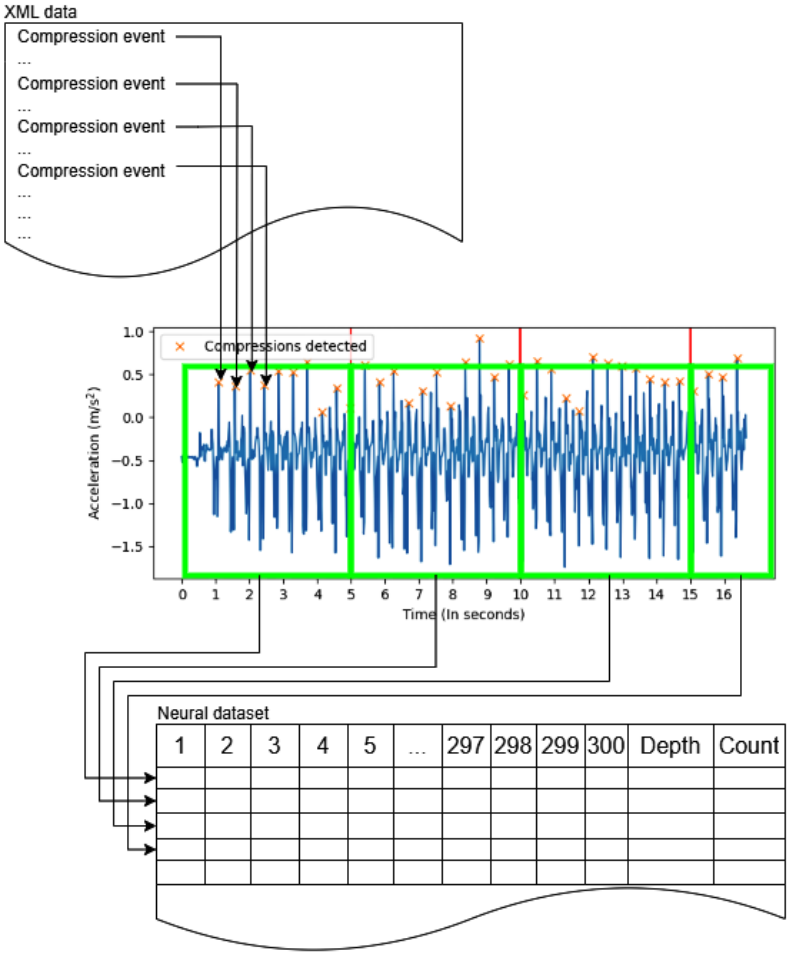
Data Chunking (Process 2)

A 5-second interval was chosen as the optimal chunking duration, with the rationale for this selection explained in the previous section. Subsequently, the aligned datasets underwent segmentation into chunks for detailed analysis. Figure 5 illustrates the segmentation process applied to a representative dataset. Following the alignment of accelerometer data with the mannequin's compression peaks, the accelerometer readings were divided into 300-point segments (indicated by a green box). Each segmented block (denoted by a green box) was then documented as a single record within the dataset used for training the proposed model, formatted in CSV. These records encompassed acceleration data for a 5-second interval (equivalent to 300 data points at a 60 Hz sampling rate), alongside the average compression depth and the total number of compressions recorded within that timeframe. For instances where the dataset was less than 5 seconds in length, the acceleration data was padded with zeros at the end to standardize it to a 5-second duration. The zero padding was performed on 124 records. The datasets prepared through this method were subsequently used to train the neural network model.

Figure 5. Process 2: Illustration of combining accelerometer and mannequin data to create the dataset for training the neural network model.



Model to Predict CPR Performance

The aim of this study was to evaluate CPR performance by analyzing accelerometer data collected from smartwatches, which inherently included various forms of sensor noise, such as vibrations due to hand movements and accelerations not associated with chest compressions. The direct elimination of this noise was deemed impractical; therefore, the decision was made to use a supervised learning approach, specifically a neural network model, to tackle this intricate challenge.

During model testing, the training data was randomly selected from 5-second chunks (2701 records), which could result in partial data from a participant appearing in both the training and test sets. However, since these chunks were not directly comparable, as determined during the review, the data were not split by participants. Although neural networks typically assume that data are independent and identically distributed, this study's approach does not violate this assumption. Figure 6 illustrates the CPR performance of 3 participants over 100 seconds, summarized in 5-second intervals. Each chunk is treated as an independent data point, with no relationship to the previous or next chunk. The objective of this research is to randomly select a 5-second chunk and predict compression depth and count based on the accelerometer data, independent of past or future data. Since the model is trained to make predictions on isolated chunks rather than sequential patterns, the independent and identically distributed assumption holds, and data splitting by participants is not necessary. Figure 6 shows that compression depth declined over time and compression counts varied significantly. However, since the model does not rely on temporal dependencies, each chunk remains independent,

XSL•FO
RenderX

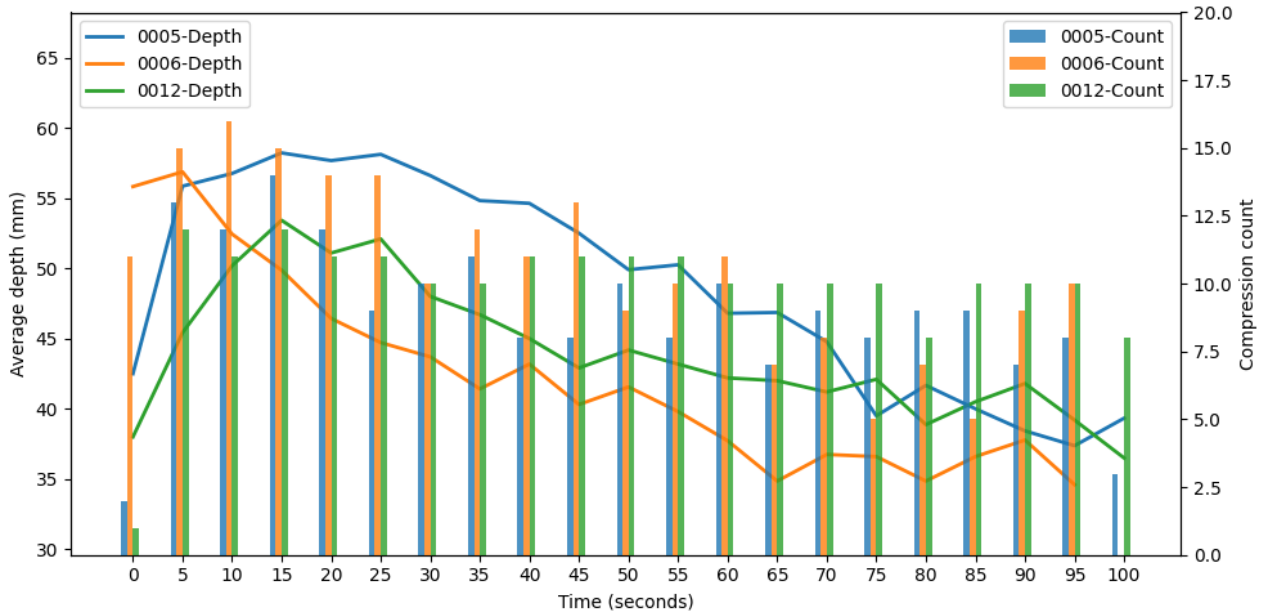
justifying the decision not to split data by participants for training and testing.

The dataset was randomly split into 80% (2161/2701) training and 20% (540/2701) validation test sets. Each record consisted of 300 accelerometer data points, corresponding to a duration of 5 seconds at a 60 Hz sampling rate. The objective of the model is to predict both the number of compressions and their average depth during this interval.

The development of the model used the TensorFlow library within the Python programming environment [52]. To optimize the model's performance, a combination of grid search and Hyperband techniques was used. In each experiment, grid search was used to explore a broad range of hyperparameters, identifying configurations that performed well or poorly. In addition, the Hyperband technique was applied to refine the search by excluding poorly performing hyperparameter sets, thereby narrowing the search space. This process was repeated iteratively, with grid search expanding the search range in each new experiment, followed by Hyperband reducing it to eliminate ineffective configurations. The key hyperparameters adjusted included the number of hidden layers, layer sizes, number of epochs, batch sizes, and dropout rates. The objective was to determine the most effective combination of hyperparameters that would allow the model to accurately interpret accelerometer data, despite sensor noise, and reliably assess CPR quality based on smartwatch data.

To evaluate the normality of the data and assess the correlation between actual and predicted values, 2 statistical tests were conducted. First, the Shapiro-Wilk test was performed on the expected depth and expected compression count to determine if the data followed a normal distribution. The results showed *P* values of 2.69×10^{-3} and 2.80×10^{-4}, respectively, indicating that both datasets deviated significantly from normality. Given this, Spearman rank correlation was chosen to measure the relationship between expected versus predicted depth and compression counts since it does not assume normality.

Figure 6. Variation in compression depth and compression rate among three participants over 100 seconds of CPR performance.



Ethical Considerations

The research ethics evaluation for this study was reviewed and approved by the TBRHSC Research Ethics Board (2022519), with all procedures conducted in accordance with the ethical standards of the responsible institutional committee and the principles outlined in the World Medical Association Declaration of Helsinki. Written informed consent was obtained from all participants before their inclusion in the study. To maintain privacy and confidentiality, all data collected were deidentified at the point of collection, with each participant assigned a unique identifier; a separate, secure document mapping participant identities to these identifiers was maintained independently and was not linked to the research data. Participants were compensated with a US $5 gift card for their participation.

Results

Table 1 contains the demographic details of participants involved in the data collection process. A total of 83 individuals contributed, resulting in 124 mannequin-smartwatch datasets, with 41 participants completing 2 rounds of CPR. The sample included 56 females and 27 males, spanning various age groups, with the largest group being younger than 30 years old. Participants also varied in their previous CPR experience, ranging from no previous attempts to over 30, offering a diverse dataset in terms of skill level and background.

[a]CPR: cardiopulmonary resuscitation.

A series of experiments were systematically conducted, exploring various hyperparameters and datasets, until no notable improvements in outcomes were observed. This investigative process entailed 12 different experiments to find the optimal set of hyperparameters. Within each trial, data on the variations in hyperparameters were documented, noting the discrepancies between anticipated and actual compression depths and counts. Given that the variance between expected and observed results could manifest in negative figures, potentially skewing average calculations, absolute values were used for a more accurate determination of the average and median. These analytical steps informed adjustments in hyperparameters for ensuing experiments aimed at enhancing performance.

Throughout this extensive testing phase, a total of 1226 iterations were conducted, each exploring different hyperparameter settings. The specific settings and the best outcomes from each experiment are presented in Table 2, while detailed information on each experiment is provided in Multimedia Appendix 2. Summarizing the testing, the most effective model across all iterations was characterized by the following hyperparameters: hidden layers configured as (2000, 1000, 250, 100, 50), a batch size of 2000 epochs, and a dropout rate of 10% after every 2 layers. Predictions from this model demonstrated an average absolute loss in compression depth of 3.8 (SD 0.16) mm and in compression count of 0.8 (SD 0.05) counts, with a median absolute loss for compression depth at 2.59 (IQR 0.24) mm and for compression count at 0.03 counts. Throughout the course of the experiments, 27 models were identified as capable of predicting an average absolute compression depth below 4.0 mm.

The Spearman correlation coefficients were 0.80 and 0.78, respectively, with *P* values of 1e-3, indicating a strong and statistically significant positive correlation between actual and predicted values for both compression depth and compression count. These findings suggest that the model effectively predicts compression depth and count, even though the underlying data distribution is not normal.

Discussion

Overview

This study introduces a neural network model capable of using accelerometer data from a smartwatch to guide users in delivering high-quality CPR. To facilitate this, apps for both Apple Watch and iPhone were developed to gather accelerometer data during CPR. This research compiled data from 83 participants using Apple Watches to perform CPR on a mannequin, resulting in a total of 27,844 chest compressions. A total of 1226 experiments were conducted to evaluate different hyperparameter settings. The most effective model used hidden layers (2000,1000,250,100,50), a batch size of 2000, and a 10% dropout after every 2 layers. This model achieved an average absolute loss of 3.8 mm in compression depth and 0.8 in compression count, with median losses of 2.59 mm and 0.03 counts, respectively. In total, 27 models achieved an average absolute compression depth loss of less than 4.0 mm.

Principal Results

Considering mannequin data as the benchmark, the neural network was trained with the accelerometer data to emulate the mannequin's feedback. After undergoing 1226 iterations of model refinement, the optimal model emerged, capable of estimating compression depth with an average discrepancy of 3.8 mm and compression count with an average discrepancy of 0.8 counts across 5-second intervals. This investigation underscores the potential of a neural network model to surpass existing models in predicting CPR quality, underpinned by a more extensive and realistic dataset than those previously reported in the literature [40,44,45,53-55].

Comparison With Previous Work

Numerous studies have highlighted significant enhancements in CPR quality when performers receive real-time feedback through intelligent technologies [40,53,56]. Gruenerbl et al [44] proposed a smartwatch app capable of measuring CPR parameters and offering visual feedback. This app analyzes accelerometer data to evaluate compression quality, providing user feedback to achieve high-quality compressions. Lu et al [45] also proposed a smartwatch app alongside an algorithm for evaluating compression metrics. However, these proposed solutions are developed on limited datasets and do not provide sufficient details to reproduce or enhance the system. Dedicated devices, such as the Laerdal CPRMeter2, which can be placed on the chest of a mannequin or patient, are available for purchase. These devices are equipped with accelerometers and pressure sensors to accurately assess CPR performance and provide real-time feedback [26]. However, these devices are expensive and must be carried by the user at all times, as emergencies can occur at any moment.

Limitations

This study demonstrates that the accelerometer data from the smartwatch can be used to provide real-time feedback to the CPR performer and can help increase the survival chances of the patient. However, there are a few limitations worth noting. First, the developed model focuses on measuring compression

XSL•FO
RenderX

depth and count but does not account for compression recoil. Compression recoil plays an important role in performing high-quality CPR, as it allows the patient's chest to fully expand. This full expansion enables more air to enter the patient's body. Compression recoil can also be measured using acceleration data from the smartwatch and compared with sensor data from the mannequin, similar to how compression events are measured. In future research, the authors plan to include this factor as well.

Second, the Apple Watch Series 7 was the exclusive device used to collect data during this study. However, sensors in smartwatches vary between brands, models, and versions, each having its own set of white noise that may impact the results. Therefore, it is necessary to investigate how other devices with different sensors perform with the presented model and whether the model needs to be tuned for each device type. In future studies, the authors plan to use an Android device to cover a broader spectrum of sensors.

Third, during data collection, it was observed that the sensor data frequency fluctuated between 48-60 Hz, although the collection rate was set to 60 Hz. This fluctuation could be due to several reasons: slower processing on the device, the device's inability to write data at that frequency to the file, or the device's processing speed being unable to read the data from the sensors at this speed. Therefore, it is important to investigate how the model's performance would be affected if the data frequency were lowered.

Fourth, while working with the Apple Watch, the authors found a limitation that restricts its use during emergency events. The Apple Watch only allows an app to run in the background for 30 seconds before it is suspended, after which the app can only execute its tasks intermittently. This restriction hinders the use of the smartwatch for providing real-time feedback during emergencies.

Finally, in data segmentation, the acceleration data were chunked based on a fixed number of data points (300, representing 5 seconds of data at 60 Hz). This chunking may occur during a compression event, potentially splitting the compression event into 2 parts, which the algorithm may not recognize, resulting in missed compressions. In future research, the authors plan to address this problem by introducing an advanced algorithm that can recognize the completion of a compression event and then segment the data accordingly to avoid splitting compression data.

Conclusions

This study presents a neural network model designed to gauge the rate and depth of CPR compressions accurately. The model has undergone training on a large dataset, ensuring a robust foundation for its predictive capabilities. Its accuracy is remarkably close to the measurements obtained from a CPR mannequin, serving as a benchmark for comparison. Notably, this model demonstrates superior performance when compared with other models discussed within the existing literature, establishing it as a significant advancement in the field of medical emergency training and response analysis. Implementation of this model in real-world scenarios could significantly improve SCA survival rates.

Abstract

Background: Consumer wearable technology quantifies physical activity; however, the association between these metrics and cardiometabolic health requires further elucidation.

Objective: This study identified latent factors derived from Fitbit heart rate metrics and their relationship with cross-sectional cardiovascular phenotypes.

Methods: This cross-sectional analysis included 457 participants from the SingHEART study, a multiethnic, population-based study of Asian individuals aged 21 to 69 years recruited in Singapore. Participants wore the Fitbit Charge HR for 7 days, and data on physical activity metrics, self-reported physical activity index (PAI), blood tests, coronary artery calcium scores, and cardiac magnetic resonance imaging were collected. Exploratory factor analysis identified latent factors from Fitbit metrics, and multivariate regression analysis assessed associations with blood and cardiovascular imaging phenotypes.

Results: Higher levels of self-reported PAI were significantly associated with a higher number of calories burned (P=.008), number of steps and floors climbed, distance, number of activity calories, and number of very active minutes (P<.001). However, there was no association between PAI and other Fitbit metrics. Using exploratory factor analysis, we identified three latent factors measured by Fitbit metrics: (1) elevated metabolic equivalents of task (METs; calories burned per day, minutes per day spent fairly active in 3-6 METs and very active in ≥6 METs, and activity calories), (2) total activity (steps per day, distance in kilometers per day, and number of floors per day), and (3) others, all with a Cronbach α of >0.7. Higher total activity was associated with increased high-density lipoprotein levels (β=0.06; P<.001), decreased triglyceride levels (β=−0.10; P=.006), and lower BMI (β=−0.63; P<.001) after adjustment for age, gender, systolic blood pressure, total cholesterol, and family history of heart disease. The interaction between total activity and elevated METs was associated with lower fasting glucose (β=−0.07; P=.004). Elevated METs were associated with higher log(coronary artery calcium+1) and higher BMI (P<.001). Total activity was significantly associated with higher indexed biventricular systolic (P=.01 for left and P=.006 for right) and diastolic volumes (P<.001) and higher indexed left ventricular mass (P=.005).

Conclusions: We identified 3 groups of wearable metrics with distinct characteristics. While total activity had a significant relationship with self-reported PAI, most metrics of elevated METs did not. Total activity had a consistent and favorable association with lipid and glucose profiles and a dose-dependent association with cardiac remodeling. Elevated METs alone did not appear to have a significant association with favorable cardiovascular profiles. This study suggests that the total activity metrics are robust and dependable when interpreting an individual's activity levels, with construct validity according to self-reported PAI and a positive association with lipid and glucose profiles, and demonstrate dose-dependent associations with cardiac remodeling

after adjustment for demographics and risk factors. Findings related to elevated METs may be due to the Hawthorne effect and require further studies.

Introduction

Background

Consumer health wearables are being rapidly adopted by the general population. Surveys have shown that up to 60% of the population own and use wearable devices [1-3]. Physical activity information is the most common measurement provided by current wearable devices. In addition, wearable-reported physical activity data have been studied and validated in various settings to ensure accuracy [4,5]. The abundance of accurate physical activity data presents an opportunity to transform them into actionable information.

Physical activity is a modifiable risk factor toward reducing cardiovascular disease, with up to 30% risk reduction in events among middle-aged adults [6]. Guideline recommendations on physical activity are largely derived from self-reported physical activity in epidemiological studies and its links to cardiovascular risk factors and events [6-13]. Self-reported physical activity has only been moderately correlated at best with actual physical activity [14], suggesting the imprecision of self-reported physical activity. Studies comparing self-reported and wearable-quantified physical activity have mainly looked at their correlation [15,16], but literature on their differences in association with cross-sectional health states is lacking. Less precise self-reported physical activity may mask significant associations with cardiometabolic profiles, which change subtly with physical activity. The inclusion of health wearables in recent large population studies [14,17,18] presents an opportunity to quantify physical activity more accurately. Moreover, there is a strong body of evidence suggesting that interventions using wearable activity trackers result in improvements in the physical activity of users; however, the effectiveness of these interventions on physiological outcomes remains uncertain [19].

Objectives

Despite widespread interest in the utility of wearable devices in health care, one of the challenges is synthesizing the vast amounts of data collected and integrating them into clinical practice [20]. While most studies have shown that step count consistently shows a positive relationship with cardiovascular health [8,21,22], other metrics such as exercise intensity and sedentary time have been less studied [22]. This study aimed to identify latent factors derived from Fitbit Charge HR (Google) physical activity metrics and correlate them with cross-sectional health outcomes. Considering the differences in activity behavior between weekends and weekdays [7], participants were given the fitness tracker for 1 week to ensure representative physical activity behavior, similar to that in previously conducted wearable studies [18,23].

Methods

Study Design

SingHEART (ClinicalTrials.gov NCT02791152) [17] was the first multiethnic prospective population-based study of healthy Asian individuals who completed detailed lifestyle and medical history questionnaires and had their activity levels recorded via wearables and their cross-sectional cardiovascular status detailed via blood tests and imaging (described in the following sections). A total of 457 individuals from SingHEART [17] were included in this cross-sectional study. Healthy male and female participants aged 21 to 69 years without any previous cardiovascular disease (eg, ischemic heart disease, stroke, or peripheral vascular disease) or diabetes mellitus were recruited from the Singapore general public via advertisements (eg, posters and the local newspaper).

Baseline Blood Tests and Measurements

A comprehensive set of assessments was conducted at baseline. Basic blood tests, including fasting lipids and glucose, and clinical parameters of height, weight, and hip and waist circumference were measured.

Physical Activity

Participants were given the Fitbit Charge HR wearable device, which tracked heart rate, step count, and intensity of physical activity. The device was worn over a course of 7 days [16]. Step counts were retrieved as daily totals, and the mean number of steps in each day was derived. There were 9 averaged metrics on physical activity presented by Fitbit Charge HR on a per-day basis: calories burned, number of floors, number of steps, distance, minutes spent sedentary, minutes spent lightly active, minutes spent active, minutes spent very active, and activity calories. The various activity intensity levels were previously defined by Fitbit: sedentary, lightly active (1.5-3 metabolic equivalents of task [METs]), fairly active (3-6 METs in at least 10-minute bouts), and very active (≥6 METs or ≥145 steps per minute in at least 10-minute bouts) [24]. Participants were asked to carry on with their regular jobs and physical activity and not to artificially inflate their activity levels so that the wearable was able to capture an accurate representation of their usual lifestyle. Self-reported physical activity was also quantified using the physical activity index (PAI) [25] derived from the General Practice Physical Activity Questionnaire [26].

Blood Pressure Monitoring

Ambulatory blood pressure (BP) was measured using a cuff monitor (Spacelabs Healthcare models 90227 and 90217A). BP was then analyzed as a continuous variable.

XSL•FO
RenderX

Coronary Artery Calcium Scoring

All participants underwent noncontrast cardiac computed tomography scans using a 320-slice computed tomography scanner. Coronary artery calcium (CAC) was quantified using the Agatston score [12] via the Vitrea Workstation. CAC was logarithmically transformed into a continuous variable (log[CAC+1]). As this cohort of individuals was free of known cardiovascular disease, the CAC helped detect subclinical, early atherosclerosis.

Magnetic Resonance Imaging Cardiac Measurements

Cardiovascular magnetic resonance was conducted for all participants using either the Ingenia 3.0T (Philips) or MAGNETOM Aera 1.5T (Siemens Healthineers) scanners. Parameters of cardiac mass, volumes, and function were measured using the cvi42 software (Circle Cardiovascular Imaging) and standardized protocols [27]. Left ventricular mass without papillary muscles was indexed to body surface area according to the DuBois formula, and left ventricular mass index was used for analysis [28].

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki [29]. Written informed consent was obtained from all participants, and the study was approved by the SingHealth Centralised Institutional Review Board (reference 2015/2601). The data used for analysis were anonymized to ensure participants' privacy and confidentiality. Participants were given SGD $50 (US $39) as compensation for their transport and inconvenience.

Statistical Analysis: Identifying Latent Factor Measures Using Fitbit Metrics

In this paper, *items* refer to the Fitbit-derived metrics. Using factor analysis, we determined the optimal number of factors using the Kaiser rule (ie, eigenvalue>1). To identify items contributing to factors, we used the criterion of factor loading of >0.4 as a cutoff [30].

Internal consistency reliability (the extent to which the items grouped together are appropriate to measure the same property) was assessed for each factor using the Cronbach α [31]. Construct validity of factors (the ability to measure the intended property in reference to acknowledged standards) was assessed against the self-reported PAI. A value of ≥0.6, 0.4 to 0.5, and 0.2 to 0.3 was considered a strong, moderate, and weak correlation, respectively [32].

Structural equation modeling [33] was used to analyze the relationship between measured items and latent constructs.

After factor analysis using oblique rotation, the identified factors were predicted using regression scoring [34]. Each individual factor was obtained as a weighted sum of standardized versions of the items with a mean of 0.

Intergroup differences in risk factors were evaluated using chi-square tests for categorical variables and ANOVA for continuous variables with Bonferroni correction. Statistical significance was considered as $P<.05$.

Multivariate regression analysis adjusting for age, gender, BMI, 24-hour average systolic BP, total cholesterol, and family history of coronary artery disease testing the identified latent factors was conducted for the lipid and glucose profiles, log(CAC+1), and cardiac magnetic resonance imaging (MRI) variables.

All analyses were conducted using Stata (version 17.0; StataCorp) [35].

Results

Overview

The baseline characteristics of the population as a whole and divided by self-reported PAI categories are shown in Table 1. The average age of the participants was 50.05 (SD 9.42) years, and 46.6% (213/457) were male. Most of the participants (234/457, 51.2%) had sedentary jobs, and 4.4% (20/457) had highly active jobs. There was a significantly higher proportion of male individuals in the moderately active and active categories. There was also a significant trend of increasing calories burned, number of steps, distance, number of floors, activity calories, and very active minutes recorded via Fitbit with increasing PAI levels but not for the activity minutes in other MET categories. Significant trends of increasing cardiac remodeling via indexed left and right ventricular volumes and indexed left ventricular mass measured through cardiac MRI with increasing PAI levels were observed. There was no significant association between increasing PAI levels and BP, lipid and glucose profiles, BMI, or log(CAC+1).

Exploratory Factor Analysis

Using exploratory factor analysis with a cutoff of eigenvalue>1, we identified 3 latent factors measured via the Fitbit metrics on physical activity. The 3 factors identified were elevated METs, total activity, and others. While elevated METs represent the time engaged in moderate- and higher-level physical activity and catabolism measured in calories, total activity describes the average activity, including activity during nonexercise time, throughout the day.

Under factor 1, elevated METs, items with loadings of >0.4 included calories burned per day; minutes per day spent fairly active, defined as 3 to 6 METs; minutes per day spent very active, defined as ≥6 METs; and activity calories. For factor 2, total activity, items with loadings of >0.4 included number of steps per day, distance in kilometers per day, and number of floors per day. Factor 3 (others) items with loadings of >0.4 included sedentary time minutes and minutes spent lightly active, defined as 1.5 to 3 METs, where the loading value for sedentary time minutes was negative (Table 2).

Structural equation modeling was conducted on items and constructs, and the results are shown in Figure 1. There was a strong correlation (>0.6) between elevated METs and total activity.

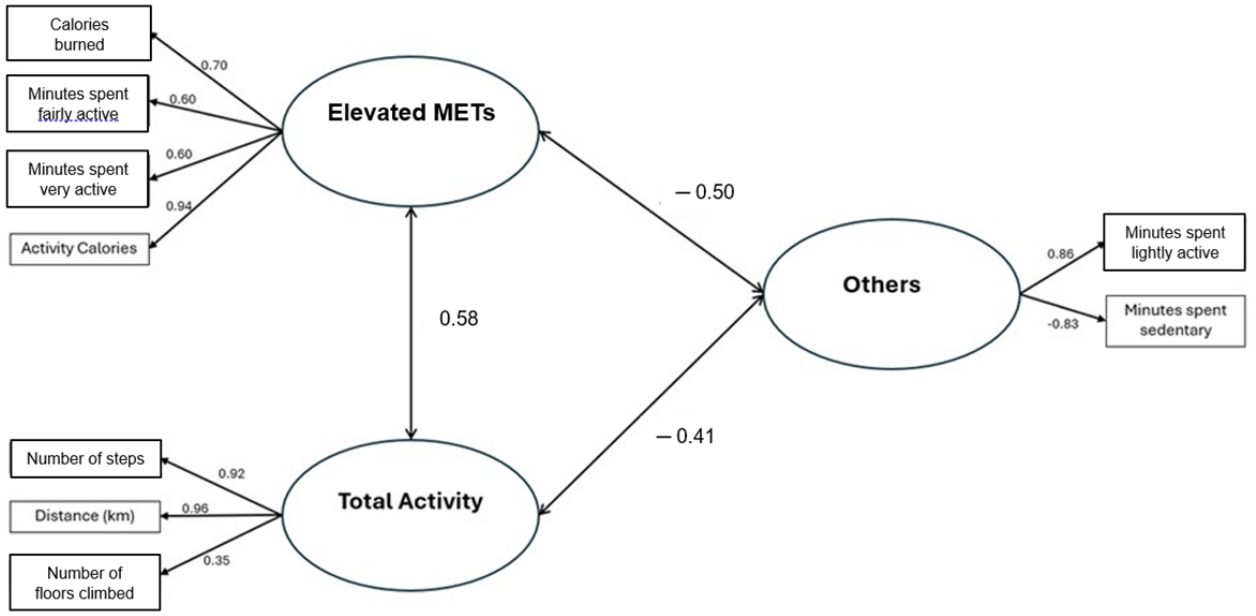
Figure 1. Confirmatory factor analysis and sequential equation modeling of the 9 Fitbit metrics. The values show the strength of association between the metrics and the factor and between the different factors. MET: metabolic equivalent of task.



Reliability

For assessing internal consistency reliability, the Cronbach α exceeded 0.70 for all 3 constructs (elevated METs=0.820; total activity=0.781; others=0.745). Correlations between the factors and hypothesized items are shown in Table 2.

Construct Validity

The correlation between self-reported PAI [36] and elevated METs and total activity was significant but weak (0.23 and 0.26, respectively; *P*<.001). The *others* factor was not correlated with PAI (*P*=.64).

Regression Analysis

As there was a strong correlation between elevated METs and total activity, we included and tested the interaction term of elevated METs and total activity in the multivariate regression analysis.

XSL•FO
RenderX

Lipid and Glucose Profiles and BMI

In contrast to the PAI, which did not show any significant trend regarding lipid and glucose profiles and BMI, total activity was associated with significantly higher high-density lipoproteins (HDLs; β=0.06; *P*<.001) and lower triglycerides (β=−0.10; *P*=.006); total activity trended toward being associated with lower fasting glucose, and the interaction term of elevated METs and total activity was significantly associated with lower fasting glucose levels (β=−0.07; *P*=.004). The total activity and other factors were significantly associated with lower BMI (β=−0.63 and −0.82, respectively; *P*<.001), whereas the elevated METs factor was associated with higher BMI (β=1.47; *P*<.001). There was no significant relationship between the various factors and low-density lipoprotein (LDL; Table 3). The coefficient plots of the variables against the lipid and glucose profiles and BMI are shown in Figure 2.

Cardiac MRI and Coronary Calcium Score

The elevated METs factor was significantly associated with higher log(CAC+1) (β=−0.51; *P*<.001; Table S1 in Multimedia Appendix 1). Total activity was significantly associated with higher indexed biventricular diastolic and systolic volumes and higher indexed left ventricular mass (Table 4). The coefficient plots of the variables against the log(CAC+1) and cardiac MRI variables are shown in Figures 2 and 3, respectively.

Quantification of Change in Lipid Profile and BMI per 1000 Increase in Steps

As the most used metric in total activity was step count, we sought to quantify the change in lipid profile and BMI with every 1000-step change. After adjusting for demographics and risk factors, every 1000-step increase per day increased HDL by 0.01 mmol/L, decreased triglycerides by 0.02 mmol/L, and reduced BMI by 0.11 kg/m^2 (Table S2 in Multimedia Appendix 1).

Discussion

Principal Findings

The purpose of this study was to identify the underlying factors measured through an activity tracker, the Fitbit Charge HR, and extrapolate these factors to cross-sectional cardiovascular phenotypes. There has been no previous study to our knowledge conducted for this. Understanding the underlying factors measured by an activity tracker is important to set specific activity goals and prescribe precise physical activity domains using activity trackers. Previous studies have looked at the effectiveness of activity trackers in increasing physical activity [37] and largely focused on step counts in reduction of all-cause mortality [8,38].

This study revealed three factors measured by the Fitbit Charge HR: (1) elevated METs (calories burned per day, minutes per day spent fairly active, 3-6 METs; minutes per day spent very active, ≥6 METs; and activity calories), (2) total activity (number of steps per day, distance in kilometers per day, and number of floors per day), and (3) others (sedentary time minutes and minutes spent lightly active, 1.5-3 METs).

Total activity, represented by steps, distance, and floors, appeared to be consistently associated with a favorable cardiovascular risk profile in our study. It appears that the absolute volume of activity, quantified via total activity metrics, was more consistent in terms of positive cardiovascular benefit [39-41] compared to elevated METs. There was a dose-dependent increase in HDL and a reduction in triglycerides and BMI. HDL is more sensitive to exercise compared to LDL and triglycerides [42]. The lack of decreased LDL with total activity may be due to the study being observational rather than interventional in nature, where an exercise program was shown to reduce LDL, especially when the mean LDL of the participants was normal at 3.41 (SD 0.83) mmol/dL. Given that the adjusted R^2 of the model was high at >0.80, it might also be that other factors played a much larger role in influencing LDL levels compared to physical activity. Compared to self-reported PAI, which had no association with lipid and glucose profiles and BMI, these results suggest that wearable-quantified activity metrics are more accurate and precise in recording activity level, as evidenced by significant associations with cross-sectional cardiometabolic profiles.

There was also significant cardiovascular remodeling based on total activity and self-reported PAI, with significantly larger indexed biventricular systolic and diastolic volumes and indexed left ventricular mass after adjustment for baseline demographics and risk factors. This finding was also consistent with those of previous exercise studies [43,44]. In our study, we can only conclude that total activity was associated with physiological adaptation of the heart, but the functional consequence is unknown.

Regarding the association between elevated METs and higher log(CAC+1), one possible hypothesis is the reverse J curve of exercise [45,46], where excessive exercise gradually precipitates cardiovascular damage. A UK Biobank study demonstrated that the cardiovascular protective effect was lost in the 75th percentile of moderate to vigorous physical activity and above [47], and a systematic review showed that endurance training increased the odds of having high CAC but without increased

XSL•FO
RenderX

prevalence of high-risk plaque [48]. Another possible explanation is a change in participant behavior due to the Hawthorne effect [49]. The METs calculated via Fitbit were based on heart rate and step count over a prespecified period [50]; it is possible that less healthy participants attempted to put in extra exercise time over the 7-day observation period, and with poorer heart rate recovery [51], this would increase their scores in elevated METs. Total activity detailed the average step count and distance covered daily and was harder to inflate compared to elevated METs. Hence, this finding warrants further prospective observational studies or longer periods of monitoring before drawing conclusions.

There are also very few studies that have correlated step count and activity levels to reduced subclinical atherosclerosis [52]. However, there is consistent literature suggesting that increasing step count reduces mortality and cardiovascular events [8,38,53]. Previous population studies have suggested that exercise is a risk modifier, especially in patients with high CAC [54]. As shown in our study, this could be mediated through increased HDL and reduced triglycerides, BMI, and fasting glucose [55,56]. While the pathophysiology might be hard to prove in human studies, animal studies have shown that exercise training reduces glucose and triglyceride levels in LDL-knockout mice [57] and reduces hyperlipidemia-induced cardiac damage through reducing oxidative stress and inflammation in apolipoprotein E–deficient mice [58], hence reducing mortality in atherosclerosis-predisposed animals. HDL is an antioxidant that provides potent protection to LDL from oxidative damage by free radicals, hence inhibiting the generation of proinflammatory oxidized lipids [59], and aerobic exercise has been found to increase both HDL quantity and quality [60]. This might be a reason for the lack of significant association between total activity and presence of atherosclerosis quantified through log(CAC+1) as atherosclerosis might have been caused by other genetic and epigenetic factors and physical activity is but a risk modifier.

Our study showed that there are distinct characteristics conveyed by the different Fitbit activity metrics. Interpreting them individually may not be as helpful; there is a need to recognize the underlying factor described by each metric to make more precise recommendations for exercise and physical health. This study shows that increased activity regardless of MET intensity, represented by total activity, has significant beneficial associations with cardiometabolic profiles. After accounting for gender, BP, and other risk factors, every 1000-step increase per day increased HDL by 0.01 mmol/L, reduced triglycerides by 0.02 mmol/L, and reduced BMI by 0.11 kg/m^2. From a clinical perspective, it may be reasonable to look at the metrics represented sequentially and hierarchically, first ensuring that the individual has achieved reasonable total activity before focusing on the intensity of the activity quantified through the metrics in the elevated METs factor. For example, for patients with no CAC, physicians can recommend 10,000 steps per day [61] and no restriction on activity; conversely, for patients with high CAC who are looking for exercise recommendations, focusing mainly on 10,000 steps per day and moderating very vigorous activity based on effort limitation, especially if the patient had no exercise regime before, may be reasonable.

This was an observational study and not an interventional study, hence limiting it to associations. The 7-day observation period, due to limitations in device availability, may also not be a true representation of activity levels in all patients, although the study team counseled participants to continue their usual activity levels. In addition, this study comprised mainly an Asian population; hence, the generalizability of these findings to other populations may be limited. It will be helpful to use the same framework and explore these associations in other populations. The upcoming 10-year follow-up for this prospective cohort will also shed light on the impact of wearable-quantified physical activity on cardiovascular events stratified by baseline CAC scores.

Conclusions

There are different characteristics conveyed by the different Fitbit physical activity metrics. This study yielded 3 main latent factors and described their associations with cardiovascular health. Total activity, rather than elevated METs, was associated with beneficial effects on cardiometabolic profiles. Total activity appears to be more sensitive and precise than self-reported PAI, with significant associations with lipid and glucose profiles and BMI. One can consider interpreting activity metrics on wearables sequentially and hierarchically, focusing first on metrics in the total activity factor before considering metrics in the elevated METs factor when providing physical activity advice.

Acknowledgments

This work was supported by the Open Fund – Young Individual Research Grant from the National Medical Research Council, Ministry of Health, Republic of Singapore (grant MOH-OFYIRG21jun-0004), and the National Research Foundation, Singapore, under its AI Singapore program (grant AISG-GC-2019-001-2B). The authors would also like to thank the Lee Foundation for their grant support for the SingHEART study conducted at the National Heart Centre Singapore. The funding bodies were not involved in design, conduct, data interpretation, or writing of the manuscript.

Data Availability

The datasets generated or analyzed during this study are not publicly available as recruitment is still ongoing and the participants have not completed their follow-up but are available from the corresponding author on reasonable request.

Abstract

Background: Missing data are inevitable in mobile health (mHealth) and ubiquitous health (uHealth) research and are often driven by distinct within- and between-person factors that influence compliance. Understanding these distinct mechanisms underlying nonresponse can inform strategies to improve compliance and strengthen the validity of inferences about health behaviors. However, current missing data handling techniques rarely disentangle these different sources of nonresponse, especially when data are missing not at random.

Objective: We demonstrate the usability of joint modeling in the mHealth context, showing how simultaneously accounting for the dynamics of health behavior and both within- and between-person missingness mechanisms can affect the validity of health behavior inferences. We also illustrate how joint modeling can inform distinct sources of (possibly nonignorable) missingness in studies using ecological momentary assessment and wearable devices. We provide a practical workflow for applying joint models to empirical data.

Methods: We applied joint modeling on empirical data comprising 1 year of daily smartphone-based ecological momentary assessment data (affect and energetic feeling) and smartwatch-tracked physical activity (PA). The approach combined (1) a multilevel vector autoregressive model for examining the reciprocal influences between daily affect and PA, and (2) a multilevel probit model for missingness. Unlike conventional 2-stage imputation methods—which first impute missing data before fitting the main model—joint modeling handles missingness during model fitting without explicit imputation. Sensitivity analyses compared results from the proposed method to other missing data approaches that do not explicitly model missingness. A simulation study designed to mirror the temporally clustered (eg, consecutive days of missing data) and person-specific missingness patterns of the empirical data validated the feasibility of the proposed approach.

Results: Sensitivity analysis indicated relative robustness of the autoregressive effects across missing data handling approaches, whereas cross-regressive effects could be detected only under the joint modeling but not with methods that did not simultaneously model missingness mechanisms. Specifically, under joint modeling approaches, participants had higher levels of PA on days following a previous day with higher self-report energy levels (95% credible interval [CrI] 0.012-0.049). Furthermore, the missing data model revealed both missing not at random and missing at random mechanisms. For example, lower PA predicted higher

XSL•FO
RenderX

missingness in PA at the within-person level (95% CrI –1.528 to –1.441). Being employed was associated with higher missingness in device-tracked PA at the between-person level (95% CrI 0.148-0.574). Finally, simulation showed that joint modeling could improve the accuracy of estimates and identify nonignorable missingness.

Conclusions: We recommend joint modeling with multilevel decomposition for addressing nonignorable missingness in mHealth/uHealth studies collecting intensive longitudinal data. We also suggest using a missing data model to explore the missingness mechanism and inform data collection strategies.

Introduction

Background

As technology advances, mobile health (mHealth) and ubiquitous health (uHealth) data collection via mobile and wearable devices has become increasingly common. This typically involves continuous tracking of physiological data, such as step counts and heart rate, through smartwatches [1], alongside self-reported ecological momentary assessment (EMA) surveys prompted on smartphones or web interfaces multiple times a day to measure self-reported behavioral and psychological variables [2,3]. Such intensive longitudinal data (ILD) [4,5] offer numerous advantages. They facilitate remote monitoring for timely interventions, reduce recall bias by capturing real-time data, and allow for examination of behavioral changes on more granular timescales. These features have the potential to enhance the effectiveness of health monitoring and research. Missing data are inevitable in mHealth and uHealth studies as triggered by myriad reasons, including variations in participants' compliance, engagement, contextual factors, and other measurements and technical issues [6,7]. Whereas various modeling methods have been proposed to deal with missing data in ILD, few mHealth or uHealth studies have systematically leveraged and integrated passive device and subjective EMA responses to inform missingness mechanisms that drive across-participant and across-time variations in compliance rates and possible consequences on health behavior inference [7-10].

Why Joint Modeling for mHealth and uHealth Studies?

Overview

Joint modeling is a technique that handles nonresponse bias by simultaneously fitting 2 interconnected models: 1 for the main analysis (substantive model) and 1 for understanding how missing data might occur (missing data model). The substantive model could be any statistical model for testing the primary research question, such as linear regression, survival analysis, and path analysis. The missing data model is a model that examines whether missingness is linked to certain factors by modeling binary missing indicators of the variables of interest (see Figure 1 for an overview).

Joint modeling is commonly used to address nonignorable, also known as nonrandom missingness, which occurs when the missingness depends on unobserved outcomes. For example, if some participants wear their smartwatches only when they are physically active, the device-tracked physical activity (PA) data are said to be missing not at random (MNAR), as the likelihood of missingness depends on the unobserved PA levels, which ought to be measured but were missing on the less active days (alternatively, more germane scenarios include missingness completely at random [MCAR], in which the missingness does not depend on any variable, and missingness at random [MAR], in which the missingness depends only on variables that are observed in the measured data). Overlooking such nonignorable missingness by examining the substantive processes only with the available data often results in incorrect inferential conclusions [11].

Past mHealth and uHealth studies that sought to identify predictors of participant compliance [8,12] have typically focused exclusively on the "missing data models." As such, the researchers miss opportunities to allow the substantive and missing data models to iteratively inform each other during model fitting, especially in MNAR scenarios.

Such a joint inferential approach has several advantages. First, by explicitly accounting for when and why missingness occurs, the missing data model informs substantive models with more plausible values for unobserved data, leading to enhanced estimates of key substantive processes (such as PA and energy levels), even when data are incomplete. Second, the missing data model also benefits from the substantive model, especially when the likelihood of missingness depends on variations in the substantive processes (ie, MNAR), as noted in several EMA studies involving subjective self-reports [13,14].

Third, in mHealth or uHealth contexts, this mutual reinforcement between models can be further enhanced by leveraging passively collected data. Passive data such as device usage indicators (eg, app engagement records) can be collected unobtrusively and may provide valuable auxiliary information for modeling missingness mechanisms.

Fourth, the enhanced ability to detect nonignorable missingness can inform better data collection strategies. For instance, if the model reveals that PA data are more likely to be missing during low-activity days (ie, less inclined to wear devices on inactive days; MNAR), researchers might implement targeted strategies to improve data quality, such as sending adaptive reminders encouraging device use particularly during low-activity periods. While direct follow-up with nonrespondents is ideal [15], it is often costly or infeasible, making joint modeling a valuable

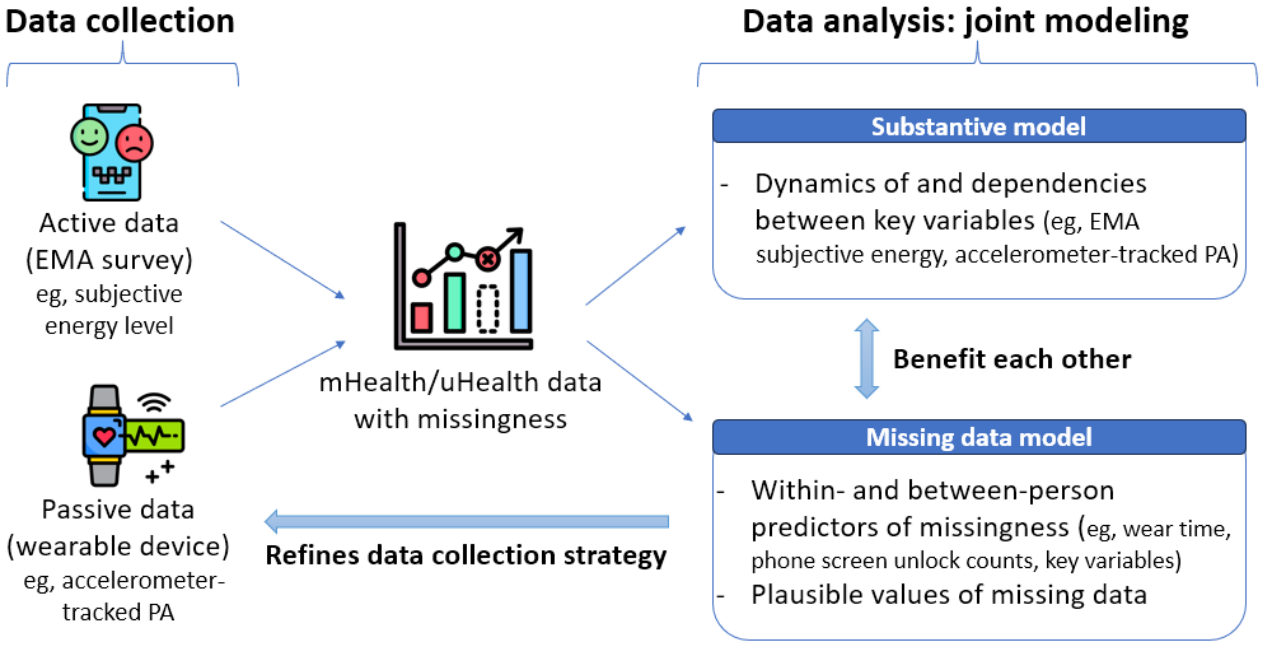
XSL•FO
RenderX

alternative for identifying potential MNAR without extra data collection.

Finally, even highly engaged participants exhibit occasional missingness in longitudinal studies, but no studies to date have considered the implications of conflating within- and between-participant variations in compliance. Examining how compliance fluctuations relate to PA and energy levels can inform the design of more sustainable health behavior interventions.

This study capitalizes on a 1-year intensive longitudinal study to demonstrate how device-tracked PA and subjective EMA reports (eg, energy levels) can be integrated within a joint modeling framework that captures both within- and between-person variations. Passive indicators such as cell phone unlock counts are incorporated as auxiliary variables to aid modeling missingness. This approach highlights the benefits of leveraging multiple data sources and the risks of ignoring key sources of variation.

Figure 1. Conceptual framework of joint modeling. EMA: ecological momentary assessment; mHealth: mobile health; PA: physical activity; uHealth: ubiquitous health.



Existing Joint Modeling Approaches

Three common approaches for handling missing data within the joint modeling framework are the selection model, shared parameter model (SPM), and pattern mixture model (PMM). We focus on the selection model and SPM, as PMM is less applicable to ILD context. PMM stratifies data by missing patterns and forms distinct models for each [16], which becomes impractical for ILD, given its diverse missing patterns.

In the selection model, we assume that the missingness depends on the unobserved values of the dependent variables (DVs). Thus, the selection model directly models the probability of missingness as a function of the (possibly unobserved) DV and uses a joint likelihood to link the substantive and missing data models [17]. For example, participants may be inclined to wear their smartwatches tracking PA only when they are physically active, leading to missing PA data when they are sedentary. To address this MNAR issue, selection models directly incorporate PA levels as a predictor in the PA missingness model, thereby correcting the bias caused by nonignorable missingness. Additionally, by integrating auxiliary variables, additional variables not part of the main analysis but providing valuable information about the missing data mechanism, as covariates [18] (eg, time of day as a proxy for habitual exercise routines), the model can also capture and adjust for MAR mechanisms. This approach enables the missing data model to serve as a tool not only for correcting bias but also for investigating potential contributors to the missingness, such as how PA levels influence the likelihood of PA data being missing.

In SPM, the missingness and substantive models are linked through shared latent parameters (eg, random effects) [19], and it assumes that the substantive and missingness processes are independent, given the shared or correlated random effects. For instance, in a longitudinal treatment study, patients may be more likely to drop out as their health deteriorates (MNAR). Here, the patient's latent health trajectory—represented by a random slope (ie, person-specific effects of time on health)—is associated with data missingness. By incorporating an individual's random slope as a predictor in the missing data model, 2 processes are linked [20]. When the missing data model's regression coefficient for the random slope is nonzero, it indicates dependence between the substantive and missingness processes.

While SPM and the selection model are often described as distinct approaches, SPM is sometimes viewed as a variant of the selection model [21,22]. Specifically, when applying a selection model within a multilevel framework, the structure closely resembles that of the SPM [22]. This similarity arises when the DV is decomposed into within- and between-person components, and the between-person component (ie, the random

XSL•FO
RenderX

intercept) is used as a predictor in the missing data model. In this case, it mirrors SPM's use of a latent random effect to link missingness and substantive processes.

These approaches form the conceptual basis of our proposed joint modeling, which specifically targets within- and between-person heterogeneity, as well as temporally clustered missingness—the tendency for missing days to be followed by more missing days. We describe each of these characteristics in turn.

Missing Data Issues in ILD

Heterogeneity in Missing Data Patterns Within and Across Individuals

Unlike conventional panel longitudinal data, ILD is characterized by a much higher frequency of assessments, leading to greater variability in missing data patterns. First, a high frequency of data collection can amplify within-person variations in compliance because the number of possible missing data patterns increases with an increase in the number of assessment occasions. Since data are collected daily or multiple days a time, more factors can influence daily compliance rates in mHealth and uHealth studies [8,9], such as daily variations in affect, technical issues, forgetting to wear a watch [23], or any disruptions in daily lives (eg, illness, vacations). Nahum-Shani et al [7] discussed how engagement in digital interventions using mobile devices can be influenced by contextual factors such as emotional, physical, and cognitive energy. As more concrete examples, nonresponse to EMA push notifications could be influenced by the emotional energy of the survey moment, as well as PA levels or sleep duration on the day, which is proxy of physical energy throughout the day.

Second, participants may miss assessment points due to baseline individual differences in compliance, such as levels of conscientiousness or familiarity with mobile technology. This between-person variation can become more pronounced with more repeated measures. Martinez et al [12] reported that compliance rates for wearable trackers and mobile EMA were related to person-specific characteristics. Older participants tended to have more difficulties using smartphones, leading to lower compliance rates [24]. A higher BMI was related to lower compliance rates in a weight intervention study because of physical discomfort with wearing the device and the collection of weight data. In summary, participants' compliance to mHealth and uHealth data collection changes not only because of their person-level traits but also due to changes in daily contextual factors. As sample size and measurement occasions increase, so does the variability in compliance rates both within and across individuals.

Our proposed joint modeling approach allows for between- and within-person heterogeneity in missingness by combining a multilevel missing data model with a multilevel vector autoregressive (VAR) model for the substantive processes of interest. Applications of such multilevel decomposition of missingness are still nascent in the literature and are primarily restricted to cross-sectional settings [25], or iterations through missing data imputation and substantive process modeling in 2 stages [23]. Although a few studies in the ILD literature have adopted joint modeling approaches (with substantive process models that were similar to that adopted here) [26], these studies did not apply multilevel decomposition to the missing data model itself.

Temporally Clustered Missingness

In our empirical data, we observed significant patterns of temporally clustered missingness (see Figure 2 for examples). Specifically, 25.2% (55/218) of the participants had at least 1 period of 7 consecutive days of missingness for EMA-measured energetic feelings (ENs), and 41.3% (90/218) of participants had at least 1 period of 7 consecutive days of missingness for smartwatch-tracked accelerometer-measured PA (see section "Motivating Empirical Data" for the valid data criterion). These patterns highlight a notable feature of missing data in ILD: burst or temporally clustered missingness, where 1 day of missingness tends to be followed by more missing days. This clustering can occur for various reasons. For instance, during busy periods or while traveling, participants may ignore survey prompts for several consecutive days. If any technical issues occur, the data can be continuously missing until the problem is resolved. Such burst missingness suggests that each instance of missing data may not be independent of the previous instances.

Incorporating this pattern into missingness models could improve the accuracy of analyses. However, existing methods often overlook these patterns, likely because it is not commonly observed in cross-sectional or conventional panel longitudinal data. To our knowledge, only 1 study has considered the temporal dependency of missingness when modeling missing processes but without substantive models [27]. In contrast, an ILD study with a joint modeling approach [26] did not incorporate such a temporal component in its missing data model. To address this gap, we integrate autoregressive (AR) terms into our proposed missing data model within the framework of the joint model. AR terms account for the autocorrelation in missing data by relating the current missing data status to the previous time points, thereby capturing the tendency for missingness to occur in clusters.

Our approach is a multilevel joint model based on the selection model framework, assuming the missingness in DV depends on unobserved variables or parameters (MNAR), and other observed covariates (thus allowing for MAR as a special case). Under this approach, substantive and missingness models are connected via joint likelihood and correlated residuals. While rooted in the selection model framework, our multilevel joint model shares some similarities with SPM: DVs are decomposed into within- and between-person components in substantive models, and the latent between-person components (ie, random intercepts) serve as predictors in missing data models. Our missing data model can be further extended from an SPM perspective by incorporating additional random effects (eg, random AR effects in VAR models). However, such an extension was not implemented, due to the lack of theoretical background to expect that person-specific AR coefficients would be systemically related to missingness. Table 1 compares the selection model, SPM, and our multilevel joint model, emphasizing their suitability for different scenarios and highlighting the unique contributions of our approach.

Figure 2. Data missingness in bursts from 2 participants. EMA: ecological momentary assessment; EN: energetic feeling; PA: physical activity.

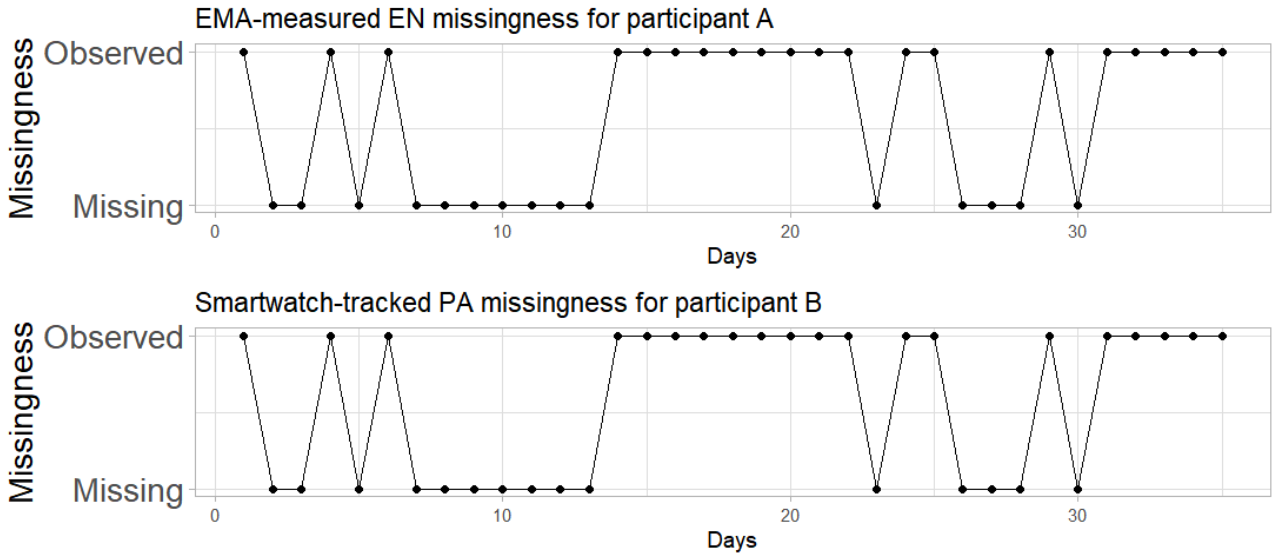

Table 1. Comparison of joint modeling missing data handling approaches.

	Key properties	When to use	Common use cases
Selection model	• Links outcome and missingness models via joint likelihood, often with correlated residuals.	When missingness depends on unobserved DVs[a].	• Widely applied in cross-sectional and panel data.
Shared parameter model	• Models share latent parameters (eg, random effects). • Assumes conditional independence given shared parameters.	When missingness relates to latent change components (eg, random slope).	• Typically to model dropout or attrition in longitudinal panel studies. • Terminal dropout or attrition does not require consideration of overtime variations in missingness.
Multilevel joint model (this study)	• Link 2 models via joint likelihood and correlated residuals. • Does not assume conditional independence given shared parameters. • Decomposes missingness into within- and between-person levels, disentangling momentary and habitual missing tendencies.	When missingness depends on either unobserved variable values or latent changing dynamics (eg, random AR[b] effects), with temporally clustered missing patterns.	• Tailored for ILD[c] with intermittent missingness. • Useful for ILD-specific challenges: mixed sources of missingness (person- and context-level), temporal dependency of missingness.

[a]DVs: dependent variables.

This Study

Due to the distinct patterns of missingness in ILD, specialized approaches are required for handling missing data. In this study, we apply multilevel joint modeling to empirical mHealth data consisting of up to a year of daily self-reports on feeling energetic and PA, tracked by smartwatches. Especially, through this empirical analysis, we provide practical guidance on building missing data models and discuss the use of joint modeling of the dynamics of the substantive health processes and missingness mechanisms.

Additionally, by comparing the empirical results obtained across different missing data handling methods—such as listwise deletion, last observation carried forward (LOCF), mean imputation, Bayesian full information maximum likelihood (FIML), and joint modeling with alternative missingness models—we highlight the importance of conducting sensitivity analysis to evaluate the robustness of substantive conclusions.

Given that true substantive and missing data models are never known in empirical analysis, we further supplement the empirical analysis with a simulation study. This simulation aims to verify the efficacy of the joint modeling approach under known data-generating mechanisms and missing data patterns designed to mirror the intricacies of empirical ILD, such as individual variations in compliance rates, clustered patterns of missingness, and the presence of ordinal DV (eg, Likert scale).

Methods

Motivating Empirical Data

Data from the Temporal Influences on Movement and Exercise study [28], collected over 1 year, were analyzed. The study

XSL•FO
RenderX

recruited young adults (aged 18-30 years; N=246) across the United States. Participants completed smartphone EMA surveys on EN at the end of the day and wore smartwatches to track PA throughout their participation. Each participant's study start date was defined as the first day with both EMA and wearable data. If EMA responses continued after wearable data had permanently stopped (eg, due to technical issues), those trailing EMA entries were excluded to preserve meaningful variation in both affect and PA.

Data were retained for participants who had at least 14 days of nonmissing data for both EN and PA and at least 30 days of participation. Participants with more than 80% missing data in either EN or PA were considered noninformative for the intended analysis and excluded to prevent excessive imputation bias. This yielded final data from 218 out of 246 individuals, with data ranging from 39 to 401 (median 323.5, IQR 153.5-347) days and a total of 55,716 data points.

Measurement

Participants rated their daily EN on a 5-point Likert scale via smartphone app at the end of the day. Smartwatch-tracked PAs were first summarized using the motion independent movement summary units [29], based on raw acceleration data from Fossil Sport 4/5 (initially in 1-second epoch), and were aggregated daily. To facilitate efficient model fitting, daily PA was scaled by its standard deviation to align with other variables, as large discrepancies in variable scales can lead to numerical instability and slower convergence in complex models [30].

Time-varying covariates included daily device wear time, self-reported daily sleep duration (in hours), a season indicator, and phone screen unlock counts per day. Device wear time was determined from the SWaN (Sleep Wake and Nonwear) algorithm [28], which categorized available data into Wear, Sleep, or Nonwear. Demographic and between-person variables were also considered: sex (female=1 and male=0), age, employment status (employed for wages=1 and no=0), self-reported depression diagnosis (yes=1 and no=0), and alcohol consumption habit (number of days of drinks per week).

Missing Data

Individual missing data percentages for EN (the proportion of missing days relative to each participant's total participation) ranged from 0% to 71.2%, with an average of 16.7% per person. For the entire dataset, the missing rate was 14.9% (8319/55,716), with continuous missing days ranging from 1 to 38 (mean 1.6, SD 1.98 days). For daily PA, missing data were defined as less than 10 hours of smartwatch wear [31]. If no data were available, it was treated as 0 wear time, and PA was marked as missing. Individual missing data percentages for PA ranged from 0% to 68.5% (average=19.5% per person). For the entire dataset, the missing rate was 18.4% (10,265/55,716), with continuous missing days ranging from 1 to 100 (mean 2.04, SD 3.56 days). The median of the continuous missing days was 6, and the 90th percentile was 30, indicating that most of the gaps were short, with only 10% exceeding a month. Notably large gaps (eg, 100), upon reviewing research notes, were confirmed to be due to technical issues, with participants resuming after the issues were resolved.

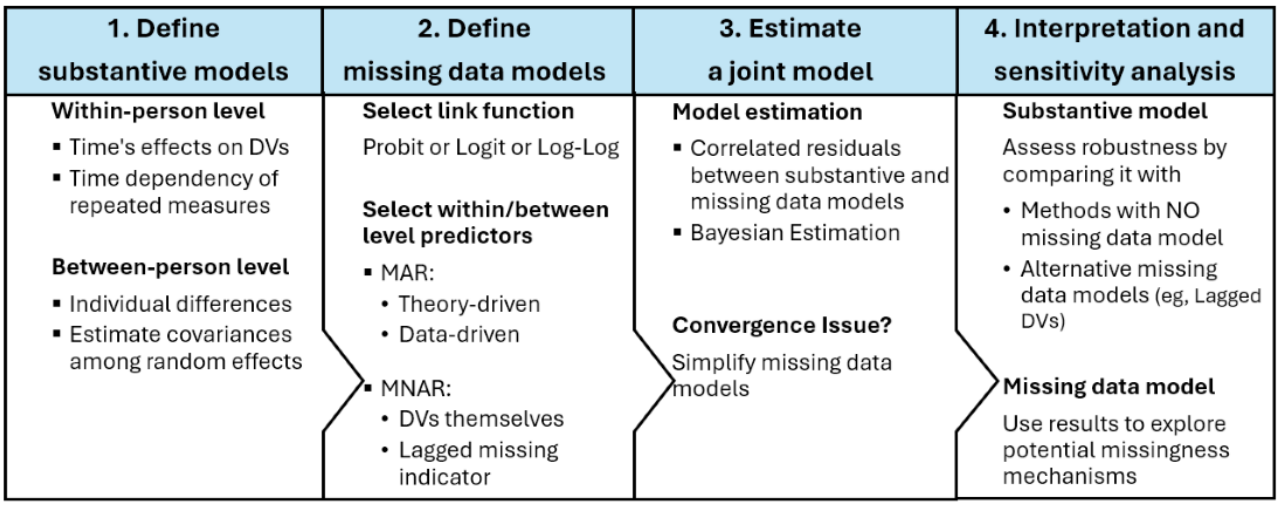
Ethical Considerations

This study analyzed fully anonymized secondary data obtained from a previous study [28] conducted at the University of Southern California (HS-18-00605). The original study was approved by the University of Southern California Institutional Review Board and conducted in accordance with the ethical standards laid down in the 1964 Declaration of Helsinki and its later amendments. All participants provided informed consent to have their deidentified data published in journals. As this study involved only anonymized secondary data and did not include direct participant contact, additional ethical review was not required.

Statistical Analysis

Figure 3 provides an overview of our analytic framework. It outlines the key steps for specifying the substantive and missing data models, estimating them jointly, conducting sensitivity analysis, and interpreting the results. The following subsections elaborate on each step of this workflow. Code for replicating empirical analysis is available in Multimedia Appendix 1.

Figure 3. Workflow of multilevel joint modeling for handling missing not at random intermittent missingness. DVs: dependent variables; MAR: missing at random; MNAR: missing not at random.



XSL•FO
RenderX

Substantive Model: Multilevel VAR (1) Model

Joint modeling involves 2 components: substantive and missing data models. The substantive model, driven by research questions, is a statistical model that tests research hypotheses. In our case, the research question focused on the reciprocal relationship between daily PA and EN over time. Specifically, we aimed to understand how the PA and EN from the previous day influenced those on the following day. This exploration of lead-lag relations can provide insights into how changes in one process may influence the other, potentially informing interventions to improve physical and mental well-being. For this, we used a VAR model as our substantive model. The VAR (1) model for EN ($EN_{i,t}$) and PA ($PA_{i,t}$) is described by the following equations. The subscripts i and t denote the values for ith individual at time t.

In these equations, $\mu_{1,i}$ and $\mu_{2,i}$ are individual baseline levels of EN and PA, when all predictors are at their average values. Individual variations in baseline were allowed and predicted by person-specific variables (sex, age, employment status, depression, and alcohol consumption habits), with EN baseline additionally predicted by person-average sleep duration, and PA baseline by person-average device wear time.

The coefficients $a_{1,i}$ and $a_{2,i}$ represent the AR effects for person i, namely, the extent of yesterday's energy (PA) on today's energy (PA), respectively. The coefficients, $b_{1,i}$ and $b_{2,i}$, termed cross-regressive (CR) coefficients, represent yesterday's PA → today's energy and yesterday's energy → today's PA effects for person i. Thus, temporal dependencies within individuals were explicitly accounted for through individual differences in AR and CR effects, which include the sample's average AR and CR coefficients (termed "fixed effects"), and stochastic parts that capture each person's deviations from the sample averages (termed "random effects"). All the random effects were allowed to covary with each other.

Daily sleep duration, a seasonal indicator, and device wear time were included as time-varying predictors. The terms $e_{1,i,t}$ and $e_{2,i,t}$ represent dynamic noises, or residuals in the 2 processes that were not accounted for by other variables, but whose effects carried on to future time points through the AR and CR terms. These dynamic noises were allowed to covary with each other.

Given the importance of modeling time effects in ILD analyses, we examined potential temporal trends in PA. We found no significant linear trend in PA over the year. However, to account for seasonal variations in PA, we included a season variable in the model [32]. Exploratory analysis showed that PA levels were higher in summer and lower in winter, with no significant difference between spring and fall. Thus, winter was coded as −1, spring or fall as 0, and summer as 1. It is worth noting that the specification of the substantive model and the omission or misestimation of covariances between random effects can impact parameter estimates, particularly in the presence of substantial missing data [33].

Missing Data Model: Multilevel Probit Model

Choice of Models for Binary Outcomes

We constructed a missing data model for each of 2 DVs (EN and PA). Each was constructed as a multilevel univariate probit regression model [27], with the binary missing indicators of whether a data point is missing (0=observed and 1=missing) on a particular day t for person i and construct d serving as the ordinal DV. Underlying the ordered binary responses for each construct were a normally distributed, time- and person-varying latent variable that represented each individual's underlying and continuous tendency missingness on a given day, with missingness occurring if this tendency exceeds an estimated threshold parameter.

While logit and log-log links are viable alternatives for modeling binary outcomes, we selected the probit model for both theoretical and practical reasons. First, although logit and probit models often yield similar results [34], theoretical considerations favor the probit model. Theoretically, the probit model aligns well with ILD missing data contexts, where a latent tendency for missingness at person level (habitual missing) and day level (short-term tendency) is plausible. Second, prior research suggests that in complex settings—such as multivariate binary response models with random effects—probit often provides better fit than logit [35]. Third, the log-log link is tailored to rare - event or survival - type dropout contexts, whereas our focus is on intermittent nonresponse. Finally, software constraints—such as Mplus's support for multilevel Bayesian probit but not logit—made probit the most feasible option in practice.

Across-Time and Person Heterogeneity in Missingness

Since missing data indicators were themselves longitudinal and nested within each person, the proposed multilevel probit regression model extended standard probit regression by decomposing the missingness mechanisms into day- and person-level missingness. The within-person part modeled day-to-day variations in missing tendency related to time-varying covariates, such as energy and PA levels themselves, and phone usage. The between-person part captures individual differences in overall missingness tendencies, linked to person-specific predictors (eg, person mean of phone usage) and demographic factors. Table 2 summarizes representative hypotheses about within- and between-person missingness mechanisms and shows how each is reflected in the multilevel missing data model.

XSL•FO
RenderX

Table 2. Plausible missingness-related hypotheses.

Levels and hypotheses	Reflecting missing data models	Mechanisms
Within-person		
On days when they feel less energetic than usual, they tend to miss more EMA[a] prompts.	EN missing$_{i,t} = \beta_1 \times EN^{b}_{i,t}$	• MNAR[c]
On days when they engage in more physical activity than usual, they tend to miss more EMA prompts.	EN missing$_{i,t} = \beta_2 \times PA^{d}_{i,t}$	• MAR[e], if PA missingness is not related to energy level. • MNAR, if PA missingness is related to energy level itself (eg, on low-energy days, people are less likely to wear smartwatches).
On days when they use smartphones more than usual, they tend to miss fewer EMA prompts.	EN missing$^{f}_{i,t} = \beta_3 \times Phone^{g}_{i,t}$	• MAR
Between-person		
People who have lower energy than others tends to miss more EMA prompts.	EN missing$^{h}_{i} = \beta_5 \times EN_i$	• MNAR
People who are generally more physically active than others tend to miss more EMA prompts.	EN missing$_i = \beta_4 \times PA_i$	• MAR, if overall PA missingness is not related to overall energy level. • MNAR, if overall PA missingness is related to overall EN level (eg, those with generally lower energy are less likely to wear smartwatches).
People who generally use phones more than others tend to miss fewer EMA prompts.	EN missing$_i = \beta_6 \times Phone_i$	• MAR

[a]EMA: ecological momentary assessment.

[b]$EN_{i,t}$: energetic feelings. Subscripts *i* and *t* denote the values for i_{th} individual at time *t*.

[c]MNAR: missing not at random.

[d]$PA_{i,t}$: physical activity. Subscripts *i* and *t* denote the values for i_{th} individual at time *t*.

[e]MAR: missing at random.

[f]$Missing_{i,t}$: missing indicator at time *t* for person *i* (1=unobserved and 0=observed).

[g]$Phone_{i,t}$: the number of times the phone screen was unlocked. Subscripts *i* and *t* denote the values for i_{th} individual at time *t*.

[h]$Missing_i$: between-person level missingness for person *i*.

Selection of Predictors for Missing Data Models

Building missing data models requires identifying appropriate predictors of missingness, a process closely tied to hypothesis generation, as illustrated in Table 2. Theory-driven approaches use prior research to inform potential predictors of missingness or compliance. For example, age was related to lower compliance rates [24]. Daily emotional, physical, and cognitive energy may influence engagement in mHealth studies [7]. In our context, daily EN, PA, and sleep duration, which are proxies of daily energy levels, can be considered potential predictors of missingness. Also, smartphone usage had a significant impact on EMA response rates [8].

When theoretical guidance is limited, statistical exploration helps identify potential predictors of missingness, particularly under MAR assumptions. To inform the multilevel probit model, we conducted correlational analyses between missingness indicators and person-mean centered (within-person) and person-mean (between-person) variables. Predictors significantly associated with missingness at each level were selected for inclusion. The full list of predictors and their correlation results is reported in the “Results” section.

Burst Missingness

To capture burst patterns in missingness observed in the data, we included lagged (yesterday’s) latent missingness tendencies of yesterday’s missingness for EN and PA on today’s missingness for EN and PA in the missing data model. By incorporating temporal dependencies (ie, AR effects) of yesterday’s missingness for DVs on today’s missingness for DVs, the model allowed a participant’s missingness tendency on 1 day to influence missingness on the following day.

Estimation of the Joint Model

After constructing the substantive and missing data models, we jointly estimated them by linking them through joint likelihood and correlated residuals between the substantive and missing data models. For estimation, we used Bayesian methods due to its pragmatic advantages in handling complex models with multilevel structures [36-38]. Following practices for Bayesian reporting [39], we presented the median of each posterior distribution as the point estimate, alongside standard deviations and 95% credible intervals (CrIs). Parameters were considered significant if their CrI did not include zero.

Model estimation was conducted on a PC (Intel i7 CPU, 32GB RAM) and took 2 hours to converge. If there are too many

XSL•FO
RenderX

predictors in the missing data model, the run time may increase and convergence issues may arise. In such cases, simplifying the model by reducing the number of predictors or restricting the random effects may help. In our experience, fitting the missing data model alone without the substantive model often led to convergence issues. This highlighted 1 practical advantage of using the joint modeling approach to allow inclusion of values of substantive processes in the missing data and vice versa to facilitate the estimation process. Details of the default Bayesian estimation settings in Mplus and the convergence criteria are outlined in Multimedia Appendix 1.

Sensitivity Analysis

To assess sensitivity to different missing data methods, we compared our joint modeling result with other commonly used techniques in behavioral science, including listwise deletion, LOCF, mean imputation, and Bayesian FIML. Listwise deletion (complete case analysis) removes any time points with missing values, resulting in the greatest extent of data loss among the methods considered. LOCF fills in missing values by carrying forward the last observed value, assuming no change since the last entry. Mean imputation replaces missing values with the variable's overall mean, disregarding individual and temporal variation. FIML is a more sophisticated technique that leverages all available data, including both fully and partially observed patterns (where some variables are measured at a specific time point while others are missing). It is considered more robust than traditional methods, such as mean imputation, and effective under the MAR assumption [17]. Bayesian FIML is an approach that uses Bayesian inference to handle missing data similarly to FIML, leveraging the computational advantages of Bayesian estimation [40,41].

Additionally, given recent advancements in deep learning for time series imputation—particularly methods that explicitly model temporal dependencies—we conducted a sensitivity analysis using 2 methods that have shown promising results: SAITS (Self-Attention-based Imputation for Time Series [42]) and BRITS (Bidirectional Recurrent Imputation for Time Series [43]). SAITS is a transformer-based model that leverages self-attention mechanisms, while BRITS is based on bidirectional recurrent neural networks. We applied SAITS-base [42] and BRITS to impute missing values in our data before estimating the substantive model. Imputation was implemented using PyPOTS [44].

Notably, the methods discussed do not incorporate explicit missing data models that we can interpret. To further assess the sensitivity of our joint modeling approach, we examined the robustness of key conclusions under an alternative missing data model specification by extending the proposed missing data model to include additional lagged variables of the DVs as predictors.

Among the approaches mentioned, listwise deletion, LOCF, mean imputation, SAITS, and BRITS are 2-stage processes, where missing data are imputed first, followed by fitting the substantive model using the complete dataset. In contrast, Bayesian FIML and joint modeling are a 1-stage process that handles missing data while fitting the substantive model, without explicit data imputation process.

Results

In this section, we first present the results from our proposed joint modeling approach, which addresses the possibility of data being MNAR, through both the substantive model and the missing data model. We then report the results of sensitivity analyses, comparing our approach with alternative missing data handling techniques and evaluating the robustness of our findings under different specifications of the missing data model within the joint modeling framework.

Correlation Analysis for Specifying the Missing Data Model

To inform the multilevel probit model, we conducted correlational analyses between missingness indicators and both person-mean centered (within-person) and person-mean (between-person) variables. At the within-person level, daily phone usage (r=–0.065; P<.001) and sleep durations (r=0.021; P<.001) were correlated with EN missingness. Similarly, daily phone usage (r=–0.022; P<.001) and sleep durations (r=0.031; P<.001) were correlated with PA missingness. At the between-person level, average phone usage was negatively correlated with both EN (r=–0.255; P<.001) and PA (r=–0.14; P=.039). Average sleep duration was related to EN missingness (r=–0.136; P=.045). It should be noted that these correlational results are based on observed data only and may differ from results obtained under joint modeling; their purpose was to inform predictor selection rather than to test missingness mechanisms.

Based on the theoretical considerations and these correlational findings the final missing data models included the following predictors: at the within-person level, daily EN, PA, sleep, and phone usage, and at the between-person level, the person means of EN, PA, sleep, and phone usage, along with participants' sex, age, employment status, self-reported depression, and alcohol consumption habit.

Substantive Model Results

To examine the daily reciprocal relationship between PA and EN, the multilevel VAR (1) model was fitted jointly with the multilevel probit regression model to represent the missingness of 2 DVs. Results showed that higher than usual levels of PA or EN on 1 day were significantly associated with higher levels of the same variable on the following day, as indicated by positive AR coefficients (EN 0.226, 95% CrI 0.196-0.254; PA 0.081, 95% CrI 0.066-0.097). This suggests that both PA and EN exhibited a certain level of continuity over time. Regarding reciprocal influence—the focus of this analysis—CR coefficients indicated that higher energy levels on 1 day predicted higher PA levels the next day (b=0.03; 95% CrI 0.012-0.049), and vice versa: higher PA levels also predicted higher energy levels on the following day (b=0.03; 95% CrI 0.006-0.054).

Covariate effects were as follows. PA levels tended to increase during warmer seasons (b=0.031; 95% CrI 0.025-0.038). Individuals with self-reported depression exhibited generally lower EN levels (b=–0.411; 95% CrI–0.735 to –0.078). Individuals who were employed (b=0.380; 95% CrI 0.178-0.582) and those who reported higher frequencies of alcohol

XSL•FO
RenderX

consumption (*b*=0.069; 95% CrI 0.009-0.128) showed higher overall PA levels. Additionally, sex differences were observed in PA baseline, with females exhibiting higher baseline PA than males (*b*=0.219; 95% CrI 0.017-0.420).

Missing Data Model Results

In this section, we present results from missing data models to explore plausible hypotheses about missingness mechanisms. Full probit model results are shown in Table S1 in Multimedia Appendix 2. It is worth noting that the estimated missingness mechanisms here are not definitive; rather, they provide preliminary insights that warrant further discussion with experts in the field.

Missing Not at Random

The results indicated that the PA level was significantly associated with missingness in both within- and between-person levels of EN and PA. Lower than usual PA levels or overall lower PA levels compared with others were linked to more missingness in both EN and PA. Since PA was passively recorded via smartwatch, the observed negative association between same day PA and missingness likely reflects that more active days coincide with consistent device wear.

Unlike PA, EMA self-reported EN levels were not associated with EN missingness at either the within- or between-person level, indicating that individuals with lower energy—whether generally or on a given day—were not more likely to miss reporting. Interestingly, at the within-person level, missingness in smartwatch-tracked PA was higher on days they reported higher than usual EN. While unexpected, this result might reflect nuanced interactions between study and other unmeasured factors that were not accounted for by the model. Follow-up sensitivity analysis (see the "Sensitivity Analysis" section) showed that this result, while unexpected, was robust to changes in variations in the missing data models.

Missing at Random

As expected, the amount of phone usage was negatively associated with missingness in EMA-measured EN at both the within-person and between-person levels. More frequent phone usage than usual or compared with others was associated with less missingness in EN. However, phone usage was not related to the missingness of smartwatch-tracked PA. Self-reported sleep duration was not significantly related to missingness of either PA or EN.

We investigated the relationship between demographic variables (sex, age, employment status, self-reported depression, and alcohol consumption) and missingness in the data. First, we found that none of the demographic variables were significantly associated with missingness in EMA-measured EN. Notably, self-reported depression and age did not affect missingness. This may be because the participants were a nonclinical sample and they were all from generations familiar with smart devices, which could have minimized the impact of these variables on missingness. Conversely, people who were employed for wages showed higher missingness in smartwatch-tracked PA, suggesting that occupational demands may interfere with consistent device wear. We address the importance of considering job-related factors in influencing uHealth missing data in the "Discussion" section.

Burst Missingness

To account for burst missingness, we included the previous time point's missing indicators as predictors. A positive AR coefficient indicates temporally clustered missingness. In the EN missing data model, the AR coefficient was positive and significant (*b*=0.332; 95% CrI 0.312-0.352), suggesting that if a participant missed responding to EMA once, they were more likely to miss responding the next day as well. However, the AR coefficient in the PA missingness model was not positive (*b*=–0.011; 95% CrI –0.019 to –0.003), which will be further discussed in the "Sensitivity Analysis" section. The different AR patterns between EMA-measured EN and smartwatch-tracked PA imply that missing data patterns may differ between active self-report EMA measures and passively recorded smartwatch-tracked measures.

Sensitivity Analysis

We compared our findings from the proposed joint model (joint model 1) with other missing data handling techniques that do not explicitly incorporate missing data models: (1) listwise deletion, (2) LOCF, (3) mean imputation, (4) Bayesian FIML, (5) SAITS base, and (6) BRITS. Furthermore, to examine the sensitivity of our conclusions to the specification of the missing data model itself, we tested an alternative joint model (7), joint model 2, that extended joint model 1 by including an additional predictor—a lagged DV—into the missingness models.

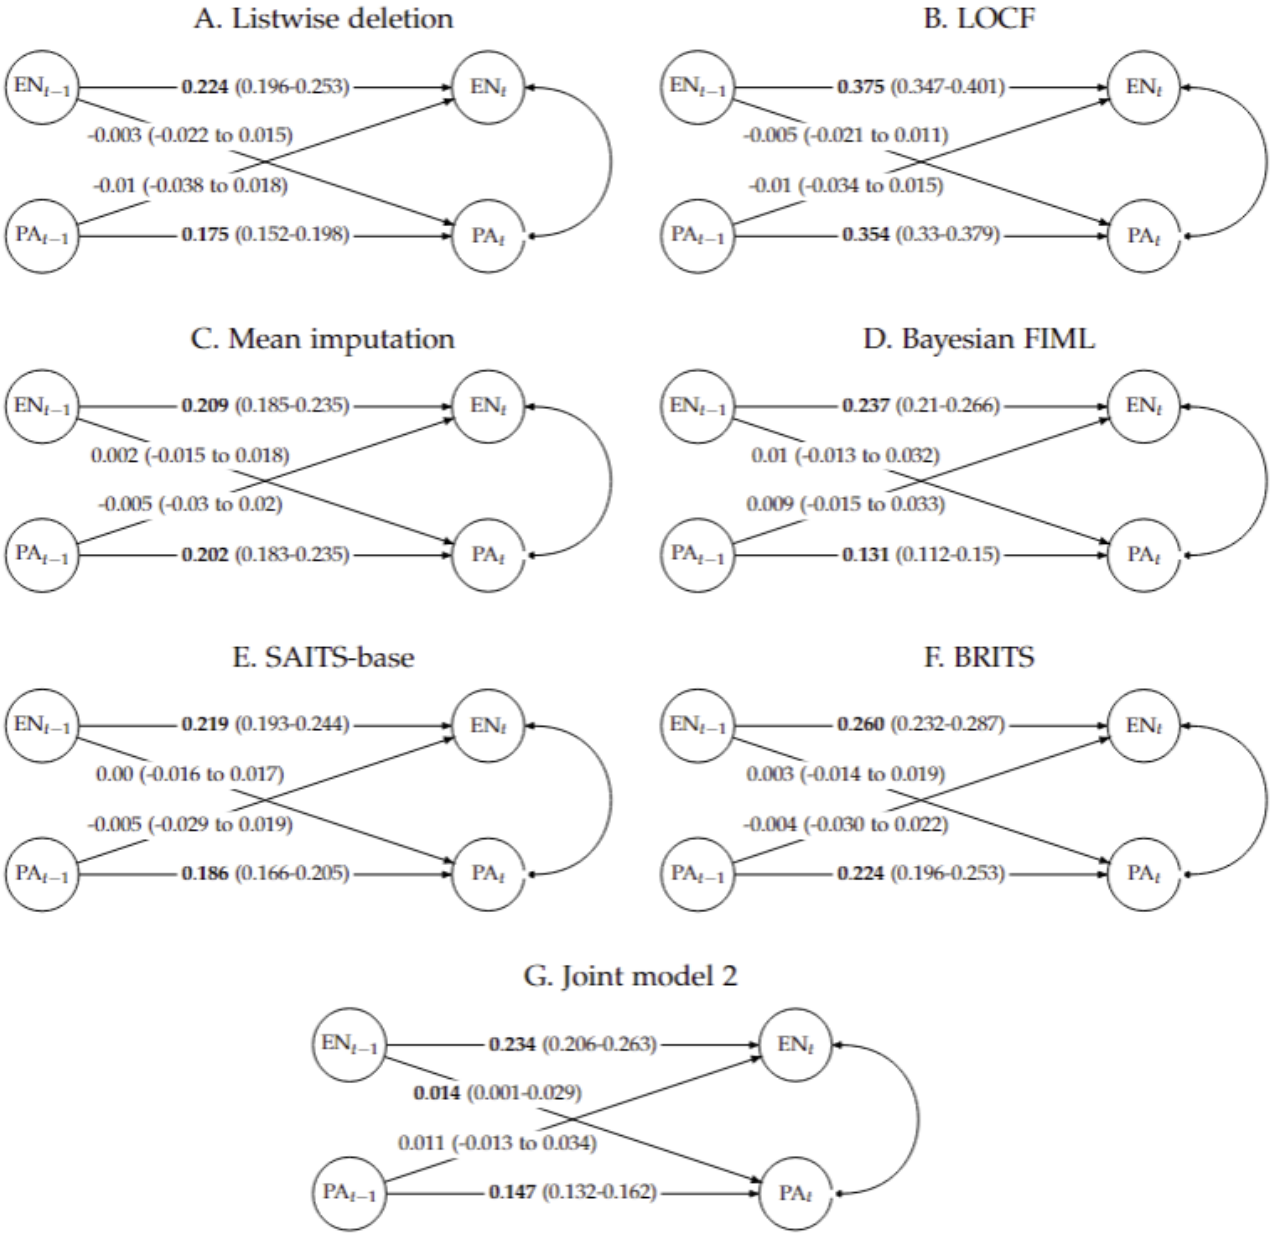
Substantive Model

AR Effect

Comparison of AR and CR effects—the key substantive model results—is summarized in Figure 4. For both PA and EN, significant positive AR coefficients were observed across all methods. The magnitudes were generally similar for EN across methods, except for LOCF, which overestimated AR parameters due to its characteristic of repeating the same value. Conversely, the AR estimates for PA were notably influenced by missing data handling methods. This appears to stem from the high incidence of MNAR missingness in PA, as discussed in the previous "Missing Data Model Result" section. As expected, AR coefficients were more similar between the Bayesian FIML and joint models than with other 2-step approaches.

XSL•FO
RenderX

Figure 4. Sensitivity analysis of autoregressive (AR) and cross-regressive (CR) parameters across missing data handling methods. Each node represents EN or PA at time t or t−1. Arrows show AR and CR paths with point estimates and 95% credible intervals (within parentheses). Labels in boldface indicate significance (95% credible interval excludes 0). (A) Listwise deletion, (B) LOCF, (C) mean imputation, (D) Bayesian FIML, (E) SAITS-base, (F) BRITS, and (G) joint model 2. BRITS: Bidirectional Recurrent Imputation for Time Series; EN: energetic feeling; FIML: full information maximum likelihood; LOCF: last observation carried forward; PA: physical activity; SAITS: Self-Attention-based Imputation for Time Series.



CR Effect

In contrast to AR effects, CR coefficients—representing the dynamic interplay between energy levels and PA—were much closer to 0, thus yielding inferential conclusions that were sensitive to changes in missing data handling methods (Figure 4). Across approaches without an explicit missing data model, in models (A) to (F), CR estimates were not statistically significant. However, when joint modeling was applied (joint models 1 and 2), a significant CR effect emerged. Similar to joint model 1, joint model 2 also showed that higher energy levels on one day predicted higher PA levels on the next, demonstrating the robustness of this finding. However, the reverse CR effect (from PA to energy) was not significant in joint model 2, unlike in joint model 1.

These findings illustrate how joint modeling can uncover dynamic associations that might be obscured when missing data are not explicitly modeled. They also show how the estimation of CR effects can be influenced by the specific construction of the missing data model, highlighting the importance of sensitivity analysis across missing data model specifications.

Person-Level Covariate Effect

We investigated whether the baseline levels of DVs are associated with person-specific characteristics such as sex, age, employment status, depression, and alcohol consumption habit. Overall, the estimates were consistent across different methods. One exception was the effect of sex on PA baseline: although estimated sex differences from other missing data handling methods were in the same direction (ie, positive), it was

XSL•FO
RenderX

significant only in 2 joint models and SAITS, where females exhibited a higher baseline PA (joint model 1: *b*=0.219, 95% CrI 0.017-0.42; joint model 2: *b*=0.226, 95% CrI 0.025-0.43; and SAITS: *b*=0.0.190, 95% CrI 0.017-0.353). This aligns with our simulation results, which are elaborated later, and indicates that while the estimates of person-level covariate effects on baseline levels are generally less sensitive than CR effects, some parameters can still be influenced by missing data handling methods.

Missing Data Model

The probit model results for joint model 2 are shown in Table S2 in Multimedia Appendix 2. Compared with joint model 1, here we address some robust findings and note key differences from joint model 2. Under joint model 2, the previous day's EMA-measured EN level was not significantly associated with EN missingness, and the overall estimation on EN missingness mechanisms remained unchanged. In contrast, the previous day's smartwatch-tracked PA level was positively associated with PA missingness (95% CrI 0.214-0.249), resulting in some shifts in parameter estimates— already noted in the "Substantive Model" subsection of "Sensitivity Analysis."

Missing Not at Random

Consistent with joint model 1, joint model 2 showed that lower smartwatch-tracked PA levels were associated with higher missingness in both EMA self-reported EN and device-tracked PA measures at the within- and between-person levels, supporting the robustness of this pattern. Additionally, both models revealed an unexpected within-person effect: on days when individuals reported higher than usual EN, there was more missingness in PA measures. While unexpected, this result remained robust across different model specifications. To investigate further, we fitted another joint model with a weekend indicator to predict outcome missingness. This revealed higher PA missingness on weekends (*b*=0.093, 95% CrI 0.068-0.119), but the other main results remained unchanged.

Missing at Random

A higher frequency of alcohol consumption was associated with more missingness in smartwatch-tracked PA in joint model 1, but not in joint model 2. While individuals who consume alcohol more frequently may experience forgetfulness or have lifestyle choices prioritizing social activities over research participation [45], this association appeared sensitive to the missing data model specification. Another less robust finding was a sex difference in smartwatch-tracked PA missingness: females showed higher missingness in joint model 2 but not in joint model 1. This suggests that certain between-person effects—alcohol consumption and sex—may be more model-dependent and should be interpreted with extra caution.

Burst Missingness

In EN missingness model, similar positive AR coefficients (0.332 in joint model 1 and 0.331 in joint model 2) suggest a robust pattern of burst EN missingness: participants who missed an EMA-measured EN response were more likely to miss the following day as well. However, the AR coefficient in the PA missingness in joint model 2 (*b*=0.031, 95% CrI 0.023-0.039) differed from joint model 1. This difference suggests that burst missingness in PA is partially driven by the PA levels themselves (ie, MNAR), as well as by other unexplained autocorrelated processes. In joint model 2, we included lagged PA as a predictor, allowing the model to attribute part of the burst missingness to the autocorrelated nature of PA. As a result, the AR term—which previously captured both structured (ie, MNAR-related) and unstructured burst missingness—changed, now reflecting primarily the unstructured component of burst missingness that is unrelated to PA levels.

Simulation Study Results

Simulated Substantive Model Results

To evaluate the consequences of omitting components or the entire missing data model, we conducted a simulation study designed to closely mirror the structure and characteristics of our empirical data (see Multimedia Appendix 3 for full simulation design). By anchoring the data generation on true parameter values, simulation lets us quantify bias when omitting specific components of the missing data model or entire missing data models.

Briefly, we generated complete longitudinal datasets for 200 participants over 300 days using a 2-outcome multilevel VAR (1) model, with known AR, CR, and covariate effects. Parameter values were set to approximate those estimated in the empirical analysis. We then introduced 30% missingness on both outcomes and a time-varying covariate under missing completely at random (MCAR), MAR, and MNAR mechanisms—incorporating within- and between-person predictors, individually different overall compliance rates, and burst missingness. Finally, we compared 5 analysis strategies (complete data, Bayes-FIML, and 3 joint model variants) across 100 replications. Results are summarized graphically in Figure S1 in Multimedia Appendix 3.

When There Were No Missing Data

Fitting the substantive model to fully observed data ("full data" condition in Figure S1 in Multimedia Appendix 3) provides a benchmark for other models. Under this ideal condition, estimations were unbiased: all closely approximate the true values. Only the covariate effects on AR were slightly underestimated, within an acceptable range.

Complete Omission of Missing Data Model

What happens if missing data models are not included at all? When missing data were handled solely through Bayesian FIML, estimates were severely biased across all parameters compared with models with explicit missing data models (see Bayes FIML condition in Figure S1 in Multimedia Appendix 3). These findings underscore the importance of incorporating dedicated missing data models, especially with MNAR.

Joint Modeling: When the Missing Data Model Was Included

When results were obtained using our proposed joint model (joint model 1; Joint DV condition in Figure S1 in Multimedia Appendix 3), which included missingness models for 2 DVs, estimation results from the joint model were almost comparable to fitting models to fully observed data despite the use of MNAR

XSL•FO
RenderX

data. Notably, despite being small (0.05), the CR coefficients were accurately estimated.

Adding a Missing Data Model for Time-Varying Covariates

In many cases, time-varying covariates also have missingness. Should we incorporate missingness models for them, too? The short answer is: when time-varying covariates have MNAR missingness, proper missing data models can improve estimation. However, compared with joint models that accounted for missingness only in DVs, adding missing data models for covariates did not always lead to substantial changes in statistical inference. Therefore, a pragmatic approach may be to include missing data models for the DVs under thorough explorations and as guided by theories but incorporate simpler missing data handling methods on the time-varying covariates (eg, partial FIML proposed by Ji et al [26]).

When Clustered Missingness Was Not Accounted for

What happens when missingness is temporally clustered but AR terms to capture the burst missingness are not included in the missing data model? Our simulation shows that while omitting AR terms is not as detrimental as excluding the missing data model entirely, it can still lead to subtle but meaningful bias in certain parts of the substantive model. For detailed results and more discussion, see Multimedia Appendix 3.

Simulated Missing Data Model Results

The missing data model estimates under the "Joint DV" condition are shown in Table S1 in Multimedia Appendix 3. Overall, the results suggested that all parameters from the multilevel probit model were well recovered under the joint modeling framework. At the within-person level, all coefficients were estimated accurately, regardless of whether the missing mechanism was MAR or MNAR, with the absolute relative bias ranging from 0.0 to 0.08—well below the commonly accepted threshold of 0.1. This demonstrated the probit model's adeptness in identifying both MAR and MNAR. Also, the AR coefficients were accurately estimated, indicating that the model can capture clustered missing patterns if they existed. At the between-person level, however, the coefficients were generally overestimated, with relative biases falling within a range typically considered unacceptable (0.1). Despite these biases, the coefficients still correctly captured the directions and approximate magnitudes of the true values. Thus, while person-level coefficients may lack some accuracy, they remain practically meaningful in terms of direction and magnitude.

Therefore, when used in conjunction with an appropriate substantive model, the proposed missing data model can offer useful insights into missing data mechanisms, even for MNAR scenarios. While testing for MNAR is widely recognized as challenging, using joint models may help in gaining a better understanding of these mechanisms. However, when applied to empirical data, caution is always necessary, as the true model for both the substantive and missing processes is unknown.

Discussion

Principal Results

We illustrated the process of fitting a multilevel VAR model to ILD, addressing potential MNAR missingness using a multilevel joint modeling framework. Our approach extends prior selection models to specifically handle intermittent missingness in ILD by incorporating within- and between-person decomposition and by capturing the temporal dependencies in the missing data model. We further conducted a sensitivity analysis comparing this approach with commonly used missing data methods, a deep leaning–based imputation technique, and alternative specifications of the missing data model—thus evaluating the robustness of findings on both substantive behavioral processes and underlying missing mechanisms.

We proposed examining the plausible missingness mechanisms through the missing data model. These insights are valuable for future mHealth and uHealth designs, as identifying patterns in missingness under certain conditions can help reduce such occurrences or address technological challenges that may disproportionately affect specific subgroups. Specifically, our analysis consistently revealed, across different missing data model specifications, that missingness in smartwatch-tracked PA and EMA-measured EN is not random but rather MNAR. That is, lower than usual PA levels, or overall lower PA levels, were associated with increased missingness in both PA and EN. This suggests that people are more likely to have missing data when they are less active, possibly because they are less mindful of wearing tracking devices during low activity. This also aligns with prior discussions in the study by Nahum-Shani et al [7], which suggest that insufficient physical energy levels may contribute to higher noncompliance rates in responding to EMA prompts or wearing wearable devices. Interestingly, yesterday's high PA was linked to more missingness in PA today. This could be due to factors such as smartwatch battery issues—where a day of high PA leads to excessive battery consumption, leaving the smartwatch uncharged the next day and resulting in missing data. Alternatively, it could be a pattern where 1 day of high PA leads to a PA drop the following day, which in turn increases the likelihood of not wearing the smartwatch. While the PA process exhibited an AR pattern in the overall sample, excessive PA on one day can reduce the next day's PA [46]. Confirming these potential reasons would require follow-up interviews or further investigation.

Additionally, employed individuals showed higher PA missing rates, suggesting that employment status may influence mHealth and uHealth data compliance. Job-related factors, such as demanding schedules, limited time to resolve technical issues, and stress, could affect missingness. For example, based on our research note, issues such as device malfunctions or charger problems often require contact with research staff for resolution. However, individuals with regular jobs may have fewer flexible schedules, making it difficult to address these issues. Additionally, Martinez et al [12] found that individuals in supervisory roles, who experience higher busyness, exhibited lower compliance. Researchers may need to consider these factors when designing uHealth studies.

XSL•FO
RenderX

Beyond identifying missingness mechanisms, we also examined how accounting for these mechanisms through joint modeling influenced the estimation of substantive behavioral inferences. Our substantive model included 2 key components: AR effects, capturing temporal stability, and CR effects, capturing the reciprocal influences between PA and EN. While AR effects remained consistent across different missing data handling methods, CR effects were significant only when using the joint modeling approach. The CR effects, although relatively small, reflected the reciprocal dynamics between variables and were of central interest in studies of health behaviors. Thus, this finding highlights the value of joint modeling and the importance of sensitivity analysis in assessing the robustness of parameter estimates in the presence of MNAR. Importantly, follow-up sensitivity analysis using alternative missing data model specification suggested that only the CR from EN to PA was robust to variations in the missing data model. The opposite CR effect (from PA to EN) was not. This underscored the need for sensitivity analyses with alternative missing data model specifications, even when using advanced missing data techniques such as joint modeling.

Nonetheless, our simulation study suggested that the joint modeling approach provided more reliable estimates than other methods under MNAR conditions. The proposed joint model yielded results comparable with those from fully observed data despite MNAR data. In contrast, simply fitting the substantive model alone, without explicitly modeling missingness, led to overall biased estimates. CR effects were particularly vulnerable due to their typically smaller magnitude than AR effects, resulting in low power (around 30%) when MNAR was not dealt with in the model. This aligned with our empirical results, where the CR effects were significant only in the joint models.

While joint modeling offers a principled approach grounded in theory, there has been a growing interest in mHealth and uHealth studies to use machine learning (eg, deep learning–based time series imputations) to handle missing data. Most of these approaches, including the approaches considered in our sensitivity analysis, typically handle the missingness and substantive model fitting as a 2-step process (imputation followed by model fitting), thus missing the opportunity to leverage the interdependence between the substantive and missing data models. Also, deep learning models often lack interpretability of conventional statistical models, making it difficult to explore missing mechanisms. They also require large sample sizes and extensive hyperparameter tuning, which can be a barrier in some studies. This may explain why SAITS and BRITS, in our sensitivity analysis, performed similarly to methods without explicit missing data models. While these models hold potential, their current performance may be limited by their assumptions about MCAR [42], the need for further hyperparameter tuning and larger samples, which may require additional refitment for behavioral data contexts. Nevertheless, the proposed joint framework can, in principle, be extended to deep learning architectures—allowing for simultaneous modeling for the substantive and missingness processes and thus “sharing” of information from these different data streams to strengthen the overall prediction as well as classification results.

Limitations

In this study, we leveraged model-implied values for the substantive processes afforded by the multilevel VAR model to shed light on the missing data processes. In practice, there is no guarantee that the multilevel VAR model reflects the true change mechanisms of the substantive processes. Thus, results from modeling, including those from the missing data model, should always be interpreted with some caution. Nevertheless, our view is that the multilevel VAR model, as one of the most commonly adopted models for describing ILD processes [47], serves as a useful proxy for describing the unfolding of PA and affective processes in the study participants.

Our proposed missing data model was also limited in that we did not consider participant attrition. The missing data model used in our example mainly addressed intermittent missingness. To address dropout as well, a multinomial logit model [11] may be used as an extension to our proposed model to categorize participants’ missingness tendency into 3 nominal categories: observed, intermittent missing, and dropout, thereby providing a more comprehensive approach to handling missing data in longitudinal studies.

Additionally, our analysis was based on daily aggregated data and did not delve into specific reasons behind the missing accelerometer data, such as data transfer issues, battery drain, or the watch being powered off. Instead, we focused on the broader issue of missingness, emphasizing psychological, physical, and individual factors. Exploring reasons related to technical issues in depth would require analysis at a finer granularity, such as minute-by-minute or second-by-second data. However, this level of detail was beyond the scope of our study.

As a future direction aligned with a finer timescale analysis, it would also be beneficial to differentiate between partial missing data (eg, 2-3 hours of device wear time less than 10 hours) and complete missing data (0 hours of wear time) for PA, as there may be qualitative differences between these scenarios. Similarly, while this paper focuses on day level, a multilevel joint modeling approach could be more advantageous in studies where EMA items are measured multiple times a day. For example, the relationship between PA and EMA missingness might appear weak or inconsistent at the day level, but at a finer scale, individuals who engage in high levels of PA during EMA prompts may be less likely to respond to those prompts [9]. Finally, we note that the results of the missing data model may depend on the choice of PA measure. Notably, there is no universally accepted convention for measuring PA [48]. Researchers who measured PA using accelerometers have constructed PA metrics in several ways, including (1) the total volume of activity counts or acceleration signals accumulated throughout a specified time interval (eg, day) [49]—similar to total daily step count; (2) the mean activity counts or signals per hour or minute, which offer an average measure of activity intensity [50]; and (3) the duration of time spent in PA categorized by intensity thresholds, such as moderate to vigorous PA [51]. Depending on the PA measure used, the definition of missing or valid data can vary, leading to potentially divergent model estimation results [52].

XSL•FO
RenderX

Additionally, PA data are often positively skewed, with a concentration of data at the lower end of the scale [53]. This deviation from normality may pose a potential limitation, as joint modeling approaches typically rely on the normality assumption [15]. While addressing this limitation is beyond the scope of this study, future research should consider modeling strategies that accommodate nonnormal data distribution, such as transformation or using a gamma link function [53].

Conclusions

This study enriches our understanding of missing data mechanisms and strategies for managing them in ILD. Key contributions include the following: First, incorporating missing data mechanisms into the model not only improves the properties of the estimation results but also provides a nuanced understanding of missing data mechanisms. Understanding the reasons for missing data holds significant value for several reasons. If the reasons are within the researcher's control, it can provide insights into how to collect data in future studies. Detecting contextual factors related to missingness can be used to pinpoint ways to improve participants' engagement. Additionally, understanding the mechanisms behind missing data can sometimes provide deeper insights into the variables themselves, thus hastening researchers' and practitioners' understanding of the phenomenon under study.

Second, we highlight the importance of sensitivity analysis. Evaluating the sensitivity and robustness of specific model aspects in relation to missing data provides crucial insights for informed medical decisions based on model outcomes. If the results exhibit sensitivity to methodological changes, it necessitates a thoughtful interpretation of the conclusions regarding their effects and suggests a potential need for further research.

Third, we demonstrated the effectiveness of our approach using simulated data that closely resemble actual datasets. We showed that our multilevel joint modeling is effective even with ordinal variables, such as Likert scale variables, and could reveal even strong MNAR mechanisms, as evidenced by the large coefficients observed in the empirical results. Furthermore, AR terms in the missing data model were able to capture frequently observed temporal dependency in missingness in ILD. However, it is important to note that the outcome of joint modeling may differ based on the chosen missing data model specification and still can give biased results if the specified model is not correct. Therefore, we strongly recommend performing sensitivity analysis with multiple missing data models to ensure the robustness of findings and avoid overreliance on a single model.

In summary, our findings highlight the importance of appropriately handling nonignorable missing data, particularly through multilevel joint modeling, followed by sensitivity analysis. This workflow will improve the validity of substantive conclusions and enhance our understanding of the underlying missing data mechanisms, which can inform better study designs and intervention strategies. While our analysis focused on a limited set of plausible variables, researchers would benefit from exploring a broader array of the psychological and behavioral factors that may influence compliance in mHealth studies. We hope this study serves as a framework for future investigations.

Abstract

Background: Hypertension, one of the most common cardiovascular conditions worldwide, necessitates comprehensive management due to its association with multiple health risks. Effective control often involves lifestyle changes and continuous monitoring, yet many individuals struggle to adhere to traditional management approaches. Digital health tools are emerging as promising alternatives, offering remote monitoring and real-time support. This study focuses on evaluating a digital tool specifically designed for hypertension management, analyzing its effectiveness, and gathering user perspectives on its functionality and impact.

Objective: The primary objective of this study is to assess the effectiveness of a digital health tool in managing hypertension. Additionally, the study aims to understand user experiences and satisfaction levels to gauge the tool's acceptance and potential for long-term use. By analyzing data from a large cohort, we seek to determine whether the tool can contribute to meaningful reductions in blood pressure and support sustained engagement over time.

Methods: The study includes a cohort of 5136 participants who used the digital hypertension management tool. This tool provides continuous blood pressure monitoring, real-time feedback, and personalized health recommendations, which are crucial for tailored intervention. Participants recorded their blood pressure values over time, and we tracked retention rates to measure adherence. An online survey was administered to gather user feedback, focusing on ease of use, satisfaction levels, and perceived health benefits.

Results: Our analysis indicates a significant reduction in blood pressure values among users, with a positive correlation observed between the duration of use and the extent of blood pressure reduction. We performed a 1-sided Wilcoxon Rank Sum test to compare systolic blood pressure values in the first and last biweekly use intervals, and descriptive statistics were used to assess survey responses. High retention rates were observed, with 2583 (50.3%) participants using the tool after 1 year. Survey responses revealed high satisfaction, with users highlighting the tool's ease of use and noting reduced anxiety related to blood pressure management. These results suggest that users found the digital tool both effective and convenient.

Conclusions: This study demonstrates the potential benefits of digital health tools in managing hypertension, emphasizing their ability to engage users over long periods and support blood pressure reduction. The high satisfaction rates and positive user feedback underscore the importance of user-centered design in creating effective health interventions. Overall, the findings suggest that digital tools, when designed with a focus on user experience, could be a valuable component in hypertension management strategies, complementing traditional health care approaches.

Introduction

Background

According to the American Heart Association, high blood pressure, called hypertension, is defined as systolic blood pressure (SBP) ≥130 mm Hg or diastolic blood pressure ≥80 mm Hg that remains elevated across time [1]. Hypertension affects over 1.2 billion people worldwide [2] and, in the last decades, the number of people with hypertension has doubled [3]. Hypertension is a major risk factor for cardiovascular diseases such as heart attack and heart failure, stroke, and chronic kidney disease [4]. Hence, effective management of hypertension is a key factor in reducing morbidity and mortality associated with cardiovascular complications.

Traditional approaches to hypertension management usually require regular visits to health care facilities for blood pressure monitoring and consultations. Such approaches can be burdensome for patients and place a strain on health care systems. Moreover, patients usually have difficulty with medication adherence and struggle to make lifestyle changes, with half of the patients stopping their treatment within a year [5], making this a complex and multifactorial challenge. These factors result in poor blood pressure control, leading to increased health risks, complications, mortality, and hospital admissions. To address these health issues, there is a growing interest in leveraging artificial intelligence (AI) and digital health technologies (eg, mobile apps and smartwatches) to facilitate home-based hypertension management. Such technologies offer long-term blood pressure monitoring, send reminders for the medication intake, provide educational content to support lifestyle changes, and provide personalized health advice.

Recent trials have demonstrated that digital applications can significantly lower baseline 24-hour ambulatory, home, and office SBP compared with the control group [6,7]. Since 2022, there has been an explosion of interest in large language models (LLMs) for their conversational ability and their potential as clinical AI chatbots. Current LLMs built on the transformer architecture have demonstrated comprehensive medical knowledge [8], human-level empathy [9], and comparable bedside manner [10] and medical safety to clinicians. Implementation of an LLM-enhanced digital solution may improve user interaction and efficacy.

While the clinical benefits of long-term blood pressure monitoring with digital technology are well documented [11], it is of paramount importance to also understand the effectiveness for blood pressure reduction as well as perspectives of users for such digital tools. Investigating users' perspectives for digital home–based blood pressure monitoring can contribute to the optimization and improvement of digital tools for hypertension as well as to ensure that such digital tools fulfill the needs and preferences of the users [12].

Objectives

In this work, we analyze the effectiveness for blood pressure reduction, user retention, and satisfaction with an innovative digital health tool that operates as a chatbot called Megi. Megi actively communicates with patients on a daily basis, reminds them to monitor their blood pressure, submits other relevant biometric data, takes their medications, and enhances their lifestyle. Specifically, we analyze the retention and engagement of 5136 Megi users and investigate whether they can achieve blood pressure reduction. In addition, we present the results of an online survey that quantifies users' perspectives about Megi. The insights obtained from this study can aid in the design, development, and effectiveness of digital tools for hypertension and enhance users' satisfaction.

Methods

Study Design

We conducted an observational cohort study with 5136 Megi users who used the platform between June 2022 and the end of July 2024 and fully completed the onboarding process. A user was considered fully onboarded once they accepted the consent; entered their first name, last name, and date of birth; and set the blood pressure measurement reminders. These users were not recruited through traditional methods; rather, they joined the platform organically through clinical referrals, health campaigns, or personal interest in self-managing hypertension. First, we analyzed user engagement and retention on the platform across the whole user base to assess the platform's overall success in retaining patients engaged and adherent with at-home blood pressure monitoring. We define retention rate as the percentage of users who continued to use Megi beyond specific time intervals after their initial use of the platform. In this study, we considered the intervals of 3, 6, 9, 12, and 24 months. Accordingly, users were grouped into cohorts based on the duration of their use of Megi. These durations correspond to the specified retention periods. We analyzed the retention based on two types of events: (1) blood pressure reporting and (2) any interaction with Megi.

Subsequently, we randomly selected a cohort of active users that had been using Megi for at least 3 months to evaluate their perspectives about Megi. The randomly selected users had to fill out an extensive online survey that consisted of 20 questions, which were designed to (1) evaluate the usefulness of Megi in improving self-management of hypertension, (2) assess their satisfaction, (3) describe their willingness to use Megi, and (4) assess their behavioral response to Megi.

Ethical Considerations

The survey was conducted in June 2023, and all participants gave written informed consent that they agreed to participate in the survey. Data were stored on a secure cloud platform that adheres to protected health information management standards. The study was approved by the Magdalena University Hospital Research Ethics Committee (195/Inf-701/22).

Digital Tool for the Management of Hypertension

All study participants used Megi, an AI-based digital health tool for hypertension management. Megi is a chatbot equipped with a specialized transformer-based AI model and is accessed via messaging apps such as WhatsApp and Viber. The chat is built on LLMs from the GPT family (GPT-3.5, GPT-4, and GPT-4o [OpenAI]). To date, various versions of OpenAI's models have been used. These models are accessed via the

XSL•FO
RenderX

Microsoft Azure OpenAI Service. Via this chatbot and through images, Megi gathers on a daily basis multimodal behavioral and biometric data from users that range from blood pressure and heart rate measurements to mood and stress levels. In addition, it provides personalized advice for lifestyle changes. On a daily basis, users receive reminders to measure their blood pressure and take their medications. All data are stored in secured cloud platforms, and clinicians have 24-7 access to all data via an online platform. Visual examples of the Megi platform and further information about Megi can be found on the Megi website [13].

Survey Questions

The online survey consisted of 19 questions. There were 3 questions that collected information about the users' age, sex, and employment status. In addition, there was 1 question that evaluated the impact of hypertension on the users' daily life. The survey had 3 questions that assessed the usefulness of the technology in improving self-management of hypertension (ie, "I understand why it is important to measure your blood pressure daily"; "I would often forget to measure my blood pressure if Megi didn't remind me"; and "With Megi, I will develop the habit of regular blood pressure measurement and monitoring"). Moreover, there were 3 questions that evaluated the users' satisfaction (ie, "I can see the benefits of using Megi"; "I have confidence in Megi"; and "I would continue to use Megi even if my doctor did not access my data"). The willingness to use the digital tool was evaluated by 4 questions (ie, "I would definitely recommend Megi to my friends"; "Anyone who cares about their health should use Megi"; "For the sake of myself and my loved ones, it is important for me to take care of my health"; and "My loved ones and friends would encourage me to use Megi"), while the behavioral response of the users was also assessed by 4 questions (ie, "Since using Megi, I feel safer and more relaxed"; "I feel happy when I receive messages from Megi"; "Megi makes me feel less lonely"; and "I wouldn't want to lose access to Megi"). Finally, the survey had 1 question that asked users to provide the unmet needs of the digital tool in free text. The answers were provided either in a 5-point Likert scale (1: I strongly disagree, 2: disagree, 3: neither agree nor disagree, 4: agree, and 5: strongly agree) or in free text.

Statistical Analysis

We analyzed the blood pressure values of all users in the first 2 weeks after their enrollment in the Megi platform and in the last 2 weeks before they stopped reporting their blood pressure values. For every user, we computed the average blood pressure values in the first and last biweekly segment. To quantify the statistical differences between the first and last biweekly segments, we applied a 1-sided nonparametric Wilcoxon Rank Sum test. Results were considered statistically significant if their *P* value was less than .05. In addition, we performed a descriptive analysis to assess the results of the online survey. Informative quotes were provided for the answers that were given in free text. All analysis was performed in MATLAB R2022a.

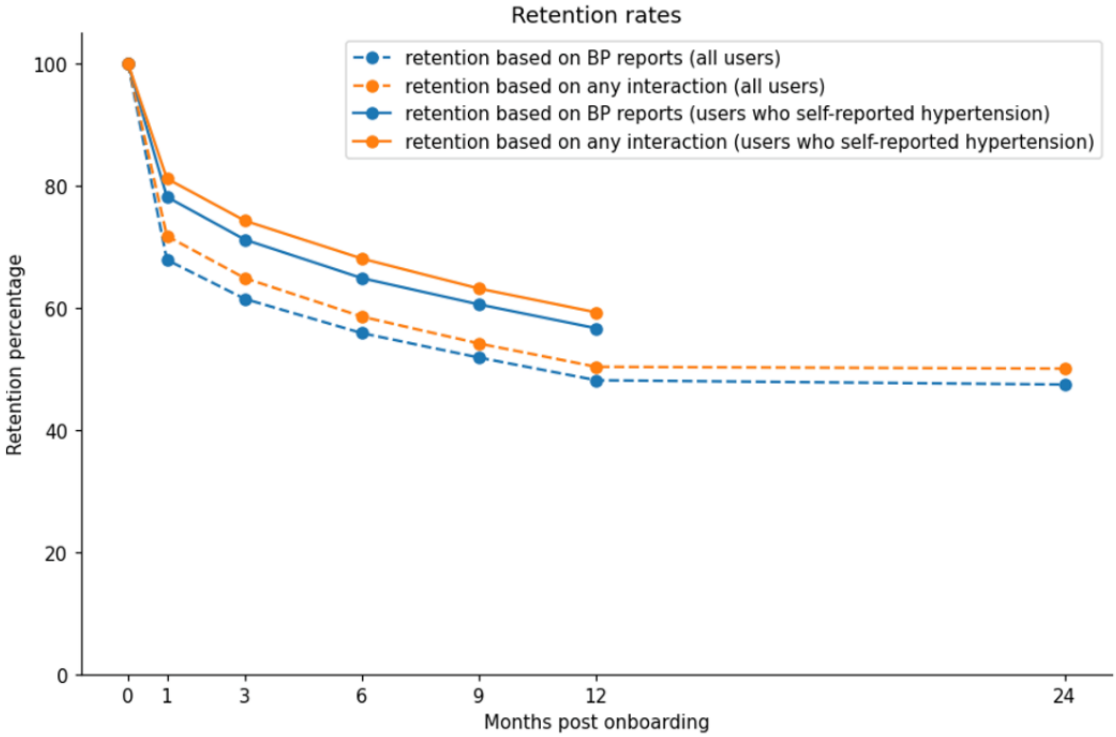
Results

User Retention

We first analyzed the retention of 5136 Megi users (n=2399, 46.71% female; n=2733, 53.21% male; n=4, 0.001% other; median age 59, range 17 - 95 y). Retention was quantified based on (1) blood pressure reporting and (2) any interaction with Megi. Figure 1 demonstrates that the retention rates after one year of using Megi were 50.3% for users based on all their interactions with Megi (eg, updating weight data, reacting to therapy reminders, and submitting feedback) and 48.1% for users based on their blood pressure measurement reports. The retention rates were even higher, that is, 60.5 and 63.1% respectively, for users who self-reported being hypertensive. Interestingly, user retention remained stable even after 2 years of using Megi.

XSL•FO
RenderX

Figure 1. User retention (N=5136) across months after onboarding based on blood pressure (BP) reporting (orange) and any interaction with Megi (blue). Dotted lines correspond to all users, while solid lines correspond to users who self-reported that they had hypertension upon their enrollment (this feature was implemented in the second year).



Blood Pressure Analysis

In total, 4736 (92.21%) of 5136 users reported their blood pressure values. We first sought to uncover whether there was a statistically significant difference in the average SBP measurements between the first and last biweekly segment. Figure 2 illustrates the distributions of the average SBP values of all users for the first biweekly segment after their enrollment and the last biweekly segment for which users reported their blood pressure values. We applied a 1-sided Wilcoxon rank sum test and found that the SBP values in the last biweekly segment were statistically significantly reduced compared to the first biweekly interval (P<.001).

Afterward, we wanted to explore whether such SBP differences were stronger for users whose average SBP values were at least 140 mmHg in the first biweekly segment (Figure 3). We saw that such differences between the first and last biweekly interval were much stronger (P=1.7×10^{-9}). We also examined the correlation between the SBP drop (ie, the difference of the average SBP during the first biweekly interval and the last biweekly interval) and the period for which users report their blood pressure values. The Spearman correlation was 0.53, and it was statistically significant (P=4.5^{-32}), which means that larger SBP reduction is positively correlated with longer use of Megi. Figure 3 illustrates the SBP drop across the months for which users reported their blood pressure values. The maximum duration in blood pressure reporting was 24 months, and we observed that there was an increasing trend of the SBP drop across time.

We performed a similar analysis for the users whose average SBP was at least 150 mm Hg in the first biweekly segment (Figure 4). For users with such high blood pressure, the differences between the first and last biweekly interval were also strong (P value=1.7×10^{-9}) and the correlation between the SBP drop and the duration for which users report their blood pressure measurements was even stronger (ρ=0.75). Figure 4 also illustrates a clear increase in the SBP drop across time.

Online Survey Analysis: Dataset Characteristics

A total of 129 people clicked on a link to access the survey (June 2023). The total number of analyzed participants is 125 (96.9%; n=3, 2.33% participants were excluded from the analysis due to the presence of missing values). Summary demographics regarding participants' age, sex, and employment status are provided in Table 1 and Figure 1. Out of the 125 participants, 55 (44%) were female, and the age of all survey participants ranged from 23 to 82 (mean 60, SD 11.6) years.

At first, study participants were asked whether high blood pressure has a significant impact on their life. The vast majority of the participants strongly agreed (n=58/125, 47%) or agreed (36/125, 29%) while just 23 of 125 (19%) strongly disagreed or disagreed.

Table . Dataset characteristics (N=125).

Characteristics	Users, n (%)
Age group (y)	
20-29	2 (1.6)
30-39	3 (2.4)
40-49	18 (14.4)
50-59	27 (21.6)
60-69	52 (41.6)
70-79	20 (16)
80-89	1 (0.8)
Sex	
Male	70 (44)
Female	55 (56)
Employment status	
Employed	54 (43.2)
Unemployed	5 (4)
Retired	64 (51.2)
Student	1 (0.8)

Participants were asked a series of questions to evaluate the usefulness of technology in managing their hypertension. The responses indicated a high level of perceived usefulness. Overall, 80% (100/125) of the participants agreed or strongly agreed that Megi helped them understand their hypertension better. Regarding the importance of blood pressure monitoring, 98% (122/125) found the technology useful for regularly monitoring their blood pressure. When the participants were asked whether they would forget to measure their blood pressure if Megi did not remind them, 80% (100/125) responded that they would. In addition, study participants felt that using Megi made them develop the habit of measuring their blood pressure regularly (118/125, 95% responded positively).

When participants answered questions that assessed their overall perception, confidence in the digital tool, and willingness to continue using it independently of their health care provider, again their overall satisfaction was very high. Specifically, regarding the statement "I can see the benefits of using Megi," 98% (122/125) of the study participants strongly agreed or agreed. In addition, when participants were asked whether they had confidence in Megi, 92% (115/125) responded positively, while when they were asked whether they were willing to use Megi independently, more than 80% (100/125) agreed or strongly agreed.

Study participants were also assessed regarding their willingness to use or recommend Megi. Specifically, they asked whether they (1) would recommend Megi to their friends (112/125, 90% of the users responded positively) and (2) would agree with the following statements: "Anyone who cares about their health should use Megi" (100/125, 80% of the users strongly agreed or agreed); "For the sake of myself and my loved ones, it is important for me to take care of my health" (112/125, 90% of the users responded positively); and "My loved ones and friends would encourage me to use Megi" (more than 55% of the users responded positively).

At the end of the survey, participants had to answer questions regarding their behavioral response with the digital tool. They had to answer the following questions: "Since using Megi, I feel safer and more relaxed"; "I feel happy when I receive messages from Megi"; "I wouldn't want to lose access to Megi"; and "Megi makes me feel less lonely." Across all questions but the last, more than 80% (100/125) of the participants felt that Megi reduced their anxiety and made them feel safe.

Unmet Needs

Study participants were also asked whether there is something that they would change about Megi. Answers were given in free text. Some users were asking for more personalized treatment (eg, "I think maybe she should adjust according to the specifics

XSL•FO
RenderX

of individual patients. I can illustrate this with my own example. I have been hypertensive for about thirty years, I regularly measure my blood pressure, so I don't think it's necessary to report my condition every two weeks"; "I would like to determine more precisely what type of pressure I have...when it is really low and when it is high, and based on the measurements…") or the possibility of clinical consultations with cardiologists (eg, "Maybe the availability of a cardiologist to guide me"; "If there were an opportunity to occasionally discuss the results with a doctor, I think I would take regular measurements more seriously"). On the basis of the qualitative feedback, several common themes emerged that can inform future improvements to Megi. These user-driven recommendations are summarized here—(1) personalization of reminders: allow users to adjust the frequency or timing of blood pressure measurement reminders based on their experience and needs; (2) flexible reporting options: give experienced users the option to reduce or customize the frequency of data entry, especially if their condition is stable; and (3) clinical support integration: offer optional access to health care professionals (eg, cardiologists or general practitioners) for periodic review or consultations.

Discussion

Principal Findings

The management of hypertension at home using digital apps presents a promising avenue for improving patient outcomes and alleviating the burden on health care systems. This study explored users' perspectives on Megi, a digital tool designed to facilitate long-term home-based blood pressure monitoring, and demonstrated the effectiveness of Megi on blood pressure reduction.

Analyzing the activity of 5136 users, our results show very high engagement and adherence to blood pressure readings that remain stable even after one year of using Megi (Figure 1). Specifically, more than 50% of the users are active on the Megi digital health platform for 12 months, which demonstrates higher user retention when compared to previously reported industry standards. For example, consistent with other large-scale digital health studies, the notable Stanford-led MyHeart Counts study experienced substantial dropout rates; mean engagement with the app was only 4.1 days [14]. Statista research into the worldwide retention rate of mobile app installs reveals that, on the day of installation, the average retention rate across the 31 categories was 25.3% [15]. Worryingly, by day 30, this percentage drops to just 5.7%, and when it comes to the health and wellness industry specifically, it is even lower at 2.8% [15].

In addition, our analysis showed the effectiveness of Megi as a digital tool for hypertension management (Figures 2-4). We demonstrated that the average SBP of the last biweekly interval for which users reported their blood pressure values was statistically significantly smaller compared to the first biweekly segment after users' enrollment (Figure 2). This difference was even stronger for users who had high (>140 mm Hg; Figure 3A) and very high SBP measurements (>150 mm Hg; Figure 4A) during the first biweekly segment. Furthermore, we showed that there is a positive correlation between the SBP drop and the duration for which users report their blood pressure values. This means that larger SBP reductions are associated with longer use of Megi (Figures 3, 4B, and 4C).

While our results demonstrate a significant association between longer Megi use and reductions in SBP, it is important to note that the observational nature of the study limits causal inference. Without a control group, we cannot fully exclude the impact of confounding variables such as concurrent lifestyle changes, improved medication adherence independent of Megi, or parallel support from health care providers. These factors may have contributed, in part, to the observed improvements. Future randomized controlled trials are needed to validate these findings and better isolate the direct effect of the digital tool on clinical outcomes.

Through an online survey, we evaluated users' perspectives on the technology's usefulness in improving self-management of hypertension, their satisfaction with the tool, their willingness to use it, and their behavioral responses to its implementation. The findings indicate a high level (ie, more than 90%) of user satisfaction with Megi. Participants strongly acknowledged the technology's usefulness in enhancing their ability to manage hypertension independently (Figures 3 and 4), as well as expressed their willingness to suggest Megi to other users. The tool's integration into daily routines led to a noticeable reduction in anxiety and an increase in feelings of relaxation and happiness, suggesting a positive impact on mental well-being. The behavioral response data—particularly users reporting feeling safer, less anxious, and more connected—aligns with previous findings on the importance of emotional engagement in digital health interventions. Previous studies have shown that user adherence improves when digital tools provide empathic, human-like interaction, particularly in long-term chronic condition management [9,12]. Megi's use of LLM-powered messaging may have contributed to these outcomes by delivering timely, personalized, and conversational support that mimics human dialog. This is consistent with recent research demonstrating that LLMs can convey human-like empathy and reassurance in health contexts [8,10]. Furthermore, the willingness of users to recommend Megi to friends reflects strong approval and confidence in its efficacy. Overall, the positive feedback from users highlights the potential of Megi as a valuable digital tool for hypertension management.

Limitations

Despite the valuable insights, this study has limitations that must be acknowledged. First, its observational design limits the ability to draw causal conclusions. Second, the online survey relied on convenience sampling and included only users with at least 3 months of continuous use, excluding those with intermittent engagement. This may introduce selection bias and limit generalizability. In addition, the single ethnicity of the analyzed cohort limits the generalizability of the findings. Cultural attitudes toward technology, patient-clinician relationships, and the structure of local health care systems may influence user engagement, retention, and perceived value of digital tools. Moreover, the evaluation focused exclusively on one digital tool, that is, Megi, which may not provide a comprehensive understanding of the broader landscape of digital

XSL•FO
RenderX

tools for hypertension management. These constraints may affect the generalizability of the findings and highlight the need for further research with more diverse and larger populations to validate and expand upon these results.

Recommendations

In addition, we recommend that future research include more diverse populations to enhance the generalizability of results and evaluate clinically validated outcomes such as cardiovascular events and treatment modifications. Incorporating structured metrics for therapeutic compliance and integrating the platform with clinical workflows would further strengthen its clinical utility. In addition, prospective studies—particularly randomized controlled trials—are needed to establish causal relationships and assess the long-term impact of digital tools such as Megi on hypertension management and overall cardiovascular health.

Conclusions

Our study demonstrated the effectiveness of a digital tool for hypertension management and highlighted the importance of understanding user views in the design and implementation of digital health interventions for hypertension management. In conclusion, the insights obtained from this study highlight the potential of digital apps to enhance hypertension management by providing continuous monitoring, real-time feedback, and personalized health recommendations.

Abstract

Background: Research about the engagement of adolescents with mobile health (mHealth) interventions is scarce, while it is generally assumed that the engagement affects the intervention efficacy.

Objective: Using an mHealth intervention that targets the general population of adolescents to promote healthy behaviors (physical activity, low sedentary time, adequate sleep, and taking breakfast) and mental health, we aimed to investigate (1) how adolescents engage with the intervention, (2) which engagement styles can be identified and how these differ according to personal characteristics, and (3) which style of engagement predicts behavior change. The intervention used, #LIFEGOALS, includes self-regulation techniques, a support chatbot, narrative videos, and gamification, brought together in an app coupled to an activity tracker.

Methods: Logged usage data and self-reports of experience with #LIFEGOALS were collected from 159 adolescents (mean age 13.54, SD 0.95 years) over a 12-week intervention period and used to describe behavioral and experiential engagement with the intervention components over time. Baseline data on sociodemographic variables, mental health, and behavioral determinants were explored as determinants of engagement and were used to characterize engagement styles that were identified through exploratory cluster analysis on the frequency of usage of the components. Linear mixed-effects regression was used to analyze the effect of engagement style on health behavior change.

Results: Average time in the app was 26 minutes (SD 26) over the 12-week period, with usage decreasing substantially after the first week. The use of self-regulation techniques and gamification was strongly interrelated ($0.65 < r < 0.70$), whereas use of Fitbit showed weaker correlations with other component usage ($0.15 < r < 0.31$). Exploratory analyses suggest that engagement was influenced by immigration background and by adolescents' attitudes, self-efficacy, and intentions toward healthy living. Younger participants tended to use the Fitbit more frequently. Cluster analysis identified 4 engagement styles: narrative usage (n=19), app usage (n=36), Fitbit usage (n=32), and no usage (n=72), which were associated with differences in age, peer support, and mental health. Engagement style did not affect change in health behavior outcomes from preintervention to postintervention.

Conclusions: Different engagement styles were identified based on the frequency and type of components used. Findings support the relevance of tailoring mHealth to individual, interpersonal, and contextual characteristics. The overall low engagement with the intervention may have limited the detection of differences in health effects between engagement styles.

Introduction

Mobile health (mHealth) is defined as the use of mobile devices such as smartphones and activity trackers in health care. Compared with in-person care, mHealth may offer advantages in promoting health by reducing barriers such as cost, stigma, confidentiality concerns, and scheduling or distance constraints [1,2]. mHealth may also facilitate health empowerment by providing personalized, real-time information and support [3] and by enabling independent health management that can bypass parental dependence [2,4]. Health apps may be particularly suitable for adolescents [5]. Following statistics from Western countries, between 93% and 98% of teens aged 12-17 years own a smartphone [6-8]. In Flanders, Belgium, 96% of adolescents use their smartphone more than an hour, and 45% even more than 4 hours on days without school [9]. The integration of smartphones in adolescents' daily life may facilitate the adoption of a health app. Nevertheless, it remains a challenge to get adolescents to initiate and sustain engagement with digital health interventions. In research trials, a high percentage of adolescents do not use the app or drop out early [10-13]. These data are estimated to be even higher in real-world usage [14]. Low intervention usage relates to fewer positive health effects [15-17], but little is known about the quality of engagement and how this relates to health outcomes.

Intervention log analytics is an approach to study and interpret engagement with digital interventions. For unstructured apps (ie, consisting of variable components that users can access and use at will), useful indicators are the frequency of interactions logged, the number of app features accessed, the number of activities completed, and the number of minutes spent in a web-based program [18,19]. Logged usage data have been used to determine user styles, either via cluster analysis or by transforming a continuous engagement outcome into discrete categories [16,18]. Users are mainly classified according to the extent of usage of the intervention [15-17,20], but user patterns can also be explored in terms of engagement with different intervention components or features. This might be relevant for multicomponent and (partly) unstructured interventions where it can reveal naturalistic user patterns, such as preferences for (the combination of) certain intervention features and their relationship with intervention effects. A few studies have identified clusters that reflect a difference in the use of different components [17,20]. Besides a cluster with overall low usage, the remaining clusters distinguished between using mainly 1 component of the intervention and using that component in combination with other features of the intervention. Effects of these types of clusters on health outcomes are mixed and likely depend on the intervention content and components. For example, the analysis of engagement with a digital intervention for young adults recovering from first-episode psychosis found health improvements only for the group with maintained use of the therapy and the social component but not for the group with maintained use of only the social component [17]. Another web-based intervention for adults with mild to moderate depression, anxiety, and stress did not find an effect of the clusters on health outcomes [18].

With the aim of maximizing intervention effects, an identification of different engagement styles and their health effects should be complemented with an understanding of the factors that influence patterns of engagement. Intervention characteristics (eg, novelty, autonomy, or complexity) or intervention components (eg, reminders or social support features) can have a different impact on individuals' engagement depending on user characteristics (eg, motivation for the health behavior, mood, or education level) [21]. More research is needed on the determinants of different aspects of engagement to inform future design and tailoring of effective mHealth interventions.

This study uses the multicomponent mHealth intervention #LIFEGOALS as a case study to (1) describe engagement with the intervention, (2) identify and characterize clusters of engagement, and (3) analyze their influence on health behavior change. #LIFEGOALS is an app coupled with an activity tracker to guide adolescents toward healthier lifestyles for promoting mental health. The intervention showed beneficial effects on physical activity, sedentary behavior, sleep quality, and emotions (ie, in a close-to-normal situation, not in case of COVID-19 pandemic restrictions) [22].

Methods

Study Design

This study used data from adolescents who participated in a quasi-randomized controlled effect study of the #LIFEGOALS intervention [22]. Participants were recruited from the general population of adolescents enrolled in nonspecial needs secondary education in Flanders, Belgium. The recruitment process was designed to ensure adequate representation of students from the vocational education track, which focuses on practical and job-oriented training. In Flanders, adolescents in the vocational track typically come from lower socioeconomic backgrounds compared with their peers in the general or technical tracks [13] and are at greater risk for engaging in unhealthy behaviors [23]. From the 184 participants allocated to the intervention group, 25 could not install the app due to technical reasons and were not included in this study, leaving a final sample of 159 adolescents (mean age 13.54, SD 0.95 years; 82/159, 51.6% girls). Data were collected in 3 waves. All waves included 2 intervention schools and started baseline assessment in October 2020, November 2020, and January 2021, respectively. At baseline, and after 2, 6, and 12 weeks of intervention, participants completed a web-based survey. Following the baseline assessment, participants were assisted to install the #LIFEGOALS app on their smartphone and were given a Fitbit Charge 2 or 3 on-lend to link with the app. The intervention

XSL•FO
RenderX

was introduced as a health app to improve lifestyle, and participants were invited to use the intervention in the next 12 weeks. As it concerns an unstructured app, users could access all components at all times and could engage with the intervention as they wished. The working of the app was explained in the classroom by means of a slide show. In the last wave of data collection (n=62), the first episode of the narrative was shown in the classroom because low viewership numbers for the narrative were observed in waves 1 and 2.

Intervention

#LIFEGOALS is an mHealth promotion multicomponent intervention for Flemish adolescent youth, which aims to promote mental health by improving healthy lifestyle behaviors. The app focuses on increasing physical activity, reducing sedentary behavior, improving adequate sleep, and daily breakfast consumption. The intervention is theory-based (Health Action Process Approach [24], Persuasive Systems Design [25], and extended Elaboration Likelihood Model [26]) and was developed using a participatory design approach. It includes (1) self-regulation techniques guiding users through goal setting, action and coping planning, and self-monitoring (using an activity tracker and graphs) to help bridge the intention-behavior gap; (2) a health narrative in the format of an entertaining storyline offered in weekly short video episodes to facilitate health behavior change through identification with the characters; (3) an automated, rule-based (non–artificial intelligence) chatbot for individual support by providing information and sending supporting messages; and (4) other content and features such as health information and gamification. The use of the #LIFEGOALS intervention was stimulated by placing a roll-up banner in the participating classes to remind participants of using the app. The intervention is described in more detail elsewhere [27], and the home screen is illustrated in Figure 1.

Ethical Considerations

The study was approved by the ethics committee of the Faculty of Psychology and Educational Sciences of Ghent University (registration no.: 2020/70). Participants, their parent or guardian, and the school director received an information form tailored to their role detailing the study process, data protection measures, and the right of the participants to withdraw. Written consent was obtained before participation. During data collection, participants' identities were safeguarded through pseudonymization, using an encrypted key file to link participant codes with identities. After data collection and merging of user log data, questionnaire follow-ups, and baseline data, the dataset was fully anonymized and the key file was permanently destroyed. As an incentive, participants received a power bank after the baseline assessment and a cinema ticket upon completing the follow-up measurement.

Measures

Behavioral Engagement

By means of a unique identifier that had to be entered when installing the #LIFEGOALS app, user app activity was continuously logged throughout the 12-week intervention period. Log files included a date stamp and time stamp, the sort of activity (eg, filling out a certain section of the app, setting a certain choice or content, or receiving a push message by the app), and the content of the activity, if relevant (eg, text filled in by the participant, the option that was chosen, or the content of the push message). The usage of different components was operationalized by the frequency of opening each component section in the app (Table 1). Usage of the narrative was additionally operationalized by the self-reported number of watched episodes after week 1 (answer options: 0, 1, or all 2), after week 6 (0, 1 or 2, or 3 or more), and after week 12 (0, 1 or 2, 3-11, or all 12). Likewise, for the Fitbit, a unique login provided during installation gave the researchers access to the Fitbit data after participants synchronized their Fitbit in the Fitbit app. A total number of daily steps that exceeded zero was coded as a day with Fitbit usage.

Table . The different app components.

App component	Description
Action planning	Self-regulation technique. Via the button "Set mission" users are guided to translate a goal (eg, increase physical activity) into an action plan (eg, going to school by bike on Friday at 8 AM).
Coping planning	Self-regulation technique. When creating their action plan, users are asked to think of possible obstacles that may occur (eg, forgetting) and to think ahead of possible solutions for that obstacle (eg, hang post-its). Coping planning is, furthermore, accessible via the "Tools" button.
Agenda	The button "My agenda" offers a week overview of all planned missions, as well as a list "My missions" where—for every mission in the past—users can tick off whether they managed to fulfill the mission.
Chatbot	"Botty" is a chatbot to which users can ask questions (about a healthy lifestyle or the functioning of the app) and which sends encouraging messages and an announcement when a new episode of the narrative is available.
Narrative	Twelve short video episodes (3-6 minutes each) screen the everyday life of 4 adolescent classmates with a focus on entertainment. Implicitly, the storyline shows the importance of a healthy lifestyle for mental well-being. Each week, a new episode comes available in the app.
Gamification	Users can earn "coins" by planning and completing missions. Earned coins can be used to purchase attributes to personalize an avatar. Gamification usage was operationalized by summing the frequency of opening the app sections "Coins" and "Avatar."
Progress graphs	The "Graphs" button presents graphical representations of user progress to self-monitor their behavior (number of steps, minutes spent in physical activities, sleep duration, and frequency of taking breakfast).
Information	Under the "Tips & Tricks" button are included: information about the health benefits of the targeted behaviors, inspiration on how to perform the health behaviors, and referral to other organizations and websites for more information or guidance.

Experiential Engagement

After week 1, week 6, and postintervention, participants reported whether they had watched any episode of the narrative and whether they had used the other parts of the app. Participants who reported nonusage were asked in an open question for the reason. For participants who indicated at least minimal usage, their user experience was measured for, respectively, the narrative component and the other parts of the app. Items from the Digital Behavior Change Intervention Engagement Scale

XSL•FO
RenderX

[28] were translated and specified to the #LIFEGOALS narrative or the other parts of the app. After factor analysis on data of the pilot study (n=35), items were limited to 3 (interest, attention, and affect) for *experiential engagement with the narrative*, and 4 (interest, attention, affect, and usefulness) for *experiential engagement with the other parts of the app*. Answers on a 5-point Likert scale (totally disagree—totally agree) were averaged with higher scores indicating higher experiential engagement.

Behavioral Determinants

Attitude (ie, the tendency to evaluate behavior with some degree of favor or disfavor), *self-efficacy* (ie, the belief in one's capability to perform the behavior), and *intention* (ie, the explicit decision to act in a certain way) were assessed separately for physical activity, sedentary behavior, sleep, and frequency of breakfast consumption. The items were based on scales used in other studies ([29] for physical activity and sedentary behavior; [30] for sleep) from which the highest loading items from factor analysis were selected (retaining 3 items for attitude, 3 for self-efficacy, and 1 for intention). The scores from 1 (not agree) to 5 (totally agree) for the different behaviors were averaged to reflect the determinant toward a healthy lifestyle in general.

Health Behaviors and Mental Health

Physical activity, *sedentary behavior,* and *sleep time* were measured at baseline and postintervention using Axivity AX3 accelerometers worn on the nondominant wrist for 7 consecutive days. Raw accelerometry data were processed in R to obtain the average Euclidean Norm Minus One per minute (ie, volume of physical activity) expressed in milligravity-based acceleration units (mg), the average of sedentary minutes per day (ie, sedentary time), and weekday-to-weekend sleep time difference (ie, sleep regularity) (see the study by Peuters et al [22]). Phillips cut points [31] were used to classify each activity minute into light or moderate to vigorous intensity physical activity. *Sleep quality* (ie, a composite score of items on sleep latency, sleep interruption, daytime sleepiness, and experience of sleep quality, based on the studies by Inchley et al [32] and Essner et al [33]) and *frequency of breakfast consumption* (ie, the average days per week taking breakfast [32]) were assessed in the web-based survey at baseline and postintervention.

Health-related quality of life, *psychological well-being*, *emotions*, *self-perception,* and *peer support* were assessed using the KIDSCREEN-10 [34] and subscales from the KIDSCREEN-27 [35] and KIDSCREEN-52 [36]. Higher *t*-scores (mean 50, SD 10) indicate better mental health. *Resilience* was measured with an adapted Dutch version of the Brief Resilience Scale [37], with higher averaged scores indicative of greater resilience. *Depressed feelings* were measured using the Custom Short Form of the Dutch version of the PROMIS-PedDepSx (Patient-Reported Outcomes Measurement Information System Pediatric Bank Depressive Symptoms v2.0) [38], with higher *t*-scores (mean 50, SD 10) indicating more depressed feelings.

Pandemic-Related Education Measures

The data collection took place during the second wave of the COVID-19 pandemic in Belgium. In this period in Belgium, people were allowed to leave the house by foot or bike, but other governmental measures were implemented to limit the spread of infections. One of these measures that might have affected adolescent usage of the intervention was a minimum of 50% per week distance learning for adolescents in the third year of secondary education and above (not affecting first and second years). A binary variable was created representing the presence of education restrictions (normal in-school education vs partly remote education).

Statistical Analyses

Describing Engagement

Linear mixed models with school class as random intercept (to deal with the nested nature of the data) were used to analyze differences in engagement according to individual characteristics. Frequency variables were log-transformed to account for their skewed distribution. The reported statistical tests use Satterthwaite's method to approximate degrees of freedom, as implemented in the *lmerTest* R package [39]. Given the exploratory nature of these analyses including multiple comparisons, *P* values are reported descriptively and not interpreted for significance.

Identifying Engagement Styles

The *cluster* R package [40] and R (version 4.0.5) were used to identify clusters in the engagement data. The selection of which engagement indicators to include in the final cluster analysis was based on the descriptive statistics of engagement and on the theoretical and evidence-based rationale for inclusion of the different components in the intervention (Multimedia Appendix 1). Because data of mixed types (continuous for frequency and ordinal for narrative episodes) were used, Gower distance [41] was used as the distance measure. The frequency variables were right-skewed and, therefore, log-transformed. Partitioning Around Medoids was used as an iterative clustering procedure. Average Silhouette Width was used to decide on the optimal number of clusters. Only those solutions with 3 or more clusters (to explore patterns of engagement outside of a dichotomous high vs low use range) and only those solutions where all clusters consisted of ≥15 participants (to be able to perform follow-up analyses) were considered.

Determinants of Engagement Style

Differences between clusters on baseline characteristics were investigated with multinomial logistic regression using the *nnet* R package [42]. Given the nested nature of the data (ie, students nested within classroom), we ran multilevel versions of the models with school class as random intercept. However, these models did not explain additional variance and resulted in the same conclusions, for which only the results from the models without multilevel structure are presented. Due to the higher number of missing values in the accelerometry data, a separate model was fitted for the health behaviors versus the sociodemographic variables (age, gender, and family affluence), behavioral determinants (attitude, self-efficacy, and intention), and mental health indicators. Education restrictions (ie, the pandemic-related measure of half-time remote education) were included as a covariate because they might have influenced engagement with the intervention by reducing live peer

XSL•FO
RenderX

interactions. The results of the full models are added in Multimedia Appendix 2. Variables that were significantly associated with the clusters (ie, age, intention, self-perception, peer support, depressed feelings, and education restrictions) were standardized and included in the final analysis.

Predicting Health Outcomes Based on Engagement Style

For each behavioral outcome, the *lmerTest* R package [39] was used to fit a linear mixed model with random intercepts for participant and school class to test the interaction between time (preintervention vs postintervention) and cluster. For the analysis of physical activity, 1 outlier was detected by inspecting residual plots and was left out of the analysis.

Results

Participant Characteristics

Sample characteristics are shown in Table 2. The participants were evenly divided over the first, second, and third year of secondary education. The proportion of participants following the vocational education track was comparable with the 24.5% of the overall Flemish population in 2020‐2021 [43]. Distribution of family affluence into low, middle, and high affluence was comparable with the general Flemish population [32]. See the study by Peuters et al [22] for sample characteristics of mental health and lifestyle behaviors.

Table . Sample descriptives (N=159).

Characteristics	Values, n (%)
Gender	
Girl	82 (51.6)
Boy	75 (47.2)
Other	2 (1.3)
Education type	
General or technical	120 (75.5)
Vocational	39 (24.5)
Grade	
First year	51 (32.1)
Second year	56 (35.2)
Third year	52 (32.7)

Low	47 (29.6)
Middle	77 (48.4)
High	35 (22.0)
Language at home	
Dutch	129 (81.1)
Other	30 (18.97)

Describing Engagement

Usage Over Time

The components that were used the most were the action and coping planning and the Fitbit, followed by the gamification and the chatbot. Users visited the narrative section in the app only a few times, but it should be taken into account that weekly only 1 new episode of the narrative appeared in the app. Behavioral engagement with the app and Fitbit drastically decreased after the first week (see Multimedia Appendix 3 for boxplots of the usage frequency of the different intervention components). Of the participants who installed the app, 76.1% (121/159) never opened the app in the last half of the intervention period. Continued usage with the Fitbit was also low, with 42.8% (68/159) of the participants who never synchronized the Fitbit with the Fitbit app in the second half of the intervention. Experiential engagement was more stable over time (Multimedia Appendix 3). Average experiential engagement at the end of the first week was positive with the app (mean 3.55, SD 0.71) and with the narrative component (mean 3.68, SD 0.68) and dropped slightly by the end of weeks 6 and 12. Of the participants who completed the postsurvey, 25.8% (38/147) indicated that they had not really used the app. The most common reasons for not or no longer using the app after week 1, week 6, or week 12 are shown in Table 3, together with the number of participants reporting this reason.

XSL•FO
RenderX

Table . Participant reasons for low usage of the #LIFEGOALS app after week 1, week 6, and week 12.

Reason for nonusage	Week 1[a], n (%)	Week 6[b], n (%)	Week 12[c], n (%)
Low ease of use (app was unclear or complicated to use)	4 (20.0)	3 (15.8)	7 (18.4)
Lack of time (having no time or too little time to use the app)	3 (15.0)	7 (36.8)	4 (10.5)
Forgotten to use the app	5 (25.0)	2 (10.5)	6 (15.8)
Technical problems (crashes, slow, or not being able to install)	4 (20.0)	1 (5.3)	6 (15.8)
No interest or not useful (no motivation, no need to use the app)	1 (5.0)	3 (15.8)	6 (15.8)
App unattractive (was no fun or boring)	0 (0.0)	0 (0.0)	3 (7.9)
Fitbit app was easier to use than the #LIFEGOALS app	1 (5.0)	0 (0.0)	1 (2.6)
Other (eg, did not know why)	2 (10.0)	3 (15.8)	7 (18.4)

[a]n=20; missing=14.5% (23/159).

[b]n=19; missing=23.9% (38/159).

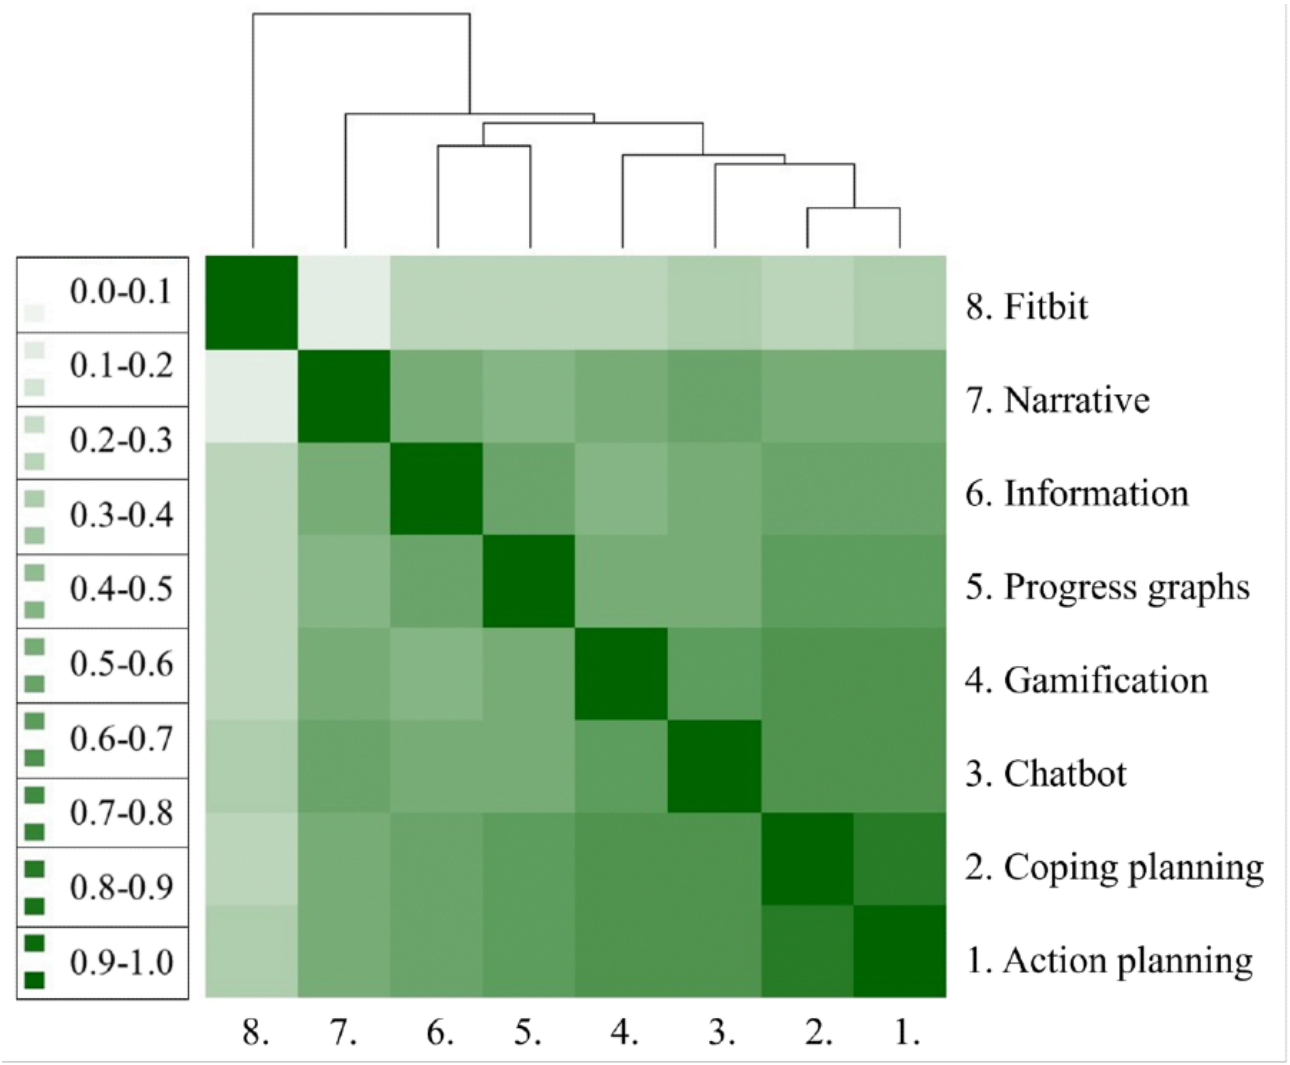
[c]n=38; missing=7.5% (12/159).

Associations Between Intervention Components

Interdependence between the intervention components was calculated via Spearman rank order correlations between the frequencies of usage (Multimedia Appendix 3), and is shown in an association heat map (Figure 2). The frequency with which the action and coping planning were used was highly associated with the usage of the gamification and the chatbot. The interrelationship between usage of the progress graphs and information was higher than their association with the rest of the intervention. The number of days the Fitbit was used was independent from the overall app use frequency.

XSL•FO
RenderX

Figure 2. App component associations. Heat map (rank-order correlations) and dendrogram of the frequency of usage of the different app components. Darker colors represent stronger positive associations.

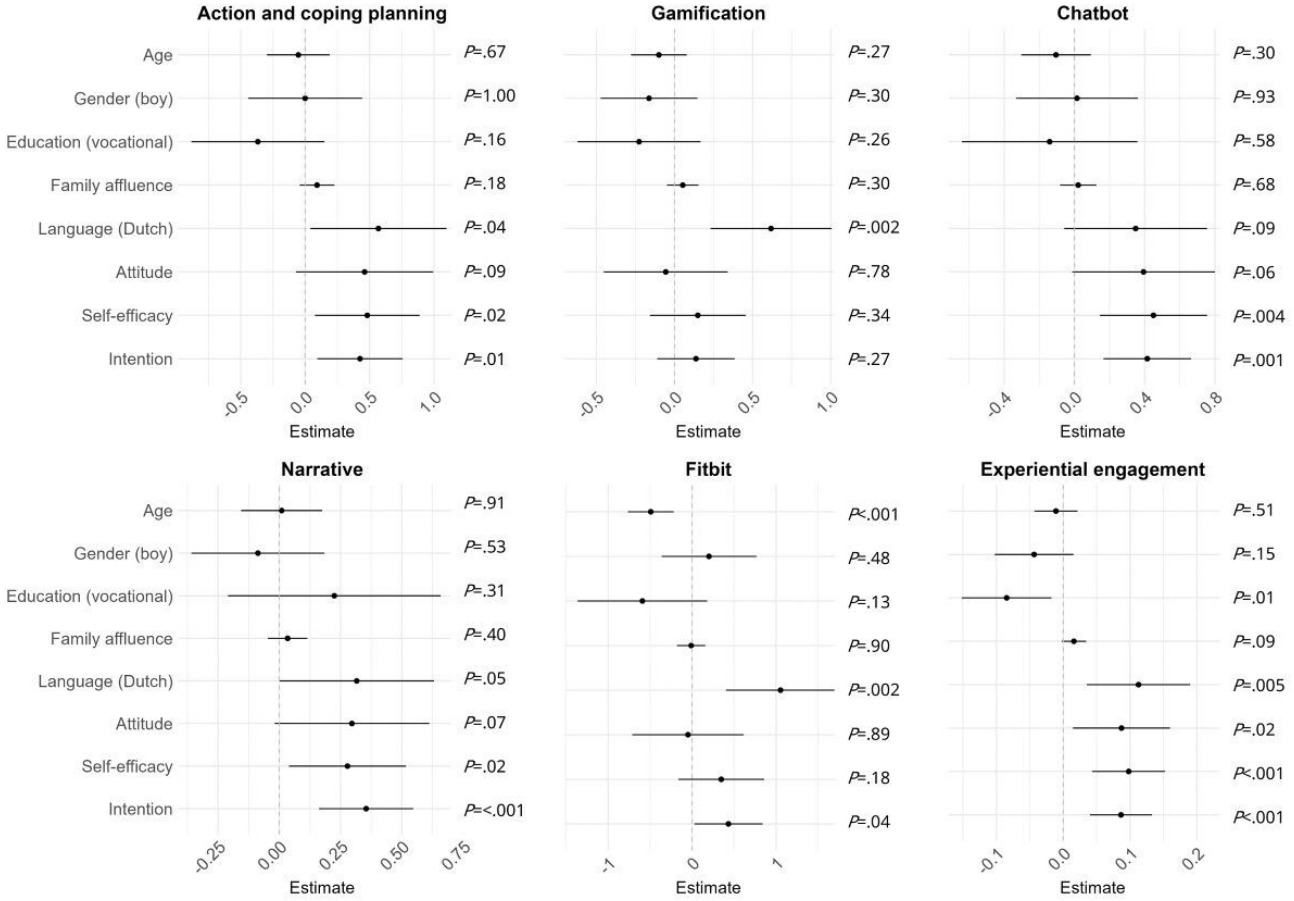


Exploring Determinants of Engagement

For each participant characteristic and baseline behavioral determinant, we ran a separate univariate linear mixed model including school class as random intercept to predict the engagement indicators. Results are shown in Figure 3, showing the estimates with 95% CIs and corresponding *P* values. Descriptive statistics for the engagement indicators across levels of the different determinants are shown in Multimedia Appendix 4. Fitbit usage varied as a function of age, with older adolescents using the Fitbit for fewer days. Age did not influence the other engagement indicators. Participants who did not speak Dutch as their primary language at home exhibited lower engagement with all components of the intervention. Gender, education type, and family affluence did not predict engagement. A positive attitude toward a healthier lifestyle, self-efficacy to change health behaviors, and the intention to change health behaviors were associated with higher usage of the action and coping planning, the chatbot, and the narrative components. However, for the gamification and Fitbit components, attitude and self-efficacy did not predict usage and intention to a lesser extent. Regarding experiential engagement with the app, participants in the general or technical education track, as well as those who spoke Dutch as their primary language at home, provided more positive experiential evaluations than participants in the vocational track or those speaking another maternal language. Additionally, higher attitude, self-efficacy, and intention were linked to more positive reporting of experiential engagement.

XSL•FO
RenderX

Figure 3. Exploratory analysis of participant characteristics predicting engagement indicators using univariate linear mixed models (1 predictor per model) with school class as a random intercept (N=159). Frequency outcomes were log-transformed. Estimates shown with 95% CIs and *P* values.



Identifying Engagement Styles

Cluster solutions with 3, 4, or 5 clusters had comparable average silhouette width (Figure 4). Exploring these cluster solutions, it was observed that different clusters were formed based on the extent to which the Fitbit was used, the narrative was watched, and the rest of the app was used. There was no clear separation between clusters according to the extent of usage of the chatbot. Because a 5-cluster solution had the greatest silhouette width but had 1 cluster that was considered too small for follow-up analyses (n=9), the 4-cluster solution was chosen.

Median usage of the intervention components per cluster is shown in Figure 5. The 4 clusters were labeled according to what distinguishes them from each other. Participants classified in the “narrative usage” cluster (n=19) were characterized by having watched multiple episodes of the narrative, those in the “Fitbit usage” cluster (n=32) by a relatively high and sustained usage of the Fitbit, those in the “app usage” cluster (n=36) had used the intervention but with less explicit usage of the Fitbit or narrative, and participants classified in the “no usage” cluster (n=72) had overall low to no usage of the intervention.

XSL•FO
RenderX

Figure 4. Average silhouette width for different numbers of clusters.

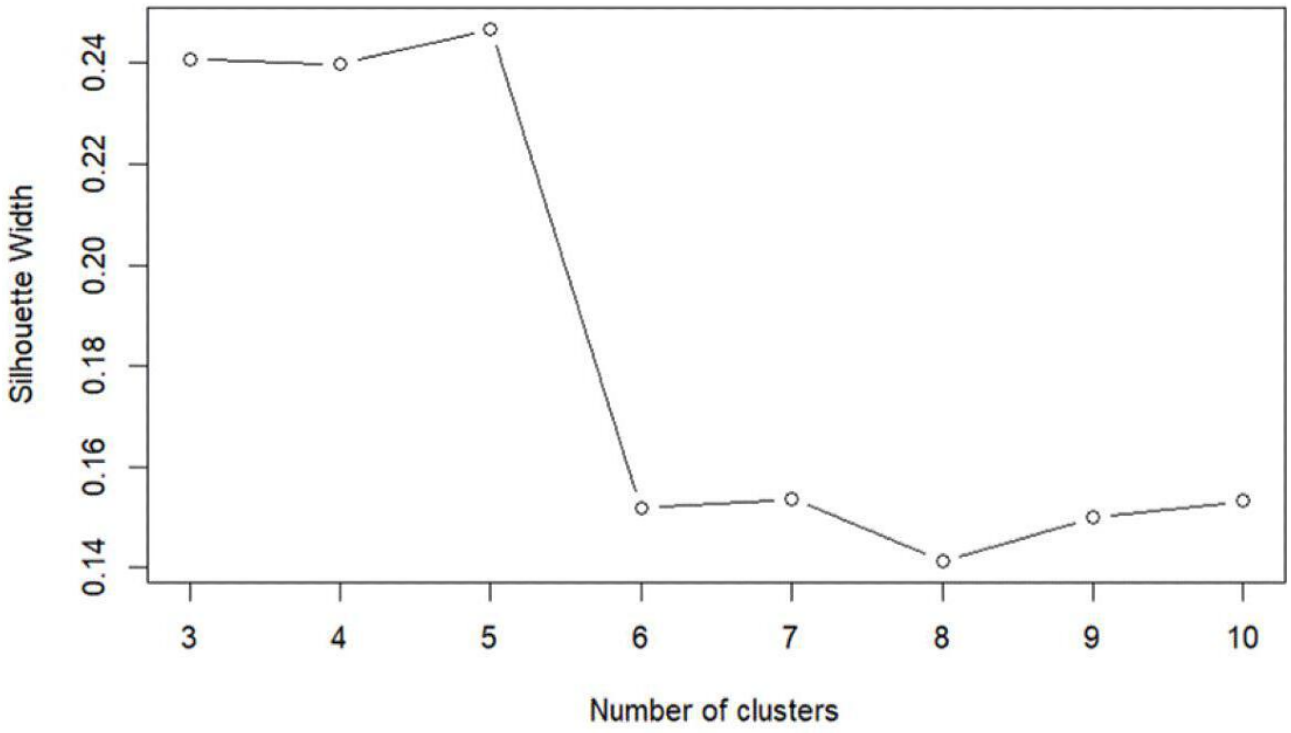


Figure 5. Average usage of the main intervention components per engagement style. Usage is presented separately for week 1 (white bars) and the weekly average of weeks 2-12 (gray bars). Presented are the median of the frequency per week using the component or the days per week wearing the Fitbit. For the narrative, the mean was calculated on the self-reported number of watched episodes after week 1 (0=none, 1=1, or 2=all 2) and after week 12 (0=less than 3, 1=3-11, and 2=all 12).

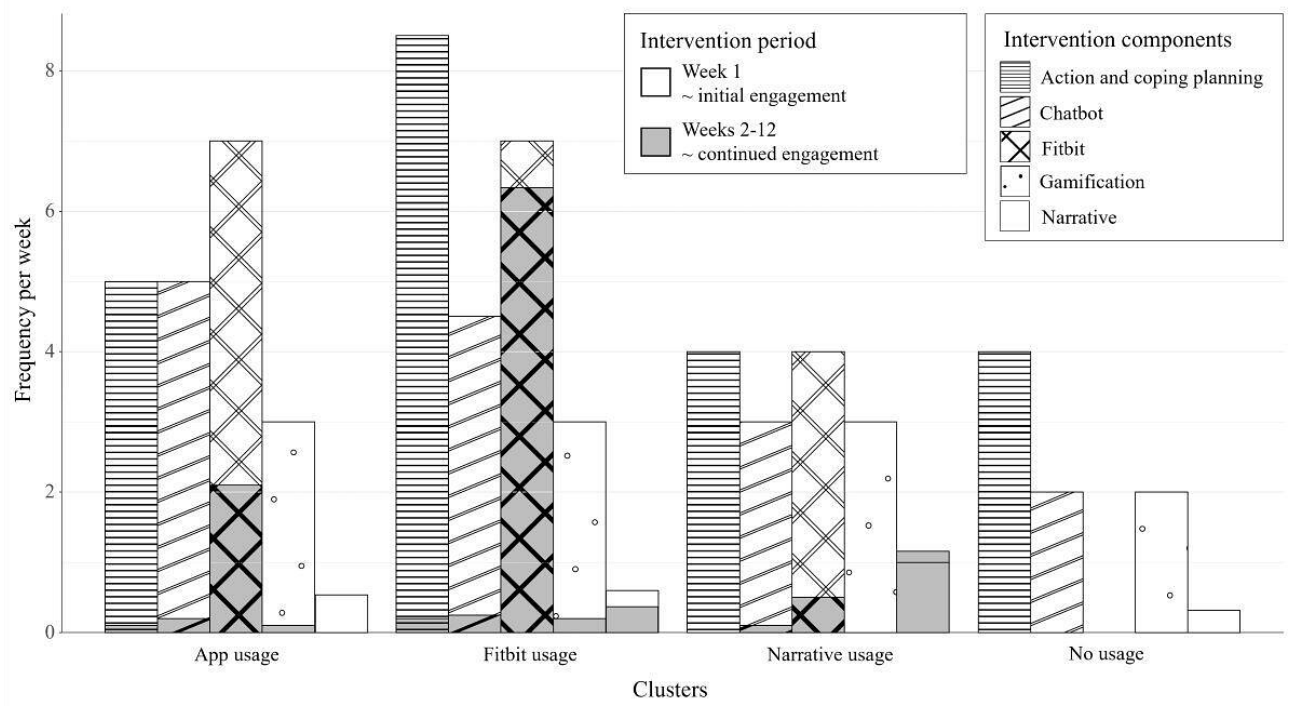

Determinants of Engagement Style

Statistics of the final multinomial logistic regression model are shown in Multimedia Appendix 2 and the statistically significant associations are reported here. Younger adolescents were more likely to be in the Fitbit usage group than in the no usage group (odds ratio [OR] 0.30, 95% CI 0.14 - 0.65; *P*=.002). Participants who reported lower peer support were more likely to be in the app usage group than in the no usage group (OR 0.43, 95% CI 0.25 - 0.74; *P*=.002) and more likely to be in the Fitbit usage group than in the app usage group (OR 1.96, 95% CI 1.08 - 3.55; *P*=.03). Participants who reported more depressed feelings were more likely to be in the no usage group than in the app usage group (OR 0.33, 95% CI 0.17 - 0.66; *P*=.002). No other baseline characteristics were significant predictors of engagement cluster.

XSL•FO
RenderX

Predictive Value of Engagement Style

The changes in the health behaviors from preintervention to postintervention did not differ significantly between clusters (Table 4).

Table . Effects of engagement cluster on preintervention to postintervention change in health behaviors[a].

	N	Chi-square (*df*)	*P* value
Physical activity, ENMO[b] (mg)	147	1.7 (3)	.63
Sedentary time (minutes)	148	0.9 (3)	.82
Sleep regularity (minutes)	132	1.5 (3)	.68
Sleep quality (scale 1 - 5)	159	2.0 (3)	.57
Breakfast (days per week)	159	4.6 (3)	.21

Discussion

Differential Engagement Between Components Over Time

This study investigated engagement with the multicomponent mHealth intervention #LIFEGOALS. #LIFEGOALS consisted of an app coupled with an activity tracker and included self-regulation guidance, gamification elements, health information, a support chatbot, and narrative videos. We aimed to gain insight into how the intervention is used, how components relate to each other, which users apply which engagement style, and how engagement style relates to health outcomes. The combination of system usage and questionnaire data allowed for the investigation of both behavioral and experiential engagement.

On average, users rated their initial experience when using the app as positive. The components that were used the most were the action and coping planning and the Fitbit, followed by the gamification and the chatbot. In the first week, many users used nearly all the intervention components (ie, self-regulation techniques, gamification, chatbot, and Fitbit). However, overall usage dropped steeply after the first week. The decrease in usage was least observed in the number of days wearing the Fitbit, although the use of the Fitbit decreased over time. This is in line with previous research showing that providing a Fitbit is not enough to achieve sustained usage [44]. It may well be that initial engagement is exploratory in nature, given that for all components, median usage was the highest in the first week, after which the extent of usage decreased. The rating of experiential engagement (ie, interest, affect, attention, and usefulness) slightly decreased only after the first week, potentially indicating that mHealth acceptability does not predict sustained mHealth usage. However, common self-reported reasons for low usage of the #LIFEGOALS intervention were low ease of use, technical problems, next to lack of time, forgetting, or no interest in the app. These findings confirm previous research highlighting the importance of technical quality and ease of use for mHealth engagement [45,46]. This might particularly play a role for adolescents in the vocational education track. They, along with participants whose maternal language was not Dutch, rated their experience while using the app less positively than participants in the general or technical education track. Another paper on this trial, moreover, found adolescents in the vocational education track to be more likely to drop out from using the intervention [13]. Overall, health is not a main concern for many adolescents, and vocational students may be less motivated to change health behaviors [13]. During data collection, it was indeed observed that vocational students showed lower motivation to participate in the study and to use the app than participants in the general track. A lower education level and Dutch language proficiency may have also contributed to greater difficulties in using the app. One proposed strategy for tailoring interventions to individuals with lower education attainment is to provide a support person with whom they can have direct contact [13].

Furthermore, exploration of engagement with #LIFEGOALS provided insight into the popularity and interconnectedness of specific intervention components. Engagement was the highest with the intervention strategies intended to enhance *self-regulation*. That is, action and coping planning were visited the most in the app, and sustained usage was the highest with the self-monitoring device (ie, the Fitbit). These components are theoretically considered important for behavior change, as has been shown in other studies [47,48]. Furthermore, usage of the action and coping planning was moderately to highly associated with usage of the *gamification*, suggesting that the gamification succeeded in its role to motivate users to set and complete action plans. Especially for an adolescent population, gamification has been put forward as an essential element within mHealth [46,49]. Results suggest that a points system with avatar appears to be an effective combination of gamification techniques. Notably, baseline attitude toward a healthy lifestyle and intentions to change health behaviors were not associated with subsequent use of the gamification features or the Fitbit. However, they did influence engagement with other components of the intervention. This pattern may suggest that reward-based elements, such as gamification and Fitbit features, have the potential to engage adolescents with lower behavioral motivation. In contrast, components such as the chatbot and narrative, which could also be considered motivational, may have less potential in this regard. There was a particularly low usage of the narrative video episodes, as well as with the tips with information for healthy lifestyles. In #LIFEGOALS, the gamification features were not designed to stimulate engagement with the health narrative or information in the app, which could

XSL•FO
RenderX

partly explain the low usage of these elements. Postintervention interviews with users suggested that tailored advertisement could improve engagement with the narrative videos [22]. Future research is needed to formulate an answer to whether increased embeddedness in the app, linkage with gamification, or other techniques could push engagement with health narrative video episodes as part of mHealth.

Engagement Styles

Cluster analyses using multiple indicators of engagement classified users according to the extent of overall usage and to the extent of usage of different intervention components. Besides a no usage cluster, the remaining clusters were characterized by relatively high usage of the health narrative, high usage of the Fitbit, or no explicit usage of the narrative or Fitbit. The identification of different clusters depending on the extent of usage of a certain intervention component was also found in other studies investigating clusters of engagement with a multicomponent intervention [17,20]. Experiential engagement did not influence the clustering in this study. It might be that experiential engagement is reflected in the amount of usage (considering, eg, that the experience of flow implies a loss of track of time, which will translate in longer in-app duration), thus explaining little additional variance on which to base cluster grouping. Indeed, previous research has indicated significant correlations between self-reported experiential engagement and logged behavioral engagement [28]. In what follows, we discuss the 4 engagement styles that were distinguished in this study, together with their determinants.

A small group of users (19/159, 12%) was classified with a *narrative usage* style, characterized by the relatively high number of health narrative episodes watched. They all reported having watched 3 or more (out of 12) episodes, did not consistently wear the Fitbit, and had average usage of the self-regulation techniques and chatbot. Based on theories on narrative persuasion, we expected that adolescents with low motivation and ability to cognitively elaborate on how to live healthier would more easily be persuaded by a health message embedded in a narrative [26]. We found no evidence that low motivation or low ability increased the likelihood of watching the narrative: low intention to live healthier (as a proxy for motivation) or vocational education type (indicative of lower ability for cognitive processing) did not increase the odds of being in the narrative usage cluster. In contrast, exploratory linear regressions showed greater narrative usage among participants with higher intention. It could be that motivation and ability do not predict who will watch the narrative but rather who would be more easily influenced by watching the narrative. Future studies with a larger sample size are needed to investigate this question.

The group of users classified with a *Fitbit usage* engagement style (32/159, 20% of the participants) wore the Fitbit nearly every day of the 12 weeks. Their usage of the app ranged from a little exploration of some components to high initial and sustained engagement with the entire app. The probability of engaging with a Fitbit usage style compared with a no usage style decreased with age (OR=0.30). Evidence indicates that although adolescents perceive the Fitbit as easy to use, they also consider it as effort-demanding [44,50]. It could be that young adolescents are more easily entertained by the Fitbit features, hence outweighing the effort required to use the Fitbit. Participants who reported higher perceived peer support were 96% more likely (OR=1.96) to continuously use the Fitbit (Fitbit usage style) than the app components (app usage style). It could be that supportive peers encouraged usage of the Fitbit by providing the opportunity to compare progress and achievements or to use the device together. Indeed, social support has been found to facilitate positive change in physical activity [51,52].

A quarter of the participants (36/159, 23%) showed usage of most or all the intervention components and were categorized in the *app usage* engagement style. The probability of engaging with an app usage style compared with a no usage style differed according to peer support and depressed feelings. Adolescents who perceived higher peer support were less likely to engage with an app usage style than with a no usage style (OR=0.42) or a Fitbit usage style (OR=0.51). It could be that the experience of sufficient support in one's social network makes a health app seem redundant. Also, participants reporting more depressed feelings were less likely to engage with an app usage style than with a no usage style (OR=0.34). Individuals with a low mood may lack the energy required to engage with the app and have been found to engage less with mHealth also in other studies [45].

The largest cluster was the *no usage* cluster, consisting of 45% (72/159) of the participants who had not or rarely used any component of the intervention after the first week. Previous studies analyzing clusters of engagement have also identified 1 group with very low to no usage [15-17,20]. Not using the intervention should not cause concern if this reflects that the individual already meets the objectives of the intervention [53]. Individuals who already perform the behaviors that are targeted by the mHealth intervention, for instance, may perceive lower usefulness and use the intervention to a lesser extent than individuals who are aware that they could make important health behavior improvements. Baseline descriptive statistics indeed indicated that a part of the sample already maintained a healthy lifestyle. However, healthier behaviors at baseline did not significantly increase the odds of a no usage engagement style, but this might be due to low statistical power given the many missing accelerometry data and relatively small sample sizes of the clusters. It is an interesting avenue to further investigate baseline levels of health behaviors as predictors of engagement style, as this could also provide an answer to the question whether the intervention reaches the target group with the highest need.

Effective Engagement

To gain insight into the characteristics of engagement that are most effective for achieving intervention effects, we analyzed whether health behavior change differed according to engagement style. Our results did not show an effect of engagement style on change in physical activity, sedentary behavior, sleep duration, sleep quality, or frequency of breakfast consumption. Among others, the overall low engagement with #LIFEGOALS may have complicated the detection of differences in health effects between engagement styles, given

XSL•FO
RenderX

that also the clusters other than the no usage cluster contained many participants with little overall usage and low continued use. Low engagement, however, does not necessarily imply a failure of the intervention to reach health effects. Usage of the intervention components (ie, behavioral engagement) and the experience while using the intervention (ie, experiential engagement) should lead to engagement with the behavior change processes that are related to the intervention goals [54]. A decrease in engagement with the intervention may then be a positive phenomenon if this reflects continued engagement with the behavioral processes. This could provide an explanation of why there exists inconsistency on whether more sustained engagement is related to greater intervention effects [15,55]. To understand "effective engagement," more studies on different mHealth contexts are needed to clarify the type and amount of engagement that are minimum required for reaching health effects.

Limitations

System usage data are a complex entity, introducing challenges to adequately register and extract engagement indicators. In our study, all registered activity in the app or with the activity tracker was assigned to the participant who logged in on these devices during installation, for which we cannot rule out that these logged data may have included activity of other individuals using those devices. Furthermore, for the duration spent in the app, we detected an error for defining the end of a session (ie, in specific circumstances, no end duration was logged). Therefore, frequency data were used instead. There are multiple ways to operationalize behavioral engagement, and we could have also opted for the intensity of use (eg, the rate of visited pages or the number of action plans created) [56]. Because different indicators of behavioral engagement might reveal different effects [18], the multiple ways to operationalize the usage of mHealth components make it difficult to compare log usage data between studies. Next, experiential engagement was measured by self-report ratings of interest, affect, attention, and usefulness. It might be that this measure did not adequately reflect individual variance in the concepts it aims to measure, which could be why experiential engagement did not influence clustering into engagement styles in this study. Future research could consider alternative measures of experiential engagement, such as ecological momentary assessment or questionnaires with more tangible items (eg, ease of use and satisfaction as in the USE Questionnaire [57]) rather than relying on more abstract items such as "I was focused when I used the app," which may be difficult for young adolescents to self-report retrospectively. Additional research is needed to investigate how best to measure the user experience when interacting with the technology and its additional value for understanding mHealth engagement. Furthermore, the data collection took place during the COVID-19 pandemic, but for the behavior change predictions, we did not control for COVID-19–related measures due to the small sizes of the subsamples of engagement styles. Generalization of the findings to a nonpandemic situation should be done with caution, given that the effect study of #LIFEGOALS showed moderation by pandemic-related restrictions for education and sports [22]. Moreover, the elevated missing data caused by using accelerometers to assess activity-related behaviors limited the statistical power to study health behaviors as determinants or outcomes of engagement styles. Overall, the low usage of the intervention limited the possibilities to identify engagement styles and detect differences between styles. A high percentage of nonusage is also observed in other mHealth studies [5,12,58], but several participants mentioned low ease of use, and the intervention might indeed have lacked in-app guidance and tutorials on what to do in the app. The overall look and feel of apps have been found to be an important factor for adolescents to adopt health apps [59], and the design and technical functioning of #LIFEGOALS were likely of lower quality than those of commercial apps. The high technical requirements of end users challenge the possibilities to investigate mHealth engagement in noncommercial research contexts.

Future Directions and Conclusions

This study was the first, to our knowledge, to focus specifically on user styles of engagement with mHealth among adolescents. Four engagement styles were identified: narrative usage, Fitbit usage, app usage, and no usage. The styles differ in extent of usage and in preferences for certain intervention components. For instance, adolescents with lower perceived social support showed higher engagement with the app, while depressed feelings, consistent with prior research, were inversely associated with mHealth usage. Interestingly, Fitbit usage was independent of app usage, with younger adolescents more likely to use the Fitbit than the older ones. Moreover, our results reaffirm the important role of social support in sustaining engagement with wearable activity trackers [51]. Interventions designed to promote physical activity are likely to benefit from incorporating interactive components to foster continued physical activity.

Furthermore, our findings support previous research emphasizing the importance of technical quality and intuitive design in fostering mHealth engagement [45,46]. These aspects may be particularly crucial for adolescents with lower education levels or from immigration backgrounds, who are already at higher risk for unhealthy behaviors. To avoid leaving behind those who might benefit the most, digital health interventions must ensure optimal navigability and ease of use. For these populations, offering in-person support may further improve accessibility and uptake [13].

Moreover, our results provide support for the inclusion of reward-based elements and self-regulation. The findings from our exploratory analyses suggest that adolescents' attitudes, self-efficacy, and intentions toward healthy living may influence engagement with mHealth behavior change interventions. In primary prevention, where intrinsic motivation to change behavior may be low, reward-based elements such as gamification and Fitbit features appear especially promising. In our study, engagement with these components did not depend on behavioral motivation, while our findings suggest that reward-based components can engage users to set and complete action plans. In contrast, components such as the chatbot and narrative, although potentially motivational, may be less effective in engaging less motivated users. Self-regulation techniques, previously shown to be effective in promoting

XSL•FO
RenderX

behavior change [47,48], were used most frequently in our study, underscoring their value in mobile behavior change interventions. The identified variations in usage of the mHealth intervention across individual characteristics underscore the importance of tailoring mHealth to the needs and motivations of diverse populations in order to ensure accessibility and sustained engagement.

Our results encourage the continuation of upcoming research aiming to tailor mHealth interventions to user profiles. Addressing the challenge of generally low engagement of mHealth remains crucial, as higher usage could provide more robust findings about the type and duration of engagement necessary to exert meaningful health effects. It can then be investigated for whom and under which circumstances a nudging toward a promising engagement style may be both feasible and beneficial.

Acknowledgments

The authors would like to thank Armand De Clercq for the technical support in gathering the log usage data, and all participants for their participation in the study. This research was conducted with the support of the FWO (grant G043319N) to Geert Crombez and Ilse De Bourdeaudhuij and a grant for the development and evaluation of the method MOV-E-STAR of the Flemish Government to Ghent University.

Abstract

Background: Implementation frameworks such as the Exploration, Preparation, Implementation, Sustainment model emphasize the importance of the *fit* between an intervention and its context, which includes the needs of its target population, as well as the culture, resources, and capabilities of the implementing organization. Although lack of fit is a major barrier to implementation, fit has not often been a focus of implementation research. This paper uses fit as a lens to examine the implementation of Tula, a mobile health app aimed at reducing risky drinking days among individuals meeting the criteria for mild to moderate alcohol use disorder, in a 3-arm (app alone, app plus peer mentoring, and app plus health coaching) randomized controlled trial.

Objective: We sought to better understand the trial results and to provide actionable guidance for future implementation of digital health interventions in health care organizations.

Methods: Semistructured interviews with 18 trial participants and 7 Tula implementers were conducted. Trial participants were pulled equally from each arm of the trial and represented participants who demonstrated both high and low engagement with the app. Implementers consisted of a project manager, 4 peer mentors, and 2 health coaches. Interviews with participants focused on their motivations, opinions, and experiences of the intervention and their perception of their drinking behavior following the intervention, including how their use of the app worked to change that behavior. Interviews with implementers were centered on their roles, theories of change, perceptions of intervention, and areas for improvement. All interviews were analyzed using rapid qualitative analysis with deductive and inductive components.

Results: We identified areas of both fit and misfit. For example, there was a good fit between implementers' theories of change and participants' description of how change occurred. Fit was improved by the versatility of the app, which allowed participants to customize their experiences. Conversely, misfit was noted in the app's inability to cultivate connection for many participants and a disjunction between the role of peer mentors in the intervention and their broader professional ethos.

Conclusions: Focusing on fit provides a useful guide to enhance future iterations of the Tula app that lead to better sustainment of the intervention.

Introduction

Excessive alcohol use is linked to increased injury risk and poor health outcomes, causing approximately 140,000 US deaths and 3.6 million years of potential life lost annually [1,2]. Alcohol use disorder (AUD) spans a spectrum of risk, necessitating interventions tailored to an individual's likelihood of developing severe AUD [3]. Despite its high prevalence and significant impact on health, alcohol use is often undertreated in general medical settings. Many patients with AUD go unrecognized or do not receive appropriate intervention due to time constraints,

limited training, and stigma associated with addressing substance use in primary care [4].

Health coaching is increasingly used in health care organizations as a strategy to promote behavior change, support chronic disease management, and enhance patient engagement. Its integration into clinical care is growing, particularly within primary care and population health initiatives [5]. Peer support models are increasingly integrated into health care systems, particularly within mental health services, to enhance recovery-oriented care and patient engagement. This integration reflects a global shift toward incorporating lived experiences into treatment frameworks to improve outcomes and support system transformation [6].

Improving access to effective interventions is crucial due to AUD's widespread and destructive nature [1,7]. Digital medicine apps show promise in treating and providing ongoing care for patients with AUD, offering a widely accessible means for self-management and clinical monitoring [8]. However, research on implementing these technologies for early intervention in AUD is limited [3]. A key research question remains: how can human support enhance the effectiveness of digital medicine apps [9-11]?

This paper reports results from the qualitative component of a hybrid effectiveness–implementation trial that systematically varied the degree of human touch offered to support use of an evidence-based mobile health (mHealth) intervention for AUD (NCT04011644) [12]. Implementation of the intervention was guided by the EPIS (Exploration, Preparation, Implementation, Sustainment) framework, which delineates 4 phases in the implementation of evidence-based interventions: *exploration* to consider target population needs, *preparation* to assess barriers and facilitators to implementation, *implementation* to assess progress and determine adjustments, and *sustainment* to assess how to maintain the context structures and supports of the intervention [12]. For successful implementation, there needs to be a high degree of "fit" between the intervention and the contexts of implementation [13,14]. Fit, which has also been described as "appropriateness" and "compatibility" [14-16], has been conceptualized as encompassing multiple domains, including alignment between the intervention and the needs and preferences of the target population and alignment between the intervention and the culture, resources, and capabilities of the implementing organization [14]. The lack of fit is one of the most often cited barriers to implementing an intervention, but the construct has not often been the focus of implementation research [14].

In this paper, we examined the experiences of the users and implementers of an mHealth intervention called Tula (Sanskrit for "balance") for AUD that was tested in a recent 12-month randomized controlled trial [17,18]. We deploy the notion of fit as a lens to explore the alignment between the Tula intervention, the various digital support models, the target population, and the implementing organizations to better understand the trial results and to provide actionable guidance for future implementation of digital health interventions in health care organizations.

Methods

Intervention Design

The Tula intervention used a harm reduction approach to support individuals with mild to moderate AUD to decrease the number of heavy drinking days (defined as days with 5 or more standard drink units for males and 4 or more for females). Trial volunteers were randomized to 1 of 3 arms that included different levels of human touch: app only, app plus peer support, or app plus health coaching (see Table 1 for details of these arms). Participants in each arm received a monetary incentive to complete periodic study surveys that assessed the number of heavy drinking days and several quality of life measures. A full description of the protocol can be found in a study by Park et al [17].

Full trial results are reported in a study by Quanbeck et al [18]. Across all 3 groups, a statistically significant time effect was observed, with the percentage of self-reported heavy drinking days dropping from 38.4% (95% CI 35.8%-41%) at baseline to 22.5% (95% CI 19.5%-25.5%) at 12 months. There were no significant differences between groups in alcohol use reduction. Participants in the health coaching arm showed statistically significant improvements in mental health–related quality of life compared to the other 2 groups. However, participants in the health coaching arm dropped out of the study at a higher rate than participants in the other 2 arms, making that result difficult to verify due to risk of bias due to survivorship effects (ie, patients who had worse mental health may have been more likely to withdraw from the study).

Table . Study arms.

	App only	App+peer support	App+health coaching
Use of Tula	Unguided use of Tula	Tula use supported by a community-based peer mentor	Tula use supported by the health coach
Intervention	Study team conducts safety monitoring and technical support	Interpersonal communication and wellness monitoring via the app	Up to three 1:1 health coaching sessions via phone call
Discussion forum	No discussion forum	A discussion forum moderated by a peer mentor	A discussion forum moderated by a health coach
Communication	No communication feature with private messaging	The private messaging feature in communication routing to a peer mentor	The private messaging feature in communication routing to a health coach
Dashboard	No dashboard access	No dashboard access	Health monitoring by health coaches supported by a dashboard

Participant and Implementor Description

Eligibility criteria are listed in Textbox 1. All participants created anonymous usernames to use the app.

We partnered with a community-based organization to have certified peer specialists provide social support for participants randomly assigned to the peer support group. We provided project-specific training regarding the app and facilitating discussions. Peer specialists were not assigned to any specific participant but were available to any participant who reached out to them via a private messaging feature of the app. Peer specialists were able to draw upon their lived experiences with recovery from substance use disorders, including mental health issues, to moderate a discussion forum while encouraging participants to use the app.

In total, 2 certified health coaches—part of the health care system—worked one-on-one with participants randomly assigned to their group. The health coaches' goal was to help participants achieve their self-identified goals toward a healthier lifestyle as they reduced their alcohol consumption. Participants were encouraged to use up to three 1:1 personalized health coaching sessions via phone during the first 90 days of their trial session.

Textbox 1. Eligibility criteria.

Inclusion criteria

- 21 years old or older
- Wants to reduce drinking
- Owns a smartphone and is willing to download and use the Tula app
- Lives within the health care system service area
- Meets at least one of the following criteria:
  - · AUDIT (The Alcohol Use Disorders Identification Test) [19] screening score 8+, OR
  - · Responds "yes" to at least 2 questions on the Alcohol Use Disorder: Diagnostic and Statistical Manual of Mental Disorders, 5th Edition [AUD: DSM-5] [20], OR
  - · Reports moderate- to high-risk drinking patterns
  - · 4+ drinks on any single day and >7 drinks per wk (women and men aged >65 y)
  - · 5+ drinks on any single day and >14 drinks per wk (men)

Exclusion criteria

- Reports symptoms consistent with severe alcohol use disorder during screening (6 or more of 11 Diagnostic and Statistical Manual of Mental Disorders, 5th Edition [DSM-5] criteria)
- Active psychotic disorder diagnosis
- Acute medical problem requiring immediate hospitalization
- Terminal illness

App Design

The app was designed according to the tenets of self-determination theory, which posits that adaptive functioning is optimized when people are able to meet their needs for autonomy, competence, and connection [17,21]. The app content was informed by the Whole Health Model, an approach to health promotion that views health as having physical, psychological, spiritual, and social dimensions and seeks to enable people to improve their health by empowering them to identify their own needs and priorities and set their own goals [22]. Figure 1 shows a visual depiction of the app.

The original trial protocol for this Tula intervention project was considered minimal risk for participants and was exempt from requiring a formal data monitoring committee review. All data collected via the app were stored in secure, password-protected servers. Participants were informed that no patient health information would be collected from their medical records, nor would any study data be entered into their medical records. All data were deidentified before any analysis.

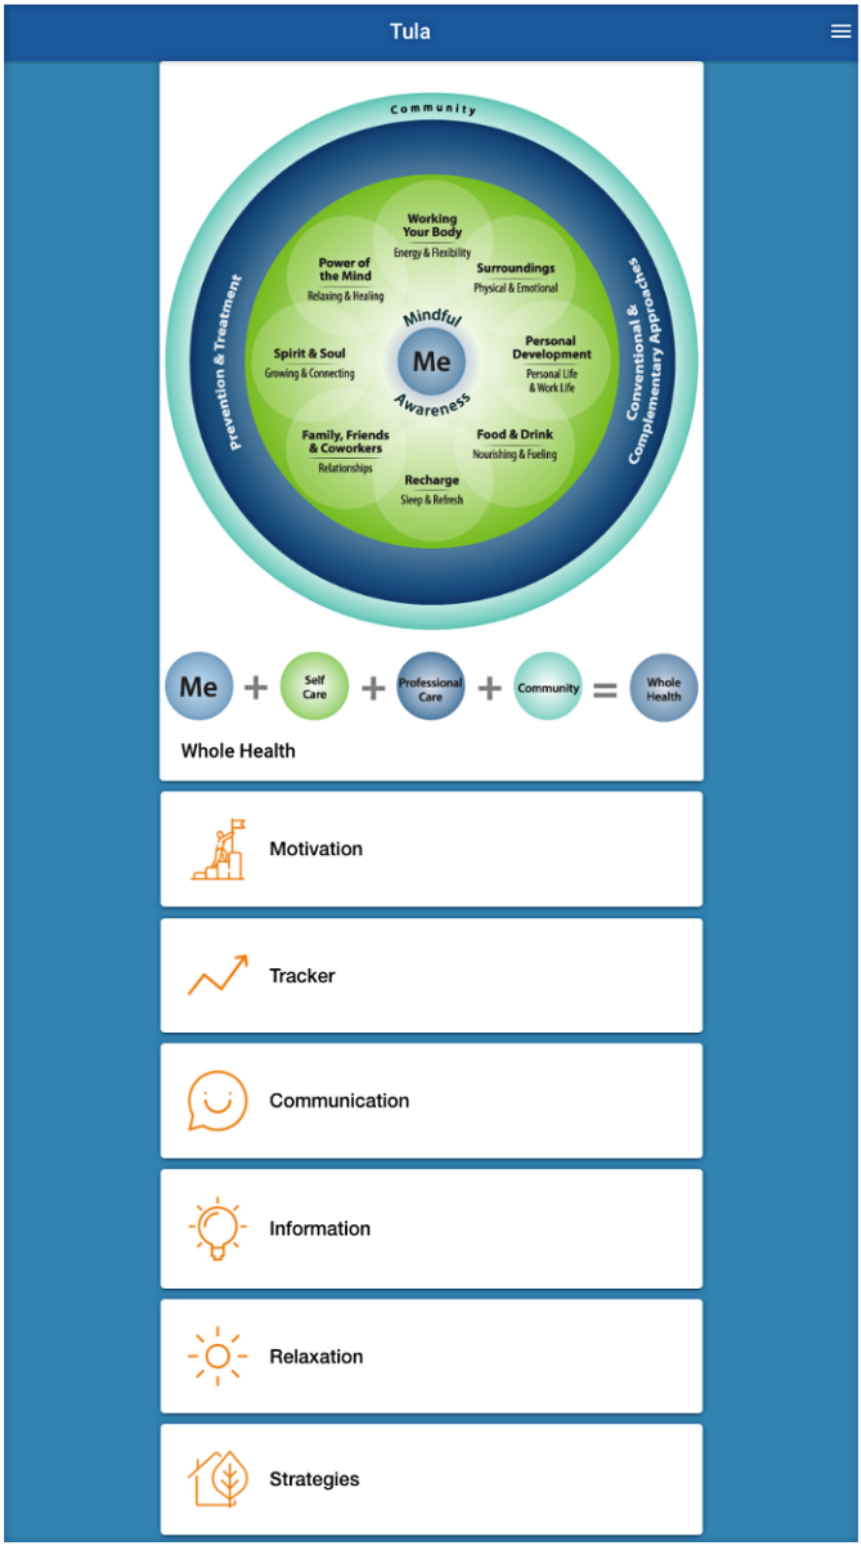
Figure 1. View of the app.



Qualitative Study Sampling

We sought to elicit perspectives from implementers of the Tula intervention and research participants. The implementer sample (n=7) included 1 research team member who had project management responsibilities, all 4 individuals who worked as peer mentors, and the 2 individuals who provided health coaching. We used the level of engagement with the Tula intervention as a criterion to selectively sample research participants. Engagement was determined by total number of app page views over 12 months for participants in all 3 arms, discussion group views and posts for the participants in the peer support arm, and number of health coaching sessions completed for those in the health coaching arm. Participants were divided into high and low engagement groups (with the most engaged listed first in their group and the lowest engaged listed first in theirs). Researchers then used these rankings to invite interview participation, with the most and least engaged invited first. All

XSL•FO
RenderX

invitations were sent via email addresses provided by the research participants. Research staff attempted contact with each participant 3 times before moving on to the next participant on the list. Participants who did not engage at all—for example, those in the health coaching arm who attended zero coaching sessions—were not eligible because they would have no direct experience with the intervention.

Qualitative Interviews

Implementers were interviewed by the first author, a public health scientist and qualitative methodologist. These interviews focused on roles played in Tula, implementers' theories of change, perceptions of how the intervention did or did not work, and suggestions for improvement of the intervention. Trial participant interviews were conducted by the first author and 2 other research team members, AP, a research program manager, and SV, an undergraduate research assistant, who participated in interview training conducted by the first author. The 3 interviewers, all women, were not involved in developing the Tula intervention and had not had previous contact with the participants. Participant interviews covered participants' reasons for joining the study and their opinions of and experiences with the different components of the intervention, as well as their perceptions of whether and how Tula had affected their drinking behavior. Interviews were conducted using semistructured interview guides developed by the research team and minimally revised following early interviews. All interviews were held virtually and included only the interviewer and the research participant. Interviewers did not have knowledge of the individual participants' outcomes—that is, whether or not they had reduced their drinking.

Qualitative Analysis

All interviews were audio recorded, transcribed verbatim, and analyzed using rapid qualitative analysis, an approach that includes both deductive and inductive elements and is particularly appropriate for implementation research [23]. An initial coding matrix used domains derived from the EPIS framework: innovation, inner context, and outer context. After sorting the data into these a priori categories, a round of coding developed new categories that were specific to the data set. For example, the inner context included participants' motivations for volunteering for the study, whereas the outer context included the impact of the COVID-19 pandemic (which coincided with the trial). The notion of fit as described by Blanchard and Livet [14] was then operationalized by searching for areas of compatibility and incompatibility between the Tula intervention and the inner and outer contexts of its implementation. Other analytic activities included memo writing and discussions among the research team about the developing findings. The first author led the analysis, including an iterative process of review and feedback from the other authors.

Ethical Considerations

The full trial was approved by the Minimal Risk Institutional Review Board (IRB) at the University of Wisconsin-Madison (2019‐0337 CP012 for IRB Study 2019‐0337, NCT06305624). In addition, the trial received a Certificate of Confidentiality from the National Institutes of Health. The qualitative study was approved by the same IRB as an addendum to the trial protocol (2019‐0337 CP012 for IRB Study 2019‐0337). The IRB allowed a waiver of written consent for the trial, but all participants were provided with a study information and consent document and were given the opportunity to ask any questions about the study at the point of recruitment. Similarly, interview participants were provided with written information about the purpose of the interviews and their rights as research participants. Verbal consent was affirmed at the beginning of each interview. Interviews were anonymized during transcription, which was completed by a University of Wisconsin–based service certified in Health Insurance Portability and Accountability Act (HIPAA) regulations and human subjects protections. All research participants interviewed received US $50 gift cards in appreciation for their time. Implementer interview participants were not compensated apart from the financial support they received for their roles in the intervention.

Results

Overview

The findings reported here were based on semistructured interviews with 7 Tula implementers and 18 research participants. All implementers approached agreed to take part in interviews. The participant response rate varied considerably, from a low of 15% in the low engagement app only arm to a high of 75% in the high engagement app only arm. The average response rate across arms and engagement levels was 41.25%. Nonresponders included participants whose email addresses proved to be nonfunctioning, as well as those who never replied to 3 invitations. Implementer interviews ranged from 30 to 70 minutes in length. Participant interviews ranged from 19 to 55 minutes (mean 27.5 min). The demographics and usage data for the 18 research participants were largely reflective of the entire trial sample (n=558). Interview participants were primarily White (17/18, 94.4%), female (13/18, 72.2%), and highly educated, holding a bachelor's or master's degree (12/18, 66.7%). The average age was 47 (SD 12.8) years (see Table 2, which also shows use data for interview participants and the overall trial sample).

Motivations

Research participants identified 2 alcohol-specific motivations for wanting to join the study: being curious about their drinking habits and wanting to cut down on their drinking. In discussing these motivations, they alluded to feelings of being at risk for problem drinking either because of their individual circumstances—for example, a family history of alcoholism or an increase in drinking during the early days of the COVID pandemic—or because they perceived their social context as being oriented toward heavy drinking.

> *Why? I guess I was just kind of, I was curious about my own habits. Alcoholism runs in my family...and I just was kind of, it's always kind of lingered in the back of my mind, like how responsible I am with alcohol. So I was just kind of curious to see how often I really did drink...and cravings and, you know, did I need it?* [Participant 04 in the app-only arm]

> *[I already have anxiety issues, but during COVID my anxiety really went up a lot, and I found that I was drinking quite a bit, like every day actually. Much more than I had before. So when the study came about...I just thought it would be really good to try to get back on track and to decrease the, how much I was drinking, because it really affects my anxiety.]* [Participant 06 in the health coaching arm]

Participants also described being motivated to participate in the Tula intervention by a wish to improve their overall health and by an interest in research.

> *[Well, for myself, it's, you know, like some people have every year where, you know, they start the new year and they're like, okay, what do I want to try to do to be better? I'm always trying to identify things of, areas work where I can, you know, get better. When I had seen that, I knew that I was probably drinking a little bit more than what I should have, and it just looked at, you know, right time, right place, right opportunity.]* [Participant 04 in the health coaching arm]

> *[Well I just wanted to cut down on my drinking, and the reason I wanted to do that was because my cholesterol levels were kind of high. Well, I attributed that to late night snacking, and you know, just overeating because that's what alcohol kind of triggers in me. So, yeah. So that's why I wanted to participate, and just to be healthier, you know?]* [Participant 06 in the peer support arm]

> *[So I found it very interesting. I have a health background, and I've always been, you know, into health and wellness and fitness. So I just thought that it sounded like a very interesting study to be a part of. I'm always kind of interested in research studies in general, but this one in particular I thought was especially interesting just because it had, you know, it related more towards overall, you know, health and wellbeing.]* [Participant 01 in the health coaching arm]

Implementer Theories of Change

Each of the 3 components of the Tula intervention—the app, the peer support, and the health coaching—had its own theory of change.

As noted, the app's design was based on self-determination theory and the Whole Health model. The app's embedded theory of change held that people's ability to change their drinking behavior would be promoted by features that were customizable and educational and that supported relationships with others.

Peer mentors told us that behavior changes, such as drinking reduction, depend on an individual's intrinsic motivation. Motivation is prompted and reinforced by increased self-awareness of the pros and cons of the behavior and, ultimately, a decision that the cons of continuing the behavior outweigh the pros. The role of the peer mentor is to use their own experiences of substance use, recovery, and relapse to establish rapport and then to "support and love [people] where they are at" by offering nonjudgmental, highly personalized, and often intensive assistance.

The health coaches described grounding their practice in the Whole Health model and the Stages of Change model of health behavior change [24]. Similar to peers, they saw health behavior change as originating in an individual's intrinsic motivation and the coaches' role as "support[ing] people in making health change that they were ready and wanting to make." Health coaches "[get] to the heart of what really matters to people" in order to provide tools that facilitate an individual's "mindful awareness" of their health habits and the ways in which these habits are or are not consonant with what the individual values. Health coaching consists of fairly structured conversations in which coaches "help [people] go from knowing to doing," or move from contemplation to action in the stages of change, by working with the individual to identify what they value, figure out how their current habits do or do not serve these values, set goals for change, review their progress toward meeting these goals, and fine-tune their goals as needed.

Change Mechanisms

Participants described 4 main mechanisms through which the Tula intervention worked to support change: accountability, encouragement, information, and connection. These mechanisms were described by participants in each of the 3 arms, though, as we explore, some components of the Tula intervention were a better fit than others in supporting these mechanisms.

Accountability came in 2 forms. In the first form, the Tula intervention raised participants' awareness of their drinking behavior by providing visibility onto the number of drinks taken each week.

> *[[The app asks you] "How much did you drink last week?" And that, for me, was enough to just kind of keep me in check. You know, like, "Ooh, I had a lot last week"...if you have three or four drinks, then you want to have a fifth drink. You're like, "Ooh, but I gotta enter that in that app".]* [Participant 02 in the health coaching arm]

XSL•FO
RenderX

> *[Well, as you know, the application itself makes you more mindful of how much alcohol you're consuming because on a weekly basis, it asks you to tally up how much you've had, and when you actually physically do that, when at the time might seem like I just had a few beers, you know, just had a few drinks, you can see where it really starts to add up. [Laughs] And so I used it, I guess on a weekly basis and then because I was doing that on a weekly basis and seeing how much I was drinking a night... it made me more mindful day-to-day as to how much I was consuming. And so it was, it became more like, "Oh, you know, you already had a couple, you know, maybe that third one is not a good idea."]* [Participant 04 in the peer support arm]

In its second form, accountability consisted of cycles of pattern analysis and goal setting and either positive or negative reinforcement for behavior change.

> *[I also liked that it had the like, mood and sleep like trackers along with the alcohol consumption trackers. Just because it was interesting to kind of see the correlation between all three of those factors and not just looking only at alcohol consumption. It's kind of interesting to see. I noticed that like alcohol consumption tend to be a little higher, like in weeks where I rated mood or lower sleep.]* [Participant 02 in the app-only arm]

> *[[The combination of the tracker and the surveys] made me reflect on my goals... If the question was, how connected do you feel to people outside of work, or, you know, to your family. If I noticed that I connected low there, and then had like three or four drinks above my goal for that week...then that was like a pretty clear, oh, you know, things are out of balance here.]* [Participant 02 in the peer support arm]

Both high and low engagement participants described accountability as having had the most impact on their drinking behavior.

Encouragement worked by promoting positive thinking, changes in perspective, mood elevation, and hope, which in turn helped to provide motivation to change behavior.

> *[Oh, just you know, [the thought of the day] was always something positive and it just launches your day in a great manner and, you know, inspiring quotes or, you know, you've got this, you can do it. You know, tough times don't last, tough people do kind of things and just very inspiring, you know, and it wasn't preachy or anything like that. It was always just kind of nice little encouraging snippets.]* [Participant 04 in the peer support arm]

> *[I dug into the gratitude list. So it was more of a reminder. If I was having a bad day that I could really point out, remember, positives of my day to go back and reflect upon.]* [Participant 05 in the health coaching arm]

> *[[The peer mentor] kind of opened up and told us about her experiences as well. I thought she was very down to earth, and very encouraging.]* [Participant 06 in the peer support arm]

> *[There was challenges and stuff like that and it wasn't always easy, that there was always being progress made. So that, it was breaking that stuff down when it's like, oh, well, you know, and [the health coach]'d be like, no, well, you know, look what you've already done and, you know, and then come with some other tools or things where I was having difficulties that I wasn't able to utilize, showing me the way to, you know. Just different ideas and things like that. So it was like, I just felt like I was going in the right direction, and that would be probably the biggest, it was very motivating, I guess.]* [Participant 04 in the health coaching arm]

Information supported change by offering new strategies for adaptive behaviors, as well as substitutions for maladaptive behaviors.

> *[[The app contained] just different ideas of things to do to occupy yourself other ways and meditation ideas, like this all kinds of different ideas. Things to keep you busy.]* [Participant 05 in the peer support arm]

Connection allowed users to exchange practical knowledge and to gain insight into others' experiences.

> *[It was insightful to get some tips from other people and it kind of led me to something new I found out, too, which has really helped me. I, well I started making mocktails, and I'd have them at home. I rarely drink at home, but every once in a while, I get really stressed out, beat up, and just, ugh, you know? I want a cocktail, but I found that mocktails were really good for me because they kind of gave me that ritual. They really helped. So, somebody suggested trying them and, you know, try some different recipes, and yeah. So I got some good information from other members that way.]* [Participant 06 in the peer support arm]

> *[So it was useful in the fact that...challenges that I would run into, I could see others that were challenged in the same manner, and some, on some occasions you could get feedback of what they were able to use or what they did that that made that difficulty something that was easier to deal with. Then there was also ones that would have comments where you like, okay, I don't want to do that. So on the positive there was there was good things, and on the negative there was good things. It was just nice to have that different perspective.]* [Participant 04 in the health coaching arm]

Fit and Misfit

We found areas of fit and misfit across the 3 components of the Tula intervention and the contexts of implementation.

Tula was a good fit with participants' motivations for joining the trial. All interview participants described the intervention

XSL•FO
RenderX

as having been successful in giving them some insight into their drinking. Many, though not all, reported that they had reduced their drinking or otherwise changed their drinking behavior. Several noticed improvements in their overall health—for example, weight loss or improved sleep.

There was compatibility between implementers' theories of change and participants' reports of how Tula worked to effect changes in their drinking behavior. The accountability, encouragement, information, and connection mechanisms were consistent with the theories of change embedded in the 3 components of Tula. That is, when it worked, Tula appeared to have worked in ways it was theorized it would.

There was also a good fit between participants' motivations, the change processes they described, and the app's features. The feature most often associated with both forms of accountability was the weekly drink tracker, which was universally popular with low and high engagement participants. All interview participants described using the tracker to become more aware of their drinking behavior, and several attributed their ability to reduce or change their drinking behavior to the tracker. Participants who experienced the second form of accountability also cited the study surveys. The app features described as being the most encouraging were the thought of the day, the modules devoted to motivation and gratitude, and, for those in the human touch arms, interactions with the peer mentors and health coaches. The Tula components that seemed most closely linked to information were the app modules focused on relaxation and drinking reduction strategies and the discussion groups, particularly the group associated with the peer support component. The Tula components mentioned as important to fostering connection were the peer support and the health coaching.

All the peers and health coaches indicated that the harm reduction philosophy underlying Tula was compatible with their own beliefs and approaches. The health coaches described their Tula work as very similar in approach to their non-Tula coaching and as personally fulfilling.

A significant misfit was the dissonance between the peer mentors' conceptualization of the peer role and the role as conceived in the Tula intervention. Specifically, the peer mentors contrasted the highly personal nature of their services as offered in the non-Tula context with the distanced and anonymous quality of the Tula work, which one peer mentor described as "dry." All peers noted this difference and suggested that it had hindered their effectiveness.

> *[I didn't have enough in-depth dialogue with each participant where I could understand where they're coming from...in a more in-depth way. And...I couldn't really share my experiences as deeply as I would if it was face-to-face.]* [Peer mentor 01]

> *[There was no face-to-face contact...there was not much of a connection made there. Whereas, you know, with [traditional] peer support, we meet in person, face-to-face. You know, we can, you know, we can see the, the body language...that's how you build a rapport, connection and trust. And so through an app there just wasn't anything like that... It's just not enough. It was, it was just really almost non-human interaction in a way.]* [Peer mentor 03]

One peer mentor experienced this misfit so acutely that they provided their contact information to trial participants and held one-on-one telephone conversations.

The discussion feature, included in the app for those trial participants randomized to the peer support or the health coaching arms, was successful for some users, especially to the extent that it was a source of information and encouragement. However, it appeared to be largely a misfit when it came to providing deeper feelings of connection. Both the health coaches and the peer mentors said they felt poorly equipped to facilitate meaningful discussions. Even the highest engagement participants in the peer support component, those who spent the most time on the discussion pages, were lukewarm about the discussions. Several participants said they had other outlets, such as AA, that met their needs for connection. Others noted that they felt they had little in common with participants who posted in the discussions.

> *[I only really read. I never really posted, to be honest... It's easier just to kind of read other peoples'.]* [Participant 03 in the peer support arm]

> *[To be honest, I did not play on the social side of it at all...it was people who weren't going to quit, and they didn't really want to. They were looking for someone to talk them into it. That's kind of the way I looked at those comments...in my opinion, if you want to do something, you just got to do it. It's not like somebody should be talking to you or anything like that. It's got to come from inside.]* [Participant 01 in the peer support arm]

Implementers identified a misfit attributable to the research context. They perceived that some trial participants were motivated not by an authentic wish to change their behavior but by the monetary compensation offered by the study. Thus, they lacked "skin in the game," and, while these participants completed the surveys that were the basis for receiving compensation, they did not really engage with any of the Tula components.

The app's technology and the volume of its content showed fit and misfit. While most implementers and participants praised how well the app functioned—"everything you click on, it works," others described it as clunky and unintuitive or reported technical glitches that interfered with use. In total, 2 participants expressed a lack of enthusiasm for any app: one because their life during COVID was taking place almost entirely online and they wanted a break from screens and another because they were trying to reduce their phone usage.

Many participants liked how much information the app contained; others felt overwhelmed or wanted a more curated experience.

> *[And so for me it was frustrating because there was so much in abundance. And I felt like you had to do it all. It wasn't like I could do a subset and be successful. So then I found myself not being as*

XSL•FO
RenderX

> *successful. That's a terrible thing to say, but I did...it became overwhelming and I felt more guilty and worse off.]* [Participant 03 in the health coaching arm]

Other domains that mixed fit and misfit were preferences related to intervention intensity and privacy.

While most participants seemed to appreciate that the Tula experience was fairly relaxed, others felt that they would have gotten greater benefit from a more intensive intervention.

> *[I probably would have benefited from it all. You know, having the group, having the counselor and the app, all three of those, would be a pretty high success rate I think, for myself personally.]* [Participant 03 in the app-only arm]

> *[I felt [the health coaching sessions] weren't memorable. I felt they were short, weren't in-depth. It was like, "what do you want your goals to be? Here are your problems. OK, that's a good goal." I just fell off the map. It really wasn't, I thought it would be more invasive at that level with the coach, and it was 15 minutes maybe each... I felt the coach didn't coach... You want someone who is skilled but is also going to provide you with expertise and solutions and ideas. I didn't feel that was done.]* [Participant 05 in the health coaching arm]

Many participants stated that they did not care to reveal themselves or make themselves "vulnerable" to strangers online, and thus, they appreciated having the ability to remain anonymous.

> *[Wanting to kind of self-improve on your own terms was really helpful for me in just having it be private, but knowing that, you know, there were strategies in there I could look at and I didn't have to, like reach out to somebody. For that, personally, for me, it was helpful.]* [Participant 01 in the app-only arm]

> *[And that way when you use the app, it's private, you know? No matter what you enter into it, it's just you and your entering info, you know? No one else around and it can, as bad as it may seem, who cares? Because no one sees it but you, you know what I mean? It goes to data for whatever you guys are doing, but at the time when you're entering stuff it don't matter, because it's just you.]* [Participant 05 in the app-only arm]

The fact that health coaching required some self-revelation during one-on-one conversations with coaches was uncomfortable for some participants in that arm.

> *[The other most difficult thing is talking to the coach on the phone whom I didn't have a relationship with, didn't know. And for me, it was already an embarrassing topic…I felt very probed and very kind of like a scientific experiment…I know it was anxiety producing for me.]* [Participant 03 in the health coaching arm]

Notably, the research team member who informed participants of which arm they had been assigned to reported that many people randomized to the coaching arm expressed disappointment with their assignments. As noted earlier, the health coaching arm had a higher rate of attrition than the other 2 arms.

Discussion

Principal Findings

While most of the literature on alcohol reduction mHealth interventions has been inconclusive, there is some evidence of promise across a range of studies [25-28]. Our examination of fit suggests some explanations for that promise.

We found a good fit between the Tula intervention, inclusive of the app, peer support, and health coaching, and many aspects of the contexts of implementation. There was a compatibility between the implementers' theories of change and participants' descriptions of how change occurred and between these change processes and several of the app's features. The best fit was between the change process participants called accountability and the app's tracking feature. This is consistent with findings from other studies, which have demonstrated positive behavior change from logging alcohol consumption as participants see real-time progress via the tracking function [26]. Giroux et al [29] conducted a study of a location-based monitoring and intervention system for AUDs, and Osth et al [30] compared 2 different smartphone apps to complement alcohol treatment. Both reported that participants found the accountability function and tracking feature increased their awareness of drinking consumption and increased their motivation for behavior change.

We also uncovered several areas of misfit. There was discordance between the peer mentor role in the Tula intervention and key features of peer mentorship in the non-Tula environment. The app's discussion feature was only minimally effective at fostering connection.

In addition, we observed several domains of mixed fit and misfit, specifically pertaining to the app technology's ease of use and its content and to participants' preferences related to intervention intensity and privacy. Patient concerns over data privacy and security are important when it comes to issues of choice in digital health. Patients expect clear guidance on how their data will be used and value the ability to control data sharing [31]. That the Tula intervention offered an array of options—"something for everyone"—was cited by both participants and implementers as an important strength. Having choices meant that participants could customize their experiences, including the choice to ignore parts of the intervention that they did not find helpful or interesting. A narrative review of 71 articles on barriers to and facilitators of digital health adoption found that patient empowerment, self-management, and personalization were the key drivers in the adoption of digital health tools [32].

Another key finding was the ways in which the research context affected both participants' and implementers' experiences. For some participants, random assignment constrained choice, pushing them into interventions they had no interest in exploring. From the implementers' perspective, the incentives offered to trial participants appealed to motivations that had nothing to do with drinking or health. In both cases, the misfit

XSL•FO
RenderX

between the intervention and the research context appeared to have threatened Tula's effectiveness. Conversely, the survey that participants were asked to fill out as part of the research seemed to have functioned as an effective part of the intervention for some participants by reinforcing accountability.

This qualitative examination helps provide an explanation for the main results of the Tula trial. The dominant mechanism of change described by the interview participants was accountability, which was closely tied to the app's tracker, a feature that trial participants in all three arms were able to access. The fact that the peer support component was not more effective than the app alone may be because what happened in the Tula intervention bore little resemblance to the highly personalized practices of outreach and response that are part of the ethos of peer support as it has developed as a profession [33,34]. The higher rate of attrition in the health coaching group compared to the other study arms may be at least in part explained by a misfit between the privacy preferences of a subset of participants and the demands of the health coaching intervention. However, it should be kept in mind that related research on other digital health apps for alcohol reduction has also shown very high attrition rates; Attwood et al's examination of the Drinkaware app for alcohol use reduction observed high attrition, with only 42.6% of users using the app after the first week and only 5% retained after 12 weeks [35]. The improvement in mental health–related quality of life among participants who stuck with health coaching seems to reinforce the idea that allowing people to customize their own intervention experiences may garner the best outcomes.

Limitations

We refer readers to a report of the primary quantitative analysis for a discussion of limitations of the parent trial [18]. The design of this qualitative study did not allow us to determine the exact nature of the relationship between fit and engagement for individuals in the primary quantitative analysis, but the data do suggest that the two are related. Participants for whom the Tula components to which they were assigned were a good fit were enthusiastic about them and appear to have been more engaged. Lower engagement users seem to have experienced more misfit.

Although the demographics of the interview participants were largely consistent with the overall Tula sample, individuals who agreed to participate in interviews might have differed from the larger sample in ways we did not measure. Our decision not to recruit participants who did not use the Tula components to which they were assigned means that the sample does not represent the group of participants with the lowest levels of engagement. However, the consistency of responses suggests that we did achieve informational redundancy and thus are able to represent the experience of participants who met our inclusion criteria. Because the overall sample for the trial was predominantly female, White, and highly educated, the findings reported here may not be generalizable to a more diverse population. Improvements in mental health–related quality of life may have been related to the personalized social support shown in the coaching group, although we do not have specific quantitative data to substantiate this claim. Finally, it could be that participants were interested in reducing the number of heavy drinking days, hence their participation in the study, and that the reduction seen was a result of their own personal motivations—not the app, peer support, or health coaching.

Future Directions

Further analysis of the specific intervention components that participants engaged with may help improve the intervention design in future research. The study found that different users have different preferences for intervention intensity. Dynamic adjustment of intervention intensity could feasibly be achieved in future intervention designs to meet individual needs by using sequential, multiple assignment randomized trial designs or microrandomized trial designs [36,37]. Future research should also explore the impact of comorbid factors common in patients with AUD (eg, depression, anxiety) on the fitness and effectiveness of mHealth interventions.

Conclusions

The results reported in this paper suggest that the concept of fit can go some way toward explaining the outcomes of the Tula trial and may provide insights into participant experiences of mHealth interventions in general. Using fit as a lens through which to examine these experiences provides insights that can be applied to iterative intervention improvement, which in turn will increase effectiveness and promote sustainment.

Acknowledgments

The authors would like to thank our community partners: Safe Community of Madison and Dane County and the UW Health Wellness Center. In particular, the authors want to recognize Tanya Kraege, Charlestine "Charlie" Daniel, Cheryl Wittke, and the peer support specialists who were integral to moderating and facilitating discussion forums with participants in this study. The authors also want to recognize Diane Scherschel, the Integrative Health and Wellness Manager at the UW Health Wellness Center, as well as Katie Eby and Ellen Houston, who provided health coaching to our participants on their journey toward a healthier lifestyle. This research was funded by the National Institute on Alcohol Abuse and Alcoholism (grant number R01-AA024150). The funder had no role in any aspect of the development, conduct, analysis, or reporting of the study.

Data Availability

The dataset containing deidentified data used to generate the results in this paper is available on request sent to corresponding author Dr. Andrew Quanbeck.

Authors' Contributions

NJ conceived the paper, led data collection and analysis, and drafted the paper. LSP contributed to the analysis and drafted the paper. AP and SV participated in data collection and analysis and contributed to the paper. MH drafted the paper and assisted with editing for submission. AQ led the Tula RCT and provided critical revisions to the manuscript. All authors read, reviewed, and approved of the final submission.

Conflicts of Interest

AQ has a shareholder interest in CHESS Health, a company that disseminates software technology to the addiction treatment field (CHESS Health did not develop the app tested in the manuscript) and consults on implementation of evidence-based health care interventions for the non-profit NIATx Foundation. These relationships are managed by the University of Wisconsin–Madison's Conflict of Interest Committee. All other authors have no conflicts of interest to disclose.

Abstract

Background: Timely and appropriate care is critical for patients with ST-elevation myocardial infarction (STEMI). Effective communication and prompt sharing of test results, particularly electrocardiograms (ECGs), between the referring emergency medicine (EM) physician or emergency medical service (EMS) paramedic and the interventional cardiologist (IC) are essential. This exchange relies on fax or SMS text messages. The SmartAMI-ACS (Strategic Management of Acute Reperfusion and Therapies in Acute Myocardial Infarction) App was developed to streamline communication. It is user friendly and privacy compliant, and enables rapid, secure ECG sharing to support faster, informed clinical decision-making.

Objective: This paper details the results of targeted preimplementation surveys to establish barriers and enablers of using a smartphone app to transmit ECG images among ICs, EM physicians, and EMS paramedics to help tailor implementation interventions.

Methods: To assess the proposed acceptability and uptake of the app, preimplementation surveys were disseminated to ICs, EM physicians, and EMS paramedics in one region of Ontario, Canada. Questions were generated based on selected components of the Consolidated Framework for Implementation Research, results from a pilot study carried out at a regional hospital where the SmartAMI-ACS app was previously implemented, and predicted barriers based on expert guidance. The preimplementation surveys consisted of 7-point Likert scale questions (1=strongly disagree and 7=strongly agree) and open-ended questions. Open-ended data were extracted verbatim and analyzed using an inductive qualitative approach, with transcripts coded into descriptive qualitative codes and then collapsed into themes.

Results: Survey uptake was acceptable, with 9 of the invited 10 ICs, 51 of the invited 223 EM physicians, and 93 of the invited 1138 EMS paramedics responding. All groups recognized that current practices for sharing ECGs allowed room for improvement, accepting that fax can be inconvenient and SMS text messages may not be secure. When asked whether there was a need for a smartphone app to transmit ECGs, ICs (mean 6.67, SD 0.5), EM physicians (mean 5.57, SD 1.3), and EMS paramedics (mean 5.79, SD 1.45) consistently agreed. Commonly reported barriers were concerns over technological challenges, privacy issues,

XSL•FO
RenderX

and cell phone reception strength. Through the identification of the barriers in each stakeholder group, implementation strategies were developed that facilitated the scale-up of this system-change intervention.

Conclusions: Results from the 3 web-based preimplementation surveys to identify key barriers and enablers to the implementation of the app helped inform the selection of tailored implementation strategies to support the rollout of the app across the health region. The surveys identified key barriers around technology, privacy, and access to required Wi-Fi that needed to be addressed during app implementation to facilitate uptake and use. Results from the surveys, and ongoing evaluation of effectiveness, are informing the expansion of the app intervention to local ambulance services and other health regions.

Introduction

Each year, approximately 7000 people in Ontario experience ST-elevation myocardial infarctions (STEMIs) requiring timely reperfusion of the affected area of the heart to restore blood flow through the coronary arteries [1]. Reperfusion can occur by a procedure called percutaneous coronary intervention (PCI) or with thrombolytic medications. When possible, PCI is preferable, and guidelines recommend that a patient presenting to a center that can perform PCI (PCI-capable center) should have this procedure performed within 90 minutes of the patient presenting to the hospital. Those who present to a non–PCI-capable center should be transferred to a center that can perform this procedure within 120 minutes [2]. However, among the 270 health care institutions in Ontario, only 20 centers have PCI capabilities on site [3]. Thus, achieving timely care can be challenging, particularly for patients who live in rural areas where access to a PCI-capable center is limited. Where on-site PCI is not available, patients must be transferred to a partner PCI-capable hospital. Patients receiving care above evidence-based best practice time thresholds show an increased risk of mortality, repeat myocardial infarction, congestive heart failure, and hospitalization [4-7].

STEMI is diagnosed based on an electrocardiogram (ECG), and care for patients with STEMI requires rapid coordination of several services, including emergency medical services (EMS), emergency medicine (EM) physicians and staff, interventional cardiologists (ICs), and the PCI laboratory staff. This can range across several centers and jurisdictions that rarely share electronic medical records. Previous research shows that efficient coordination of these services through timely communication leads to improved outcomes for patients with STEMI [2]. The current process for STEMI activation for many centers in Canada relies on a variety of technologies that are poorly integrated or inefficient. For example, STEMI activation at the Hamilton General Hospital, a high-volume quaternary cardiac care hospital in Ontario, Canada, used fax for ECG transmission, which is secure but slow, inconvenient, and sometimes unavailable. To improve communication and efficiency in this pathway, a quick, easy-to-use, privacy-compliant smartphone app (SmartAMI-ACS [Strategic Management of Acute Reperfusion and Therapies in Acute Myocardial Infarction]) was developed for rapid ECG sharing between health care providers, enabling timely decision-making.

The SmartAMI-ACS app has been pilot tested with ICs and select EM physicians since May 2020 for patients presenting to Niagara Health and requiring transfer to Hamilton General Hospital for primary PCI. Although preliminary data show promise [8], additional research is required to promote the technology more widely as an evidence-based innovation for care. Similar smartphone apps with capabilities of sending ECG images to ICs for decision-making have demonstrated outcome improvement in patients with STEMI and a reduction in decision time [9-13]. However, there is limited evidence on users' perspectives regarding the barriers and enablers to implementing an app that allows for the sharing of ECG images in the care of patients with STEMI, which may influence its acceptability and long-term use. To promote the app as the standard means to communicate ECGs in the setting of patients with STEMI beyond the pilot sites in the Niagara region, we sought to gather an understanding of the perceived usefulness and acceptability of the technology in routine practice from prospective app users across a wider region (ie, Southeastern Ontario) [14]. This paper details the findings from the preimplementation surveys, which will be used to assist with the potential scale-up and implementation of the app across other provincial STEMI systems in Ontario and beyond.

Methods

Study Design

The development and administration of the survey were led by a collaborative team consisting of medical professionals, public health researchers, and experts in implementation science. A multicenter cross-sectional study was conducted to assess the need, usefulness, and acceptability of the SmartAMI-ACS app in practice through the development and distribution of web-based surveys to key stakeholders, including ICs, EM physicians, and EMS paramedics who care for patients presenting with STEMI within the Hamilton General Hospital cardiac catheterization laboratory catchment area. The catchment area includes the Hamilton, Niagara, Haldimand, and Brant

XSL•FO
RenderX

regions, which cover an area of 6473 km^2 and a population of 1.8 million people [15,16]. Figure 1 illustrates the partner hospitals from which EM physicians were sent survey invitations, as well as a geographical map depicting the locations where sampled EMS paramedics respond to emergency calls. ICs were sampled from the primary PCI hospital indicated on the map as Hamilton Health Sciences.

Figure 1. Primary PCI hospital STEMI partnership map, adapted from the 2017 - 2018 Ontario Local Health Integration Network Annual Report [17]. PCI: percutaneous coronary intervention; STEMI: ST-elevation myocardial infarction.

Survey Development

In 2021, three surveys were developed and tailored for each stakeholder group (ICs, EM physicians, and EMS paramedics). These surveys were focused on gathering a better understanding of the barriers and facilitators that may impact the successful implementation of the SmartAMI-ACS app intervention on a larger scale (see Multimedia Appendices 1-3 for the surveys). Development of survey questions, analysis, and interpretation were guided by results from the Niagara Health pilot study, predicted barriers based on expert guidance from study team members (including implementation science researchers, ICs, EMS paramedics, and EM physicians) and the Consolidated Framework for Implementation Research (CFIR) [18]. The CFIR is a determinant framework, with a list of 39 constructs organized across 5 major domains, and provides a practical structure to identify multilevel factors that can impact implementation [19]. CFIR is a widely used framework in implementation science, with great breadth in its application across study design, objectives, settings, and outcome measures [20]. Through an iterative process involving input from research team members, questions were drafted and selected for inclusion in the surveys around the potential need for an app to transmit ECG images, the fit of an app into existing workflow processes, the potential for an app to improve patient care and reduce treatment times, and the overall comfort level of using an app in the treatment of suspected STEMI cases. The preimplementation surveys consisted of both 7-point Likert scale questions and open-ended questions. Likert scales were used to identify participant opinions on app implementation and usefulness. We applied a 7-point scale (1=strongly disagree and 7=strongly agree), as this has been shown to reach the upper limits of the scale's reliability, in comparison to a 5-point scale [21]. The surveys developed for each group are fully presented in Multimedia Appendices 1-3. Additional questions on the usage of the STEMI activation system (known locally as the Heart Investigation Unit Hotline) were included; however, results from those questions will not be reported in this paper.

Sample Population

Our study targets the health care providers who use the STEMI activation system for a quaternary care hospital to activate and respond to a STEMI. These include ICs, EM physicians, and EMS paramedics. All IC and EM physicians working at one of the referring centers (Figure 1).

Survey Distribution

The preimplementation surveys were hosted in REDCap (Research Electronic Data Capture; Vanderbilt University), and questionnaires were designed for anonymous completion. Senior

XSL•FO
RenderX

leaders of each survey group used a list of physician and EMS paramedic contact details provided by administrative distribution lists to develop the survey sampling frame. Senior leaders were asked to distribute a survey invitation by email to their staff, which included a summary of the evaluation project, a link to the survey, and details about consent; they were also encouraged to send out a reminder email to staff approximately 1 month after the initial invitation was sent.

Data Analysis

Quantitative data were analyzed using descriptive statistics of frequencies through Excel Microsoft 365, with continuous variables presented as means and SDs. Open-ended data were extracted verbatim and analyzed using an inductive qualitative approach, with transcripts coded into descriptive qualitative codes and then collapsed into themes using qualitative data analysis software (NVivo 12, QSR International). Initial coding was completed independently by 2 researchers (KJC and KM), and the development of themes was carried out collaboratively by 2 researchers (KJC and KM), with themes then validated by a third researcher (JC) to ensure rigor and enhance the trustworthiness of data analysis.

Ethical Considerations

Consent was obtained from participants through the use of a question at the beginning of each survey. As survey responses were anonymous, participants could not withdraw their data after submission; however, participants were notified that they could withdraw consent by exiting the survey without submitting any responses. There was no compensation provided for participation. This study was approved by the Hamilton Integrated Research Ethics Board (REB #7691). That approval did not include the ability to publish verbatim survey responses.

Results

Quantitative

Between the period of June and August 2021, senior leaders of each survey group sent out survey requests to physicians and EMS paramedic staff, with response rates varying among each of the stakeholder groups sampled. Of the 10 ICs at the Hamilton General Hospital, 9 (90%) completed the survey. Of the 223 invited EM physicians, 51 (22.9%) completed the survey, and 93 (8.2%) of the 1138 invited EMS paramedics completed the survey.

Of the 51 EM physicians, 49 (96%) reported that they currently submit ECGs to ICs. Nearly all (50/51, 98%) did so through SMS text messages, while 39% (20/51) also reported sending ECGs via fax. All 9 ICs indicated that they received ECGs via SMS text message, while 33% (3/9) reported receiving ECGs also via fax. EMS paramedics reported that they rarely submitted prehospital ECGs to ICs (7/93, 8%), and physical ECGs were typically exchanged in person at patient handoff.

Among all groups, there was recognition that current practices for sharing ECGs allowed room for improvement, accepting that fax can be inconvenient and SMS text messages are not secure. When asked whether there was a need for a smartphone app to transmit ECGs, ICs (mean 6.67, SD 0.50), EM physicians (mean 5.57, SD 1.30), and EMS paramedics (mean 5.79, SD 1.45) consistently agreed one was needed. Furthermore, among ICs, EM physicians, and EMS paramedics, use of the app was believed to fit well into existing workflow processes, with mean Likert responses of 6.67 (SD 0.50), 5.65 (SD 1.31), and 5.56 (SD 1.77), respectively. Staff also noted feeling comfortable with using an app for ECG transmission and review, with mean Likert responses of 6.44 (SD 0.88), 5.51 (SD 1.92), and 5.22 (SD 2.05) reported. Table 1 highlights viewpoints on the implementation of a smartphone app to transmit ECGs from each group.

Qualitative

Through inductive qualitative analysis, 24 codes were identified for ICs, 46 codes were identified for EM physicians, and 57 codes were identified for EMS paramedics (Table 2). The codes were grouped into four key themes, which housed both barriers and enablers to app implementation: (1) technological issues and constraints; (2) perceived capabilities, alternatives, and comparisons of the app; (3) attitudes and beliefs toward the app; and (4) impact on current workflow and requirements for implementation (Table 3). Table 4 demonstrates how the identified barriers were mapped to implementation strategies.

Commonly reported barriers to implementation were concerns over technological failures within the app. Given that STEMI activation is a medical emergency, there were concerns that app updates could be required during urgent scenarios, making the app unusable and thus affecting clinical care. EMS paramedic providers and physicians practicing at hospitals with unreliable internet signals also expressed concerns about their ability to reliably call and transmit ECGs using their smartphones. Another important barrier was the uncertainty about the proven risks and benefits of the app, as this is a new technology without extensive real-world data. Privacy and security of the tool to transmit personal health information was raised. There was concern that the app could take more time than the current clinical workflows, thus worsening the process of STEMI activation. Respondents also expressed a desire to follow up with referring or accepting physicians to discuss the case in the future, which is a feature not offered via the app.

Discussion

Principal Results

Responses from the preimplementation surveys addressed the objectives of this study, which sought to develop an understanding of the barriers and enablers to implementing an app that facilitates emergency cardiac communication. The primary use case is to securely transmit ECG images and enable telephone calls directly via the app in the case of suspected STEMI in a large health region in Ontario, Canada. Although previous studies have examined the diagnostic use of ECG image transmission via an app for STEMI care [11,22,23], this paper is the first to report on the barriers and enablers to implementing such an app from target users, allowing for tailored implementation strategies to be used in future to increase uptake. Overall, survey findings demonstrated agreement on the perceived need for an app and consensus that the app would fit well within existing workflow processes, reduce time to STEMI treatment, and reduce inappropriate activation of the on-call IC team. Commonly reported barriers were concerns over technological challenges, privacy issues, and cell phone reception strength.

While all 3 groups shared concerns over potential technological challenges, privacy issues, and cell phone reception strength, there were differences in the barriers and enablers reported by each group (Table 3). As the app was previously implemented in the IC group during the pilot phase in 2020, several of the barriers expressed by the EM physicians and EMS paramedics were not reported by the ICs. For example, the ICs were aware of app functionality and ECG image quality and so did not report these as a barrier to use. However, the majority of EM physicians and all EMS paramedics had no prior experience with using the app at the time of survey collection, and so responses illustrate apprehension of the unknown. Across each stakeholder group, common enablers were the expected speed of ECG image sharing and the associated timely access to that knowledge distribution. All groups reported comments that were both in favor and against app implementation. Given the rapid growth of smartphone technology in recent decades and its increasing adoption among consumers, it is unsurprising that survey responses reflected a high level of comfort with using an app to transmit ECG images. Furthermore, mobile health technology has the potential to enhance system efficiencies and streamline workflow processes, which may account for our

XSL•FO
RenderX

findings indicating both a recognized need for an app to transmit ECG images and its perceived compatibility with existing practices. From the barriers and enablers that were identified in the survey responses, select CFIR constructs were found to be represented more frequently than others (Table 3). Under the technological issues and constraints theme, CFIR constructs such as complexity and knowledge and beliefs about the intervention were commonly referenced. This indicated that the individual's personal perception on how difficult the app would be to use and their personal attitudes toward using the app for cases of suspected STEMI were going to be contributing factors to whether they took the necessary steps to download and use the app. In the perceived capabilities and comparisons theme, CFIR constructs of compatibility and relative advantage were frequently cited. Participants' willingness to use the app depended on whether they saw it as valuable, fulfilling a clinical need, and offering advantages over existing ECG transmission methods. In the attitudes and beliefs toward the intervention theme, there were no dominant CFIR constructs; however, responses indicated that participant perception on the evidence supporting the need for an app to transmit ECG images influenced whether they themselves would download and use it. Finally, in the impact on current workflow and requirements for implementation theme, complexity and relative advantage were again most commonly referenced, demonstrating that the perceived difficulty of incorporating the app into their current workflow processes and their perception on the benefits to using the app, would impact uptake. Our findings of the barriers identified in the survey responses, combined with our analysis of the most commonly cited CFIR constructs, facilitated the development of implementation strategies for app use and scale-up.

Results from the web-based surveys allowed for the application of stakeholder-specific implementation science interventions that supported the uptake of the app on a wider scale across the health region. For example, we obtained an understanding of the preferred mechanism of training on app use and applied appropriate education strategies, such as offering Zoom drop-in question and answer training sessions at accessible times during the day, to accommodate shift work hours. Furthermore, we cultivated relationships with opinion leaders (EM chiefs) and early adopters and sought advice from experts in implementation science research to maximize survey responses and increase uptake and use of the app. To address password recall concerns among ICs, biometric authentication was introduced to streamline log-in. Finally, key barriers related to concerns over technological challenges and privacy issues were addressed with the development and distribution of educational materials, such as user guides that highlighted multiple successful security tests from internal privacy, security, and information technology staff along with external third-party vendors. Table 4 illustrates the barriers by theme and the implementation strategies that were used to facilitate the uptake and use of the app.

This study focuses on a specific region in Ontario, Canada; however, the results can be generalized to other regions or countries where an app is being considered for inclusion in patient care by health care providers, as noted by the similarity of findings to published literature. A systematic review of barriers and facilitators to using digital health technologies representing North America, Europe, Asia, Africa, and Latin America highlighted infrastructure and technical barriers as well as privacy and security as commonly reported concerns by health care providers when using app-based technology [24]. As reported in our findings, concerns over insufficient network and connectivity speed were found, with a higher prevalence of these barriers being reported by those working in rural or remote regions. Furthermore, a published study on app use among nurses reported similar findings, highlighting perceived usefulness and ease of use as key factors influencing adoption [25]. The alignment of this study's findings with previously published research on barriers and enablers to app use by health care providers underscores the importance of engaging users before implementation, which can assist in developing targeted strategies to enhance the adoption and integration of new technology.

These findings are relevant to clinical practice improvements as they highlight the potential for mobile health technology to enhance communication in STEMI care and improve coordination among health care providers. By addressing identified barriers and leveraging enablers, the successful integration of an app for ECG transmission could improve the efficiency of STEMI activation, reduce unnecessary patient transfers, and ultimately enhance patient outcomes by minimizing delays in critical care. While emerging technology can allow for the integration of a machine learning model to enhance the ECG diagnosis of acute coronary occlusion, research testing the precision and sensitivity of such models combined the judgment of trained health professionals for ECG review [26]. The findings presented in this paper can support the integration of new technologies, including artificial intelligence–enabled apps, into acute STEMI care, as without understanding how to effectively implement and maintain an app in the acute management of STEMI, similar barriers are likely to hinder the successful adoption of artificial intelligence technologies in this setting.

Following this analysis of barriers and enablers to implementation, further research is needed to evaluate the impact of mobile health technology on the care of suspected STEMI cases. Specifically, it is important to assess whether addressing the identified barriers and leveraging enablers leads to successful implementation strategies that enhance app adoption and sustained use. Further analysis from this implementation will explore data on app uptake, usage, and effectiveness, with findings to be published in subsequent papers.

XSL•FO
RenderX

Table . Mapping barriers identified from survey responses to implementation strategies.

Theme	Barrier	Implementation strategy
Technological issues and constraints	• Potential to forget log-in credentials which could delay care • Privacy and security • Time needed to update app • Technology failure	• Biometric authentication (face/fingerprint ID) was enabled for ICs[a] to assist with faster log-in and to address concerns over password recollection • Targeted education messages were developed, which noted third-party security testing to relay privacy concerns • App updates automatically • In the app invitation email, users are encouraged to notify the study team should they have any issues with the app functionality or logging-in to the app
Perceived capabilities, alternatives, and comparisons of the app	• Follow-up capacity to referring physician • Usability across multiple platforms	• Referring physician required to call the STEMI[b] activation number through the app and speak to on-call IC, allowing for the opportunity to discuss patient care • User guide and app invitation email provide links to both the Apple App Store and the Google Play Store
Attitudes and beliefs toward the app	• Ease of use • Resistance to new system process • App believed to be unnecessary	• User guide contains images depicting app simplicity • Cultivated relationships with opinion leaders (EM[c] chiefs) and early adopters from the pilot study • With the support of EM chiefs, a newsletter was sent out to EM physicians that included important reminders about app use, a link to the education session recording, and a general update on app downloads across the region to demonstrate uptake by peers
Impact on current workflow and requirements for implementation	• Concerns about how app would fit into existing workflows • Asynchronous training	• Developed a user guide with clearly structured guidance and step-by-step instructions on how and when the app should be used • Hosted a collaborative web-based education session for EM physicians discussing the regional STEMI program and the app. A recording of the session was made available for asynchronous learning on a dedicated web page that also housed additional educational materials. In addition, scheduled web-based drop-in Q&A sessions at multiple time periods throughout the day during time of app launch, to accommodate shift work hours

[a]IC: interventional cardiologist.

[b]STEMI: ST-elevation myocardial infarction.

[c]EM: emergency medicine.

Limitations

As the surveys were distributed prior to the majority of EM physicians and EMS paramedics gaining access to the app, there was limited understanding of app features, capabilities, and usability among these 2 groups. This made it difficult for participants to answer certain questions and was reflected in survey responses that noted inadequate knowledge affected their ability to reliably answer some questions. Nonetheless, this provided valuable, unbiased responses to questions aimed at understanding the need for such a tool. Additionally, as links to the survey were shared directly by senior leaders of each stakeholder group, it was challenging for the research team to manage follow-up emails that may have improved survey

XSL•FO
RenderX

completion rates, as well as calculate accurate response rates. However, this was the preferred means of communication by the senior leaders to maintain anonymity, confidentiality, and avoiding coercion to respond to questionnaires. It is also possible that response rates were improved as participants were being directly asked to complete the survey by the chief or chair of their department. This study leveraged a convenience sampling strategy, which can introduce selection and sampling bias. As such, caution is necessary in the generalization of the results. Reassuringly, there was significant representation from each hospital and paramedic region with similar themes and responses for both the qualitative and quantitative questions.

Conclusions

The implementation of system-level interventions in health care can be affected by unexpected barriers, leading to poor uptake and acceptance. In order to circumvent the challenges of implementing change to an organization's culture, understanding the variables that influence or have an impact on the population's willingness to accept and adopt the change is critical. This study exemplifies the importance of identifying barriers faced by the target population and using that knowledge to create successful implementation strategies to optimize research interventions. Results from the preimplementation surveys disseminated to ICs, EM physicians, and EMS paramedics helped inform the strategies for the SmartAMI-ACS app implementation program in Hamilton and the surrounding region. They will be vital in informing active scaling of the app into additional areas throughout the province and local ambulance services.

Acknowledgments

We wish to thank the emergency medicine physicians and emergency medical service paramedic chiefs who assisted in distributing the survey invitation email. Their contribution made it possible to gather important insight into the barriers and facilitators to the implementation of the smartphone app technology. This study was funded through the Hamilton Academic Health Sciences Organization Innovation Fund received in 2021 - 2024 (HAH-21 - 015).

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request. All relevant data are included in this article.

Authors' Contributions

HM, MKN, JDS, and MM contributed to the design of the study. KJC, KM, and MC managed the ethics application, implementation, and evaluation of the app. KJC, KM, and JC contributed to the analysis of survey findings. All authors contributed to writing the manuscript and approved the final version.

Conflicts of Interest

HM is an inventor and sole owner of the background intellectual property of the smartphone app used in this study. There is no specific financial conflict of interest to declare as the tool is being used for research. However, it may be commercialized in the future. None of the other authors have a relevant conflict of interest to declare.

Abstract

Background: Anticoagulation management is important in preventing complications in patients undergoing cardiac valve replacement. The development of mobile apps offers new opportunities for the management of long-term anticoagulants. However, there is a lack of randomized controlled trials evaluating the effectiveness, safety, cost-effectiveness, and user demand for internet-based anticoagulation management.

Objective: This study aimed to evaluate the efficacy, safety, and cost-effectiveness of a 3-month warfarin dose adjustment mobile app Alfalfa compared to offline management in patients postcardiac valve replacement. We also explored the app's feasibility on user satisfaction and demand.

Methods: This study was a randomized controlled trial with assessments conducted at baseline and at a 3-month follow-up. Participants were eligible if they had been on warfarin therapy for at least 3 months, received warfarin management either through the Alfalfa app or through pharmacist-led anticoagulation outpatient clinic visits, consented to regular follow-ups, and had not experienced serious bleeding or thrombotic events in the 3 months before warfarin treatment. A *P* value of ≤.05 was considered statistically significant.

Results: A total of 405 participants were included in the analysis. The time in therapeutic range was significantly higher in the Alfalfa app group than in the offline group (66.46% vs 46.65%, *P*<.001). Participants in the Alfalfa app group had a higher monitoring frequency (8.14 vs 4.47, *P*<.001) and a greater percentage of international normalized ratio values within the target range (896/1660, 53.98% vs 346/899, 38.49%; *P*<.001) than those in the offline group. In addition, the Alfalfa app group exhibited lower rates of subtherapeutic (235/1660, 14.16% vs 152/899, 16.91%; *P*<.05) and extreme subtherapeutic international normalized ratio values (273/1660, 16.45% vs 186/899, 20.69%; *P*<.05) than the offline group. However, the incidence of minor bleeding was higher in the Alfalfa app group (12/204, 5.9% vs 3/201, 1.5%; *P*=.02). In terms of cost-effectiveness, the Alfalfa app group had a significantly lower average cost per test (42.37 vs 78.3, *P*<.001), average time per test (47.42 vs 90.74, *P*<.001), and cost-effectiveness ratio (385.9 vs 662.9) than the offline group. A total of 86 participants completed the satisfaction questionnaire, and the vast majority of participants expressed high levels of satisfaction with the Alfalfa App, while also providing further suggestions for improvement.

Conclusions: The integration of "Internet+Pharmacy Care" using the Alfalfa App can improve the effectiveness of warfarin anticoagulation management in patients following heart valve surgery. The Alfalfa app provides a more efficient, secure, and cost-effective solution to warfarin management than traditional offline methods.

smartphone; mobile phone; alfalfa app; warfarin; anticoagulation; internet + pharmacy care

Introduction

Valvular heart disease is one of the most prevalent cardiac conditions in China. According to 2019 extracorporeal circulation statistics, the number of heart valve surgeries continues to rise, with approximately 73,000 procedures performed annually, accounting for nearly 30% of all cardiac surgeries [1,2]. The primary treatment modalities for valvular heart disease include artificial valve replacement and valve repair surgery, both of which require long-term oral anticoagulant therapy postoperatively. Warfarin, a traditional oral anticoagulant, which widely used in clinical practice, remains the primary medication for reducing the risk of thrombosis and stroke after heart valve replacement surgery [3-5]. Patients undergoing biological valve replacement typically require 3 to 6 months of oral warfarin therapy, while those with mechanical valves need lifelong anticoagulation. Managing warfarin therapy poses challenges due to its narrow therapeutic range, interactions with food and drugs, and significant interindividual variability in dosage requirements. These challenges have been observed both domestically and internationally [6-8].

In recent years, anticoagulation clinics and home-based follow-up management models have been established in various countries. In developed regions of China, pharmaceutical services led by pharmacists in hospitals have moderately enhanced the effectiveness of anticoagulation treatment. However, both globally and in China, issues persist regarding the low efficiency and high use of human and material resources in postoperative anticoagulation management for patients with valve disease [6,9]. Many patients receiving oral anticoagulation therapy reside in rural areas where access to quality medical resources is limited. Even urban patients often face constraints such as doctor-to-patient ratios and limited consultation time. Outpatient physicians always struggle to provide comprehensive medication guidance and follow-up for every oral anticoagulation therapy patient, which can negatively impact the long-term treatment outcomes for these individuals [10,11].

With the development of information technology, countries worldwide are actively exploring personalized, intelligent and efficient eHealth tools based on their own anticoagulation management models. Some guidelines emphasize the potential of eHealth tools in improving anticoagulation management and medical outcomes [12]. The use of these eHealth tools to assist physicians with anticoagulation decision-making is recommended [13]. In April 2018, the General Office of the State Council of China issued the “Opinions on Promoting the Development of “Internet+Healthcare,” which clearly supports medical institutions in providing telemedicine services and promoting effective communication between doctors and patients.

In 2020, our research team developed an app called Alfalfa for warfarin dose adjustment [14], which has demonstrated significant advantages compared with other eHealth tools in China [15]. Through the app, patients can report coagulation results and health status to their doctors or pharmacists through mobile devices. Medication is then adjusted based on the recommendations, and international normalized ratio (INR) values are monitored accordingly [14]. Our previous retrospective observational cohort study explored the safety and efficacy of warfarin anticoagulation management through the Alfalfa App. The study confirmed that patients who use the app to manage experienced improved anticoagulation quality, reduced major bleeding events, and lower emergency and hospitalization rates compared with those receiving traditional offline management. This model has been demonstrated to be particularly suitable for patients in rural and remote areas [15].

Based on the previous study and the “Internet+pharmaceutical service” model we established, we further designed this prospective randomized controlled study in the Yunnan region of western China. The aim is to further investigate the safety, effectiveness, and cost-efficiency of the Alfalfa app in managing warfarin anticoagulation in patients with valvular disease and to better understand the app’s usage requirements.

Methods

Study Design

This study was a single-center randomized control trial (trial registration: ChiCTR1900021920) with assessments conducted at baseline and post intervention (3 months). Participants randomized to the intervention group received anticoagulation management through the Alfalfa App (“Internet+pharmacy care”), while the control group received offline management at a pharmacist-led anticoagulation clinic. Both groups were followed up for 3 months.

Sample Size

The primary outcome indicator, time in therapeutic range (TTR), was used to calculate the required sample size. Our previous research suggested that TTR for the web-based and offline groups was 73% and 60%, respectively [7]. With a power of 80% and a significance level of .05, 1:1 ration of test and control groups, a minimum of 201 patients per group is required, calculated using PASS 27 software. Assuming 10% dropout rate, each group needed at least 223 patients, for a total of 446 patients.

Recruitment and Selection

Participants were recruited from Fuwai Yunnan Cardiovascular Hospital. Patients diagnosed with valvular heart disease, who underwent valve surgery at the hospital received warfarin education from clinical pharmacists before discharge. After training, a validated questionnaire [16] was used to assess the patient’s understanding of warfarin management. If patients missed a question, they would be retrained and answered until all the questions were answered correctly. These patients were eligible for the study if they had been on warfarin treatment for at least 3 months, received warfarin management through either the Alfalfa app or pharmacist-led outpatient clinic visits, agreed

XSL•FO
RenderX

to regular follow-up, had no serious bleeding or thrombotic events in the 3 months before warfarin treatment. The exclusion criteria included pregnancy, switching to another anticoagulant during the study period, and having 3 or fewer INR records during the follow-up period. After obtaining informed consent and completing the baseline questionnaire, participants were randomized into either the web-based group or offline group.

Randomization and Blinding

Participants were randomized using a Microsoft Excel–generated randomization list in a 1:1 ratio. After participants completed baseline assessments, a research team member (unblinded) assigned participants to a group based on the randomization list. Due to the nature of the intervention, the study was open labeled and blinding was not feasible.

Web-Based Group (Intervention Group）

After randomization, participants in the web-based group were instructed through WeChat (Tencent) to download and install the Alfalfa app on their smartphones. Detailed instructions on app usage were provided. The Alfalfa app (Alfalfa Health Management) was used for remote warfarin management in the web-based group; a detailed description of the app has been published earlier [14,15]. Patients selected a pharmacist within the app who would manage their warfarin dosage. The chosen pharmacist reviewed INR results uploaded by the patient and provided recommendations on dosage adjustments and the timing of subsequent INR tests. The coagulation management team consist of 4 cardiologists and clinical pharmacists specializing in anticoagulation from Yunnan Cardiovascular Hospital. A senior clinical pharmacist responded to patient queries within 30 minutes of receiving uploads.

Offline Group (Control Group)

Participants in the offline group were instructed to visit the pharmacist's office for periodic INR testing. Warfarin dosage adjustments were supervised by the same senior clinical pharmacist who managed the web-based group.

INR Testing and Warfarin Dose Adjustment

All participants adjusted their warfarin dosage as needed and underwent periodic INR testing throughout the study. Participants in the web-based group could test INR at nearby hospitals and receive adjustment suggestions from clinical pharmacists through the app. Patients in the offline group were required to visit the hospital's anticoagulation clinic. Warfarin dose adjustment protocols were standardized by the coagulation management team. Monitoring was conducted weekly during the first 2 weeks of therapy and then every 2-4 weeks. The target INR range was 1.7 - 2.5 for patients with valve replacement.

Measures and Incentives

All participants received free pharmaceutical care and advice during the study period. Offline group participants were exempted from consultation fees in the anticoagulation pharmacy clinic during the study period. After the study, offline group participants were recommended to use the Alfalfa app. Registration and use of the Alfalfa app remained free for participants during and after the study. And the app also provided a free "anticoagulation circle" for patients to access educational resources of anticoagulation treatment and communicate with one another.

Primary Outcome

The primary outcome was the percentage of TTR, calculated using the standard linear interpolation method [17]. TTR is a widely recognized measure of anticoagulant control quality, with TTR ≥60% indicating high-quality anticoagulation and TTR <60% indicating low-quality anticoagulation [18,19].

Secondary Outcomes

Monitoring Frequency and INR Value Distribution

Monitoring frequency and INR distribution were assessed to evaluate compliance rates. According to the patient's target range, INR values were categorized into 5 levels referring to previous studies [20,21]: extreme subtherapeutic, subtherapeutic, therapeutic, supratherapeutic, and extreme supratherapeutic. Definitions of these categories are provided in the Multimedia Appendix 1. Patients with multiple anticoagulation indications were assigned the highest INR target based on their conditions.

Clinical Events

The incidences of clinical events were used to evaluate safety differences between the 2 groups, including bleeding events, thrombotic events, and other related incidents. Bleeding events were classified as either minor or major bleeding events according to the International Society on Thrombosis and Haemostasis (ISTH) criteria. Minor bleeding events included epistaxis, gingival or oral bleeding, skin ecchymosis, fundus bleeding, increased or prolonged menstruation, hematuria and other bleeding symptoms that could be quickly stopped. Major bleeding events were defined as any bleeding requiring hospitalization or blood transfusion, including gastrointestinal bleeding and intracranial hemorrhage [22]. Thrombotic events included transient ischemic attack, ischemic strokes, venous thromboembolism and valve thrombosis. Other clinical events included warfarin-related emergency department visits and hospitalizations.

Costs

We conducted a cost analysis for both groups to demonstrate the economic differences observed during the follow-up period. The cost-effectiveness analysis was used to identify the most optimal solution. Economic indicators included the average cost per test, total cost per capita, average time per test, overall total cost, and the cost-effectiveness ratio. The average cost per test was defined as the mean expense per test per patient, including transportation costs. The total cost per capita referred to the average expense for all tests over a 3-month period per patient, also including transportation costs. The average time per test indicated the mean time required for 1 test per patient. The cost-effectiveness ratio was calculated as the ratio of total costs to efficiency, with costs including direct expenses such as INR testing fees and transportation expenses. A patient with TTR ≥60% was considered to have achieved an effective outcome. A lower cost-effectiveness ratio suggests that the intervention is more cost-efficient, indicating a more favorable and rational solution. All currency conversions in this paper are based on the exchange rate as of December 31, 2021.

Feasibility

Feasibility measures included acceptability and demand. Acceptability was measured through a satisfaction survey administered post intervention. A questionnaire designed by our previous study [23,24] was distributed to participants through WeChat in the form of a link to assess patient satisfaction and further demand for the Alfalfa app. Since the Alfalfa App did not support real-time one-on-one chats, we distributed survey links twice daily for 1 week in a WeChat group that included all participants. Completion of the surveys was voluntary, and each participant was allowed to submit only once (Multimedia Appendix 2). The surveys were distributed to all participants who had been using the Alfalfa App for at least 3 months (not limited to the web-based group). The percentage of responses for each question was calculated once the questionnaires were returned.

Data Collection

Basic information, including demographic characteristics of all participants, was collected from electronic medical records. The data automatically recorded in the Alfalfa app included duration of anticoagulation, target INR range, INR values and warfarin doses at each report, bleeding events, thromboembolic events, emergency department visits, hospitalizations, disease state, concurrent medications, and dietary habits. Information provided by clinical pharmacists, such as adjusted warfarin dosage, timing for subsequent INR tests, and recommendations on diet and exercise, was automatically collected in the Alfalfa app. Data from the offline warfarin management service, as well as costs for all participants, were collected from electronic medical records and telephone follow-ups.

Statistical Analyses

Data were analyzed using Excel 2010 and SPSS (version 17.0, IBM Corp) statistical software. Different statistical methods were applied depending on the variable type results. An independent 2-sample, 2-tailed *t* test was used for statistical analysis of continuous variables, such as age, TTR, and costs. A chi-square test or Fisher exact test was used for categorical variables, such as sex, conditions, diseases, target INR, efficacy outcomes, adverse events, and INR results. Continuous variables are presented as mean (SD), while categorical variables are reported as frequency (percentage). Statistical significance was set at $P<.05$.

Ethical Considerations

This study complied with the Declaration of Helsinki and was approved by the Ethics Committee of Fuwai Yunnan Cardiovascular Hospital, Kunming, Yunnan, China (Ethics No. 2020-010-01). It was also registered with the Chinese Clinical Trial Registry (ChiCTR1900021920). All participants provided written informed consent before the study and signed an electronic informed consent form again upon registering for the Alfalfa App. Participants were allowed to withdraw from the study at any time during the research process. All medical records and test reports of the participants were stored in the hospital where they received care, and personal privacy information was strictly protected. No additional compensation was provided to the patients for participating in this study; however, some free services were offered during the research period (see the *Measures and Incentives* subsection). The datasets generated or analyzed during the study are available from the corresponding author upon reasonable request.

Results

Participant Enrollment

Between January 2020 and December 2021, a total of 457 patients from Fuwai Yunnan Cardiovascular Hospital were recruited for eligibility assessment, and 450 were enrolled in the study. Of these, 225 participants were randomized to the web-based group and 225 to the offline group. Participants were excluded if they completed registration but did not submit INR records (n=5), did not visit the pharmacist clinic (n=8), provided incorrect medication information (n=7), were pregnant (n=2), switched to another anticoagulant (n=3), or had fewer than 3 follow-up visits or INR records (n=20). This resulted in a total of 405 participants included in the final analysis (Figure 1). There were no missing data among these participants, and baseline characteristics were comparable across study groups (Table 1).

[a]INR: international normalized ratio.

Primary Outcomes (TTR)

Table 2 shows that the mean TTR was significantly higher in the web-based group compared with the offline group (66.46% vs 46.65%, *P*<.001). In addition, the percentage of INR values within the therapeutic range was higher in the web-based group compared with the offline group (124/204, 60.78% vs 67/201, 33.33%; *P*<.001; Table 2).

Table . Percentage of time in therapeutic range per study group.

Variable	Web-based (n=204)	Offline (n=201)	*P* value
TTR[a] (%), mean (SD)	66.46 (25.22)	46.65 (39.13)	<.001
Control ratio, n (%)			<.001
TTR≥60%	124 (60.78)	67 (33.33)	
TTR<60%	80 (39.22)	134 (66.67)	

[a]TTR: time in therapeutic range.

Secondary Outcomes

Monitoring Frequency and INR Value Distribution

The Alfalfa app group had a higher monitoring frequency compared to the offline group (8.14 vs 4.47, *P*<.001) and a greater percentage of INR values within the therapeutic range (896/1660, 53.98% vs 346/899, 38.49%; *P*<.001). Participants managed through the Alfalfa app also had lower rates of subtherapeutic INR values (235/1660, 14.16% vs 152/899, 16.91%; *P*<.05), and extreme subtherapeutic INR values (273/1660, 16.45% vs 186/899, 20.69%; *P*<.05) compared with those managed by offline services. The incidence of supratherapeutic and extreme supratherapeutic INR values was similar between the 2 groups (Table 3).

XSL•FO
RenderX

Table . Monitoring frequency and distribution of international normalized ratio values.

Variable	Web-based (n=204/1660)	Offline (n=201/899)	*P* value
Monitoring frequency (times), mean (SD)	8.14 (4.75)	4.47 (3.84)	<.001
Extreme subtherapeutic, n (%)	273 (16.45)	186 (20.69)	.003
Subtherapeutic, n (%)	235 (14.16)	152 (16.91)	.02
Therapeutic, n (%)	896 (53.98）	346 (38.49)	<.001
Supratherapeutic, n (%)	251 (15.12)	204 (22.69)	.11
Extreme supratherapeutic, n (%)	5 (0.3)	10 (1.11)	.25

Clinical Events

The incidence of minor bleeding events vs was higher in the Alfalfa app group compared with the offline management group (12/204, 5.9% vs 3/201, 1.5%; *P*=.02). However, there were no significant differences between the groups in major bleeding events (3/204, 1.5% vs 1/201, 0.5% *P*=.63), thromboembolic events (1/204, 0.5% vs 0/201, 0%; *P*=.99), warfarin-related emergency department visits (1/204, 0.5% vs 2/201, 1.0%; *P*=.99) or warfarin-related hospital admissions (3/204, 1.5% vs 2/201, 1.0%; *P*=.99; Table 4).

Table . The incidences of clinical events.

Variable	Web-based (n=204)	Offline (n=201)	*P* value
Minor bleeding, n (%)	12 (5.9)	3 (1.5)	.02
Major bleeding, n (%)	3 (1.5)	1 (0.5)	.63
Thromboembolic, n (%)	1 (0.5)	0 (0)	.99
Warfarin-related emergency department visits, n (%)	1 (0.5)	2 (1)	.99
Warfarin-related hospital admissions, n (%)	3 (1.5)	2 (1)	.99

Costs

The *t* test revealed that the average cost per test (42.37 vs 78.3, *P*<.001) and the average time per test (47.42 vs 90.74, *P*<.001) were significantly lower for the web-based group compared with the offline group. While the total cost per capita was similar between the 2 groups (234.55 vs 220.98, *P*=.58), the cost-effectiveness ratio was lower for the web-based group (385.9 vs 662.9; Table 5).

Table . Economic differences.

Variable	Web-based (n=204)	Offline (n=201)	*P* value
Average cost per test, mean (SD)	42.37 (31.6)	78.3 (77.91)	<.001
Total cost per capita, mean (SD)	234.55 (270.25)	220.98 (224.74)	.58
Average time per test, mean (SD)	47.42 (41.01)	90.74 (74.57)	<.001
Total cost	¥47848.7 (US $7502.68)	¥44417.6 (US $6964.68)	—[a]
Effective, n (%)	124 (60.8)	67 (33.3)	—
Cost-effect ratio (C/E; as in Table 1)[b]	385.9	662.9	—

[a]Not applicable.

[b]C/E: total cost/effective value.

Acceptability and Demand

After 1 week of distributing and reminding participants to complete the survey links, a total of 86 voluntarily completed questionnaires were collected. Of these, 59.3% (51/86) had used the Alfalfa app for over a year, and 77.9% (67/86) preferred to stay in contact with their doctor through the app. The vast majority (83/86, 96.5%) found the app convenient, noting the ability to receive timely responses from doctors without needing to visit the hospital and to view all their report records within the app. Approximately 80% (69/86) of the patients expressed positive experiences with the doctor's responses (82/86, 95.3%), the completeness of records (75/86, 87.2%), and the free services (69/86, 80.2%).

XSL•FO
RenderX

All participants were satisfied with warfarin dose adjustment (100%, 86/86), timely responses from doctors (86/86, 100%), the report submission process (78/86, 90.7%), and the history records functions in the app (85/86, 98.8%). Nearly half of the respondents (42/86, 48.8%) indicated they would be willing to pay a fee ranging from ¥3 (US $0.4704) to ¥10 (US $1.568) for the app's services. A large majority (77/86, 89.5%) expressed a preference for services provided by experts with senior professional titles. A few participants (10/86, 11.6%) suggested improvements, such as simplifying the app's operation, adding a feature for video interactions with doctors (3/86, 3.49%), and establishing a more comprehensive medical history record function (1/86, 1.16%; Multimedia Appendix 2).

Discussion

Principal Findings

The main goal of this study was to evaluate the efficacy, safety, and economic impact of using the Alfalfa app, a smartphone app designed for dose consultation and adjustment in patients undergoing long-term anticoagulation therapy with warfarin. TTR was selected as the primary outcome, with a TTR of 60% or higher generally considered indicative of high-quality anticoagulant therapy [25]. In our study, TTR was significantly higher in the Alfalfa app group compared with the offline group (66.46% vs 46.65%, $P<.001$). While a study by Lee et al [26] reported contrary findings, our results align with the majority of telemedicine-based anticoagulation studies, which show improved TTR outcomes compared with traditional management methods [27-32]. Previous cohort studies in Eastern China also supported the efficacy of the Alfalfa App, reporting significantly higher TTRs in their intervention groups (61% and 79.35%, respectively) [15,33]. Our findings further confirmed the effectiveness of Alfalfa App in improving the quality of anticoagulation management.

Our research also demonstrated that participants in the web-based group had a significantly higher frequency of INR monitoring compared with those in the offline group (8.14 vs 4.47, $P<.001$). This indicates that the Alfalfa App facilitated better interaction between patients and health care providers, enabling participants to easily upload their INR records and receive timely feedback from clinical pharmacists. In addition, the app's supervision and tracking features likely contributed to the regular monitoring observed. These findings are consistent with 2 other retrospective cohort studies, which also reported higher rates of therapeutic INR values in the web-based group [15,33]. However, compared with the other 2 retrospective studies, there was no consistent pattern in the distribution of extreme subtherapeutic, subtherapeutic, supratherapeutic, and extreme supratherapeutic INR values between the groups. The result indicates that the web-based management model helps improve the percentage of INR values within the therapeutic range (indirectly equivalent to TTR), but when the INR values fall outside the therapeutic range, they do not necessarily tend to be too high or too low. This suggests that there may be no direct association between INR value distribution and anticoagulation management methods, indicating a need for further exploration with larger sample sizes.

Our research also revealed the higher incidence of minor bleeding events in the Alfalfa app group, consistent with the results reported in a similar cohort study [15]. According to a meta-analysis of 12 randomized controlled trials, telemedicine combined with portable coagulometers significantly improved TTR and reduced the incidence of thrombotic events in cardiovascular patients [34]. However, several studies reported no statistically significant difference ($P>.05$) in bleeding or thrombotic events between the eHealth tools group and the conventional management groups [28,30,35]. eHealth tools can be broadly categorized into 4 types, namely computer-based support systems, electronic health records, telemedicine platforms, and mobile apps. Among these, mobile apps offer the greatest convenience, allowing patients to communicate with doctors or pharmacists at any time [36]. This may explain the higher detection rate of minor bleeding events in the Alfalfa app group, as patients were more likely to report symptoms to clinical pharmacists through the app in time, especially during the period of COVID-19 pandemic, when patients were less willing to go out for medical treatment. This made minor bleeding in the web-based group of the study easier to detect. The pandemic also limited our ability to fully assess clinical event outcomes due to the reduced sample size and limited participant enrollment.

Our findings also suggest that the Alfalfa App may reduce the cost per visit for anticoagulation management and save participants time in return visits. The convenience of using the app led to higher adherence to follow-up visits in the web-based group, resulting in a greater number of return visits per capita during the follow-up period. Although we did not calculate the incremental cost-effectiveness ratio due to a lack of authoritative data, the cost-effectiveness value suggests a positive economic outlook for the Alfalfa App. It should be noted that patients in both the web-based and offline groups were exempt from registration fees. If web-based services were to be charged, combined with the increased number of follow-up visits, this could potentially offset the cost savings from not visiting the hospital, and the overall expenses might even be higher [37], and more research is needed to explore the full economic impact of the app.

Two studies revealed that most patients were satisfied with the use of eHealth tools, which also improved their quality of life [38,39]. Consistent with these findings, our survey results of the experience and satisfaction with pharmaceutical care and Alfalfa App also showed that the vast majority of patients were highly satisfied with the dose adjustment, timely responses, and free service provided. The timeliness and convenience of the Alfalfa App were particularly appreciated. However, a small number of participants complained the app difficult to use. During the follow-up, 5 participants discontinued to submit their results, resulting in withdrawals. This suggests that both the app and anticoagulant management services have areas for improvement. With the advancements of machine learning, the integration of deep learning, reinforcement learning, and ensemble learning in warfarin management after heart valve surgery is becoming more prevalent [40]. Internet+pharmacy care through app has the potential to enhance efficiency, reduce time and economic costs, and improve the quality of medical

XSL•FO
RenderX

care, especially by reducing the disparities among primary care providers.

Limitations

Although our study demonstrates promising results regarding the efficacy of internet+pharmacy care through Alfalfa Appin improving anticoagulant quality among patients following heart valve surgery, several limitations must be acknowledged. First, because the study's enrollment period overlapped with the COVID-19 lockdown, patients reduced their hospital visits. The significant decline in hospital patient flow from 2020 to 2022 confirms this trend. As a result, the study's sample size was limited, preventing us from conducting subgroup analyses. Second, this was a single-center study conducted in southwestern China, which may limit the generalizability of the findings to other populations. Further prospective, randomized, multicenter studies are needed to confirm these results.

We estimated a sample size of 446, assuming a low dropout rate of 10%. By the end of the study, 405 participants were included in the analysis, and the actual dropout rate was within expectations. With strong effect sizes, we maintained adequate statistical power. However, due to limitations with the Alfalfa App, we were unable to send private information to participants, which prevented us from distributing the satisfaction questionnaire individually. As a result, only 86 questionnaires were collected. In the future, we aim to address this limitation to enhance the completeness of research data.

Conclusions

In conclusion, the "Internet+Pharmacy Care" model through the Alfalfa App can improve the quality of warfarin anticoagulation in patients after heart valve surgery. Compared with traditional outpatient service, web-based management does not increase the risk of major bleeding, embolism, or hospitalization events, and is both economical and cost-effective. Looking forward, we anticipate that machine learning and artificial intelligence will bring new opportunities for innovation in anticoagulation management. Future studies with larger sample sizes, multicenter designs, and long-term follow-up are needed to further validate the role of these technologies.

Abstract

Background: Nearly one-third of adults in the United States will meet criteria for alcohol use disorder in their lifetime, yet fewer than 10% of individuals who meet for alcohol use disorder criteria will receive treatment for it. Mobile health (mHealth) applications (apps) have been suggested as a potential mechanism for closing this treatment gap, yet there is a wide variety of quality and integrity within these apps, leading to potential harms to users.

Objectives: The aim of this paper is to systematically record and qualitatively examine user reviews or mHealth apps to identify features in the existing apps that may impact usefulness and adoption of them.

Methods: The researchers used Apple App and Google Play stores to identify mHealth apps that were focused on modifying alcohol use and treating common comorbidities. Apps that were free without in-app purchases and provided multiple features for users were included. User reviews from the apps were downloaded and coded using content analysis.

Results: A total of 425 unique apps were found in our search. Of these, the majority of apps (n=301) were excluded from the present analyses for not focusing on reducing alcohol-related concerns (eg, many apps were for purchasing alcohol). Eight apps were identified and had user reviews downloaded. The apps examined in this study were VetChange, SMART, DrinkCoach, SayingWhen, AlcoStat, Celebrate Recovery, TryDry, and Construction Industry Helpline. A total of 370 reviews were downloaded and 1353 phrases were coded from those reviews into a total of 11 codes. The 5 most common themes identified were praise (498 counts coded; 36.831%), tools (150 counts coded; 11.062%), suggestions for improvement (118 counts coded; 8.756%), criticism (105 counts coded; 7.768%), and tracking (104 counts coded; 7.724%).

Conclusions: The current findings suggest that alcohol mobile app users broadly found the apps helpful in reducing their drinking or meeting their drinking goals. Users were able to identify features that they liked or found helpful in the apps, as well as provide concrete feedback about features that they would like included or improved. Specifically, flexible and expansive tracking features and comprehensive whole health tools were cited as valuable and desired. App developers and those looking to expand access to and uptake of alcohol reduction apps may find these user reviews helpful in guiding their app development.

Introduction

It has recently been estimated that a third of US adults engage in risky alcohol use and just under a third of US adults (29%) will meet criteria for alcohol use disorder (AUD) in their lifetime [1]. Moreover, only 7.9% (2.3 million people aged 12 years and older) of individuals who met criteria for AUD in the United States received any kind of formal treatment [2]. Common reasons for not engaging in treatment include the fear of stigma or privacy concerns and lack of access to in-person resources [3]. Further complicating treatment utilization is the fact that individuals with AUD have a higher prevalence of other co-occurring mental health conditions than individuals with nonsubstance use disorder diagnoses [4]. Rates of co-occurring anxiety, depression, posttraumatic stress disorder (PTSD), or attention-deficit/hyperactivity disorder (ADHD) have been found to be particularly high among individuals diagnosed with AUD [5]. For these individuals with co-occurring diagnoses, formal treatment is often restricted to providers qualified to treat those co-occurring diagnoses simultaneously or to health care systems that are capable of providing coordinated care [4]. Unsurprisingly, having co-occurring AUD and other mental health diagnoses is often associated with poorer treatment outcomes [6].

Mobile apps and other mobile health (mHealth) interventions have been proposed as one potential solution to help overcome many of the current barriers for receiving help with one's

XSL•FO
RenderX

relationship to alcohol [7]. First, mHealth interventions are highly accessible, given that at least 85% of all US adults report owning a smartphone, including members of historically underserved communities [8]. Second, mHealth interventions are also ready 24/7 and available for brief, impromptu interactions compared with scheduled appointments during business hours associated with traditional in-person treatment. Accordingly, mHealth interventions hold promise to overcome access barriers traditional treatments face: geographic and provider restrictions [7].

While some critics argue that mHealth interventions are limited in that clients will not feel connected to a mobile app the same way they would to an in-person provider, some research has shown that clients can develop a therapeutic alliance with their mHealth tools [9,10]. Furthermore, mHealth interventions have been touted as particularly well suited to reduce stigma-related barriers compared with in-person treatments where individuals have to attend treatment visits or clinics where they must interact with others who may judge or stigmatize them [7]. Finally, mHealth interventions allow clients to have levels of autonomy, flexibility, personalization, and depth that is often unparalleled in traditional individual or group treatments [7]. For example, mHealth interventions are often designed with tools and resources sections of the intervention that clients may navigate at their own pace and based on their own individual interests and needs. Instead of having to navigate complex health care systems or potentially inaccurate or unreliable web-based resources, mHealth interventions can be programmed to contain reliable and accurate information that may be relevant for some clients (eg, psychoeducation about PTSD symptoms and PTSD symptom monitoring contained on the National Center for PTSD's VetChange mobile app for alcohol use).

Several mobile apps have been developed to target alcohol use concerns, yet the quality and integrity of those apps are highly varied. For instance, many alcohol-focused apps are created commercially with limited oversight from government and scientific communities. A recent review highlighted the myriad potential harms of unregulated health-focused apps, including apps that are falsely advertised as "safety apps" but instead "promote binge drinking" [11]. Even apps that are not designed for-profit or that do not contain overtly harmful content are potentially harmful due to the lack of oversight and regulation since they may not be evidence-based and may, therefore, fail to work as desired. Not only do these apps potentially harm users by taking their time to no positive outcome but may also cause secondary harms by making app users feel that there is no help possible for them. As pointed out by Businelle and colleagues [7], "nearly all of the mHealth interventions that are available for download today have not been evaluated for efficacy or effectiveness. Thus, individuals are downloading interventions that may not be effective for addressing their problems, which could delay or discourage the use of future well-studied and effective interventions" [7]. Moreover, recent studies suggest that the utilization of existing mobile apps remains low; yet when apps are used, there is a positive association between user engagement and intervention effectiveness [7]. Accordingly, there is a critical need to evaluate which mobile apps may be evidence-based and which apps are well used in order to inform the public about which apps may be most helpful. One such strategy to accomplish this goal is to examine user reviews of existing apps since user ratings in digital marketplaces have been found to influence app quality and, therefore, impact the usage of that app [7]. Information from these publicly available app user reviews may be used to inform app refinement without associated costs of User Experience (UX) or other User-Centered Design research projects. Therefore, the aim of this paper was to systematically review freely available alcohol mobile apps, identify potentially evidence-based options, and conduct qualitative analyses of user reviews to identify features of existing apps that may impact use and helpfulness of mHealth interventions for alcohol use.

Methods

Ethical Considerations

All data used in this study were publicly available as posted by users themselves on Apple App and Google Play app stores. Accordingly, it is within the institutional review board's policies for the authors' home institution to consider this research exempt from institutional review board review. Moreover, all data presented in this study were analyzed without usernames and findings herein are presented in aggregate. Where specific quotes are used as examples of thematic codes, no identifying information was included.

Data Selection Procedures

Both authors for this study have prior qualitative data analytic experience and met at the beginning of the study to discuss procedures for this study aims in February 2024. The first step in achieving the proposed study aims was to identify apps that were potentially evidence-based. The authors searched in the Google Play and Apple App Stores for mHealth apps focused on alcohol. Given the high degree of comorbidity of AUD with other mental health diagnoses, and the stigma associated with AUD specifically, app search terms were extended beyond alcohol alone. Five search terms were used in Google Play and the Apple App Stores: "alcohol," "alcohol and depression," "alcohol and anxiety," "alcohol and PTSD," and "alcohol and ADHD." Depression, anxiety, PTSD, and ADHD were selected since those are the mental health diagnoses with the highest prevalence of comorbidity with alcohol [5]. The authors independently reviewed their results to exclude duplicates and restricted the results to apps that were available for free, without in-app purchases, to prevent potentially harmful, for-profit corporate apps from being included in final analyses. Next, authors proposed to exclude apps that were solely for single purposes, such as blood alcohol concentration calculating apps, and any disagreements were resolved through mutual discussion and reaching consensus. Finally, since the current authors are fluent only in English, all non-English apps were excluded from this study. Of the remaining apps, reviews were extracted using the Export Comments website. Since several apps contained only few reviews and other apps contained hundreds of reviews, the authors restricted the number of exported reviews to only the most recent 50 reviews in Google Play and 50 reviews in the Apple App Store. Although this restricted the available data, it allowed results to be more balanced toward the apps generally,

XSL•FO
RenderX

rather than app-specific for the most widely reviewed apps. Moreover, reviews limited to the most recent reviews ensured that outdated reviews were not considered in this study, which is particularly important, given that the widely reviewed apps may have been updated such that previous reviews are no longer relevant. App store searches and user review extractions were completed in March 2024.

Qualitative Analyses

Exported user reviews were downloaded into a spreadsheet program in which coding was conducted. Conventional content analysis was used to examine thematic content to user reviews [12,13], which is a method of qualitative data analysis used to identify themes in text data through systematic classification. In this approach, the researchers examine the data with no preconceived, theory-based hypotheses about what kinds of codes or themes will be found and instead use the data itself to drive the codes identified.

Initial themes were identified by both authors independently generating codes for a third of the reviews from each app identified for data analysis. These codes were then compared by the authors, discussed, and a reviewed codebook was agreed upon. Based on qualitative methodology recommendations and this study aims, the following codebook rules were agreed upon by the authors: (1) assign only 1 code per utterance, with "utterances" distinguished by parts of speech (eg, "and") or punctuation; (2) emojis are not to be coded, given the propensity for emojis to be transcribed as nonsubstantive text in the data extraction (ie, smiley faces were distorted into uninterpretable characters); (3) specific features identified within coded themes should be noted (eg, when concrete tools or specific tracking features are mentioned); and (4) any time a user review is explicitly not referring to the mobile app itself should be coded as "null" (eg, reference to in-person meetings being helpful vs the app itself). These codebook rules were established to ensure clarity, prevent overlap, and prevent artificially inflating interrater reliability [14,15].

The authors then completed coding using the revised codebook for a different third of the reviews from each app. The selection was made to code a third of reviews at each of these 2 stages based on the authors' prior experience with qualitative data analysis and expectation for it to take approximately 3 iterations to finalize a codebook. However, the second iteration of the codebook was agreed to be sufficient after the second third of data were independently coded and then discussed by the authors. This final codebook was used to code all of the app user review data by each author until 80% interrater consistency was achieved, which is considered the standard consistency for these types of analyses [16]. Specifically, both authors used an iterative process of coding to create the final codebook and increase rater agreement on the application of each code to each utterance in user reviews. Once the codebook was finalized, raters compared their codes and discrepant codes were flagged and rereviewed by both raters who were then allowed to reconsider their coding upon closer review. Any final discrepancies were discussed by both raters until agreement was achieved and overall interrater consistently met the predetermined 80% guidance from the empirical literature.

Results

Apps Analyzed

Data extraction was completed in early 2024; see Figure 1 for a flow diagram of app store search results. More than 200 apps were initially returned in search results within Google Play (n=285) and Apple App Stores for the specified search terms (n=240; n=425 unique results between both stores). The majority of these apps were excluded because they were for-profit (ie, had in-app purchases), were not mHealth apps (eg, alcohol-purchasing apps), or were explicitly harmful (ie, alcohol-drinking game apps). The remaining apps were excluded because they were of single purpose (eg, blood alcohol concentration calculators), or were not in English. The remaining results were researched by the authors to determine whether they were made by reputable and legitimate entities (eg, governmental agencies such as the National Center for PTSD) as a proxy for potential evidence basis of the app content. Findings were discussed until a consensus was established for which apps to include. A total of 8 apps were retained for data analysis: VetChange, SMART, DrinkCoach, SayingWhen, AlcoStat, Celebrate Recovery, TryDry, and Construction Industry Helpline. See Table 1 for a list of each of these apps and relevant descriptors. Each app had varying levels of user reviews provided, with Celebrate Recovery and TryDry being the only 2 apps that had more than 100 user reviews on each system platform. Accordingly, these 2 apps' user review data extraction was limited to only the most recent 50 reviews for Google and Apple (total of 100 reviews for each app). The other apps contained the following number of reviews: VetChange (n=14), SMART (n=35), DrinkCoach (n=51), Saying When (n=56), AlcoStat (n=7), and Construction Industry Helpline (n=7). A total of 370 reviews were included in this study (N=370).

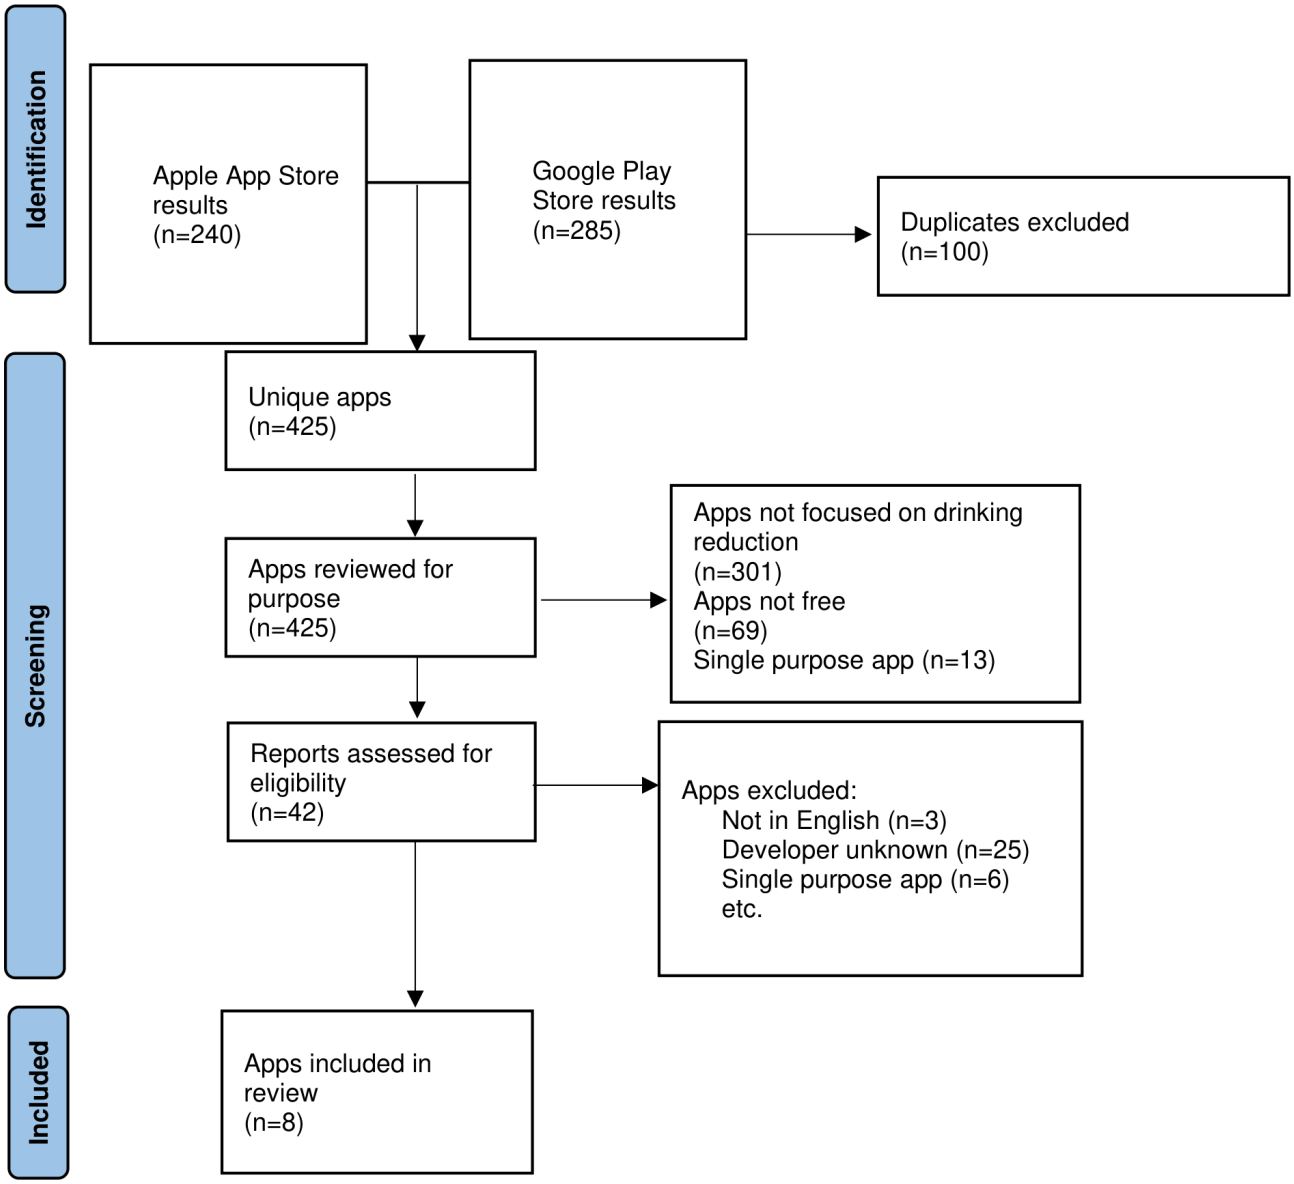
Figure 1. Flow diagram of app store search results and inclusion in the present analyses.



XSL•FO
RenderX

Table . Name and description of app store search results included in the present analyses.

App name	Number of user reviews	Platform	Developer	Description
AlcoStat	7	iOS	Andrey Shestakov	Categorized as a "lifestyle" app on Apple App Store. Features include alcohol calendar to track and personal statistics of alcohol use tracked in the app such as number of ounces and cost of alcohol consumed.
Celebrate Recovery	>100	Android; iOS	Bobbi McWilliams	Categorized as a "lifestyle" app on Google Play and Apple App Stores. Features include Celebrate Recovery meeting locator, Celebrate Recovery tools, and other resources.
Construction Industry Helpline	7	Android; iOS	Construction Industry Solutions Limited	Categorized as a "health & fitness" app on Google Play Store and as a "lifestyle" app on Apple App Store. Features include coping tools, mood-tracking features, resource locator, and psychoeducation.
DrinkCoach	51	Android; iOS	Humankind	Categorized as a "health & fitness" app on Google Play and Apple App Stores. Features include alcohol tracking, calorie and cost tracking, goal-setting features, and coping skill videos.
SayingWhen	56	Android; iOS	Centre for Addiction and Mental Health (CAMH), Education	Categorized as a "health & fitness" app on Google Play and a "medical" app on Apple App Store. Features include alcohol use tracking, urge tracking, coping skills, and goal setting.
SMART Recovery	35	Android; iOS	SMART Recovery USA	Categorized as a "lifestyle" app on Google Play and as a "health & fitness" app on the Apple App Store. Features include SMART Recovery meeting locator, coping tools, and psychoeducation.
TryDry	>100	Android; iOS	Alcohol Change UK	Categorized as a "health & fitness" app on Google Play and Apple App Stores. Features include alcohol use tracking, coping skills, goal setting, and "badges" for reinforcement of achievements logged in the app.
VetChange	14	Android; iOS	US Department of Veterans Affairs	Categorized as a "health & fitness" app on Google Play and Apple App Stores. Features include alcohol tracking, coping skills, mental health tools, and goal setting.

Themes From User Reviews

Reviews varied in length and each new idea or utterance was given a unique code for a total of 1353 coded phrases. Initially, 14 themes were identified but codes that contained <1% of the total data were collapsed into other, broader codes. Specifically, the theme of technological distrust was collapsed into "criticism" and the themes of "credibility" and "nonjudgmental" were collapsed into "praise." The final codebook contained 11 codes, listed in Table 2.

Table . Rank-ordered list of thematic codes and their frequencies.

Rank	Theme	Examples	Frequency	%
1	Praise	"Absolutely fantastic," "Definitely a useful little app," "This app helped me just raise my awareness of how much I was drinking"	498	36.831
2	Tools	"Useful links to pdfs, "lots of good tools"	150	11.062
3	Suggestion	"Being able to create my own drink category, for example Hard Seltzer," "it doesn't allow me to manually input drink log data for any date prior to the current month. Please [sic] fix this!"	118	8.756
4	Criticism	"It's not very flashy or feature rich," "Terrible interface."	105	7.768
5	Tracking	"Keeps you accountable by having you log how many drinks you have to keep up with daily," "it helps keep track of dry days, mood, energy levels and alcohol cravings"	104	7.724
6	Personal Story	"HI!! I'M GRATEFUL BELIEVER IN JESUS WHO use to struggle with alcohol & Denial," "I personally didn't get any benefit from trying to put my recovery in the hands of a 'higher power', but I don't mind that some people do."	86	6.366
7	Technical Issue	"It also erased data from two days ago," "but it it [sic] quit working after the ios update that just came out"	79	5.808
8	Usability	"Easy to use, beautifully presented and functional app," "really easy to use"	77	5.697
9	Null	"U r funny," "I Cannot Cannot Get Pads Your Bernhardt"	66	4.885
10	Advice	"Get Help!," "If you want to recover you've got to come out of isolation."	38	2.812
11	Gamification	"There are badges to claim," "I love getting entering [sic] 'stayed dry' in the calendar and seeing the confetti. The reward really works!"	31	2.291

XSL•FO
RenderX

Top 5 Themes

The top 5 most commonly occurring themes were praise, tools, suggestions for improvement, criticism, and tracking (see Table 2 for a rank-ordered list of all the themes coded and their frequencies). Within the theme of "praise," reviews frequently contained general praise for the app such as "absolutely fantastic" but reviews within this category also frequently mentioned specific, positive outcomes they attributed to the app. For instance, many reviews contained concrete drinking outcome data as well as other concrete outcomes they experienced: "52 days not drinking today and soon 4 month not smoking too!!!!!," "No doubt sleeping better," and "Has massively helped to cut down!"

Closely related to "praise" was the second most frequently coded theme of "tools," which was used to identify reviews that spoke specifically to functional tools programmed into the app that were not just tracking tools (see "tracking" code descriptions in the final paragraph of this section). To better inform future app development and refinement, any time "tools" were coded in the present analyses, the authors noted which specific tools were referenced as helpful by the app users. Future app programming efforts are recommended to consider these tools in their apps. Example tools that were commonly mentioned as being enjoyed and helpful were time- and location-specific reminders and specific coping tools such as guided mindfulness exercises and ways of coping with cravings, goal-setting functions, community resources, and psychoeducational resources. Examples of reviews that contained "tools" content are "useful links to pdfs and videos which are supplementary," "There's access to podcasts and videos, local meetings, motivational memes," and "gives you info on where you are compared to city wide average drinkers."

Similar to the "tools" code, the code for "suggestions for improvement" was used to indicate when users desired tools or features of the app that did not exist in the current version of the app being used. The authors also noted which specific suggestions were requested to best inform future app development efforts. The most common suggestion for improvement in apps was related to personalization and flexibility in the tracking components of the app. For instance, several instances of "suggestion for improvement" were coded for TryDry in relation to US users requesting US-specific quantities and standard drinks (ounces, 14-g standard drinks) since the app was developed in the United Kingdom (milliliters, 8-g standard drink units). One user of the TryDry app said in their review: "The one thing that could be better is using oz for the US but I understand it is for UK." Other app reviews for TryDry and the other apps analyzed in this study called for personalization and flexibility around entering their drink information and having the app calculate standard drinks for them. Examples of this suggestion include "Have a calculator to convert units to abv% ," and "Really don't understand why it can't show half units on the calendar." Other suggestions for improvement included increased tracking features such as the ability to add notes to document particular circumstances that may explain their tracked event (eg, specific events that related to increased drinking and different moods), the abilities to customize the display settings on the tracking calendar (eg, start the week on a Monday vs a Sunday), and the option for daily reminders or notifications to ensure that users accurately tracked their drinking (eg, several apps automatically assumed that a day without alcohol consumption entered was an alcohol-free day, and several users mentioned that this led to inaccurate tracking during times when they forgot to enter drinks consumed, so a daily notification to confirm lack of alcohol consumption would be helpful instead).

It is intuitive that one may take the time to write reviews only for apps about which they have strong opinions; therefore, it is unsurprising that "criticism" was one of the top 5 most frequently coded themes. In contrast to "suggestions for improvement," reviews that contained utterances coded as "criticism" did not provide specific, constructive feedback. As such, the authors did not note specific subthemes within this category and the majority of reviews coded with "criticism" did not yield particularly helpful feedback for future app development or improvement. Examples of reviews that contained "criticism" included "Having 1 drink in the past 30 days means I am drinking more than "28%" what bunk statistics is this based on. It acts like I'm abusing substances because I had one drink," "I really wish I could rate this better, but it just doesn't work at all," and "Very frustrating."

Nearly equal to the frequency with which "criticism" was coded was the code for "tracking" in the present analyses. While potentially considered a "tool," the mention of "tracking" specifically was so common that the authors agreed that it warranted its own code. Examples of reviews containing "tracking" codes were "keeps you accountable by having you log how many drinks you have to keep up with daily; and weekly goals," "Good tool to track drinks per day," and "has helped me a lot to track my drinking habits." However, tracking capabilities across the reviewed apps were not limited solely to tracking drinking behavior, and several reviews specifically mentioned the helpfulness of tracking more than drinking behavior alone. The most commonly mentioned tracking features that were mentioned as helpful to track included cost, calories, cravings, and mood. That "tracking" was among the top 5 most frequently mentioned codes beyond "tools" more broadly highlights just how valuable and well-liked tracking features are in alcohol apps.

Additional Themes

The remaining 6 codes were observed in moderate and low frequency, compared with the codes of the top 5. "Personal story," "technical issues," "useability," and "null" codes were found in moderate frequency, comprising around 5% of the total codes each. The "personal story" and "null" codes were used when the review contained information that was not clearly related to the app. For instance, many user reviews contained personal anecdotes about their lives that may have led them to seek help through the mobile app but did not indicate any information for others about the app per se (eg, "Other 12 step programs weren't doing it for me."). The "null" code was used for reviews that were non-English or contained nonsensical text (eg, "I Cannot Cannot Get Pads Your Bernhardt") or where the text clearly was reviewing something outside of the app itself such as reviews of in-person meetings associated with but not

XSL•FO
RenderX

part of the app directly (ie, SMART Recovery or Celebrate Recovery in-person meetings). Complaints about particular "technical issues" or glitches experienced in the apps were also found at moderate frequency, likely highlighting a need for apps to have tech support options available. Conversely, "useability" was coded when reviews mentioned positive qualities about the user experience from an app interface perspective.

At lower but still prominent frequencies were the codes for "advice" and "gamification." While less useful feedback for mobile app development and refinement, many reviews contained advice to others that may or may not have been explicitly about the app itself. The "advice" code was found for most but not all of the apps reviewed and so may speak to population-level differences (eg, veterans advocating for other veterans and in-person meeting-focused apps advocating for community). For TryDry and DrinkCoach, several reviews mentioned the gamification that has been programmed to reinforce abstinence days such as confetti appearing on the screen to celebrate abstinent day entry. Other app reviewers also highlighted that color coding of drinking data tracking that aligns with their drinking goals was helpful. The fact that only 2 of the 8 total apps evaluated in this study contained mention of gamification and yet still was coded 31 times speaks to the high desirability of gamified features for mobile apps and suggests that other apps should program gamified functionality.

Discussion

Principal Results

Central to the primary aims of the study, qualitative analyses yielded significant insights into features of alcohol-focused mobile apps that may inform app development and enhancement to make apps more accessible and helpful. Broadly, the central research question of this project was to identify overarching themes across alcohol app user reviews. We found common topics of reviews shown in Table 2. However, while conducting formal qualitative analyses of these overarching themes, both individual coders also took note of any mention of specific features that were praised, suggested, or criticized that may provide deeper insights for future app developers. Given these were subthemes and counts were inherently very small compared with the overall themes identified in Table 2, formal qualitative analyses were not completed to obtain counts of each specific feature highlighted by reviewers. Nevertheless, these subthemes may be particularly helpful for guiding future app development and enhancement, given their specificity. Features that were commented in user reviews as helpful or desired include tools to help access resources (eg, in-person meeting locators and psychoeducational materials) or coping skills, customizability to add personalized notes, and tracking functionality. While several user reviews commented on the helpfulness and importance of tracking alcohol use itself, being able to calculate standard drinks flexibly and track nondrinking data such as mood, craving, costs, and calories was prominent across mobile app reviews. The presence of reminder capabilities was also frequently commented on as a helpful tool to enhance the benefits of tracking features of apps. Moreover, including gamification (eg, color changes of tracking data when goals are met and rewarding displays such as confetti for achieving goals) explicitly into app programming was well received by app users (gamification was coded 31 times despite the majority of the reviewed apps lacking gamification features). Of note, only 2 of the 8 apps included in this study contained user reviews of "gamification" codes, yet "gamification" alone consisted of 2.29% of all coded responses. If gamification was programmed into more of the apps, one would expect that the proportion of reviews mentioning "gamification" would have increased significantly.

Additional Insights on mHealth Mobile Apps

A number of mHealth mobile apps are available for individuals interested in changing their relationship with alcohol. On one hand, the ubiquity of mobile apps provides individuals with many options to access resources that may not otherwise be available to them. On the other hand, without research and regulations, serious negative consequences can occur if people find the apps unhelpful or harmful [11]. In this study, we reviewed freely available mobile apps that may help individuals reduce their alcohol use and alcohol-related harms. We found hundreds of results, yet the vast majority of these mobile apps were available for-profit, for entertainment and potential harm (eg, drinking game apps), or for single purposes that restrict the potential usefulness of an app (eg, blood alcohol concentration calculators). This information alone highlights one current problem for the state of app development.

In addition to the current potential harms for app stores providing such limited mHealth interventions as opposed to predatory products, another important finding from this study is the inherent limitations in app store search features. For instance, Apple App yielded drastically different search results compared with Google Play. Moreover, apps known to exist failed to be returned in search results (eg, DrinkLess and DrinksRation from the United Kingdom, and Less, which is currently available on iPhone in the United States). Given the present methodology for searching not only for "alcohol" but also for other highly related terms (ie, "alcohol and anxiety"), this finding is concerning. One of the primary advantages of mobile apps is their accessibility; however, if the majority of available apps are for-profit or not viewable with very basic search terms, many individuals who may benefit from mHealth interventions may fail to access them.

One anticipated theme for this study was that privacy concerns may play a large role in user reviews, given concerns regarding privacy and mHealth in the academic literature [17]. However, this concern did not feature prominently in user reviews, with only 1 review mentioning concerns regarding location tracking in the app. This suggests that these users did not find privacy concerns to be a barrier to mHealth app adoption. However, it also highlights that mHealth app users may not be attending to their data privacy, and thus it is important for mHealth apps to provide transparent data usage policies and follow best practices regarding maintaining mHealth data [18]. Other primary takeaways from the user reviews include areas of criticism that highlight the need for improvements in existing apps (criticism was coded 105 times). Specifically, user interface, the ability for the app to perform multiple tasks (ie, not simply a meeting

XSL•FO
RenderX

locator and readings interface), availability of technical support to report glitches with the app, and customizability were highly sought (eg, ability to change volume measurements from milliliters to ounces). Future app developers and organizations with active app portfolios are recommended to use these findings to develop more well-received apps.

Limitations

While many of the present findings have significant and novel implications, the study is not without limitations. One limitation is that not all known alcohol-related apps were included in the present analyses. However, this is useful information since it highlights the inadequacies of current search engines in mobile app stores and shows a current gap that needs to be addressed by app developers and app stores in order for their products to be useful to real-world users. A second limitation is that not all existing app reviews were examined in this study. Specifically, TryDry and Celebrate Recovery had several hundred of reviews across Google and Apple but the present analyses were restricted to only the most recent 50 reviews from each store (100 reviews total for each app). Accordingly, additional nuances may have been missed that would have resulted in different codes in our qualitative analyses. However, had all reviews been included, the current findings would not generalize to other alcohol-related apps since the codes would be overly specific to those 2 apps alone. The fact that "gamification" occurred frequently enough to warrant a code and, yet, it was only a feature in 2 of the 8 apps highlights the appeal of gamified features within apps to users. Furthermore, many "technical issues" that were found may have been specific to unique versions of an app, so analyzing all existing reviews may have resulted in skewed findings about glitches or other app features that no longer exist in the current apps. Another limitation of this study was the restriction to English language apps. In our search for freely available mobile apps, we did find non-English apps such as "Oz Ensemble" developed by Fabrique numérique des ministères sociaux. The inclusion of non-English apps may have resulted in different findings, and future studies should be done to examine and compare non-English apps with the present results. Another point of potential limitation in our findings was the reliance on limited tools to examine the mobile app stores more systematically such as machine learning or other techniques that require different expertise or software support. Given the present research was completed without independent funding, our methodology was restricted to approaches that were freely available and fell within the scope of our existing expertise; it is possible that purchasable or other tools that conduct systematic reviews of app stores may have yielded different findings. A final limitation of this study is the inherent limitations of using publicly available user review data as opposed to other methodology for app development such as UX studies [19]. Yet, the advantages of UX studies may also be considered disadvantages that the present methodology addresses: UX studies are costly and formal. The current data were obtained freely and without the same potential desirability that may result from formal research, which may have resulted in different findings than if this study had been conducted through formal research methods such as UX studies [19].

Comparison to Prior Work

The present findings echo previous research regarding mHealth interventions for substance use. Specifically, that "nearly all of the mHealth interventions that are available for download today have not been evaluated for efficacy or effectiveness" [7]. In addition, the wide difference in the number of available reviews across apps evaluated in this study highlights findings from previous research that user's ratings influence perceptions about the apps' overall quality [7]. TryDry and Celebrate Recovery had significantly more user ratings and reviews than the other apps, and those apps have more downloads. Moreover, our findings are consistent with previous research examining app user reviews of nonsubstance use mental health apps, which highlight user preferences for usability, minimization of technical issues, and personalization [20-22]. As such, app developers should listen to what user reviews say in order to learn what makes one app successful compared with another from user experience and access perspectives. Also consistent with previous studies of formal AUD treatment and behavior change literature more broadly, skills-based tools and tracking capabilities of alcohol-related mobile apps arose as 2 of the most widely referenced content in the present qualitative analyses.

Conclusions

Mobile apps hold great promise to help the millions of individuals worldwide who experience serious harms associated with alcohol use. They may reach a wider audience than traditional, in-person therapy due to the ubiquity of smartphones and the free nature of these apps. Moreover, as compared with in-person treatment, receiving help in changing one's relationship with alcohol through a mobile app provides the app user with inherently increased privacy and autonomy. However, many apps that have been developed are not accessed or are not science-based: this study highlights ways to translate evidence-based techniques to mobile apps by listening to what the app users themselves have to say. Although many of the reviews for these apps are similar to reviews of any product by being either generic praise or generic, nonconstructive criticism, many of the present findings highlight concrete features that users want in an app to help change their relationship to alcohol. Flexible and versatile tools to access resources such as coping skills, psychoeducation, and community support; easy to use and rewarding or fun tracking capabilities; and ways for users to individualize their experience stand out among the more than 1300 coded utterances contained in the reviews that were examined. Similar to traditional therapy, skills-based and behaviorally based interventions that allow users autonomy were widely recognized as being helpful, appreciated, or, where lacking in an app, desired.

Abstract

Background: Mobile health (mHealth) apps provide innovative solutions for improving treatment adherence, facilitating lifestyle modifications, and optimizing blood pressure control in patients with hypertension. Despite their potential benefits, the adoption and recommendation of mHealth apps by physicians in Germany remain limited. This reluctance may be due to a lack of understanding of the factors influencing physicians' willingness to incorporate these digital tools into routine clinical practice. Understanding these factors is crucial for fostering greater integration of mHealth apps in hypertension care.

Objective: The aim of this study was to explore the relationship between physicians' information needs and acceptance factors, and how these elements can support the effective integration of mHealth apps into daily medical routines.

Methods: We conducted a qualitative study involving 24 semistructured telephone interviews with physicians, including 14 cardiologists and 10 general practitioners, who are involved in the treatment of hypertensive patients. Participants were selected through purposive sampling to ensure a diverse range of perspectives. Thematic analysis was conducted using MAXQDA software (Verbi GmbH) to identify key themes and subthemes related to the acceptance and use of mHealth apps.

Results: The analysis revealed significant variability in physicians' information needs regarding mHealth apps, particularly concerning their functionalities, clinical benefits, and potential impact on patient outcomes. These informational gaps play a critical role in determining whether physicians are willing to recommend mHealth apps to their patients. Key determinants influencing acceptance were identified, including the availability of robust knowledge about the apps, high-quality and reliable data, generational shifts within the medical profession, solid evidence supporting the effectiveness of the mHealth apps, and clearly defined areas of application and responsibilities within the physician-patient relationship. The study found that acceptance of mHealth apps could be significantly increased through targeted educational initiatives, enhanced data quality, and better integration of these tools into existing clinical workflows. Furthermore, younger physicians, more familiar with digital technologies, demonstrated greater openness to using mHealth apps, suggesting that generational changes may drive future increases in adoption.

Conclusions: The successful integration of mHealth apps into hypertension management requires a multifaceted approach that addresses both the informational and practical concerns of physicians. By disseminating comprehensive knowledge about the

XSL•FO
RenderX

variety, functionality, and proven efficacy of hypertension-related mHealth apps, health care providers can be better equipped to use these tools effectively. This approach necessitates the implementation of various knowledge transfer strategies, such as targeted training programs, peer learning opportunities, and active engagement with digital health technologies. As physicians become more informed and confident in the use of mHealth apps, their acceptance and recommendation of these tools are likely to increase, leading to more widespread adoption. Overcoming current barriers related to information deficits and data quality is essential for ensuring that mHealth apps are optimally used in routine hypertension care, ultimately improving patient outcomes and enhancing the overall quality of care.

Introduction

Advancing digitalization of health care has a transformative impact on the prevention and treatment of diseases, particularly in the realm of hypertension. In this context, mobile health (mHealth) apps are increasingly gaining significance, offering innovative means for monitoring, maintaining, and preventing high blood pressure [1-3].

Hypertension poses a substantial health challenge, affecting millions of people worldwide [4]. In Germany, it is one of the most prevalent health conditions, affecting a considerable portion of the population. In Germany, 19 million people with statutory health insurance (26.3%) were diagnosed with high blood pressure in 2018 [5]. Prevention and successful management of hypertension are imperative in averting potentially severe complications, including ischemic heart disease, stroke, and renal disorders. In addition, these measures play a pivotal role in enhancing the overall quality of life of patients with hypertension [6-8].

Preventing high blood pressure using a smartphone app that can be accessed at any time appears to be a promising tool [9]. Lifestyle interventions for preventive behavior, such as improving medication adherence, restricting food intake, or promoting activity, can generally be encouraged with the help of mHealth apps [10-17]. A systematic review concluded that the use of mHealth apps in hypertension care by general practitioners could be very useful, although various barriers, such as generational differences in willingness to use digital devices and the lack of knowledge of available mHealth apps, need to be overcome [18]. In the future, an increasing number of digital technologies will be used in health care [19]. To address this development, it is necessary to understand the current health care situation, especially the insights of physicians and their perspectives on benefits and challenges, as well as their information needs, to best integrate digital technologies into care.

To date, there has been limited research on physicians' perceptions of mHealth apps and devices and their willingness to prescribe them for hypertension care. In general, research has shown that physician adoption of mHealth apps depends on several factors, including perceived usefulness, ease of use, and trustworthiness of the technology. For example, Gagnon et al [20] found that the acceptance of mHealth apps by health care providers was highly dependent on their perception of clinical usefulness and ease of use. An Australian study highlighted concerns, including the digital divide between generations, lack of knowledge about prescription mHealth apps and devices, additional working hours, and data security concerns [21]. A French study [22] investigated general practitioners' attitudes toward prescribing mHealth apps and identified three main attitudes among general practitioners: (1) digital engagement, emphasizing the benefits of mHealth as a complementary tool for medical practice; (2) patient protection, focusing on concerns about data security, misinformation, and patient safety; and (3) doctor protection, highlighting concerns about increased workload and the impact on the doctor-patient relationship. A recent study on attitudes toward the use of digital health applications (in German: digitale Gesundheitsanwendungen, DiGA; digital therapeutics that can be prescribed by physicians in Germany) in Germany revealed information deficits. Both doctors and patients are insufficiently informed about mHealth apps and their health benefits, leading to a lack of trust [23]. A descriptive study of German general practitioners found that 60% of general practitioners recognized mHealth apps as beneficial for the health management of their patients, but only 36% had an overall positive opinion, and only 18% regularly recommended such mHealth apps [24]. However, despite these findings regarding diverse information needs, there is little evidence specifically examining the acceptance of mHealth apps by physicians in the context of hypertension management in Germany. Although physicians generally have a positive perception of such apps, this has not yet translated into widespread adoption in practice. This discrepancy suggests the presence of underlying, unaddressed barriers—whether related to information gaps, workflow integration issues, or confidence in the technology—which prevents clinicians from actively recommending or using these tools. It is these hidden factors that our research aims to uncover and address in order to gain a deeper understanding of the dynamics influencing the adoption of mHealth apps in hypertension care. Most previous studies have either focused on other chronic diseases or on the patient's perspective, leaving a gap in understanding physician-specific barriers related to hypertension management.

XSL•FO
RenderX

In addition, the German health care system has specific structural and regulatory characteristics that can affect the integration of mHealth apps. Germany is characterized by strict data protection regulations, as laid down in the European Union's General Data Protection Regulation (in German: Datenschutz-Grundverordnung, DSGVO). Especially in the sensitive context of mHealth apps, this leads to additional uncertainties and reservations among physicians who want to integrate these technologies into their clinical practice. Furthermore, fragmented digital infrastructures, complex reimbursement mechanisms for digital health applications, and varying degrees of digitalization in the different health care sectors further complicate acceptance. It is crucial to address these barriers by exploring the specific information needs of physicians regarding mHealth apps to ensure their effective implementation. Evidence shows that eHealth implementations often fail because physicians are not adequately involved in the development and integration processes [25]. These structural and informational gaps contribute to the disconnect between the theoretical openness toward mHealth apps and their practical adoption in routine care.

A comprehensive understanding of physicians' concerns, expectations, and knowledge gaps could guide the development of training programs that enhance their skills in handling digital preventive tools. Furthermore, investigating the acceptance of these technologies provides insights into the potential challenges that medical staff may face, enabling the design of user-friendly mHealth apps that can seamlessly integrate into clinical practice.

This study focused on investigating the information needs and acceptability of mHealth apps for the prevention of hypertension by health care providers. The aim of this study was to develop an understanding of how information needs and acceptance factors are related to the best integration of mHealth apps into hypertension care. This study addressed the following research questions: (1) What is the self-perceived acceptability of mHealth apps in hypertension care by physicians, and how could it be increased? (2) What information needs do physicians have, and how can these be met? (3) What is needed to integrate mHealth apps into the health care system in the long term, and what practical implications can be derived from this?

Methods

Study Design

This paper presents an investigation of physicians' perspectives on the use of digital technologies in preventing hypertension. Using qualitative data collection methods, comprehensive interviews were conducted with general practitioners and cardiologists.

Ethical Considerations

All the ethical issues were addressed. All experimental protocols were approved by the institutional or licensing committee. All methods were performed in accordance with relevant guidelines and regulations. Written consent was obtained from all participants after they were given the opportunity to ask clarifying questions. This study was approved by the Ethics Committee of the Brandenburg Medical School Theodor Fontane (E-02-20220620). Participants were informed verbally and in writing about the purpose, the procedure, the significance of the study, and the benefits and risks that may be associated with it and had the opportunity to ask questions. They were also informed that they had the right to withdraw their consent to participate in the study at any time, either verbally or in writing, without giving reasons. They were also informed that personal data would be recorded and stored, whereby the data would be pseudonymized, but that no data would be published that could be used to identify the person. For security reasons, the data received from the participants was always stored in a password-protected folder on a secure desktop computer. Written consent was obtained after participants were given the opportunity to ask questions. Patients were not involved in designing this study. Participants were offered €75 (approximately US $77.89) as an incentive for their participation in the study.

Participant Recruitment

The participants were selected using purposive sampling [26]. We included both general practitioners and cardiologists. Further inclusion criteria were current involvement in the treatment of patients with hypertension and interest in participating in an interview. The participants were recruited by snowball sampling. The following sources were used for the recruitment:

- Social media accounts of the university (Brandenburg Medical School Theodor Fontane): Facebook, Instagram, and Twitter.
- Association of Statutory Health Insurance Physicians Brandenburg: newsletter.
- General Practitioners Association Brandenburg: information study participation at events.
- Personal contact among colleagues.

Physicians were offered €75 (US $77.89) as an incentive for their participation in the study, which was financed from the earmarked research funds. This measure was taken to reward the time spent by doctors and to ensure sufficient willingness to participate. This study was conducted independently and was not directly related to the Innovation Committee of the Federal Joint Committee (G-BA: Committee in Germany that determines which medical services are provided to people with statutory health insurance). There were no external influences on the design, conduct, or evaluation of the study, and there were no conflicts of interest that could compromise the independence and reliability of the results.

Data Collection

A preliminary semistructured interview guide was collaboratively developed by a multiprofessional team (SM, FM, DB, and SS). The interview guide comprised open-ended questions exploring participants' familiarity with digital applications, particularly mHealth apps, their perceived benefits and barriers, their information needs for prevention, and aspects that influence their acceptance of mHealth apps. Sample questions included inquiries about the use of mHealth apps in hypertension treatment, perceived benefits, encountered barriers, and level of knowledge about mHealth apps (please see the interview guide in Multimedia Appendix 1). In addition,

XSL•FO
RenderX

sociodemographic data, such as profession, gender, age, number of inhabitants, duration of professional activity, and setting, were collected. The present findings report on information needs and aspects of acceptance.

To ensure the clarity and relevance of the questions, a pilot test of the interview guide was conducted with 5 eligible participants recruited from clinics and outpatient physicians in the study's catchment area. All interviews were conducted through telephone between October 2022 and March 2023 and were recorded and transcribed verbatim. Data collection continued until no new findings emerged and content saturation was achieved. Saturation was defined as code saturation, indicating no additional issues identified, and meaning saturation, indicating no further dimensions, nuances, or insights [27]. Field notes were recorded for each interview. They were used to understand the interview situation better.

Data Analysis

Qualitative analysis of the interviews was performed iteratively by SM and FM based on thematic analysis [19] using MAXQDA Analytics Pro 2022 (release 22.1.0; Verbi GmbH). After transcription of the audio material, the analysis began with familiarization with the interviews. A sample of the transcripts was then independently analyzed using SM and FM to iterate and finalize a comprehensive codebook. The main categories and subcategories are formed from these codes. The thematic analysis included reading each transcript, identifying patterns, assigning codes, and formulating themes and subthemes from the data. After this process, the data were checked, compared, and discussed to eliminate discrepancies [28]. If no new data, themes, or relationships could be identified, data saturation was achieved [29]. To present these findings, significant excerpts from the transcriptions were chosen as representative quotes. These quotes have been translated into English and incorporated into the manuscript. The manuscript was compiled in accordance with the COREQ (Consolidated Criteria for Reporting Qualitative Research; see Multimedia Appendix 2) [30].

Results

Overview

A total of 24 interviews were conducted and analyzed. The mean duration of the interviews was 42 (SD 5.75; minimum 33, maximum 56) minutes. The mean age of the participants was 50 (range 35-74) years. Most participants were male (13/24, 54%). In total, 14 cardiologists and 10 general practitioners participated in the study. A total of 7 individuals worked in the inpatient setting, and 18 people worked in the outpatient setting. Furthermore, 1 person worked in both settings. In addition, 4 of the physicians already had experience with digital applications in daily practice or were working with them. Table 1 shows the detailed characteristics of the study participants.

XSL•FO

H8	General practitioner	12	36	Male	7000	Inpatient
H9	General practitioner	30	63	Female	900	Outpatient
H10	General practitioner	21	54	Female	3.6 million	Outpatient

Self-Perceived Acceptability and Acceptance-Increasing Factors

Neither a particularly positive nor negative attitude toward mHealth apps was identified. Rather, physicians' response behavior is characterized by heterogeneity. mHealth apps are generally accepted by physicians, as long as they are not part of their daily medical routines. This means that they are certainly open-minded but not in their own care settings, especially due to a lack of experience in using mHealth apps.

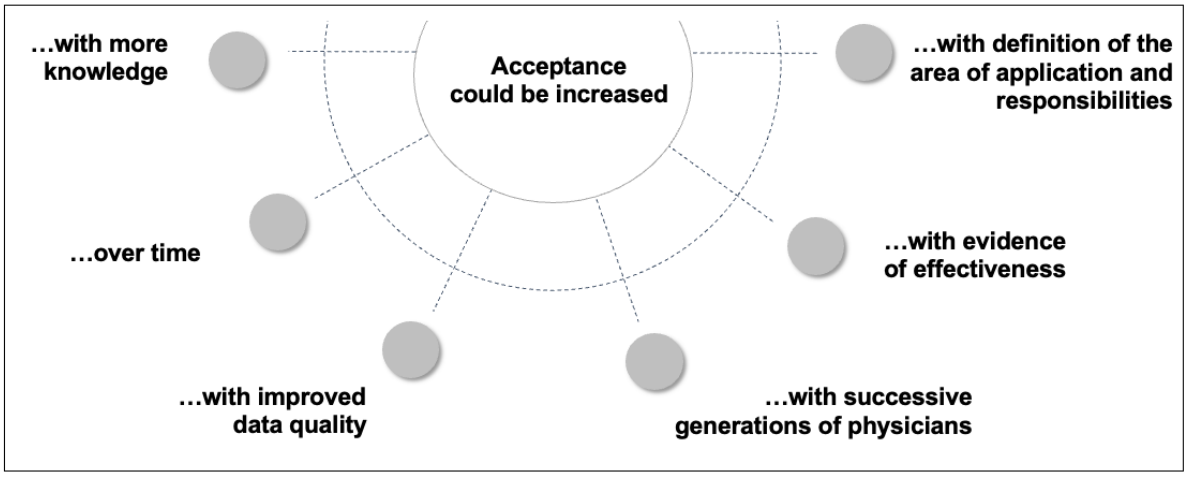
> *Well, I have to answer that in such a way that it is neutral, so to speak, because I simply do not have enough experience so far.* [K3]

> *I do not think I need it in my daily routine. I know a bit about high blood pressure and about general measures and therapies, and I try to convey that to the patients in conversation and then use it. So, I do not think I have discovered the need for it at the moment, to what extent it could take work off my hands or to what extent the patients could be better blood pressure controlled, or something else.* [K3]

Nevertheless, physicians emphasized that acceptance could increase. Figure 1 shows the factors associated with the increase in acceptance, and are further discussed in the following subsections.

XSL•FO
RenderX

Figure 1. Identified subthemes of the acceptance-increasing factors (coding tree).



Acceptance Could Be Increased With More Knowledge

Overall, the data revealed that physicians' acceptance of hypertension apps could increase with a deeper understanding of their benefits, targeted training, and seamless integration into existing clinical workflows.

> *And these reservations are simply ignorance and also ignorance of the actual tools that are available.* [K2]

Acceptance Could Be Increased Over Time

The interviewed physicians emphasized that the acceptance of digital technologies and mHealth apps in medical practice is often subject to a natural maturation process in which initial concerns and uncertainties diminish over time. This also applies to hypertension apps, which serve as technologies for the monitoring and self-management of blood pressure. For example, physicians indicated that increasing acceptance is significantly influenced by time as experience accumulates, research findings grow, and technology proves its reliability. In the early stages of mHealth app adoption, some physicians may be hesitant due to uncertainties about data accuracy, privacy concerns, and integration into existing workflows. However, over time, positive experiences and feedback from colleagues who have already implemented such technologies will help alleviate concerns and build confidence in the effectiveness of mHealth apps.

> *It will be unavoidable (the use of apps in daily routines). Thus, the industry is flooding us with apps. Studies are certainly required to be conducted. That's all true. We will certainly be doing a lot of things digitally in ten or 20 years.* [K14]

Acceptance Could Be Increased With Improved Data Quality

A key factor influencing the acceptance of hypertension apps among physicians is the data quality offered by these apps. Physicians reported concerns regarding the reliability of the collected data, leading to reluctance to rely on such technologies. In particular, it is not always guaranteed that patients enter their blood pressure data correctly. Overall, the ongoing improvement in data quality will help reduce existing reservations about hypertension apps and further increase their acceptance among physicians.

> *I believe that we can foresee that this will be accepted because the data [on use and effectiveness] will presumably also have better quality in the future.* [K2]

Acceptance Could Be Increased With Successive Generations of Physicians

The ongoing generational shift in the medical profession plays a decisive role in increasing acceptance of hypertension apps. Physicians emphasize that younger physicians who have grown up in an era of digital innovation are often more open to the use of modern technology in medical practice. Unlike the older generations, who may be more familiar with traditional methods of patient monitoring, young physicians already have an affinity for digital health solutions. Digital natives recognize the potential of mHealth apps as efficient technologies for improving patient care. Their willingness to accept and integrate innovative technologies is fueled by the realization that these apps can not only promote patient autonomy but also increase efficiency in clinical practice. The younger generation's openness to new technologies is driving the integration of mHealth apps into the modern medical landscape. As the digital-savvy generation enters medical practice, the use of mHealth apps is likely to be seen as a natural part of treatment. Interestingly, participants in all age groups expressed this impression.

> *Of course, this [use of mHealth apps] comes with younger physicians who have grown digitally in a completely different way. For them, it will be a matter of course that they send their data, laboratory results, and everything else digitally.* [K2]

Acceptance Could Be Increased With Evidence of Effectiveness

The physicians reported that they need solid evidence that the use of hypertension apps is not only technologically advanced but also achieves positive results in clinical practice. Clear evidence of improvements in blood pressure control, reduction

XSL•FO
RenderX

of complications, and overall better health care is essential from the point of view of strengthening physician conviction.

> *Certainly, scientific proof that it makes sense. I am always in favor of prescribing something like this if it is proven to be beneficial for the patient. However, I do not see that yet.* [K9]

Acceptance Could Be Increased With a Definition of the Area of Application and Responsibilities

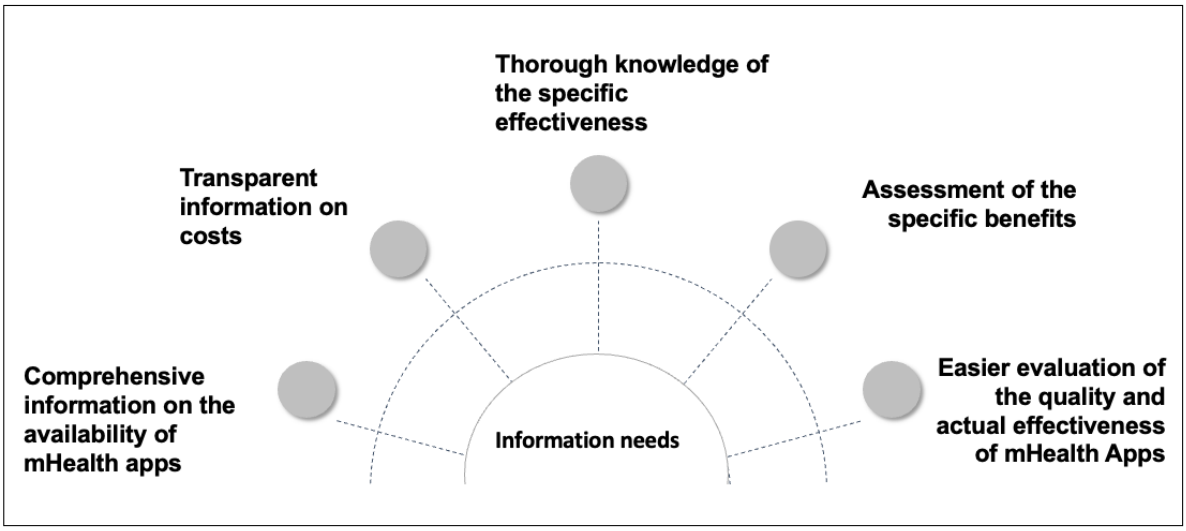
In the interviews, the physicians addressed the fact that the purpose and functions of the use of mHealth apps are often not defined, either for the patients themselves or within physician-patient communication. Physicians point out that it should be clear to both patients and physicians how an mHealth app is integrated into care. Whether the mHealth app is used as a lifestyle product or a monitoring tool. Whether physicians are actively involved in the evaluation of the data, whether they should take on a controlling function, and whether the use of the mHealth app is only for observation or should even have consequences, for example, through advice from the physician.

> *I always think the question is interesting: what do I want to achieve with the app? Do I want truest for therapy management? These are the patients we were just talking about, who are not health-conscious per se. Do we want people to feel comfortable with their illness and feel that they are doing an incredible amount for themselves? That brings us to advice, offers, and lifestyle apps - that is, what I call it, right? Somewhere along the line, if it is from a medical context, it should take both facets into account but focus more on the medical context.* [K14]

Information Needs

A variety of information needs became apparent in the interviews. Figure 2 shows the subthemes of information needs.

Figure 2. Identified subthemes of the information needs (coding tree). mHealth: mobile health.



Comprehensive information on the Availability of mHealth Apps

Physicians are generally interested in using mHealth apps in their daily routine. However, there is a lack of information on the range of mHealth apps that can be integrated into hypertension care. There is a knowledge gap regarding the functions, data security, accuracy, and clinical benefits of hypertension apps.

> *In my opinion, the market has been overly flooded. And then you do not even know which apps are actually certified and which are available. Thus, we cannot know all apps that are buzzing around the market.* [K7]

Transparent Information on Costs

A challenging aspect in the context of integrating mHealth apps into medical practice is that many physicians are often not fully informed about the costs associated with these mHealth apps. Nontransparent pricing and diverse pricing models of various providers lead to uncertainty. This lack of clarity regarding financial aspects can affect physicians' decision-making and even make them reluctant to integrate such mHealth apps into their treatment plans.

> *I do not know enough about what is available or what you can choose from and what that means in terms of costs.* [K3]

Thorough Knowledge of the Specific Effectiveness

The lack of knowledge regarding the specific effectiveness of hypertension apps poses a further challenge for physicians. There is often a lack of clear information about how these apps can have a positive effect on the treatment of patients with high blood pressure in practice. In contrast, physicians emphasize that they know and can assess the use and effects of medication. Physicians need detailed insights into the algorithms, data analysis methods, and interpretation of the information generated by the mHealth apps to understand and assess their effectiveness.

> *Yes, and I mean, when I prescribe ramipril, it's because I know this medication, I know its effects, side effects, I have used it for a long time, and I know*

XSL•FO
RenderX

it. However, these apps are expensive. They cost 500 euros, so I want to know in advance what I am prescribing and how they work. [H10]

Assessment of the Specific Benefits

The limitations in assessing the specific benefits of hypertension apps pose a challenge to physicians. There is often a lack of clear and convincing information about how these mHealth apps actually benefit patients. In addition, physicians are unable to assess the extent to which apps benefit their daily practice.

So, I think at the moment I just have not identified the need for myself to what extent this could take work off my hands, how it would benefit the patients, and to what extent the patients could be better blood pressure adjusted or something. [K3]

Easier Evaluation of the Quality and Actual Effectiveness of mHealth Apps

Physicians' difficulty in assessing the quality of mHealth apps is a key barrier. There is often a lack of clear benchmarks and objective criteria for evaluating the actual benefits of these mHealth apps for individual patient care. The lack of standardized evaluation methods makes it difficult for physicians to determine the degree of effectiveness of a particular hypertension app and assess its clinical relevance.

And I would always look at the study situation first because many of them have only been proven with very poor studies and are, therefore, only provisionally approved. I do not think I would prescribe them at the moment because I think they cost money and have not been sufficiently tested. I do not even know how good they are. [H6]

Evaluating the effectiveness of hypertension apps is a complex challenge for physicians. The lack of standardized criteria for collecting outcome data and comprehensive clinical trials makes it difficult to draw objective conclusions about the effectiveness of these mHealth apps. Physicians often struggle to assess how well hypertension apps actually work in practice and what concrete contribution they can make to improving blood pressure control and the health of their patients. To make matters worse, many of the available hypertension apps have different functions and approaches, which further complicate a standardized assessment.

As I said, I'm too uneducated when it comes to this. I am unfamiliar with any studies and do not know how they work or how effective they are. [K3]

Discussion

Principal Findings

This study provides new insights into the factors influencing physicians' adoption of mHealth apps in the context of hypertension management in Germany. Our findings reveal a complex interaction of factors—from information gaps and workflow integration challenges to uncertainties around data security and reimbursement structures—which influence physicians' willingness to integrate these technologies into their daily routines.

This study provides a nuanced view of the acceptance of mHealth apps among cardiologists and general practitioners, particularly in the context of hypertension management. While there is a general openness to digital technologies among physicians, hesitation persists, primarily due to a lack of familiarity and experience with these technologies. A significant barrier to the adoption of mHealth apps is a limited understanding of their benefits and functionalities. Physicians have indicated that targeted training could greatly enhance acceptance. Over time, acceptance is expected to increase as experience grows and positive outcomes are observed. However, concerns regarding the accuracy of patient-entered data remain a major issue, with improved data reliability being essential for building trust in these technologies. Younger physicians, who are more familiar with digital technologies, tend to be more receptive to mHealth apps, suggesting that acceptance is likely to grow as the medical field evolves. Nevertheless, substantial information gaps, including a lack of awareness of the range and benefits of available apps, hinder adoption. In addition, unclear cost structures and the absence of standardized methods for assessing quality and effectiveness further contribute to physicians' reluctance to recommend and use these technologies.

Comparison With Previous Work and Theoretical Embedding

Self-Perceived Acceptability of Physicians Toward mHealth Apps in Hypertension Care

A major obstacle to the introduction of mHealth apps into standard hypertension care is a lack of understanding of their benefits and functions. The aspect "Acceptance could be increased with more knowledge" can be linked to the theoretical concept of the "Technology Acceptance Model" (TAM). TAM, developed by Davis [31], postulates that the acceptance of technology depends largely on 2 factors: its perceived usefulness and perceived ease of use. In terms of mHealth apps, physicians with a sound understanding of the specific benefits and ease of integration of these technologies into their clinical practice are more likely to accept and use them. When physicians are better informed about the positive clinical outcomes that can be achieved through mHealth apps, as well as aspects related to practical application, such as data integrity and privacy, their perceived usefulness and ease of use increase. This increased knowledge reduces uncertainty and skepticism, which ultimately leads to greater acceptance and integration of technology into everyday medical practice. A systematic review examining factors influencing acceptance concluded that the lack of routine use of mHealth apps is primarily due to insufficient knowledge and information regarding their integration into daily routines. [32]. The need for information is a key component of acceptance, particularly in telemedicine [33], as well as in mHealth apps. The way in which information is provided and how well users' information needs are met have a significant influence on their willingness to accept and use a particular technology. A recent study [34] pointed out that the level of awareness of mHealth apps for hypertension should be increased through targeted information campaigns and physician training. In addition, physicians need to test mHealth apps, and experience and acceptance would increase.

XSL•FO
RenderX

Acceptance is expected to increase over time as more experience is gained and positive outcomes are observed. This aspect can be linked to the diffusion of innovation theory proposed by Rogers [35]. According to Rogers' theory, the adoption of new technologies follows a specific pattern over time and is categorized into 5 stages: innovators, early adopters, the early majority, the late majority, and laggards. Initially, only a small group of innovators and early adopters might embrace mHealth apps; however, as more physicians witness positive outcomes and share their experiences, the early and late majority will gradually adopt these technologies. Over time, as research continues to provide robust evidence of the effectiveness and reliability of mHealth apps and as the technology becomes more integrated into standard medical practices, the remaining skeptical physicians (the laggards) will also start to accept and use these technologies. The stronger the habit of using mHealth apps, the stronger the connection between user satisfaction and willingness to continue using the apps [36]. People who are satisfied with and develop habits related to new technologies are more likely to use these apps in the long term [36].

Another important finding of our study is that there are concerns about the accuracy of the data entered by patients, and improved data reliability is crucial for building trust in these technologies. This is in line with the Unified Theory of Acceptance and Use of Technology 2 (UTAUT2) [37]. One of the key determinants within this framework is the concept of trust, which is strongly influenced by the quality of the data provided by technology. High-quality data, characterized by accuracy, reliability, timeliness, and relevance, can significantly increase physician trust in mHealth apps. When data quality is assured, physicians are more likely to perceive technology as useful and reliable, reducing their uncertainty and increasing their willingness to adopt and integrate these technologies into their clinical practice. This improved confidence and the perceived benefits of better data quality can lead to higher overall adoption of mHealth apps among healthcare professionals. A recent study [38] showed that doctors were willing to use mHealth apps if they felt comfortable and safe. This highlights the importance of user experience in the adoption of mHealth apps by health care professionals. The intention to use mHealth apps in everyday health care depends on the perceived reliability of these technologies. If physicians perceive mHealth apps as reliable and trustworthy, they are more likely to regularly integrate them into their workflows [36].

The identified aspect, "Acceptance could be increased with successive generations of physicians," can be linked to the concept of the "Digital Divide," which highlights the disparities in access to and use of digital technologies across different demographic groups [39-41]. Younger physicians with digital technologies are less likely to experience the barriers associated with the digital divide. They generally have better access to digital technologies, higher levels of digital literacy, and greater confidence in using technology in medical practice. As these younger, more technologically adept physicians enter the workforce, acceptance and integration of mHealth apps will naturally increase. Several studies have shown that younger doctors are more likely to use mHealth apps, and in an Australian study, both patients and physicians cited age as a barrier to mHealth app prescription but also provided examples of exceptions to this age-based divide in digital readiness [21]. A German study also identified a trend in physician age. Younger physicians are often more open to digitalization and welcome innovations such as digital health applications [42]. Another study from Germany specifies the age aspect and shows that the highest acceptance rates of digital health applications are expected in the 30-49 years age group [43].

Physicians' Information Needs and How to Address Them

Based on the assumption that acceptance could be increased with more knowledge, it is particularly important to determine what information needs exist in the context of mHealth apps in hypertension care. The interviewed physicians expressed a high demand for information regarding mHealth apps for hypertension care and various information deficits. At the same time, however, there are reservations due to uncertainties regarding effectiveness, data security, and integration into the clinical workflow. A thorough and, at the same time, a low-threshold explanation of the benefits and security aspects of such applications is therefore crucial to increase acceptance of mHealth.

The lack of information also explains why mHealth apps are not yet integrated into the health care infrastructure. Few specialists currently use or recommend mHealth apps in their daily routines [44]. This leads to a discrepancy between the available digital technologies, such as mHealth apps, and their actual use in clinical practice. The gap between the daily work with patients and the availability of mHealth apps is becoming increasingly apparent, and in this context, the "digital divide," which refers to differences in access, use, and understanding of digital technologies in health care, is also prevalent among health care practitioners [40]. On the one hand, there is the daily interaction with patients, which is characterized by personal contact, traditional diagnostic methods, and conventional treatment approaches. On the other hand, a growing number of mHealth apps offer digital solutions for monitoring health parameters, managing diseases, and accessing health information. Our results show that physicians do not know what mHealth apps can do, what it means to use them, or how much effort is involved.

In addition, a lack of information regarding costs also contributes to this. Reviews demonstrate that physicians are less willing to use eHealth technologies if the reimbursement is not clearly defined or communicated transparently [45,46]. This uncertainty surrounding financial compensation not only hinders the adoption of mHealth apps but also undermines their potential integration into routine clinical practice. Clear guidelines and transparent communication regarding reimbursement policies are essential to enhance healthcare providers' confidence in adopting these technologies.

An approach to closing the information gap resulting from the lack of assessment of the quality and effectiveness of mHealth apps is to use assessment tools. Various studies have already examined this and concluded that quality assessment tools are a viable approach to distinguish high-quality mHealth apps from lower-quality mHealth apps [47,48]. By implementing

XSL•FO
RenderX

standardized evaluation criteria, these tools can provide health care professionals with the necessary insights to make informed decisions about which apps should be integrated into their practice, ultimately enhancing patient care. Establishing clear and transparent evaluation metrics covering aspects such as design, information/content, usability, functionality, ethical issues, security and privacy, and user-perceived value would not only build trust among health care providers but also facilitate broader acceptance and integration into routine care [47].

Integrating mHealth Apps Into the Health Care System: Practical Implications

Based on our findings, we derived 4 fields of action (Multimedia Appendix 3) to achieve a more successful implementation of mHealth apps in physicians' daily routines.

Definition of Areas of Application of Responsibilities

Before mHealth apps are used for hypertension treatment, their functions should be specified in advance. The physician and patient should discuss the area of application, therapy goal, and type of collaboration. If the mHealth app is used as a lifestyle product, the patient tracks their parameters alone, and the physician is not directly involved in medical treatment. This means that the physician has no control, and there are no responsibilities for the physician; that is, they do not have to actively intervene. If the mHealth app is used as medical advice, the patient and physician monitor the parameters together, and the effectiveness and benefits should be proven in advance. This implies that physicians are directly involved in medical treatment. The physician and the patient discuss the parameters together, and the physician assumes a certain degree of control and can actively intervene. This approach could lead to mHealth apps being better accepted by physicians as medical advice and used by them more frequently. Multimedia Appendix 4 illustrates the proposed approach.

Specific Recommendations for Integration Into Daily Routines With Guidelines and Options for Measuring Outcomes

A consistent methodology for collecting outcome data and establishing evidence-based criteria is essential to enable clinicians to better understand the performance of these applications. Creating clear guidelines and evaluation tools will help reduce uncertainty about their effectiveness and provide physicians with a solid foundation for making decisions about integrating hypertension apps into their practice. In addition, interfaces and clear guidelines for the integration of such technologies must be created to promote their use by physicians. Intensive efforts should be made to obtain more information about the range, effects, and modes of action of mHealth apps [34].

Information Campaigns

In health care, knowledge translation plays a key role in the integration of new medical technologies into everyday care [49]. The acceptance of new technologies depends heavily on how well physicians understand the underlying scientific evidence, how effectively these are implemented in clinical practice, and how they bridge the gap between research and practice. Knowledge translation is essential as it facilitates the dissemination of evidence-based practices, ensuring that the latest research findings and medical innovations reach health care practitioners, policymakers, and, most importantly, the general public. Information campaigns serve as powerful vehicles for knowledge translation, acting as conduits for conveying complex medical information in an accessible and understandable manner. As the acceptance of mHealth apps is also generation-dependent, strategies that appeal to both younger and more experienced physicians should be developed. This can be achieved through various approaches, such as peer learning or mentoring. Furthermore, there should be special training programs for physicians that provide detailed information about the available mHealth apps, their functions, and scientific evidence for their effectiveness [22].

Active Use of the mHealth Apps in Collaboration With the Developers

For physicians, actively engaging with and experimenting with these apps is both practical and crucial. By exploring digital technologies, such as mHealth apps, physicians can gain valuable insights into their functions, usability, and potential benefits [50]. By actively using health apps, physicians can develop a nuanced understanding of how these technologies operate in real-world medical settings. This hands-on experience not only equips physicians with the knowledge to recommend suitable apps to patients but also fosters a deeper appreciation of the role these technologies can play in modern health care. Furthermore, physicians acting as early adopters can contribute significantly to the overall acceptance and integration of health apps within the medical community.

Strengths

To the best of our knowledge, this is the first qualitative thematic analysis to provide an in-depth understanding of the acceptance and information needs related to mHealth apps for hypertension prevention. While our study specifically examined physicians' acceptance and information needs regarding mHealth apps in hypertension management, the findings suggest that many of the factors identified, such as the need for reliable data, evidence of effectiveness, and clearly defined areas of application, may also be applicable to the management of other chronic diseases such as diabetes. This potential transferability indicates that barriers and facilitators to adopting mHealth apps in medical practice share a common foundation that extends beyond individual conditions.

Limitations

The findings could potentially be influenced by selection bias, as individuals with a greater interest in the topic might have been more inclined to participate in the study. The sampling strategy employed may not have reached a representative cross-section, leading to a lack of recording of the essential aspects. Consequently, the generalizability of the results is hindered. It should also be mentioned that the interviews were conducted over the telephone. The lack of nonverbal cues, such as body language, facial expressions, and eye contact, can make it difficult to capture the full range of emotions and reactions.

XSL•FO
RenderX

Another limitation of this study is that only 4 participating physicians had experience with mHealth apps in their daily routines. This could limit the validity of the results, as the perspectives of physicians without experience using such apps could be less informative. In addition, it is important to note that the patient interviews were not conducted during this study. Including patient perspectives could have provided a more rounded understanding of the acceptance of and information needs related to mHealth apps in hypertension care. Their absence from our research presents an area for future exploration to enrich and validate our findings. In other parts of the study, in which this study was also conducted, the patients are specifically interviewed [32].

Recognizing the preliminary nature of this broad exploration into "hypertension mHealth apps," the authors acknowledge that this serves as an initial foray. Given the extensive and diverse nature of the topic, future studies should be tailored to specific health care contexts to expand on these initial findings. These limitations present a clear avenue for future research. Plans are underway to broaden the study scope by including a larger sample in Germany [51] and to validate the qualitative outcomes through a comprehensive questionnaire survey. Subsequent investigations should focus on the identification of patients suitable or unsuitable for mHealth apps in hypertension care. Attention should also be directed toward effective strategies for educating health care professionals about mHealth and digital health in a broader sense. In addition, exploring reimbursement strategies that reinforce the optimal use of mHealth for managing chronic conditions is imperative.

Finally, the potential barriers identified here regarding the prescription of apps for hypertension by physicians pertaining to the German health care system. Further studies are required to determine whether these aspects are applicable to physicians in other countries.

Conclusion

The use of mHealth apps in hypertension management is currently characterized by information deficits and reduced acceptance among physicians. This study underlines the need for intensive knowledge translation and transfer. The active involvement of physicians in the development and implementation of mHealth apps in hypertension care is particularly important to move from individual self-management by patients to formalized mHealth app-supported health care to prevent hypertension.

Acknowledgments

The authors would like to thank all interview partners and participants for their valuable contributions and time. We would like to express special thanks to the Association of Statutory Health Insurance Physicians Brandenburg (KVBB) and the General Practitioners' Association Brandenburg for their support during the recruitment process. This study was supported by the Innovation Committee, the Federal Joint Committee (Innovation Fund; grant 01VSF18014).

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request. For further questions regarding the reuse of data, please contact the corresponding author.

Authors' Contributions

SM contributed to the design of the study, data acquisition and analysis, interpretation of data, and drafting of the manuscript, and had full access to all the data in the study and took responsibility for the integrity of the data and the accuracy of the data analysis. FS contributed to data analysis and substantively revised the manuscript. DB contributed to the design of the study, obtaining funding, data acquisition, and analysis, and substantively revising the manuscript. MH contributed to the design of the study, obtained funding, and substantively revised the manuscript. SS contributed to the study design, obtaining funding, data acquisition and analysis, and substantively revised the manuscript. FM contributed to the design of the study, data analysis, data interpretation, and substantially revised the manuscript. All authors approved the submitted manuscript. In addition, the authors have agreed to be personally accountable for the author's own contributions and to ensure that questions related to the accuracy or integrity of any part of the work, even those in which the author was not personally involved, were appropriately investigated and resolved, and the resolution documented in the literature.

Abstract

Background: The increasing use of direct-to-consumer artificial intelligence (AI)–enabled mobile health (AI-mHealth) apps presents an opportunity for more effective health management and monitoring and expanded mobile health (mHealth) capabilities. However, AI's early developmental stage has prompted concerns related to trust, privacy, informed consent, and bias, among others. While some of these concerns have been explored in early stakeholder research related to AI-mHealth, the broader landscape of considerations that hold ethical significance to users remains underexplored.

Objective: Our aim was to document and explore the perspectives of individuals who reported previous experience using mHealth apps and their attitudes and ethically salient considerations regarding direct-to-consumer AI-mHealth apps.

Methods: As part of a larger study, we conducted semistructured interviews via Zoom with self-reported users of mHealth apps (N=21). Interviews consisted of a series of open-ended questions concerning participants' experiences, attitudes, and values relating to AI-mHealth apps and were conducted until topic saturation was reached. We collaboratively reviewed the interview transcripts and developed a codebook consisting of 37 codes describing recurring or otherwise noteworthy sentiments that inductively arose from the data. A single coder coded all transcripts, and the entire team contributed to conventional qualitative analysis.

Results: Our qualitative analysis yielded 3 major categories and 9 subcategories encompassing participants' perspectives. Participants described attitudes toward the impact of AI-mHealth on users' health and personal data (ie, influences on health awareness and management, value for mental vs physical health use cases, and the inevitability of data sharing), influences on their trust in AI-mHealth (ie, endorsements and guidance from health professionals or health or regulatory organizations, attitudes toward technology companies, and reasonable but not necessarily explainable output), and their preferences relating to the amount and type of information that is shared by AI-mHealth apps (ie, the types of data that are collected, future uses of user data, and the accessibility of information).

Conclusions: This paper provides additional context relating to a number of concerns previously posited or identified in the AI-mHealth literature, including trust, explainability, and information sharing, and revealed additional considerations that have not been previously documented, that is, users' differentiation between the value of AI-mHealth for physical and mental health use cases and their willingness to extend empathy to nonexplainable AI. To the best of our knowledge, this study is the first to apply an open-ended, qualitative descriptive approach to explore the perspectives of end users of direct-to-consumer AI-mHealth apps.

Introduction

Background

Direct-to-consumer mobile health (mHealth) apps present an opportunity for widely accessible health management and monitoring, with the integration of artificial intelligence (AI) offering immense promise to enhance the effectiveness and expand the capabilities of these apps [1]. Indeed, many direct-to-consumer AI-enabled mHealth (AI-mHealth) apps are already in widespread use by individuals seeking to address particular health concerns, obtain personalized insights into their health, promote health-seeking behaviors, and help set and achieve well-being goals [2].

While AI-mHealth apps offer potential for improving proactive health management and monitoring, the rapid pace of AI innovation has outpaced research efforts aiming to facilitate the ethical development and adoption of AI-based apps and maximize their benefits. Recent normative work has articulated concerns related to privacy, informed consent, and bias, among others [3-5]. For example, integral to the training of AI models and the appeal of AI use cases (eg, personalized health recommendations and digital phenotyping based on ecological momentary assessments) is the collection of behavioral data, many times more than what are typically analyzed by mHealth apps that do not use AI, and these data may encompass a wider range of tracking modalities [6,7]. Mobile devices' capabilities to passively collect biometric data (eg, motion, heart rate, and sleep) and contextual data (eg, location and browser activity) have raised novel considerations around data privacy, including users' ownership of these data, consent for data collection, AI capabilities of inferring private information, and potential for surveillance [8-10]. Another challenge for AI-mHealth is unwanted algorithmic bias, which, if inadequately addressed, could perpetuate existing health inequities and even widen health disparities, conflicting with the goals of personalized medicine [11-13]. A further set of considerations relates to how AI use cases may shape how users think and feel about their health status and health behaviors, for example, whether self-monitoring features, depending on how they are framed and implemented, could support or threaten experiences of autonomy and agency [6,14].

These considerations relating to trust, privacy, informed consent, bias, and autonomy have been repeatedly highlighted in the AI-mHealth literature; however, the perspectives on these issues of the stakeholders in direct-to-consumer AI-mHealth who arguably stand to assume most of its benefits and risks (ie, end users) are yet to be adequately explored in the empirical literature [15]. Empirical work assessing trust in *health care provider*-to-consumer conversational agents has shown that trust has interpersonal (eg, trust in companies and health care providers), social (eg, testimonies from loved ones and health care providers), and technological dimensions (eg, trust in the capabilities of the tool and design cues) [16]. A scoping review of studies assessing user views of AI-mHealth apps identified a number of likely barriers to adoption related to user-centered explainability, trust, empathy, usability, privacy, AI accountability, and diversity of model training and test populations [17]. Importantly, the study revealed that direct-to-consumer AI-mHealth user research has been largely limited to quantitative studies that evaluated specific dimensions of user experience collected via structured questionnaires and performance metrics generated by the apps, which tend to rely heavily on researchers' a priori assumptions about what the major user considerations are.

The small body of published qualitative work has used interviews of actual or anticipated users of direct-to-consumer AI-mHealth apps to shed light on their attitudes and perspectives, yielding several ethically salient insights. An interview study of university students by Nadarzynski et al [18] explored their attitudes toward hypothetical conversational AI apps. The study identified several sources of hesitancy related to AI interactions (a lack of empathy and understanding, especially in mental health use cases) and accuracy and quality concerns as well as perceived advantages around anonymity, convenience, accessibility, and guidance toward relevant health services. In semistructured focus groups with young people about their attitudes toward AI-mHealth apps, Götzl et al [19] found nuanced attitudes toward data sharing and safety; participants reported willingness to share their data provided that they would truly support their health interests and expected transparency about how their data were being used, discretion in requesting more sensitive data, and user controls for personalization features. In a report by Tsai et al [20], focusing on users' needs related to explainability in AI-enabled symptom-checking tools, interviewees reported that they often felt confused by the order and content of the differential diagnosis questions asked by these apps and hesitated to trust the accuracy of their results due to low transparency about their reasoning procedures and underlying data.

Objectives

As AI advances, direct-to-consumer AI-mHealth apps may create more opportunities to improve population-wide health awareness, disease prevention, and well-being. To realize these aspirations, it is essential to engage with the end users whom the tools are intended to help and develop a comprehensive picture of the views of the end users of direct-to-consumer AI-mHealth apps, including their own reservations or anxieties that may remain overlooked and pose barriers to establishing trust and fostering adoption. Although previous qualitative study designs have focused on exploring users' views on specific use cases and topics of ethical importance, no single study has examined their ethical perspectives on AI-mHealth broadly. Therefore, in this paper, we set out to describe, using semistructured interviews and a qualitative descriptive approach, the topology of ethical considerations of individuals who have experience interacting with mHealth apps with respect to AI-mHealth.

Methods

Study Design

The findings presented in this paper were collected and analyzed as part of a larger study that aimed to identify and describe ethically laden sentiments and anticipated issues of AI well-being apps' use in work environments from the

XSL•FO
RenderX

perspectives of current and potential future end users. This study addressed a supplemental aim to an ongoing study about the ethics of AI use in medicine (NCATS R01-TR-003505) [21]. To accomplish this aim, we conducted semistructured interviews with existing users of AI-mHealth apps (N=21) to identify and describe their perspectives relating to ethical dimensions associated with the use of such apps, specifically in the workplace.

A qualitative descriptive approach was applied to the study design, as this approach emphasizes the description and analysis of stakeholders' experiences and perceptions using language and ideas that emerge directly from the stakeholders themselves [22,23]. While other methods of qualitative research and analysis prioritize the development or advancement of theory, qualitative description allows for the emergence of new knowledge that may not be readily available from theoretical deduction and is grounded in the experiences of participants.

Recruitment and Participants

Adults aged ≥18 years who reported current or previous use of an mHealth app were eligible to participate in this study. Participants were recruited for this study via an electronic advertisement posted to the Stanford Psychiatry Department's *Currently Recruiting Studies* web page. The advertisement described the study and contained a link to a web-based screening survey and was posted from August 1, 2022, through August 29, 2022.

A total of 32 individuals completed the screening survey; 31 (97%) individuals met the eligibility criteria for participation. All eligible individuals were contacted via email to schedule a Zoom (Zoom Communications, Inc) interview; 21 (68%) of these 31 eligible individuals scheduled and completed an interview. Interviews continued until the minimum target sample size of 20 was exceeded. At that point, interviewers jointly determined that content saturation had been reached, as no new substantive themes were emerging from additional data collection [24].

Procedures

Semistructured interviews were used to facilitate discussion that encouraged participants to reflect on their experiences and opinions and allow them the flexibility to focus on topics that they found the most important. This approach allowed interviewers to ask unscripted follow-up questions where relevant or skip questions that did not apply in the context of the conversation. By conducting interviews via Zoom, participants outside of the local area were able to participate in the study.

The semistructured interviews contained 4 sections: a baseline question set, 2 video vignettes and associated question sets, and a comprehensive question set (Figure 1). In order to stimulate discussion of ethical considerations among a population that may not have encountered AI use cases in mHealth previously, 2 video vignettes demonstrating the use of example AI-enabled workplace health interventions were used. The presentation of these video vignettes was followed by ethically salient questions related to the presented technology (eg, questions relating to understanding, trust, and autonomous decision-making).

Interviews were conducted between August 2022 and September 2022 by 1 of our team's 3 trained interviewers. The interviews lasted 75 minutes and 35 seconds on average (SD 24 minutes, 28 seconds; range 35-131 minutes) and were audio recorded for the purposes of transcribing.

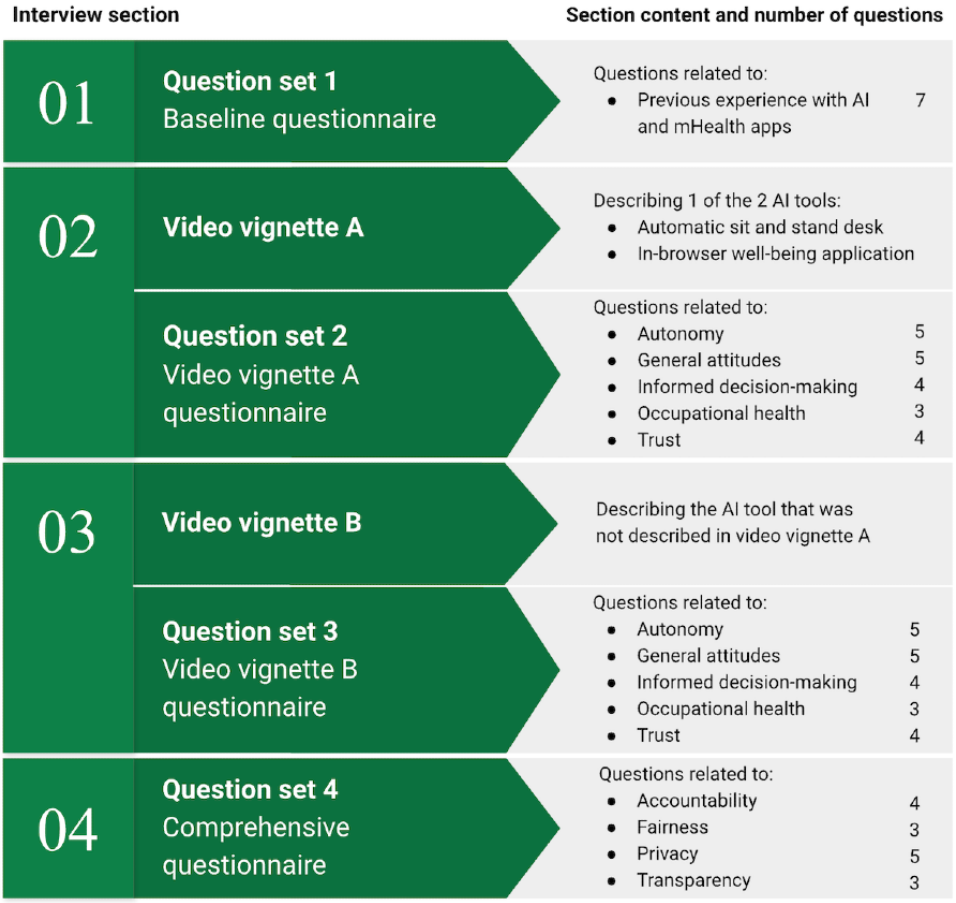
Figure 1. Outline of the semistructured interviews. AI: artificial intelligence; mHealth: mobile health.



Data Coding and Analysis

Auto-transcriptions created by Zoom were reviewed, edited, and deidentified by a member of the research team. Data analysis was guided by the principles of qualitative content analysis [25]. This inductive approach, in which transcribed data are broken down into descriptive units that are named and sorted based on their content, allows for the emergence of codes and themes directly from the dataset [26]. As we were primarily interested in identifying and describing ethical considerations of AI-mHealth users that have been underexplored in the existing literature, this inductive approach was selected over a deductive approach, which would have relied more heavily on a priori assumptions about user priorities and perspectives.

An initial round of open coding was performed on each transcript by 2 authors. The authors reviewed their assigned transcripts independently, identified interview content that they felt was substantive, and suggested descriptive codes for this content. The authors then met as a group to discuss the descriptive codes that emerged during open coding and compare the content associated with each code. They collaboratively identified topics that recurred throughout the transcripts and established preliminary code names and definitions for these topics. The transcripts were then rereviewed by the same 2 authors using the preliminary codes and definitions as a guide. At the completion of this phase of intermediate coding, the authors met as a group to compare the coded units, further refine the code names and definitions, and draft the final version of the codebook.

The final version of the codebook contained 37 codes derived directly from the content of the interviews describing baseline characteristics and tool-specific, personal, and contextual factors influencing participant attitudes toward AI-mHealth. The transcripts and codebook were then uploaded to NVivo (version 1.0; Lumivero) for final coding, which was completed by a single research team member and then reviewed for consistency by a different team member.

Data analysis began upon the completion of coding. A conventional qualitative analysis approach was used to guide the analysis [25,26]. At the completion of final coding, all authors met as a group to analyze the content and meaning of the coded units and develop categories and themes that described the associations between units. This process resulted in the identification of 3 “buckets” detailing different aspects of participants’ experiences and attitudes toward well-being AI (Table 1). For the purpose of providing an accurate and in-depth analysis of the content of these interviews, this paper will only address the codes, categories, and themes associated with bucket 1. Those associated with buckets 2 and 3 will be analyzed in future publications.

Ethical Considerations

This study obtained human participant research approval from the institutional review board of Stanford University on June 21, 2022 (58118). A copy of the institutional review board–approved informed consent form was emailed to all potential participants before the interview. Interviewers then reviewed and explained the content of the consent form to all participants at the start of the interview using the screen share function on Zoom. All participants signed an electronic consent form before the start of the study-related procedures. Participants were able to opt out at any point during the consent process or during the research interview. Identifiers were removed from the dataset during the transcription process, before analysis. Participants were compensated in the form of a US $50 electronic gift card.

Results

Overview

The demographic information of participants can be found in Table 2. The final cohort of participants included young adults, aged between 20 and 36 years, and was primarily composed of individuals whose reported sex was female (15/21, 71%) and whose reported race was Asian (8/21, 38%), Black (5/21, 24%), or multiracial (4/21, 19%). In their open-ended responses, participants reported having experience using AI-mHealth apps, such as Apple Health, Headspace, Calm, and Flo.

All participants in this study commented on considerations related to bucket 1: user attitudes toward and understanding of AI-mHealth (Table 2). These considerations primarily arose from responses that emerged in parts 1 and 4 of the interview question set (ie, the baseline questions at the start of the interview and the comprehensive questions at the end of the interview; Figure 1). In discussions relating to attitudes and understanding of AI-mHealth, 3 major categories, each with 3 related subcategories, emerged (Figure 2). The content of these categories and subcategories is described in detail in the subsequent sections.

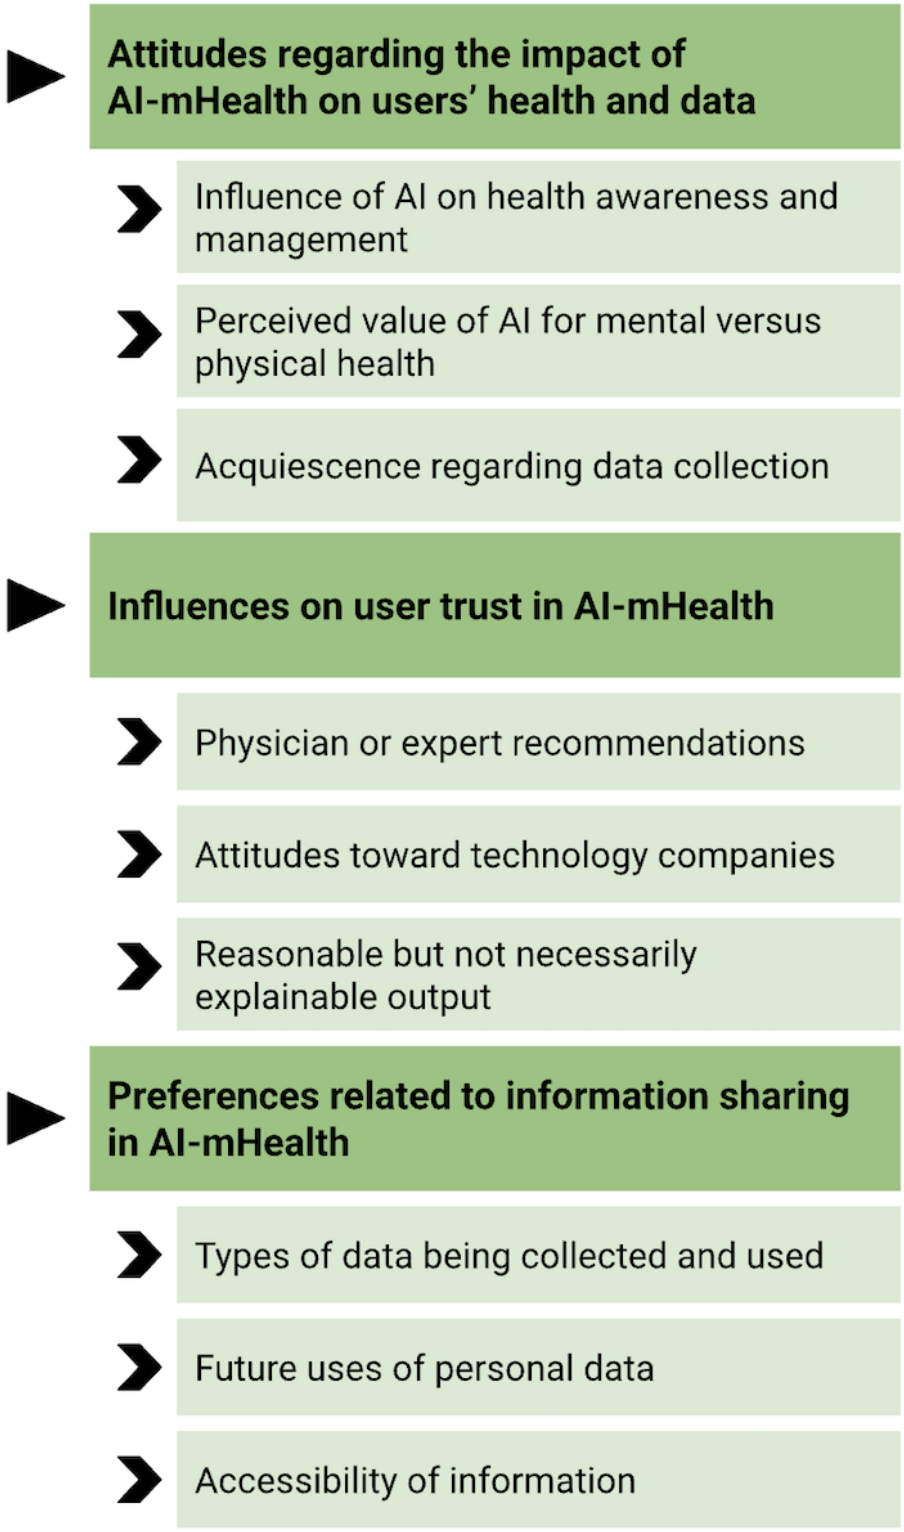
Figure 2. Categories and subcategories describing users' attitudes toward artificial intelligence (AI)–enabled mobile health (AI-mHealth) apps.



Attitudes Regarding the Impact of AI-mHealth on Users' Health and Data

Influence of AI on Health Awareness and Management

Participants expressed positive sentiment toward the potential for AI-mHealth apps to support health awareness, health maintenance, and preventative care. Several users acknowledged the value of AI-mHealth in encouraging users to take steps to manage their own health, with one participant noting that "Sometimes we can't acknowledge the moment ourselves" (P101) and another noting that a major benefit of the incorporation of AI into mHealth is its ability to "[help] you know when you should be thinking about your mental health and wellbeing" (P130).

While improved health awareness was perceived as a benefit of AI-mHealth apps, participants also described ways in which they felt such technology could undesirably influence their health behavior. While some participants referenced having

XSL•FO
RenderX

"blind trust" (P096 and P117) in AI-mHealth to manage aspects of their health, others emphasized that AI-mHealth apps should act as a supplement to an individual's health management, with one user noting, "Any AI use should just be a healthy sidestep to us taking control of our mental health versus taking over and trying to do it for you" (P130). Another described a desire to feel in control over the management of their own health and explained how AI-mHealth could interfere with feelings of autonomy:

> *Part of me doesn't like to have too many orders. I like having the ability to choose a bit...When it comes down to health, my body and my movements, that's one of the main things that we can control, that we should control. And someone telling me to "Do this right now," it's just eh. The way I view health is as an investment in myself, but I also want to do that, I want to invest in my health. I want it to be voluntary in that sense. And just having [technology do that instead] makes me feel like a robot, just not completely autonomous.* [P101]

Perceived Value of AI for Mental Versus Physical Health

When discussing their attitudes toward AI-mHealth apps, users differentiated between the domains of mental health and physical health. Multiple users noted that physical health could be more easily quantified than mental health, thus making mental health more complex and difficult to measure. Users commented that "Physical health is more quantitative and mental health is more qualitative...there is so much more to unpack from it than just a number for physical health" (P101); "Mental health is, more often than not, harder to measure than physical health" (P104); and "Technology can compensate for physical health, as opposed to, mental health can become so complicated" (P130). Several users noted that, because of mental health's resistance to measurement and quantification, they would be more skeptical of AI-mHealth recommendations for mental health and more accepting of recommendations for physical health:

> *[AI] could work for certain things but...It maybe needs more work on other aspects, especially when it comes to emotions and people's decisions. In math, it totally works. But if it can tell you when you're going to have this episode of sadness or happiness, I'm not very sure about that.* [P118]

> *Physical health has been a lot more black and white. When I get a suggestion for my physical health, I don't question it as much. I am more likely to accept it...I am less hesitant about software that is telling me to do a physical activity.* [P101]

Users further emphasized that they would desire the ability for greater personalization, customization, or control of AI-mHealth apps that target mental health, with the aforementioned user noting the following:

> *With the mental health app, I want it to be more customizable. I feel like it requires more factors to consider before suggesting or working.* [P101]

Acquiescence Regarding Data Collection

Users expressed a reluctant acceptance toward the amount and type of personal data collection that occurred while using AI-mHealth apps. Although many described discomforts regarding the volume of data collection, they acknowledged that it felt "unavoidable" due to how deeply ingrained this process is in modern technology use (Textbox 1).

Textbox 1. User quotes regarding data collection.

- "[Sharing data] feels unavoidable to me unfortunately. I don't feel great about this but it feels like there's some of my data that I will just have to give up." [P097]
- "I feel like our generation is so used to using applications and we don't really question what happens with [our data]." [P101]
- "Ideally I don't want that to happen, but I think in reality they already have access to all of our data." [P105]
- "I am very into providing my data for research purposes, because I know that [data collection] is still happening anyway." [P106]
- "I already know companies use my data to sell, but that's just also inevitable." [P114]
- "I honestly just think it's so much a part of everyday life. I would not say I am 100% comfortable with all the data collection that is happening." [P124]
- "I don't particularly want data that isn't already out there to be going out there...I deeply hate that expectation of handing over [my] data about what I am doing." [P131]

Several users admitted a conflict between their theoretical preferences relating to data collection and sharing and their actual use of technology, with one user summarizing the following:

> *I feel like in theory I care a lot about how my data is being used, what type of data, who it's being sold to. In practice, I feel like I don't really know what kind of data [the apps I use] collect.* [P097]

A different participant acknowledged that, while data sharing likely would not incur any real risks, their negative feelings toward these practices were based "on principle" and their desire to feel as if they had control over information about themselves:

> *When I think about data privacy, it comes more down to the principle of wanting my information to stay private and not feel like I am being tracked all the time. Because in reality when I think about it, nothing terrible seems like it is going to happen if my information is going to be used other than them telling me what to buy. It is not a huge issue, but it is almost the principle of the thing, and wanting to feel like you*

XSL•FO
RenderX

> *have ownership over your day-to-day and it not being up to outside controlling factors.* [P130]

Influences on User Trust in AI-mHealth

Physician or Expert Recommendations

Multiple users agreed that endorsements from physicians or guidance from health or regulatory organizations would increase their trust in an AI-mHealth app and their willingness to use it, with one stating that "having some kind of affiliation with an actual medical professional does actually instill a little more trust and make you more willing to share your information" (P130). Several users specifically mentioned that they would be more comfortable sharing personal health data with apps that were recommended to them by a trusted physician. One user described the following:

> *Depending on the original intent of the app, if it greatly benefits my health, if my therapist told me to use this specific app and then I saw that it had great improvements in my health because it tracked my specific triggers or mental health and it took record of everything, I don't think I'd question the data that is being collected.* [P114]

One user specifically referenced the Food and Drug Administration approval of AI-mHealth apps, commenting on how the regulatory process of Food and Drug Administration approval gave them confidence and had the potential to give other users more trust about using such apps:

> *One of the applications I used is a FDA approved method for tracking something. That gives me a lot more trust. For AI situations where it is making recommendations based on your health, it should be like any other thing. Drugs that increase your mental wellbeing, those are FDA approved. It should go through the same scrutinizing process and the same regulatory process as well. I think the public would be more willing to use it too.* [P096]

Attitudes Toward Technology Companies

Users expressed mixed levels of trust in companies that develop AI-mHealth apps. Several users saw the reputation of large companies as a reason to have trust in being a consumer there because these companies were "reputable and reliable" (P114). Two participants specifically referenced feeling more comfortable sharing their data with larger, established companies, noting that "I would feel safe...if it's a reliable company like Google" (P127) and "A big company that people would know, I would feel comfortable sharing the information" (P130). Although most users did not provide additional details about why they trusted larger companies, one participant acknowledged the advantages that large companies have that may keep user data safer:

> *The paradoxical part is I'd rather almost want it to be Amazon other than somebody I don't know, because I know that Amazon is large enough and asks the employees to do a better job at keeping my data safe from outside people.* [P131]

Others described mistrust in technology companies based on their perceptions about how these companies collect, use, distribute, and profit from users' data, with one user stating the following:

> *They use all this data to benefit their company and they have all this money, but none of the users receive it...I feel like they are just using [our data] for personal selfish gain without it really benefiting anybody except their own company.* [P114]

Another user cited the history of such companies benefiting from the collection of personal user data as evidence against trusting them to genuinely work toward creating benefit for their consumers:

> *All the mental health applications, we can see that they want to earn money. I think the consumers that are looking for mental health services in any kind of different formats, including applications, are essentially looking for a little more authenticity in their services because it is mental health care. If the consumers can see they profit over us, once they see that, it's like, "I don't really trust this service."* [P106]

Reasonable but Not Necessarily Explainable Output

Multiple users indicated that understanding the rationale behind an AI-mHealth app's recommendation was not crucial to their trust in the app. Users acknowledged the complexity and black box nature of AI reasoning and did not think that having increased access to weights or other data used by the AI would be beneficial to their own trust or understanding. Instead, there was agreement that the perceived reasonableness of an AI recommendation had a greater influence on their trust and willingness to implement a recommendation (Textbox 2).

Textbox 2. User quotes regarding the explainability of artificial intelligence output.

- "I can appreciate the fact that a complex algorithm is a black box, but as long as I know that their training sample was diverse and big enough and their results are interpretable and make sense I don't mind as much. I think it's fine that they don't know what is happening." [P97]
- "I've learned that the neural network is a black box. You can only know what you add in and what you get out of it. It's still a mystery to everybody. I have accepted that with the AI tools that I have used in the past. If the conclusion isn't outrageous and I think it's useful, I'll do it." [P104]
- "I believe the rationale for the AI is based on a bunch of different factors and I don't think I'm interested in learning which factors weigh a little bit more than the other." [P105]
- "It's the zeros and ones in the computer. How can I interpret that and equate that with the human thought process? It's not possible." [P124]
- "I honestly don't care as long as the actions and recommendations don't seem ridiculous, I would not care about the exact reasoning." [P126]

XSL•FO
RenderX

In addition, several users conveyed tolerance for the "black box" limitations of AI recommendations, noting that humans often cannot explain exactly what drives their intuitions and judgments, and extending this idea to AI:

> *There are some things that we think about and we can't really explain our reasons for it...We don't really know how to quantify certain things, so I can't completely blame the AI for having a black box concerning my data either.* [P114]

Multiple other users similarly compared the limits of explainable AI to the covert processes of the human brain:

> *It is sometimes really hard for even the software engineers to design the specific algorithm to know exactly what is going on in that thought process. It is really hard for even us to walk someone through, "I thought about this and then this thought led to that, because of the specific factors..." It is really hard even for ourselves to talk that through.* [P106]

> *[Humans] can't always pinpoint exactly where something comes from, where an idea comes from, where feelings come from. If I'm being empathetic to the AI, I would be like, "Yeah I get that. You don't know where this suggestion is coming from but you feel like it's correct." I would probably trust that.* [P115]

Preferences Related to Information Sharing in AI-mHealth

Type of Data Being Collected and Used

Several participants clarified that, while they felt comfortable with not knowing *how* an AI app makes a decision, it was important for them to understand *what personal* data were being collected and used in such decisions, as described by these participants in the following statements:

> *The initial information they are collecting I would want to know. How those decisions are made, I definitely can understand that that would be too complicated to be explained. That I don't really mind.* [P130]

> *It wouldn't be too much of an issue if they can't explain how it's making the decision, but at least knowing what is being considered in the process would give me some peace of mind.* [P101]

One of these users wanted to know, "What information do they need from me to decide?" (P130), while other users summarized, "I would love to know what kind of data is being taken in" (P127) and "I would really appreciate knowing what behaviors and responses they are using to create that output...I think people 100% deserve to know every piece of data they are using and knowing what that is for" (P097). Several others described how being provided with information regarding the type of personal data that are being collected and used in an algorithm's decisions would increase their willingness to consistently use an app (P096, P117, and P120).

Future Uses of Personal Data

Many users expressed a desire to have access to information regarding the potential future uses of data collected via their use of AI-mHealth apps. Specifically, they wanted to know if personal data collected by an app would be sold to or shared with other corporations or entities (Textbox 3).

Textbox 3. User quotes regarding future uses of personal data.

- "I would like to know if the applications that I'm sharing data with have plans to sell that data." [P097]
- "[I want to know] what it's being used for. And I think it should only be used for the optimization and my de-identified data should be used for the training of the model to make it more accurate, better for future uses." [P104]
- "I really would like to know what data are being collected and how exactly they are being used. Because I don't want my health data to be floating around." [P106]
- "I would love to know who is the end user of my data. Has my data been sold to another person?" [P111]
- "I really want to know specifically how they use it. Are they selling my data, what agencies or companies have access to that? What is the background of these companies? Are they just going to spam email me, put it on the dark web? I really want to know the security of that." [P114]
- "How are you using my data, is it going anywhere where it's identifiable?" [P120]
- "We are hearing stories that they are selling data. I would love to know if the data that is collected, is it being sold to hospitals or is it being sold to the black market? If it is sold to a hospital for further research then I will be okay with it, but if the app is using it for other malicious activities, that would be very wrong." [P127]

Multiple users discussed how the collection of highly sensitive health data increased their level of concern about potential sharing or selling of the data to third parties and their desire to know whether this was occurring. Three users specifically mentioned menstruation-tracking apps as examples of health apps where concerns of data being shared or sold involved additional or elevated risks (P097, P114, and P115). One participant argued that exposing sensitive health data to third parties could lead to serious social, legal, and medical harms:

> *[I would want to know] who has access to that data. I read some discourse about the banning of abortion and then they were telling people to delete period tracking applications because if they're able to detect when you're on your period or trying to get an abortion, you could legally be arrested for that...If [the company is] able to sell that data or give the government access to that, it could potentially put certain people in danger.* [P114]

XSL•FO
RenderX

Accessibility of Information

Users expressed a range of suggestions about how companies might better communicate to users about the collection and use of their personal data. Multiple users described the lack of engagement that users have with traditional terms and conditions pages, noting that "Many people just don't read them, and I am one of those people usually" (P115); "For me, and probably a lot of people, [when] reading those small text notices, I always push 'agree' and move on" (P096); and "A lot of people blow through that stuff and are like, 'Yes, yes, accept'" (P120). The length and complexity of these agreements were frustrating to users, with one commenting that "I just don't like how a lot of us aren't really informed how our data is being used, and then they make it so complicated to the point where we don't really look through it" (P114).

Several users described wanting to receive clear and digestible information regarding the risks and benefits of AI-mHealth apps as a more straightforward way to understand considerations related to their data. Two users described that, "It would be good to know the risks and benefits" (P096) and "[I would like] an explanation of pros and cons, rather than a sales pitch-type view of it" (P124). Other participants commented that companies should provide a "condensed version" of the terms and service agreement that "just gives the bullet points" (P101), with one participant noting how a shift toward providing more accessible information could demonstrate a company's concern for and efforts to safeguard users:

> *Privacy policies are often not very accessible. I want to see, not just do you provide the information, but do you provide it in a way that is clear with its language which to me also expresses that you care about what you are doing with the data? [To see] if you take the time and energy to make something that people understand because you care about conveying that information.* [P131]

One participant further expanded on their request for more accessible information regarding the risks, benefits, and data policies of an AI-mHealth app and posed an analogy to the informed consent process they completed for this interview study:

> *I want the app to highlight the very important data that they will be collecting and to put that into layman's terms so that I can just understand it very easily...I am thinking of something like the informed consent procedure that you just did to me. The document itself looked pretty intimidating...[but] you highlighted the components I really needed to know as a study participant...If the app could do something like that...if it can be that transparent and simple, that will definitely boost my trust and credibility as the app's consumer.* [P106]

Some participants suggested technology- and media-based alternatives to the current text-based terms of service agreements that they felt would provide information relating to risks, benefits, and how personal data are collected and used in a more digestible and accessible format. Two suggested videos as an alternative to text (P096 and P115), with one noting that this format could be useful for "forcing" users to engage with the information:

> *If it were presented in a really digestible way where you were basically forced to read it or hear it if you use the app, like a video where you couldn't move on unless you play the whole thing.* [P096]

Multiple other participants commented that apps could have associated websites where users could look up information if questions arose through their use of the app, with one noting the following:

> *It would be great to have a resource that is just live all the time. A website where you can access that information and then contact them if you have questions that aren't answered on their website.* [P120]

Discussion

Principal Findings

In this semistructured interview study, users expressed attitudes and concerns about a number of ethical considerations related to the use of AI-mHealth apps, including considerations related to autonomy, privacy, trust, transparency, and information sharing. The major findings are discussed in detail in the subsequent sections.

The Value of AI-mHealth: Perceived Limitations of Apps for Mental Health

Interviewees expressed comfort with the idea of using AI-mHealth apps to supplement their health management, citing their value in organizing and tracking health data and providing users with prompts or knowledge that could benefit them. Several users were adamant that AI-mHealth should supplement rather than replace health care services and preferred technologies that encouraged informed and autonomous health decision-making, as opposed to more assertive recommendations, which they felt could be perceived as orders that could ultimately detract from health awareness. This finding aligns with previous research by Almourad et al [27], which found that users' feelings of increased self-awareness and a sense of control over the use were acceptance factors in their use of mHealth technologies.

Users in this study notably distinguished between the potential value of AI-mHealth apps designed for physical health and those intended for mental health. Strikingly, some were less confident that AI could be as effective for mental health use cases compared to physical health use cases. They perceived mental experience as highly personal, intimate, and resistant to observation and measurement (admitting also the limits of human introspection) and therefore did not feel that AI-mHealth apps could "know" them well enough to make accurate inferences that lead to helpful predictions or guidance. These attitudes deviate from previous findings among avid users of AI mental health chatbots, who report high engagement and trust in such apps [28], and suggest that less experienced or laypersons, such as those in our study, may be more hesitant to accept predictions and guidance that rely on AI inferences

XSL•FO
RenderX

regarding more subjective and phenomenal mental processes (eg, underlying emotions or affective states) compared with apps that target physical health. The design and implementation of AI use cases for mental health will benefit from additional empirical inquiry to help understand how users with less experience think AI can benefit this domain and develop a clearer picture of ethically salient factors that may influence adoption.

The Collection and Sharing of User Data: Acquiescence and Mistrust

There was a general admission among interviewees that, as users of modern technology, they often must concede control over their data and their future uses. They acknowledged discomfort with the fact that personal data are systematically collected through their devices, partly to help advance corporate and business interests, but expressed acquiescence about their ability to prevent or change this reality. These attitudes have been documented frequently in the technology literature, having been described as privacy cynicism [29], digital resignation [30], privacy apathy [31], and privacy fatigue [32]. Notably, participants in our study were young adults whose interactions with technology have likely always involved concessions relating to privacy, possibly resulting in a reluctant acceptance that the use of technology by default incurs the loss of certain privacies. Future studies assessing feelings of acquiescence across technology users of different age groups would be of interest.

In addition, participants in this study described how the pervasiveness of data collection and sharing influenced their trust not just with specific technologies but also with the corporations or entities associated with them. Some expressed greater trust in large companies that they believed were better suited to protect their data, while others asserted no trust in these same companies due to their historical collection of user data. This, too, is consistent with findings from the technology literature, which found mistrust in corporations that users associate with data sharing. As was described by Lutz et al [33] in their survey study, the potential benefits of an individual technology or app may be trumped by "mistrust and powerlessness in relation to those platforms ostensibly providing the infrastructure." Although a recent user-review analysis found an overall high degree of public trust in individual AI-mHealth apps for mental health, our results, along with findings from the technology literature, indicate that there are users whose attitudes toward AI-mHealth are influenced by their existing trust, or lack thereof, in large technology companies [34]. More research is needed to assess how the systematic collection and distribution of personal data have contributed to users' trust or mistrust in technology companies and the impact that this may have on their trust in and adherence to AI-mHealth apps.

Users' Desire for Information: Understanding What, Not How

In a previous interview study with users of AI-mHealth apps representing an array of mHealth use cases, participants reported desiring more straightforward and precise information about the apps, including how they used AI, how the AI-enabled features worked, and how well the AI might solve the health needs the apps purported to address [35]. Participants in this study consistently expressed similar high-level concerns; however, they were less concerned with *how* an AI-mHealth app generated its outputs than they were about *what* types of data it collected and used to generate its feedback or guidance. A related, frequently expressed worry was whether their personal data could be used by additional parties or for other purposes in the future. These findings suggest that AI-mHealth users may put less stake in understanding the underlying technology and reasoning procedures driving an app and have more reservations about the collection and use of their personal data.

Experimental studies with users of AI tools in health care and other sectors engaging in AI innovation have shown that enhanced explainability is not always favorable to user understanding, decision-making, or trust [36-38]. Our results contribute much-needed stakeholder data to this literature and reveal that explainability tools or technical explanations of algorithms and models may not be crucial to secure users' trust and facilitate adoption, provided that they have access to resources that assuage personal data–related concerns.

Beyond noting that understanding an AI's reasoning procedure was not essential to their sense of trust, several participants in this study strikingly related black box algorithms to human intelligence and decision-making processes. Specifically, they described how both algorithmic and human reasoning involve processes that are obscured from the observer. A previous interview study by Gkinko and Elbanna [39] documented the tendency of people to extend empathy to AI chatbots into their workplace environments; however, the association of black box AI decision-making and human intelligence appears to be a novel finding that has not been previously documented among users of AI-mHealth apps. This association provides a reminder that humans are accustomed to making decisions based on mental processes that are not necessarily able to be articulated or explained. Taking action based on incomplete or obscured information is not a novel experience for humans, and as our participants acknowledged, this willingness could possibly extend to their interactions with AI.

Informing Users: Concerns and Recommendations

Users in this study repeatedly acknowledged that they do not read terms and conditions agreements, which they felt were overly lengthy and not designed to inform users. Participants offered a range of alternatives for how they would prefer to be informed about the use and future distribution of their personal data. User-friendly summaries of risks and benefits of an app were suggested, as were videos or accessible websites. As highlighted by several participants, the inclusion of easily digestible lists or videos regarding risks and benefits of use is a fairly minor addition to an app that could be incorporated before or after existing terms and conditions pages. Comments from our participants indicate support for concepts, such as the "Nutrition Label for Privacy" proposed by Kelley et al [40]. As AI-enabled technology that collects increasing amounts of user data becomes more accessible to the public, offering users clear and comprehensible information regarding the use and sharing of their data may influence their trust in a tool and willingness to incorporate its recommendations.

XSL•FO
RenderX

When discussing how information sharing in digital health could be improved, one participant referenced the informed consent method that is typically used in medicine and research. Informed consent forms share similar challenges to terms and conditions documents, in that they often include content that is not necessarily relevant to participant understanding or decision-making, but that instead is required for the purpose of protecting the interests of the funding or managing institutions. Studies testing shorter consent forms have found that participants were more likely to fully read shorter forms and that those exposed to shorter forms comprehended more of the information, indicating that the length of the terms and conditions pages could be a primary factor in users' tendency to bypass them without engagement [41]. Furthermore, the accompanying informed consent process in which the information from informed consent forms is distilled into accessible language that highlights the risks and benefits is often positively rated by participants, possibly indicating that terms and conditions pages that are followed by summaries highlighting the information relating to specific risks and benefits may be well-received by users of AI-mHealth apps [42,43]. Informed consent processes are established within medical practice and research and could provide a useful road map for AI-mHealth apps, which may require both templated legal disclosures and access to product information that encourages participant engagement and understanding.

Limitations

This study has several limitations relating to its sample. Most notably, all participants were aged between 20 and 36 years at the time of the interview. It is documented that attitudes toward technology are influenced by age and life stage, so the findings from this study should therefore not be generalized to older populations [44,45]. Furthermore, our sample primarily consisted of individuals who identified as female and belonged to a racial or ethnic minority group. As we did not specifically intend to prioritize the interviewing of these populations, the attitudes documented in the interviews and analysis should not be assumed to be representative of all users of mHealth apps. In addition, our findings are limited by the fact that interviews were completed in 2022, before the first release of ChatGPT, which represented a major shift in the public's perceptions toward AI and AI-enabled technologies.

Conclusions

In this qualitative study using semistructured interviews, users expressed their attitudes and concerns about a number of ethical considerations in the use of AI-mHealth apps, including considerations related to autonomy, privacy, trust, transparency, and information sharing. Notably, users distinguished between the potential value of mental and physical AI-mHealth apps, cited existing feelings of loss of control and ownership of their data in everyday use of technology that appeared to influence their trust in AI-mHealth broadly, and expressed a desire for more proactive and accessible information sharing about aspects of AI-mHealth apps. These findings present recommendations for consideration in the development and distribution of AI-mHealth apps that may enable greater ethical alignment between producers and consumers of AI-mHealth apps. Future evidence-based research examining the intersections between mHealth and AI with the attitudes of relevant stakeholders is still needed as is research that analyzes how the actual use of AI-mHealth apps aligns with the ethical perspectives identified in this study.

Abstract

Background: Cigarette smoking is prevalent in many countries worldwide, especially in low- and middle-income countries (LMICs), presenting an urgent public health challenge. Disseminating freely available smoking cessation treatments that effectively decrease cigarette smoking globally is urgently needed.

Objective: Identify the highest impact and most cost-effective values-based social media advertisements to disseminate our smoking cessation smartphone app, “iCanQuit”, among adults living in 7 major cities of India. Values represented in the advertisements included family, relationships, self-care, health, and self-control. Using a quasi-experimental design, we aimed to determine (1) which values-based advertisements had the highest smoking cessation app dissemination reach, as measured by click-through rate (CTR), app installs, and app usage metrics; and (2) which values-based message advertisements were more cost-effective as measured by cost-per-impression, cost-per-click, and cost-per-install. The study population included a selected media market of individuals living in 7 metro cities of India – Delhi, Mumbai, Kolkata, Chennai, Bengaluru, Hyderabad, and Pune – who were exposed to one of 6 social media advertisements from January 16 to May 5, 2024.

Methods: The advertisement campaign design for each of the identified values, based on previous smoking cessation trial data, followed a collaborative iterative process. Advertisements ran sequentially for 16 weeks. Advertisement exposure and app usage data were objectively collected via Google’s Display & Video 360 advertisements campaign management and Firebase app development platforms. Advertisement exposure impact on app engagement was measured via several metrics, including click-through rate (CTR, ie, the likelihood of user clicks on an advertisement after seeing it), the number of app installs (ie, a user opening the app for the first time after downloading it), and the number of app sessions (ie, app usage). Cost efficiency was measured via cost per click and cost per install for each ad.

Results: Overall, the CTR was 5%. The app was installed 5111 times. The average cost per click and cost per app install across all advertisements were US $ 0.006 and US $ 6.43, respectively. The advertisements with the lowest cost per install (range: US $4.83-US $5.16) and highest CTR (between 6% and 9%) focused on the values of family, health, and self-control. Advertisements focused on the values of relationships and self-care had modestly higher levels of engagement.

Conclusions: Advertisements focusing on the values of family, health, and self-control had the highest potential reach at the lowest cost. Overall, these findings provide insights into the reach and cost-effectiveness of values-based messages in social media advertisements, guiding future outreach efforts for population-level dissemination of smoking cessation apps.

Introduction

Globally, cigarette smoking is a significant public health challenge across many demographic groups [1]. Worldwide, one in 4 adults currently smokes cigarettes and men have almost 5 times higher smoking rates than women [2,3]. India, China, and Indonesia, which are low- and middle-income countries (LMICs), account for 51.4% of the world's men who smoke. More than half of all smoking-attributed global deaths occurred in China, India, Russia, and the United States combined, with men alone accounting for 75% of these deaths [4].

Quitting smoking is the single most effective method for preventing cigarette smoking-related morbidity and mortality—especially in LMICs [5,6]. Unfortunately, barriers to access to health care, lack of health professionals trained in evidence-based smoking cessation treatments, lack of access to and subsequent usage of such treatments, and transportation-related barriers contribute to smoking cessation programs being out of reach for those who are most in need. Implementing free, remotely accessible digital interventions may improve access to evidence-based smoking cessation programs at the population level.

Digital interventions, such as smartphone apps, offer a newer approach to in-person interventions, with the potential for broader reach and greater acceptance [7,8]. They are freely available on app stores, accessible anytime, and do not always require internet access [9-12]. An efficacious smoking cessation application could be a feasible method for community, clinical, and public health programs to offer scalable smoking cessation services—thereby addressing health inequities in tobacco control.

Our group developed iCanQuit, an Acceptance and Commitment Therapy (ACT)-based smartphone smoking cessation app [13]. Unlike standard interventions for smoking cessation [14], ACT-based smoking cessation interventions teach people to observe, acknowledge, and accept their cravings to smoke rather than avoid them, and focus on life values, instead of expectations, as motivation to quit [13,15]. iCanQuit targets 2 core theoretical processes of ACT, acceptance and values. The acceptance component teaches skills to accept sensations, emotions, and thoughts that cue smoking via distancing from thoughts about smoking, mindfulness, and flexible perspective taking. The ACT-based emphasis on values teaches skills for determining the importance of valued life domains (eg, family, health, and self-care) that motivate quitting smoking.

We tested the efficacy of iCanQuit against a US Clinical Practice Guidelines-based app (QuitGuide) for cigarette smoking cessation in a full-scale randomized clinical trial (RCT) among 2415 adults residing in the United States [16]. iCanQuit was 1.5 times more efficacious than QuitGuide for smoking cessation at 12 months (P<.001) [16]. In addition, the intervention's impact on smoking cessation was mediated by an increase in acceptance of cues to smoke and higher engagement with the app [17]. Although iCanQuit is the only known smoking cessation app proven efficacious for smoking cessation in a full-scale randomized trial, we are aware of no published studies on methods to disseminate any smoking cessation app.

Historically, exposure to antismoking mass media (ie, television) advertisement campaigns has been deployed to disseminate smoking cessation programs at the population level [18-21]. The most used approach is "negative advertising" or the use of advertisements with graphic content that provoke a strong negative emotional response, such as fear, disgust, and sadness about the serious harms of smoking [22]. Tobacco control advertisement campaigns are also more effective when they provide actionable resources for cessation (ie, telephone number for a support line) [23].

An alternative approach to negatively framed advertisements is to design an advertisement campaign with personal values known to motivate behavior change [24]. According to the ACT approach underlying the iCanQuit app, values are "chosen qualities of an action with purpose" [25,26]. Personal values motivate people's choices, depending on the importance of the value-behavior domain [24]. Personal values can influence behavior change and an individual's response to health-related information [27,28]. However, little is known about the use of values-based messages in tobacco control population-level advertisement campaigns. A recent study aimed at developing antismoking communication campaigns examined the associations between personal values and tobacco control policies [29]. The most frequently selected values by participants included (1) "assuring my family is safe and secure," which reflects the value of family and (2) "keeping myself in good health," which reflects the value of health. These results suggest that values-based messaging is a promising approach in public health communication efforts to increase the adoption of smoking cessation programs at the population level.

Building on this research, we tested the use of values-based messages to disseminate the iCanQuit smoking cessation app at the population level. For this, we selected adults in India, the largest and fastest growing population globally (surpassing China in 2023) [30], with disproportionately high rates of cigarette smoking, especially among men (17.4%, equivalent to >100 million men in India), who have over 6 times higher rates of cigarette smoking than women (2.8%) [4]. Therefore, there is an urgent need to access evidence-based smoking cessation programs.

Given that cigarette smoking is a significant public health challenge in India [31], and to address the need for freely available smoking cessation resources, we tested the dissemination potential of the iCanQuit app to individuals in India. We first conducted user-centered qualitative research to inform the tailoring of iCanQuit to users in India. We then conducted user-centered qualitative research to inform the selection of values-based messages in social media advertisement campaigns. Subsequently, we conducted a pilot social media advertisement campaign to determine the most efficient and cost-effective strategies for reaching a broad audience of adults who smoke. The 16-week advertisement campaign aimed to compare the reach of 5 personal values-based message advertisements (ie, family, relationships, self-care, health, and self-control) known to motivate behavior change in promoting installation and usage of the iCanQuit app [24,32].

XSL•FO
RenderX

The study's main objective was to identify the highest impact values-based social media advertisements to disseminate our smoking cessation smartphone app, "iCanQuit," among adults living in 7 major cities of India. Using a quasi-experimental design, the goals were to (1) determine which values-based advertisements had the highest smoking cessation app dissemination reach, as measured by click-through rate (CTR), app installs, and app usage metrics; and (2) determine which values-based message advertisements were more cost-effective as measured by cost-per-impression, cost-per-click, and cost-per-install.

Methods

Overview

The main objective of this quasi-experimental comparative study was to identify the highest reaching and most cost-effective values-based social media advertisement to disseminate a smoking cessation app already proven to be efficacious to help adults quit cigarette smoking [16]. The visual advertisement messaging was focused on various personal values hypothesized to motivate adults to quit smoking. In the context of this campaign, we tested various personal values messaging that may motivate viewers exposed to the advertisements to install the app, thereby promoting app engagement.

Adults in a selected media market in India were exposed to one of 6 advertisements that ran sequentially from January 16, 2024, to May 5, 2024 (Table 1). The user sees the ad, finds the message interesting, clicks on it, and is directed to the advertisement's website (ie, the app store iCanQuit page). Over the course of 16 weeks, the digital advertisement campaign sequentially deployed each advertisement. The generic control advertisement ran for about 6 weeks, while each values-based advertisement ran for about 2 weeks.

Table . Advertisement campaign active dates.

Type of value-based advertisement	Dates advertisement was active	Number of days
Generic control ad	01/16/2024-02/26/2024	42
Family	02/22/2024-03/12/2024	20
Relationships	02/22/2024-02/26/2024 03/16/2024-03/23/2024	13
Self-care	03/25/2024-04/07/2024	14
Health	04/08/2024-04/22/2024	15
Self-control	04/23/2024-05/05/2024	13

Priority Population

The study population included individuals living in 7 metro cities of India – Delhi, Mumbai, Kolkata, Chennai, Bengaluru, Hyderabad, and Pune—as the test areas due to their high population density as well as cultural and linguistic diversity [33].

Values-Based Visual Advertisements

Personal values were identified based on empirical research data from previous digital smoking cessation intervention trials conducted by our group [16,34]. We selected the most frequently reported personal values that participants cited as motivations for quitting cigarette smoking. These values include: (1) family, (2) health, (3) money, (4) spirituality, (5) relationships, (6) pets, (7) self-growth, and (8) friends.

The advertisement campaign design for each of the identified values, based on previous smoking cessation trial data, followed a collaborative 2-step process. Step 1 involved an expert-guided development of values-based messages to motivate adults who smoke to quit smoking. Our research and clinical team of investigators and colleagues with expertise in ACT worked together to generate values-based messages based on their expertise in delivering behavior-based interventions [13,26]. Step 2 involved developing visual advertisements for each of the 5 selected messages through an iterative design process. We collaborated with a vendor specializing in visual advertisement creation (GroupM) [35], ensuring each advertisement was aligned with a specific message.

Visual advertisements were created to align with the 5 personal values of family, relationships, self-care, health, and self-control. A sixth generic control advertisement that did not correspond to a specific value served as a reference (Figure 1). Advertisements ran in the English language. Each visual advertisement ran in 4 mobile-friendly image sizes: 250 × 250, 300 × 250, 320 × 480, and 320 × 50 pixels.

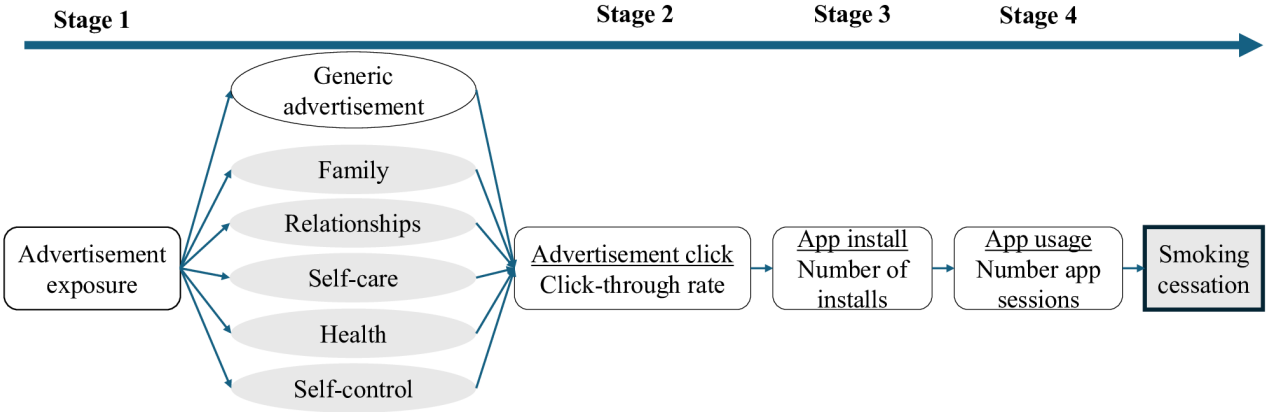
Conceptual Model

We hypothesized that exposure to values-based messages via social media advertisements results in app engagement via a 4-stage process (Figure 2). In stage 1, adults in a selected media market in India are exposed to one of 6 advertisements—a generic control advertisement and 5 values-based advertisements—that run sequentially. In stage 2, the values-based messaging in the ads, which is theorized to resonate with adults who smoke, leads to advertisement clicks, which guide users to download the app. In stage 3, users download and install the app on their smartphones. In stage 4, users engage with the app, and it is theorized that engagement with the smoking cessation app leads to smoking cessation given that engagement is a strong predictor of smoking cessation [17,36]. Note that smoking cessation is not an outcome of this study and thus was not measured.

Figure 2. Conceptual model: values-based messages in social media advertisement.



Data Collection Overview

Data were objectively collected via Google's Display & Video 360 (DV360) advertisements campaign management and Firebase app development platforms. Advertisement exposure and advertisement clicks were measured through DV360, while app installs and app usage metrics (user usage of the iCanQuit app once installed) were tracked via Firebase. Once an app was successfully installed, the user was linked to the advertisement they clicked as captured via the DV360 platform.

XSL•FO
RenderX

Stage 1. Advertisement Exposure

We used Google's Display & Video 360 (DV360) platform for content-oriented advertising. DV360 is an advertising platform within the Google Marketing Platform, which is designed for managing display and video advertisement campaigns. DV360 seamlessly integrates advertisements into the user's web browsing experience through tailoring and real-time bidding processes, ensuring relevant advertisements are shown to the right users at the right time. The details of each step in this process are outlined in Table 2.

Table . Steps in visual advertisement exposure through DV360.

Step	Description
Browsing online	A user browses the web by visiting a blog or web page.
Real-time bidding and advertisement request sent	As the page loads, it sends an advertisement request to an advertisement exchange (ie, DV360 platform).
User profile matching and DV360 bids	DV360 identifies the user as "interested" or "high intent" based on the set of content-oriented parameters and places a bid. Advertisements are also triggered on web pages that include relevant keywords (ie, content-oriented keywords).
Auction and advertisement selection	DV360 wins the auction, and an advertisement is selected.
Advertisement display	The advertisement appears in a banner slot on the blog or web page that the user is browsing.
Post advertisement user interaction	The user sees the ad, finds the message interesting, clicks on it, and is directed to the ad's website (ie, the app store iCanQuit page).

Advertisements were tailored to affinity and in-market audience segments, as well as to users of 48 competitor smoking cessation apps, for their likely interest in smoking cessation to maximize the impact and cost-efficiency of the campaign. Affinity groups used for advertisement tailoring included the following: food and dining, frequently dines out, frequently eats breakfast out, frequently eats lunch out, frequently eats dinner out, coffee shop regulars, fashionistas, beauty mavens, shutterbugs, technophiles, frequently attends live events, pop music fans, theater aficionados, and media and entertainment. In-market segments selected included makeup and cosmetics, soccer tickets, party supplies and planning, event planning services, business financial services, and vacation packages. Advertisements were compared descriptively on several metrics. For instance, they were compared on impressions, which is the number of times a visual advertisement is displayed to a user on a webpage or blog.

The full advertisement campaign ran from January 16, 2024, to May 5, 2024 (Table 1). Over the course of 16 weeks, the digital advertisement campaign sequentially deployed each ad. The generic control advertisement ran for about 6 weeks, while each values-based advertisement ran for about 2 weeks.

Stage 2. Advertisement Clicks

Clicks are the number of times users interact with an advertisement by clicking on it. CTR is the ratio of clicks to impressions, expressed as a percentage. It measures the likelihood of users clicking on an advertisement after being exposed to it, indicating interest in the message.

Stage 3. App Installs

App installs are the number of times an app is successfully downloaded and installed on a device. The conversion rate is the ratio of installations to clicks. The cost per install is the average cost for each app installation, calculated by dividing the total advertisement campaign cost by the number of app installs. To monitor app installs and assess the impact of the advertisement campaign on app usage metrics as a measure of app engagement, the mobile measurement platform, Firebase, was integrated with the advertisement serving platform Campaign Manager DV360. Firebase is a Backend-as-a-Service (BaaS) platform developed by Google that provides a suite of tools and services to help developers build, deploy, and manage applications, particularly mobile and web apps, with features like real-time database, authentication, and cloud storage. This integration facilitated the tracking of app installations and app usage metrics described below.

Stage 4. App Usage Metrics

Once the iCanQuit app was successfully installed, all in-app activity was tracked by Firebase. Several usage metrics were summarized for the first 30 days for each app user, including the (1) number of app sessions, (2) time per session, (3) unique days of use, and (4) length of use from the first to last session. Smoking status and cessation were not measured.

Statistical Analysis

Users were linked to the advertisement they viewed through advertisement tracking within Firebase, the Google platform used to track app installs and app usage. When an app was successfully installed, the user was assigned an advertisement tracking ID corresponding to the Google advertisement clicked to initiate the app download. For users who had advertisement tracking disabled, we assigned the advertisement campaign based on the installation date, selecting the campaign closest to that date.

Given the quasi-experimental design, there were no inclusion or exclusion criteria nor missing data. However, there were 34 users who had advertisement tracking features disabled and installed the app between February 22 - 26, 2024, when 3 advertisements were running simultaneously. As it was

XSL•FO
RenderX

impossible to assign these users to a specific advertisement, they were excluded from the analysis.

To compare the values-based advertisements on advertisement metrics, we used chi-square tests for CTR and cost per install and ANOVA for the number of installs per day. Advertisements were compared on app usage counts using negative binomial models for the number of app sessions, unique days of use, and length of use, given their heavily right-skewed distributions. Finally, advertisements were compared on time per session using ANOVA.

Ethical Considerations

All study procedures, protocols, and procedures for the advertisement campaign were approved by the Fred Hutchinson Cancer Center's Institutional Review Board and determined to be a nonhuman subject research since we did not interact directly with individuals, nor collect any personally identifiable information.

Results

Advertisement Clicks

The advertisement campaigns resulted in a total of 119,258,689 impressions and 5,635,114 clicks (Table 3). CTR significantly varied across advertisements (P<.001), averaging 5% across ads. The relationships and health values-based advertisements had higher CTRs, at 9% each.

Table . Advertisement metrics.

Variables	Type of ad							*P* value
	Overall	Generic	Family	Relationships	Self-care	Health	Self-control	
Number of impressions	119,258,689	25,939,433	21,783,538	14,292,366	26,077,665	14,093,203	17,072,484	NA[a]
Number of clicks	5,635,114	911,843	1,261,810	494,136	153,747	1,285,553	1,528,025	NA

Number of app installs	5111	1149	1192	509	346	946	969	NA
Average number of installs per day, mean (SD)	46.0 (28.3)	27.4 (13.8)	59.6 (27.6)	39.2 (19.2)	24.7 (19.9)	63.1 (30.5)	74.5 (17.2)	<.001
Conversion rate[c], %	0.09%	0.13%	0.09%	0.10%	0.23%	0.07%	0.06%	<.001

[a]NA: not applicable

[b]Click-through rate = Number of clicks/Number of impressions.

[c]Conversion rate = Number of app installs/Number of clicks.

App Installs

The advertisement campaigns resulted in a total of 5111 app installations (app installs; Table 3). App installs per day varied significantly across advertisements (P<.001). The self-control and health value-based advertisements averaged the greatest number of installs per day, with means of 74.5 (SD=17.2) and 63.1 (30.5), respectively. The conversion rate, or the ratio of installations to clicks, also varied significantly between advertisements (P<.001). The self-care value-based advertisement had the highest conversion rate of 0.23%, while the self-control value-based advertisement had the lowest conversion rate of 0.06%.

App Usage Metrics

The number of app sessions, minutes spent per session, unique days of use, and days from the first to last session were summarized for the first 30 days for each of the 5111 app users in India. Summary usage statistics are given in Table 4 for all app users combined, and separately by advertisement viewed. Most app usage metrics were similar between values-based advertisement campaigns, except number of app sessions varied significantly across campaigns (P=.04). The relationships value-based advertisement averaged a higher number of app sessions per user (mean=2.3, median=1). The mean length of app use in the first 30 days was 9.3 (SD=15.8) days

[c]Median=0.2

[d]During the first 30 days after downloading the app.

Advertisement Budget and Cost

The campaign budget was evenly divided across the 5 values-based advertisements to ensure equal exposure and allow for unbiased results. The total budget for the iCanQuit India initiative was Indian Rupees 26 lakhs, equivalent to 2,600,000 rupees or US$ 34,211 (exchange rate on February 27, 2024). The total campaign media advertisement spend was US $32,847.18. The 3 top-performing advertisements in terms of cost per install and number of installations were family, health, and self-control value-based ads, while the worst-performing advertisements were relationships and self-care value-based advertisements. The full cost breakdown by advertisement is given in Table 5. The average cost per install across all advertisements was US $6.43; the average cost per install across the family, health, and self-control value-based advertisements was US $4.97, with the family value-based advertisement having the lowest cost per install at US $4.83.

Table . Advertisement budget and cost.

Variables	Type of advertisement						
	Overall	Generic	Family	Relationships	Self-care	Health	Self-control
Advertisement spending, USD	$32,847.18	$6016.61	$5756.81	$4976.20	$6400.43	$4885.89	$4811.24
Cost-per 1000 impressions, USD	$0.275	$0.232	$0.264	$0.348	$0.245	$0.347	$0.282
Cost-per-click, USD	$0.006	$0.007	$0.005	$0.010	$0.042	$0.004	$0.003
Cost-per-install, USD	$6.43	$5.24	$4.83	$9.78	$18.50	$5.16	$4.97

Discussion

Principal Findings

The success of the iCanQuit values-based advertisement campaign was measured by its ability to effectively communicate personal values hypothesized to motivate change in behavior (ie, smoking cessation) and its yield of app installs by the selected audience (users in India). The advertisement campaign generated approximately 119 million impressions and 5.6 million clicks with an average click-through rate of 5% total. This click-through rate was greater than industry standards, which range between 0.5% and 1% [37]. The campaign resulted in approximately 5111 app installs, with reach (click-through rate and conversion rate) and cost efficiency of the campaign varying across advertisements.

The self-control value-based advertisement achieved the highest reach and cost-effectiveness, followed by the health value-based advertisement, suggesting that self-control and health are key motivators for smoking cessation among people in India. In contrast, the self-care and relationships value-based advertisements showed relatively low reach and cost-effectiveness. The self-care value-based advertisement had the highest conversion rate of all advertisements, but its absolute volume of conversions remained the lowest. We are unsure why the self-care advertisement did not perform well, though we believe the advertisement's high conversion rate is due to its

XSL•FO
RenderX

absolute number of impressions. Specifically, the self-care advertisement had nearly twice as many impressions (26,077,665) as the health advertisement (14,093,203), even though both advertisements ran for a similar number of days (14 and 15 days, respectively). There are a few plausible explanations for this. First, it is possible that the algorithm favored the self-care advertisement more than the health advertisement, giving it more exposure. Second, the self-care advertisement may have won more advertisement auctions, which is an iterative process in which both tailoring and real-time bidding processes ensure relevant advertisements are shown to the right users at the right time. For instance, if the self-care advertisement initially generated a higher click-through rate, the algorithm would predict strong performance and therefore show it more often. In other words, the advertisement received more screen time because it was perceived as more engaging and better suited for the audience.

While the relationship values-based advertisement resulted in the greatest engagement with the app, the advertisement had relatively low reach and cost-effectiveness. Finally, while the generic control advertisement had a relatively low cost per install (US $5.24), this advertisement yielded a total of 1149 installs in 6 weeks compared with the family value-based advertisement which yielded 1192 in half the time.

Importance of Findings

This is the first study, to our knowledge, to draw a direct comparison of the reach and cost-effectiveness of values-based advertisement campaigns for disseminating a smoking cessation app at the population level. We found that advertisements focusing on the values of self-control and health yielded the highest reach at the lowest cost, suggesting potential for broad dissemination and scalability. The high performance of self-control-based messages indicates that the ability to regulate urges to smoke as a strategy to quitting smoking may resonate with adults in India. The health-based messaging confirms previous research suggesting health is an important motivator to quitting smoking [38].

Comparison With Previous Work

To put the findings of this study in context, the only known previous study of a mobile-based smoking cessation program is a media campaign for SmokeFreeTXT (SFT), a text messaging program for adolescents in the United States [39]. This was a nationwide campaign that included traditional (television and radio), online, and social media outreach with action-based advertisement messaging. The SFT social media campaign resulted in a click-through rate of 0.14%, as compared with 5% in our study. In terms of cost, the cost-per-click in the SFT social media campaign was US $0.63 compared with a cost-per-click of US $0.0006 in our study. These results suggest that our social media campaign was more effective in reach and cost among adults in India. The SFT measure of engagement was the number of new website sign-ups, which was 2384 new sign-ups in 8 weeks. In comparison, our study achieved 5111 app installs in a period of 16 weeks, demonstrating the feasibility and dissemination potential of our values-based social media campaign to LMICs in a relatively shorter period of time.

Our work extends previous research by demonstrating the feasibility of a social media advertisement campaign as a cost-effective strategy to disseminate a smoking cessation app in an LMIC such as India. While most tobacco control advertisement campaigns, whether digital or traditional, have been conducted and evaluated in high-income countries (ie, the United States of America, Canada, Australia, and the United Kingdom) [40], our study focused on a priority population in an LMIC. Second, antitobacco campaigns have historically focused on the negative health consequences of smoking, whereas our study provides first-time data on the potential reach and cost-effectiveness of a mobile-based visual advertisement campaign for a smoking cessation app that focused on personal values known to motivate behavior change. Finally, beyond providing data on advertisement exposure, our study also extends this literature by further evaluating app usage metrics provided, an overall measure of engagement, known to contribute to smoking cessation [17,36].

The results also offer specific insights for future media advertisement campaigns. First, close monitoring of advertisement campaign performance is essential. While some advertisements may initially show higher engagement and be favored by platform algorithms, the click-through rates need to be put in perspective with other important metrics. For instance, these early signals, such as the click-through rate, must be interpreted alongside other outcomes such as the conversion rate and cost-effectiveness. Second, greater exposure does not necessarily translate to better performance. For example, although the generic advertisement ran longer (6 weeks vs 2 weeks on average) and had a lower cost per impression, it yielded modest click-through rate and conversion rate compared to shorter values-based advertisement campaigns. Finally, the resonance of advertisement content with the target audience matters. Tailoring advertisement messages to the cultural and motivational context of the audience is critical, and user-centered research in the intended market is a key step for campaign success.

Limitations

This study has several key limitations. First, the nonrandomized design introduces the potential for selection bias, as users who engaged with a particular type of advertisement may differ systematically from those exposed to other advertisements in this study. In addition, user characteristics were not collected, meaning unmeasured confounders, such as socioeconomic status or smoking behaviors, could have influenced both advertisement engagement and app usage. Second, individuals may have seen multiple advertisements or viewed the same advertisement multiple times, and thus, previous exposure to earlier advertisements and their potential influence on engagement could not be measured. Third, in rare cases when multiple advertisement campaigns ran simultaneously, it was not possible to objectively determine which advertisement(s) an individual was exposed to if they had advertisement tracking turned off (n=34 users excluded, 0.7% of the sample). Fourth, findings are limited to individuals in 7 selected urban areas in India comprising a total population of 107.3 million people. Replication is needed in other regions, including rural areas in India and other countries. Finally, this study did not evaluate

XSL•FO
RenderX

the impact of advertisements on key smoking cessation outcomes, such as intentions to quit, quit attempts, or sustained cessation. Future research should assess whether these types of advertisement campaigns ultimately lead to smoking cessation.

Conclusions

The results of this study indicate that exposure to advertisements focusing on the values of family, health, and self-control had the highest potential reach at the lowest cost. Overall, these findings provide insights into the reach and cost-effectiveness of values-based messages in social media advertisement, guiding future outreach efforts for population-level dissemination of smoking cessation apps.

Acknowledgments

We appreciate the tireless contributions of the entire study staff and the development services of Moby, Inc. We are very appreciative of the study participants. Funding statement The study was funded by a generous donation from the Ladir Foundation to the Fred Hutchinson Cancer Center.

Abstract

Background: Smartphones provide a precise method to study human mobility at an unprecedented scale, allowing researchers to explore the links between mobility, HIV risk, and treatment outcomes. However, leveraging smartphone technology to study HIV risk in rural settings presents unique challenges and opportunities.

Objective: This study assessed the feasibility of using smartphone GPS technology to collect mobility data from young adults in rural KwaZulu Natal, South Africa. We also present key lessons learned during the study.

Methods: The study was conducted in 2 phases (June 2021-May 2023) with males and females aged 20 - 30 years old. In phase I, participants received smartphones with a customized study app (Avicenna research software). In phase II, they used their personal smartphones and installed the study app. The app used Android location services to record the smartphone location every 30 minutes and send it to a secure study server hourly. Participants were followed up for 6 months (26 wk). If location data were missing for 48 - 72 hours, participants were contacted for troubleshooting. Engagement strategies, including reverse billing and gamification (Wheel of Fortune), were implemented to address internet connection barriers and aid data collection.

Results: A total of 207 participants were enrolled (phase I: 163; phase II: 44) with 204 providing mobility data. Participants recorded 27.6 million location points with a median number of 74,865 (IQR 28,471 - 186,578) per participant. The mean weekly location points recorded was 95.3 out of 336 possible half-hour intervals (28.4%). Phase II saw more stable data collection in the latter half of the study, due to increased user engagement with the app. Challenges included phone-related issues (screen malfunctions, lost and broken phone), app terminations, and limited internet connectivity. Reverse billing and gamification strategies improved location data collection through increased user engagement.

Conclusions: This study demonstrates that the use of smartphone-based GPS technology is feasible among young adults in a rural South African setting. Although only 28.4% (95.3/336) of expected weekly location data were collected, the study offers insights into engagement strategies that can be used to enhance location data collection in similar contexts. Continuous troubleshooting identified challenges and informed solutions to data collection gaps. Reverse billing system and gamification resulted in significant increases in location data received. These findings underscore the potential of integrating mobile health tools into health systems to better support high-risk mobile populations.

KEYWORDS

geographic mobility; migration; HIV; global positioning system; smartphone; young people; GPS

Introduction

Mobility and HIV Prevention and Care Outcomes

The scale-up of antiretroviral therapy (ART) has significantly increased adult life expectancy for people living with HIV and reduced HIV transmission [1-3]. Despite this, in 2022, there were 1.3 million new HIV infections and 630,000 HIV-related deaths globally, with the majority occurring in sub-Saharan Africa [4]. Migration, including short-distance and frequent geographic relocations, is sustaining the HIV epidemic [5,6]. Previous studies indicate that highly mobile individuals face a greater risk of acquiring HIV [7-9] and once living with HIV, are less likely to adhere to treatment or achieve viral suppression compared to less mobile individuals [10,11]. Consequently, highly mobile people are at an increased risk of developing AIDS [12] and dying from HIV-related causes [13]. In addition, mobility is linked to high-risk behaviors (eg, multiple and concurrent partners and substance use), which can increase the risk of HIV transmission if individuals are not virally suppressed [14-17]. For example, the treatment and prevention trial in rural KwaZulu-Natal showed that the new HIV infections among transient individuals within the trial communities slowed down efforts to increase ART coverage and population viral load suppression [18]. Therefore, understanding mobility patterns, including destinations, duration, and frequency, is important to inform the development of effective interventions to improve HIV prevention and treatment outcomes.

Potential of Location-Aware Technologies

Location-aware technologies, such as smartphones, offer simple and accurate tools for capturing both spatial and temporal dimensions of human mobility. A growing body of research has used portable GPS devices, smartwatches, and phones to examine relationships between mobility and health-related outcomes [19-21]. These studies reported sufficient acceptability among participants for using such technologies. However, there were challenges with standalone GPS devices, including satellite signal loss [22], the burden of carrying devices [21], complaints about discomfort or appearance [19], privacy and confidentiality concerns [20], and the need for active user effort to facilitate data collection [23]. Familiar technologies such as smartphones and wearables can mitigate some of these challenges. For instance, potential participants in rural South Africa perceived smartphone GPS valuable and appealing for studying human mobility and HIV risk due to their familiarity with smartphones [24]. Another United States study tested the use of smartphones and smartwatches in chronically ill patients with noncommunicable diseases [23]. Participants preferred smartphones because of ease of use. Also, there was more complete location data from the smartphones compared to smartwatches [23]. However, this study only assessed short-term use (28 days) and focused on noncommunicable diseases, which are typically less stigmatized than infectious diseases like HIV.

We conducted a pilot study to assess the feasibility of using smartphone GPS technology to study linkages between human mobility and poor HIV outcomes among young adults in rural KwaZulu-Natal, South Africa. Young adults in this setting are highly mobile [7] and experience complex and intersecting vulnerabilities (poor risk perception, economic hardships, and lack of social support), increasing their risk of poor HIV care outcomes [14,25]. This paper evaluates the long-term use of smartphone GPS for collecting mobility data among these young adults. We also present key lessons learned from this study.

Methods

Study Setting

This study was conducted in uMkhanyakude district, northern KwaZulu-Natal, South Africa, using the Africa Health Research Institute (AHRI) population-based HIV surveillance program. The study area is predominantly rural, with limited access to water and electricity [26]. Internet connectivity is low, mainly accessed via mobile phones on a prepaid basis. Over 85% of youth aged 20 - 24 are unemployed [27], and 20% of young adults migrate annually for economic and educational opportunities [7]. The area has high HIV burdens with an incidence rate of 8% among women aged 20 - 24 and 4% among men aged 25 - 29 years [28].

Study Design and Dates

The study was conducted in 2 phases from June 2021 to May 2023 (see Figure 1). In phase I, participants received an Android smartphone (Proline Falcon XL, Proline, South Africa) with a customized Avicenna app. These smartphones, purchased in October 2019, were chosen for their low cost and compatibility with a proposed app developed for the study. However, this app was found unusable in March 2020, leading to delays in the study to search for an alternative. The COVID-19 pandemic led to further delays, and the study began in June 2021. In phase II, participants used their personal smartphones to address operational challenges faced in phase I.

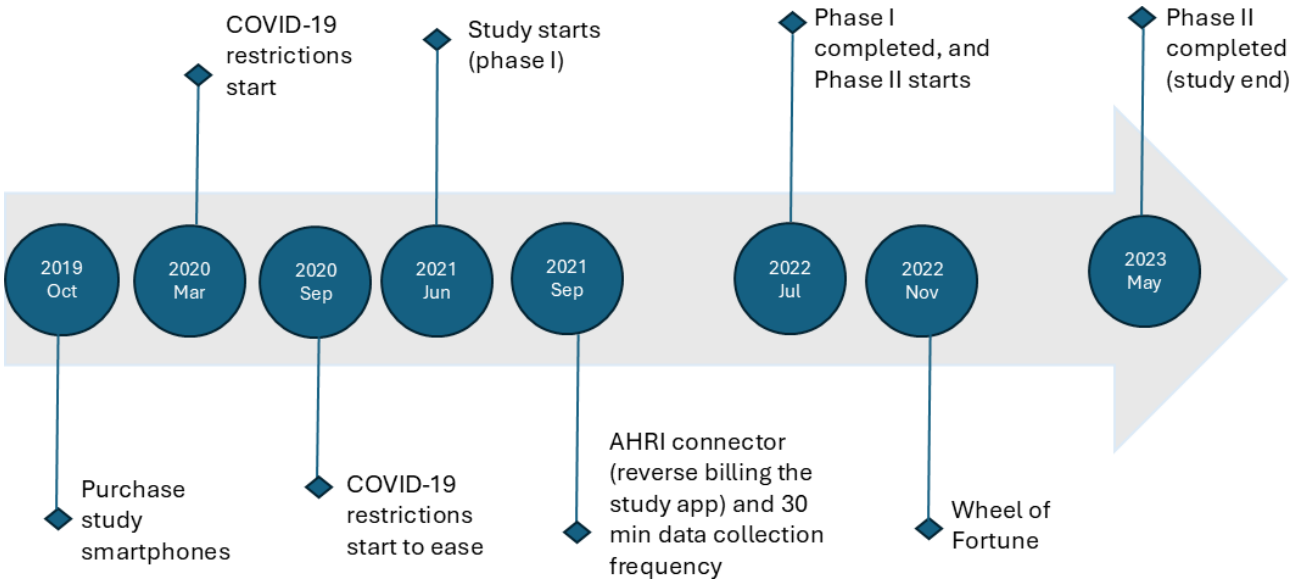
Figure 1. Sesikhona study timelines. AHRI: Africa Health Research Institute.



Recruitment, Enrollment, and Follow-Up

Individuals were eligible if they: (1) were aged 20 to 30 years old; (2) participated in the 2019 annual AHRI HIV surveillance round; (3) resided in the southern AHRI HIV surveillance area; (4) were willing to participate in the study; and (5) owned a compatible smartphone (minimum random access memory [RAM]: 1GB, sufficient free space for study app installation - phase II only). Eligibility was not limited by HIV status; the study aimed to include both those living with HIV and those who were not. The age criterion excluded individuals aged 18-19 years because they were more likely to be in school, raising parental concerns about smartphone use.

Using the 2019 AHRI HIV surveillance program population as a sampling frame, we generated a random sample of 1467 eligible individuals. Fieldworkers contacted them by telephone to introduce the study, assess eligibility, and interest. Data collection was conducted using Android tablets. Interested individuals were scheduled for a home visit. During the home visit, fieldworkers provided more comprehensive study information, including an informational video addressing privacy and confidentiality concerns identified in preliminary research [24]. The video used animations to explain GPS technology, study procedures, and data protection measures. Participants had the opportunity to ask questions before giving informed consent. After obtaining informed consent, participants were guided through the app installation (phase II) and registration. They were also provided with instructions on the app's functionality and usage. Participants were followed for 6 months (26 weeks).

Participants received mobile data bundles (phase I: 1GB, phase II: 2GB) at enrollment and monthly thereafter. A portion of the data was intended for app connectivity with the study server, but this was not implemented due to changes with the app service providers. In phase II, monthly mobile was provided only if participants provided location data for at least 10 days. Figure 2 illustrates the study enrollment, participation, and follow-up process.

XSL•FO
RenderX

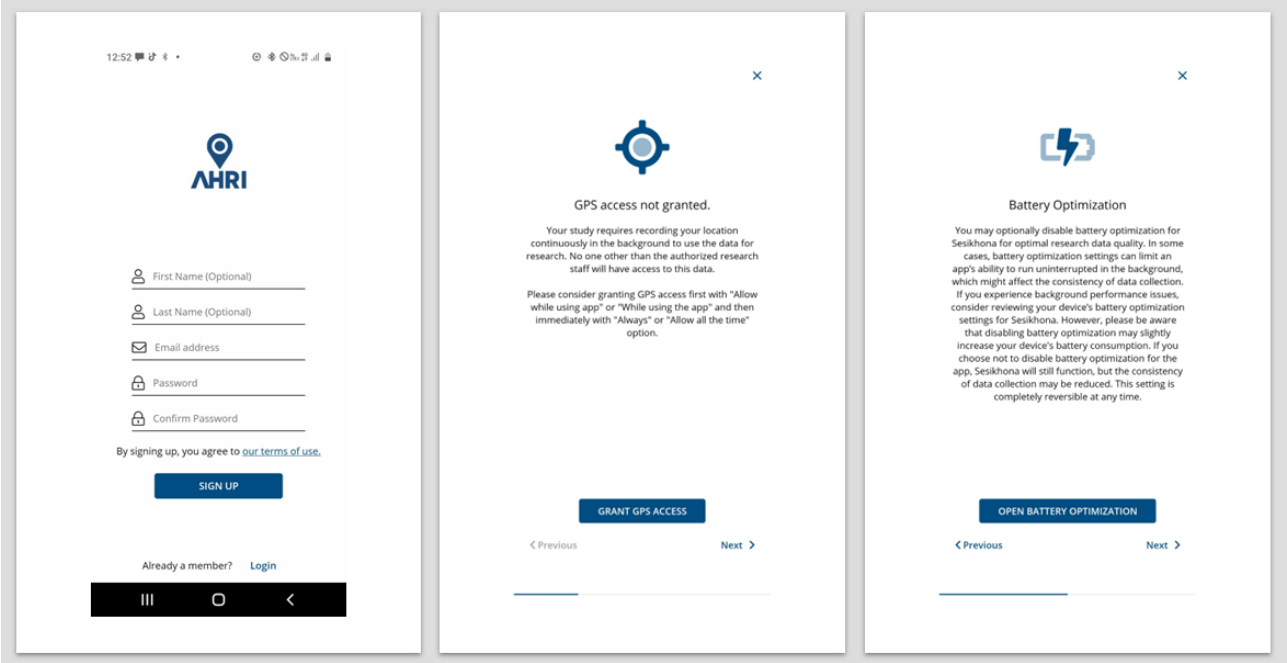
Figure 2. Description of the study enrollment and follow-up process.

Study App and Data Collection

We used the Avicenna software platform [29], customized into a smartphone app called "Sesikhona." The Sesikhona app, available on Google Play Store, used Android location services to capture GPS coordinates of the device using a combination of Wi-Fi routers, cell towers, and GPS satellites. Initially, the app collected location data every 5 minutes but was later adjusted to 30 minutes (refer to Figure 1), to capture at least 48 location points per smartphone daily. For accuracy, the app recorded GPS data over 60 seconds until 3 precise location points were obtained.

For the app to collect location data, participants needed to: (1) grant the app GPS access; (2) enable location services; and (3) exclude the app from battery optimization (see Figure 3). Participants could revoke these permissions at any time to prevent location data collection. The app uploaded collected location data hourly to a secure study server hosted by Avicenna. If the smartphone lacked internet connection, data was supposed to be stored locally and uploaded during the next scheduled cycle. The data were then transferred from Avicenna to a MySQL database at AHRI.

Figure 3. Screenshots of the Sesikhona app showing the registration page, GPS, and battery optimization permissions.



XSL•FO
RenderX

App Registration, Troubleshooting, and App Updates

To ensure confidentiality, the app did not collect personal identifying information. Instead, participants were registered with an alias, comprising an AHRI internal number, a study-specific email address, and password. The fieldworker aided the initial app setup by tethering the smartphone to their tablet for internet access. To ensure data integrity, participants were contacted by phone or visited at home if location data was missing for 48 - 72 hours. Troubleshooting involved checking app settings such as location permissions, battery optimization, and internet connectivity using REDCap (version 14.044). Fieldworkers used tablets as temporary internet hotspots, enabling the app to resume data transmission.

App updates were managed in 2 processes. Study modifications, such as changes to location data collection frequency, were automatically pushed from the Avicenna platform to participants' devices in the background. These updates required an internet connection. If offline, participants had to manually initiate the update by selecting the "reload studies from the server" option in the app. Updates to the Sesikhona app, including performance enhancements or bug fixes, were provided through the Google Play Store. Participants had to manually approve and install these updates. Initially, fieldworkers conducted home visits for assistance but later provided remote support via phone calls and data bundles to ensure internet access. App updates were discussed in weekly debriefing meetings with the project operations team, reviewing recruitment, enrollment and follow-up progress, technical challenges, and study procedures. Notes from these meetings informed revisions and improvements.

Data Analysis

We report on participants' enrollments, key demographics, HIV status at enrollment, age group, education years, and socioeconomic status. Feasibility was assessed using collected location data, including the number of location data points and weekly averages per participant. Also, we reviewed project operation meeting notes to construct a narrative of our study implementation experiences. This review highlights challenges in data collection, like phone replacement and device settings, and strategies to improve data collection.

Ethical Considerations

The study was designed with special attention to ethical considerations related to location data collection. We conducted formative research and applied the Emanuel ethical framework to identify the ethical issues and used the findings to inform the development of the informed consent materials and overall study design [24]. The study was approved by the Biomedical Research Ethics Committee of the University of KwaZulu Natal (BREC Ref 460/15). All participants provided written informed consent before participation, and study participation was entirely voluntary. To ensure privacy, all data were deidentified, with no personal identifying information in the final dataset. Participants received smartphones in phase I to keep after the study, along with data bundles in both phases as incentives for participation.

Results

We first describe participant characteristics, then summarize the collected location data. Finally, we discuss the operational challenges faced and opportunities identified during the study implementation.

Enrollment and Participant characteristics

A total of 516 individuals were contacted (including 88 in phase II), of whom 207 consented to participate (phase I: 163 and phase II: 44). Of the 207 participants, 3 did not provide location data (Table 1): one due to incomplete registration and 2 due to device incompatibility. Among those who provided location data, 131 out of 204 (64.2%) were female. Most participants, 95.2% (160 out of 168 that reported education) completed 10 to 17 years of education, and 39 out of 204 (19%) were living with HIV. Regarding age distribution, 80 out of 204 (39.2%). However, phase II participants were slightly older with a higher socio-economic status (Table 1).

[b]Socioeconomic index with [1-2] representing very low socio-economic status, [2-3] low socioeconomic status and [3-4] lower-middle socioeconomic status.

Location Data

A total of 204 participants recorded 27,589,855 location points, with a median number of 74,865 (IQR 28,471 - 186,578) points per participant. Participants provided a median of 2906 (IQR 856 - 6688) location points weekly, though consistency varied. Ideally, location data were collected every 30 minutes, equating to a minimum of 336 location points weekly (48 daily). However, on average, participants collected 95.3 out of the expected 336 points (28.4%) weekly. The range and volume of location data varied by participant (Figure 4).

In phase I, weekly location data peaked at 45.4% (SD 29.7%; 152.5/336) in Week 2 and declined by more than half to 21.5% (SD 22.2%; 72.3/336) by Week 26. In phase II, data collection fluctuated with participant engagement, increasing in the latter half of the study and peaking at 43.3% (SD 36.5%; 145.5/336) in Week 26. However, the overall difference between the 2 phases was 28.3% (SD 15.6%; 95.0/336) versus 29.0% (SD 26.6%; 97.4/336) was not statistically significant (P=.82) using a 2-sample t test. (Figure 5).

Operational Challenges and Opportunities

Several operational challenges emerged during phase I of the study. A major issue was the app's reliance on internet connectivity to upload location. In the first month, we found that many participants quickly exhausted their prepaid data bundles, leading to gaps in location data. To address this, we partnered with Datafree technologies [30] to implement a reverse-billed app (AHRI connector) which allowed the Sesikhona app to upload collected location data without an

XSL•FO
RenderX

active data bundle on participants' devices. However, deploying the AHRI connector app (available as an APK file) required home visits to install via Bluetooth. While this was a logistical challenge, it presented an opportunity to initiate the study update to the increased 30-minute data collection frequency. Reverse billing initial data bundle balance requirements were bypassed by tethering participant devices to the fieldworker tablet. Another challenge stemmed from hardware limitations. The study smartphones, purchased in 2019, faced significant technological issues due to their prolonged storage and aging hardware. Common malfunctions included frozen touchscreens, loss of network signal, and hardware failures, resulting in 77 phone replacements, with some 20 participants requiring multiple replacements (refer to Multimedia Appendix 1). Some participants lost or broke their phones. Notably, 16 participants opted to install the app on their personal phones, demonstrating early acceptability of personal phone use for the study.

In addition, the app was prone to frequent app terminations resulting in missing location data. Despite participants maintaining correct app settings, including 90% (324/360) with location services enabled (on), 95.5% (345/361) with battery optimization disabled, and 76.8% (274/357) with AHRI connector on (refer to Multimedia Appendix 2), the app was not collecting location data. Subsequent analysis by the Avicenna team determined that these disruptions were due to the smartphone operating system background task management, which automatically terminated apps running in the background, including Sesikhona, to optimize system performance for active apps.

Adaptations and Phase II

In response to the phone-related challenges and participants' preference for switching to personal phones, phase II adopted a revised approach. Unlike phase I, where the study provided smartphones, phase II required participants to install the Sesikhona app on their own devices. Of the 44 participants who consented, 2 had smartphones with 512 MB RAM, insufficient for the app. This issue was not initially identified, but discussions with Avicenna established that at least 1 GB RAM was needed for optimal app performance. Similarly to phase I, participants reported losing (n=2) or breaking (n=2) their phones, and 8 participants switched to different phones. In addition, a few participants changed their phone numbers. Nine participants deleted the app across both phases (5 in phase I and 4 in phase II), 6 reinstalled it, and 3 were no longer interested. Reasons for deletions included unintentional removal by children, app performance issues, or insufficient storage. Some intended to reinstall but were unable to due to forgotten login details. Fieldworkers provided reinstallation assistance and technical support to minimize data collection disruptions.

Location data gaps persisted in phase II despite correct app settings. To enhance user engagement and reduce app terminations, we introduced a gamification (Wheel of Fortune) in November 2022. This daily lottery game (available from 9 AM to 4 PM) with additional plays on Saturdays offered participants an opportunity to win prizes like airtime, data bundles, and shopping vouchers (see Figure 6).

Engaging with the game was positively correlated with the frequency of location data collection. The probability of participants providing location data was 77.6% days when they played the game, versus 27.5% if they did not play (refer to Multimedia Appendix 3). The odds ratio was 9.12 (95% CI 5.44 - 15.29) with a $P<.001$. In addition, playing the game was associated with +15.7% (7.5/48; $P=.007$) increase in the amount of location data received per day (refer to Multimedia Appendix 4).

Table 2 summarizes the key findings from phase I and II. While phase II had few participants, having AHRI connector at the outset and introduction of the gamification enhanced user engagement and data collection. Overall, there were fewer technical challenges reported in phase II compared to phase I.

Figure 6. Wheel of Fortune aimed to increase user engagement with the app. Screen 1: how it appears on the Sesikhona app homepage; screen 2: spinning wheel with an example of a win; and screen 3: the prizes.

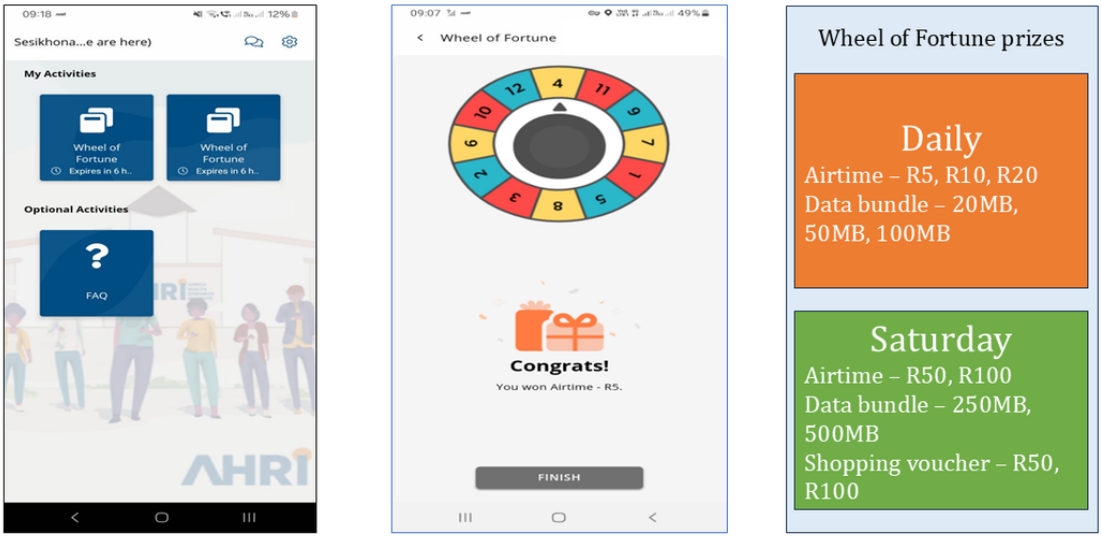

Table . Summary of phase I and phase II results.

Parameter	Phase I (June 2021 to July 2022)	Phase II (July 2022 to May 2023)
Participants enrolled, n	163	44
Participants contributing location data, n	162	42
Average number of location points/participant, median (IQR)	67,398 (29,771 - 168961)	47,510 (12,252 - 172,613)
Range of location points/participant	389 - 670,384	53 - 950,597
Percentage of location points per week (out of 336 half-hour intervals), mean (SD)	28.3 (15.6)	29.0 (26.6)
Introduction of AHRI[a] connector (reverse billing app)	Implemented midway	Implemented at the start of the phase
Phone replacements	77 phones replaced due to technical issues	2 participants' phones were incompatible, with 4 reporting broken/lost phones
Gamification (Wheel of Fortune) impact	N/A[b]	Increased probability of receiving location data by 77.6% if the participant played the game, versus 27.5% if they did not play and associated with +15.7% more data received in a per day compared to not playing (*P*=.007)
Challenges faced	Aging hardware, data bundle exhaustion, app termination	Some phone compatibility issues, but fewer technical problems overall
Engagement strategy	Relied on troubleshooting and participant support	Gamification introduced to enhance engagement and data collection

Discussion

Principal Findings

In this study, we found that smartphone-based GPS technology is a feasible approach for studying human mobility in rural settings using commercial software, provided that key implementation challenges are addressed. Individuals living with HIV and without accepted both study-provided and personal smartphone use for location data collection. Although most participants complied with study protocols, only 28.4% (95.3/336) of the expected weekly location data were collected,

XSL•FO
RenderX

largely due to operational challenges such as hardware malfunctions, lack of internet connection, and frequent app terminations, particularly during phase I. Frequent troubleshooting provided insights into context-specific adaptations needed for rural settings, including implementation of the reverse billing to facilitate data transmission with an active data bundle.

The introduction of gamification in phase II significantly increased the likelihood of receiving location data from participants who engaged with the game. This highlights the potential of gamified strategies to enhance participant engagement and improve data completeness in long-term studies. Notably, phase II participants were slightly older and from higher income brackets, raising important considerations for equity in future studies. Requiring smartphone ownership could exclude younger or lower-income populations, who may be at higher risk for HIV and stand to benefit most from mobility-informed interventions.

Comparison to Prior Work

Our results align with previous studies demonstrating feasibility and acceptance of smartphone GPS apps to understand HIV risk [31-33], substance use and violence among people living with HIV [34]. The lower median data collection of 28.4% highlights challenges in rural settings. Two South African smartphone-based studies reported significant technological and operational issues with using personal phones, where inadequate RAM, storage, and device type affected implementation [35,36]. Furthermore, Clouse et al noted how lack of internet contributed to missing location data [36].

Although Hardy et al [23] found that smartphones provided more complete location data with less user effort, our study showed that the app required significant user effort to collect data. The high number of days with missing location data, especially later in the study, is comparable to findings from studies using standalone GPS devices [20,21]. However, these studies had smaller sample sizes, shorter follow-up periods, and different settings. Finally, other research shows that game elements enhance user engagement in mobile apps [37].

Implications for Future HIV Research and Interventions

The mobility data from this study will provide a granular understanding of how mobility intersects with HIV risk. Identifying geographic hotspots and mobility patterns linked to high-risk behaviors, such as multiple concurrent partnerships or inconsistent condom use, can enable more targeted and efficient allocation of prevention resources. For example, interventions can be tailored to specific locations and times where risk is highest to maximize impact.

Mobility data can also reveal disruptions in HIV care, such as missed clinic appointments due to travel, informing the design of tailored interventions like mobile clinics or targeted outreach programs at critical locations. Integrating mobile health tools, like the Sesikhona app, into broader health systems offers opportunities to prospectively monitor human mobility and deliver real-time support to individuals at risk of disengagement. For example, automated reminders or check-ins could be triggered on an individual's location to encourage care engagement or treatment adherence protocols. However, for these strategies to be effective, technological and access barriers must be addressed, and the interventions should be co-designed with communities to align with privacy expectations and ethical standards. Overcoming these challenges will be critical to leveraging mobility-informed approaches to achieving the UNAIDS 95-95-95 targets, particularly among highly mobile and hard-to-reach populations.

Study Strengths and Limitations

This study provides important evidence on the feasibility of using commercially available smartphone GPS apps to collect mobility data in a rural, resource-limited setting. While the high adoption rate and engagement demonstrate potential, feasibility was constrained by technological and operational challenges related to device and internet connectivity. These findings suggest that use of smartphone-based GPS to study mobility is feasible if key barriers are addressed. However, generalizability may be limited. The study was conducted within a cohort already engaged through the AHRI HIV population-based surveillance program, where established trust likely enhanced participant acceptance. In addition, reliance on smartphone technology may have introduced access and literacy barriers, which could affect scalability in other settings.

Conclusion

This study provides critical insights into the feasibility of using smartphone-based GPS technology to collect mobility data among young adults in a rural, HIV-hyperendemic setting in South Africa. By comparing the outcomes of 2 distinct phases, the study highlights the success and challenges of using both study-provided and personal smartphones. Although the collected data was lower than expected, high adoption rates, sustained engagement, and the success of solutions such as reverse billing and gamification demonstrate the potential of smartphone-based approaches to study mobility, provided technological barriers are addressed.

The implications of this study extend beyond its immediate context, offering valuable lessons for the broader field of HIV research and intervention. Our findings underscore the potential of integrating mobile health tools into health systems to support high-risk mobile populations. Mobility-informed approaches could enhance real-time monitoring, targeted service delivery, and ultimately improve HIV prevention and care outcomes. Further research is needed to refine engagement strategies, address technological and access barriers, and optimize data integration methods to fully leverage mobility data for achieving global HIV epidemic control.

Abstract

Background: Carbohydrate counting (CC) is vital for individuals living with type 1 diabetes mellitus (T1DM); yet, formal training is often lacking in many contexts. To bridge this gap, the parents of a person living with diabetes and a team at the Geneva University Hospital (HUG) developed WebDia, a free-access app that helps patients with T1DM assess meal carbohydrates and make informed decisions regarding insulin dosage. In the context of Peru, where dietary patterns and meal compositions may differ, customizing WebDia to suit the components of the Peruvian diet becomes particularly relevant.

Objective: This study aimed to customize WebDia according to the composition of the Peruvian diet to facilitate CC, and to provide training to health care workers (HCWs), children and adolescents living with T1DM, and their caregivers in the proficient use of WebDia-Mundi (new version of the Swiss app WebDia adapted to other geographic contexts).

Methods: A dietitian compiled a database of Peruvian foods and their carbohydrate content. This was reviewed by a Swiss nurse specialized in diabetes, a Peruvian pediatric endocrinologist, and 2 researchers. Validation was conducted with a small group of children and adolescents living with T1DM and their caregivers. Subsequently, a 3-day workshop was held in 3 Peruvian regions for HCW and children and adolescents living with T1DM. The first 2 days were a training course for HCW to gain knowledge in T1DM and learn CC skills. This was followed by a 1-day workshop involving HCW, children and adolescents living with T1DM, and their caregivers. At the end of the workshop and 3 months later, an evaluation was performed to assess the app's usability, glycated hemoglobin, quality of life, and knowledge perception for children and adolescents living with T1DM and their caregivers. Furthermore, changes in knowledge among HCWs and overall workshop satisfaction were measured.

Results: WebDia-Mundi was customized for the Peruvian context in 2022-2023. The training was attended by 25 HCWs, 25 children and adolescents living with T1DM, and 31 caregivers. Following the training, HCWs exhibited a significant 3.5-point increase in their knowledge of T1DM, while achieving positive results regarding the usability of WebDia-Mundi. Children and adolescents living with T1DM and their caregivers also reported a favorable perception of the ease of use and functionality of WebDia-Mundi, which enhanced their CC skills.

Conclusions: This study underscores the importance of collaboration among multidisciplinary teams and the involvement of individuals with T1DM. Adapting mobile health solutions to new contexts and sharing experiences can help standardize this process.

KEYWORDS

diabetes mellitus type 1; user-centered design; counting carbohydrates; eHealth; mobile applications; low-income countries; middle-income countries; diabetes; insulin; quality of life

Introduction

Diabetes represents a global health challenge, directly contributing to 1.5 million deaths annually, with a significant proportion of these deaths occurring in low- and middle-income countries (LMICs) [1]. While type 2 diabetes mellitus constitutes most diabetes cases, there are still approximately 9 million individuals grappling with type 1 diabetes mellitus (T1DM) [2]. Nonetheless, the persistent barrier of the cost of insulin and the supplies needed to maintain treatment for T1DM has a direct impact on individuals' daily lives [3].

A notable barrier within the health care system revolves around the inadequate nutrition education, particularly the emphasis on carbohydrate counting (CC) and the management of T1DM through a therapeutic patient education approach [4]. CC, in conjunction with insulin dosage adjustments, plays a pivotal role in the effective management of T1DM, improving metabolic control and enhancing the quality of life [5]. CC involves a dietary management strategy that quantifies the carbohydrate content of food, enabling individuals to administer the appropriate insulin dose to maintain optimal blood glucose levels [6]. The use of technology has proven effective in enhancing CC education and the overall learning experience [7,8]. To respond to the urgent demand to reach a balance in the treatment of T1DM, WebDia is an app designed to speed up CC by providing a complete list of foods, accompanied by their corresponding carbohydrate content [9]. The implementation of WebDia in Switzerland has yielded promising outcomes among individuals with T1DM, resulting in a reduction of glycated hemoglobin levels by 0.33% without a concurrent increase in hypoglycemia prevalence [10]. Moreover, users of WebDia have reported increased independence and self-confidence in managing their condition, leading to enhanced self-efficacy and improved self-management of T1DM [9].

Deficiencies in the health care system, such as the exclusive availability of specialized care at the tertiary level and insufficient training of health care workers (HCWs) in managing and diagnosing T1DM, impact the quality of life for individuals with this condition in LMICs, including Peru [3]. Peru's health care system faces a number of challenges, including poor accessibility to information at different health care levels, insufficient financial resources, and a shortage of HCWs with adequate training in diabetes management [11]. Furthermore, the health care system's response to individuals living with T1DM is notably deficient in terms of understanding the disease, and the information provided does not align with the unique needs and characteristics of this particular population [12]. Additionally, dietary patterns vary widely across different cultural and geographical contexts, influencing how people with T1DM approach CC. In Peru, the complexity of gastronomy, characterized by diverse ingredient combinations and traditional dishes, adds an additional challenge.

In this context, Peru finds itself in a favorable position to benefit from a tailored adaptation of WebDia, accompanied by the essential training of HCWs. The study had a dual purpose: first, to adapt WebDia to the Peruvian context as previously detailed, and second, to empower HCWs to enhance the quality of care they provide to individuals living with T1DM. Additionally, the study assessed the impact of WebDia-Mundi (new version of the Swiss app WebDia adapted to other geographic contexts) on the quality of life and glycated hemoglobin levels of children and adolescents living with T1DM.

Methods

Study Design

The study design was pre-post and usability study using mixed methods. The study used both qualitative and quantitative approaches across 3 regions of Peru with distinct demographic characteristics that contribute to their cultural and socioeconomic diversity (Arequipa, Lima, and Trujillo).

This study was carried out in 3 phases. The first phase involved adapting the WebDia app to the Peruvian context, spanning from March to December 2022. The second phase centered on training HCWs, children and adolescents living with T1DM, and their caregivers. A series of workshops was conducted to enhance diabetes care management, with a particular emphasis on refining skills related to CC. The third phase consisted of the evaluation of usability, knowledge acquisition, glycated hemoglobin levels, quality of life, perception of knowledge, and workshop satisfaction. Both phases were developed in March 2023. Furthermore, follow-up sessions were conducted 3 months later, from June to July 2023, to assess the sustainability of the acquired knowledge and skills.

Participants

The study had different participants for each phase. The first phase (adaptation) involved a collaboration with a specialized dietitian and comprised individuals older than 18 years living with T1DM and caregivers of children with T1DM. In the second phase, HCWs responsible for managing individuals requiring insulin for diabetes were actively involved, alongside children and adolescents living with T1DM, 6 to 18 years old, and their corresponding caregiver. Subsequently, during the third phase (evaluation), all participants from the second phase were considered. Recruitment of participants across all 3 phases was conducted through a strategic social media outreach, using a snowballing technique to expand the participant pool.

Study Procedures

First Phase: Adaptation

WebDia, an innovative mobile health (mHealth) app developed by JLM in response to his daughter's diagnosis of T1DM, assists individuals with diabetes who use insulin to count carbohydrates and adjust insulin treatment [10]. Originally in French and tailored to the Swiss diet, the app required adaptation to suit the

XSL•FO
RenderX

Peruvian context. One of the primary modifications was the translation of WebDia into Spanish, ensuring accessibility for most of the Peruvian population. Additionally, user-friendly features were adjusted, including redesigning the logo. The most critical adaptation involved integrating a food database that reflects the diversity of Peruvian cuisine, incorporating locally available foods, traditional dishes, and commonly consumed ingredients with culturally appropriate portion sizes.

For this purpose, the most prevalent foods consumed in Peru were identified by using food data from a previous CRONICAS project [13] and consulting a recipe book authored by a dietitian specializing in macronutrient counting. The selection of typical dishes was based on popular local foods from Lima, Arequipa, and Trujillo. However, we did not have access to a systematically compiled dataset of the most commonly consumed dishes by region. Instead, our selection was based on available data sources and expert consultation. Information on carbohydrate composition was then incorporated using different sources. For natural foods and traditional dishes, we used the Peruvian table of food composition [14] and values extracted from WebDia. For processed and ultraprocessed food, carbohydrates information was taken from the database developed by CRONICAS Center of Excellence in Chronic Disease at Universidad Peruana Cayetano Heredia, in collaboration with the University of North Carolina at Chapel Hill [13]. Additionally, although accessibility was considered in the app's adaptation process, WebDia-Mundi is not currently designed to support multiple languages beyond Spanish.

This adaptation was then validated with a small group of participants, including people living with T1DM from different ages and their caregivers. The validation process consisted of collecting first impressions about the app, such as missing foods on the list, technical issues, and overall usability feedback. During this process, we also addressed specific needs to enhance accessibility, ensuring that the app could be used even by individuals who do not speak Spanish or who are illiterate. In the Peruvian version, we also incorporated multiple food photos to help users estimate food portions and make the weight of foods more visible. Based on this input, an improved version, now called WebDia-Mundi [15], was developed. Finally, a pilot usability study was conducted with the same group of participants, generating data that facilitated enhancements to various app functions, considering diverse perspectives (Figure S1 in Multimedia Appendix 1).

Second Phase: Training

Workshops were conducted across 3 regions of Peru (Arequipa, Lima, and Trujillo) targeting HCWs, children, and adolescents living with T1DM, and their caregivers (Table S1 in Multimedia Appendix 2). These workshops primarily focused on comprehensive training in CC, instructions on using the app to perform CC as part of self-monitoring, and how to adjust insulin doses in a personalized way.

For this purpose, the HCWs were involved in a 2-day face-to-face theoretical and practical training during which they lived like a person living with T1DM (they practiced doing CC and applying to themselves several insulin injections simulated with sodium chloride). HCWs were instructed to previously watch 3 short videos produced at Geneva University Hospitals (HUG) to lay the foundations for diabetes management using CC [16-18]. These instructional days were followed by a one-day practical workshop, bringing together HCWs, children and adolescents living with T1DM, and their caregivers. During this session, HCWs who were already acquainted with the WebDia-Mundi app collaborated with children and adolescents living with T1DM and their caregivers to provide guidance on CC and how to adapt insulin treatment. To ensure effective participation, participants were encouraged to download the app from either the Apple Store [19] or the Play Store [20] to ensure effective use during the session.

Third Phase: Evaluation

During the 2-day face-to-face session, a knowledge test was applied before and after the training. In addition, at the beginning of the third-day practical workshop, sociodemographic data, perceptions of knowledge, and quality of life (self-reported by the children and adolescents living with T1DM and the evaluation of them provided by their caregiver) were collected. If consent was provided by children and adolescents living with T1DM and their caregivers, a blood sample was collected for glycated hemoglobin analysis. At the end of the workshop, the usability of WebDia-Mundi and workshop satisfaction were assessed. Three months later, participants were recontacted for follow-up evaluations to assess the usability of WebDia-Mundi, perceptions of knowledge, quality of life, and glycated hemoglobin (specifically for children and adolescents living with T1DM).

Outcomes

The primary outcome was the usability of WebDia-Mundi to explore the main issues in the app from the end users' perspective. The usability assessment was carried out using the System Usability Scale (SUS) for children and adolescents living with T1DM and their caregivers [21]. This questionnaire is considered a reliable tool to measure the usability of products and services, including hardware, software, mobile devices, and apps. In addition, the questionnaires were supplemented with questions about perceived operability of the app, perceived ease of the app, satisfaction with the app, and open-ended questions about the participants' experience of use. All questions were adapted and translated into Spanish using simple terminology to enhance comprehension.

Another primary outcome was enhancing knowledge of the HCWs. For this purpose, a pre and posttest was conducted at the beginning and at the end of the 2-day workshop sessions, to assess their knowledge. The test was developed by a diabetes educator. The questions were related to the topics taught during the training, such as diabetes, diet, CC, insulin adjustment, etc.

The following were predefined as secondary outcomes: glycated hemoglobin assessed by blood sampling using a validated clinical laboratory (SynLab ISO 9001:2015) in the 3 regions. Quality of life was measured using the Spanish validated PedsQL Diabetes Module (version 3.0; Mapi Research Trust) [22] using child self-report and parent proxy-report scales tailored to the respective age groups of the children. Perceptions of knowledge through specific questions. Workshop satisfaction

XSL•FO
RenderX

was assessed by a questionnaire developed by the research team. To ensure accuracy and appropriateness, we carefully reviewed the Spanish version. Knowledge perception and workshop satisfaction were assessed using specific questions developed by the research team (Table S5 in Multimedia Appendix 2).

Data Evaluation

The SUS

The SUS was administered to all participants, using a Likert scale ranging from 1 to 5, where 1 indicates strongly disagree, and 5 indicates strongly agree. For the analysis, we used the standard approach to generate a final score ranging from 0 to 100. To do so, we converted the scores with a different setting for odd and even items (respectively, positive and negative tone items). In addition, if a respondent leaves an item blank, it is assigned a raw score of 3 (the center of the 5-point scale). The adjusted scores were then summed and multiplied by 2.5 to obtain the standard SUS score [21].

Knowledge Test (Pre-Post)

A pre-post knowledge test was administered to HCWs, and the final score, ranging from 0 to 20, was calculated by adding the individual scores for each question. For more details on the content and level of the test, please refer to the questions in Table S5 in Multimedia Appendix 2.

Glycated Hemoglobin

The assessment of the glycated hemoglobin test was conducted in children and adolescents living with T1DM. The results were obtained from blood samples analyzed in a laboratory that had been validated across all 3 regions.

Quality of Life

The PedsQL 3.0 Diabetes was used to assess the quality of life in children and adolescents living with T1DM, considering perspectives from both children and adolescents living with T1DM and their caregivers. Like the SUS, a Likert scale (0 - 4) was used across five domains: (1) diabetes symptoms, (2) treatment I, (3) treatment II, (4) worry, and (5) communication. Treatment I is used to indicate the presence or absence of a problem, while Treatment II is used to measure the degree of difficulty associated with the problems identified. The items were then reverse transformed to a scale of 0 - 100 (0=100, 1=75, 2=50, 3=25, 4=0), with higher scores indicating better quality of life. If a respondent left an item blank, it was assigned a score of 2 (the center of the 5-point scale) [22].

Perception of Knowledge

Knowledge perception questions were assessed for all participants, using a knowledge rating scale from 1 to 5, with 5 representing the highest score.

Workshop Satisfaction

Satisfaction with the workshops was evaluated for all participants by extracting the most recurrent phrases from the open-ended questions.

Statistical Methods

Data analysis was conducted in STATA for Windows (version 17; StataCorp). The description of the study population was carried out using absolute and relative frequencies for categorical variables, while numerical variables were summarized using the median and the 25th and 75th percentiles. To assess changes in quality of life, perceived knowledge, and usability as reported by children and adolescents living with T1DM and their caregivers, the Wilcoxon matched pairs test and McNemar's chi-square test were used. A P value <.05 was considered significant. In addition, we used line graphs to visualize the progression of acquired knowledge before and after the training workshop, as well as to illustrate changes in glycated hemoglobin levels at the 3-month mark.

Ethical Considerations

The study was approved by the Institutional Review Board of Universidad Peruana Cayetano Heredia (approval number 513-35-22, registration code 208867). All participants provided their consent, with the option to withdraw at any time. Given that the study population was from urban areas and no specific cultural adaptations were required, the main consideration was ensuring that the language used in the consent form was clear and easily understood by participants. For children younger than 18 years, assent was obtained after a detailed explanation of the study's objectives, benefits, and risks. During the workshop phase, consent from only one caregiver was required. In cases where the child was below 6 years old, both the child and the caregiver had the option to participate in the activities; however, the data collected from this group were excluded from the analysis. All collected data were deidentified, and only the first authors had access to safeguard participant information. While no direct financial compensation was provided, participants received support for travel, accommodation, and meals as needed, particularly for those coming from regions outside the study site.

Results

Demographic Characteristics

Participants for all study phases were selected using a convenience sampling approach, based on their availability and willingness to participate. A total of 25 HCWs and children and adolescents living with T1DM, along with their caregivers, were initially enrolled. Subsequently, 24 HCWs and 19 children and adolescents living with T1DM and their caregiver were included in the study. For the follow-up phase, 12 children and adolescents living with T1DM and their caregivers were retained in the study (Figures S2 to S4 in Multimedia Appendices 3-5). Of the total HCWs, 18 (75%) were female. They reported caring for a diverse range of diabetes patients, with a median of 50 (IQR 5-150) patients with T2DM and a median of 5 (IQR 2-12) patients with T1DM. The perceived knowledge of T1DM was 12 (50%) fair and 9 (38%) good, perceived knowledge of CC was rated as 6 (25%) poor and 11 (46%) fair, and perceived knowledge of insulin therapy was reported as 11 (46%) poor and 7 (29%) good (Table 1).

XSL•FO
RenderX

Regarding children and adolescents living with T1DM, the median age was 12 (IQR 10 - 16) years, and their caregiver had a median age of 47 (IQR 40 - 51) years, with 15 (79%) caregivers being female. The primary caregiver of children and adolescents living with T1DM included other family members in addition to parents, but most of the attendees were mothers. Around 13 (72%) caregivers had a university or technical education. In terms of perceived knowledge, 13 (68%) caregivers had a fair perception of T1DM, and 4 (21%) caregivers considered it good. For CC, 7 (37%) caregivers rated their knowledge as poor, and 6 (32%) caregivers rated it as fair, while for insulin therapy, 8 (42%) caregivers considered it fair, and 8 (42%) caregivers considered it good (Table 2).

[a]T1DM: type 1 diabetes mellitus.

[b]Results may not add due to missing values.

WebDia-Mundi Usability

HCWs achieved a median overall usability score of 76%, reflecting positive results for perceived operability of the app and partially positive findings for perceived app, ease of the app, and satisfaction with the app (Table S2 in Multimedia Appendix 2).

HCWs also highlighted the practicality of CC in the diet as follows:

> *Very useful in our country, where carbohydrates are prevalent, and misconceptions about their restriction in diabetes cases are common.*
>
> *It's user-friendly, allows saving calculation data, and the dish photos are highly beneficial.*
>
> *It fosters creativity, letting me combine available ingredients to meet carbohydrate limits.*

On the other hand, the app recorded an overall usability score of approximately 81% for children and adolescents living with T1DM, which significantly dropped to a median of 57% at 3 months. Likewise, caregivers had an initial median score of 74% during the workshop, which decreased significantly to 54% at 3 months. Notably, positive results were observed for perceived operability of the app, perceived ease of the app, and

XSL•FO
RenderX

satisfaction with the app in both groups, with no significant changes noted at the 3-month mark (Table 3).

Children and adolescents living with T1DM and their caregivers consistently emphasized the app's advantages. Statements from children and adolescents living with T1DM included:

> *It helps to calculate carbohydrates more accurately.*
>
> *It improves control of quantities at mealtimes.*
>
> *It promotes independence, gradually building knowledge in carb counting.*

Moreover, they expressed that they found the app highly useful and user-friendly. In parallel, caregivers mentioned their perspectives with comments such as:

> *It makes it easier for me to understand carbohydrate amounts for my children.*
>
> *It has the potential to prevent hypoglycemia and hyperglycemia.*
>
> *I can refine carbohydrate counting for enhanced control.*
>
> *It increases my confidence in accurately calculating carbohydrates.*

[a]T1DM: type 1 diabetes mellitus.

[b]Wilcoxon matched pairs test was used.

[c]McNemar chi-square test was used. Results may not add due to missing values.

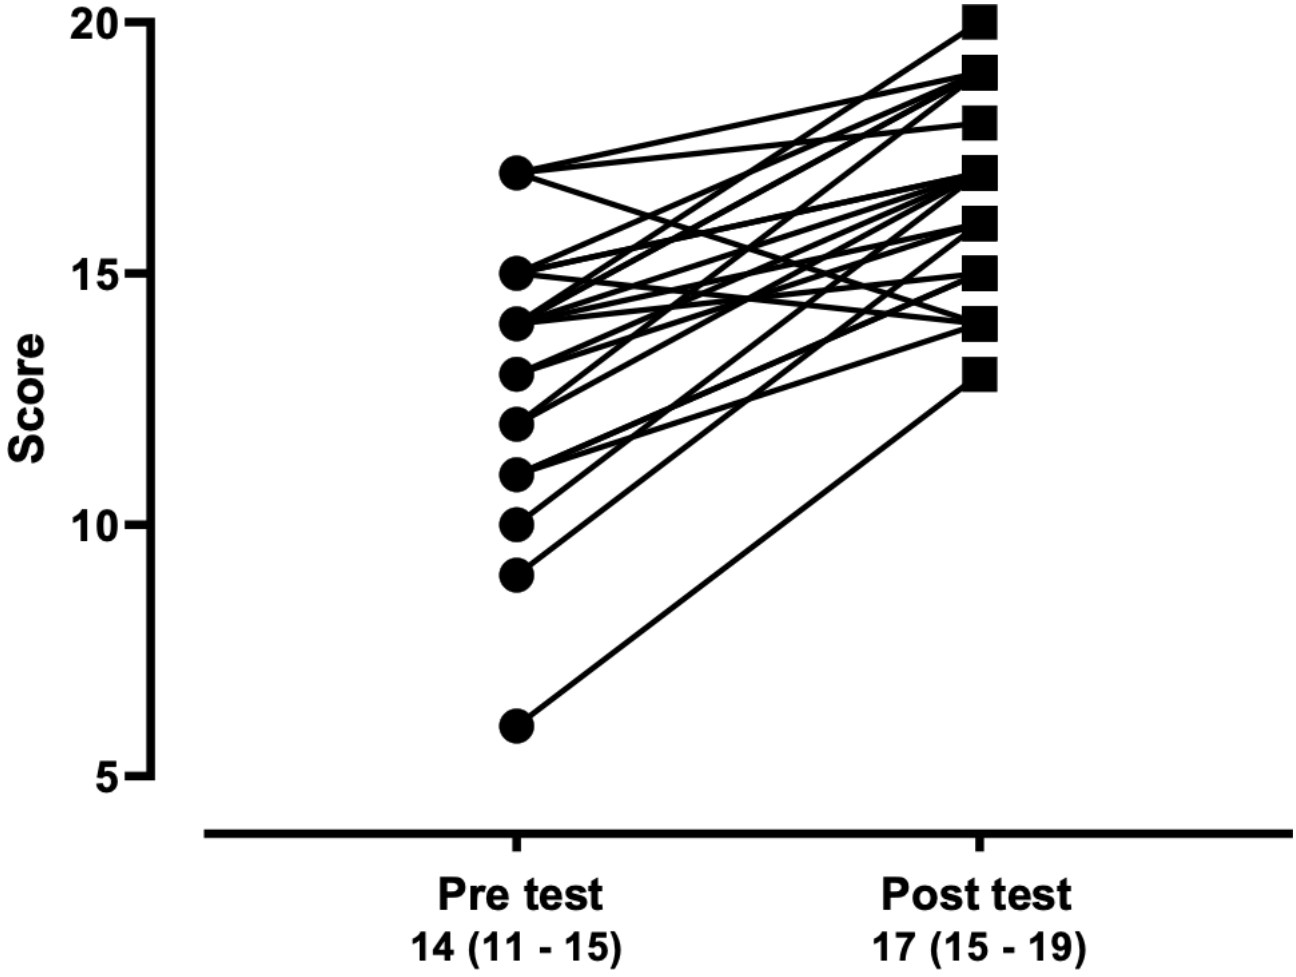
Common drawbacks identified during the workshop included the absence of specific dishes and foods, the necessity for adaptations tailored to different cities, the significance of differentiating between rapidly absorbed and complex carbohydrates, the demand for more detailed information regarding individual meal ingredients, and the desire to compare multiple meal options simultaneously based on their carbohydrate content. Furthermore, technology access was acknowledged as a potential limitation, particularly for individuals residing in areas with limited internet or smartphone connectivity. However, both children and adolescents living with T1DM and their caregivers expressed a strong motivation to frequently use WebDia-Mundi.

Knowledge Obtained in the Workshops

Overview

The HCW pretest scores ranged from 6 to 17, with a median of 14.0 (IQR 11.5 - 15.0), while the posttest scores ranged from 13 to 20, with a median of 17.0 (IQR 15.0 - 19.0). There was a significant increase between pre- and posttest scores (*P*=.001, Figure 1).

Figure 1. Pre- and posttest scores from health care workers (n=23) attending the workshops.

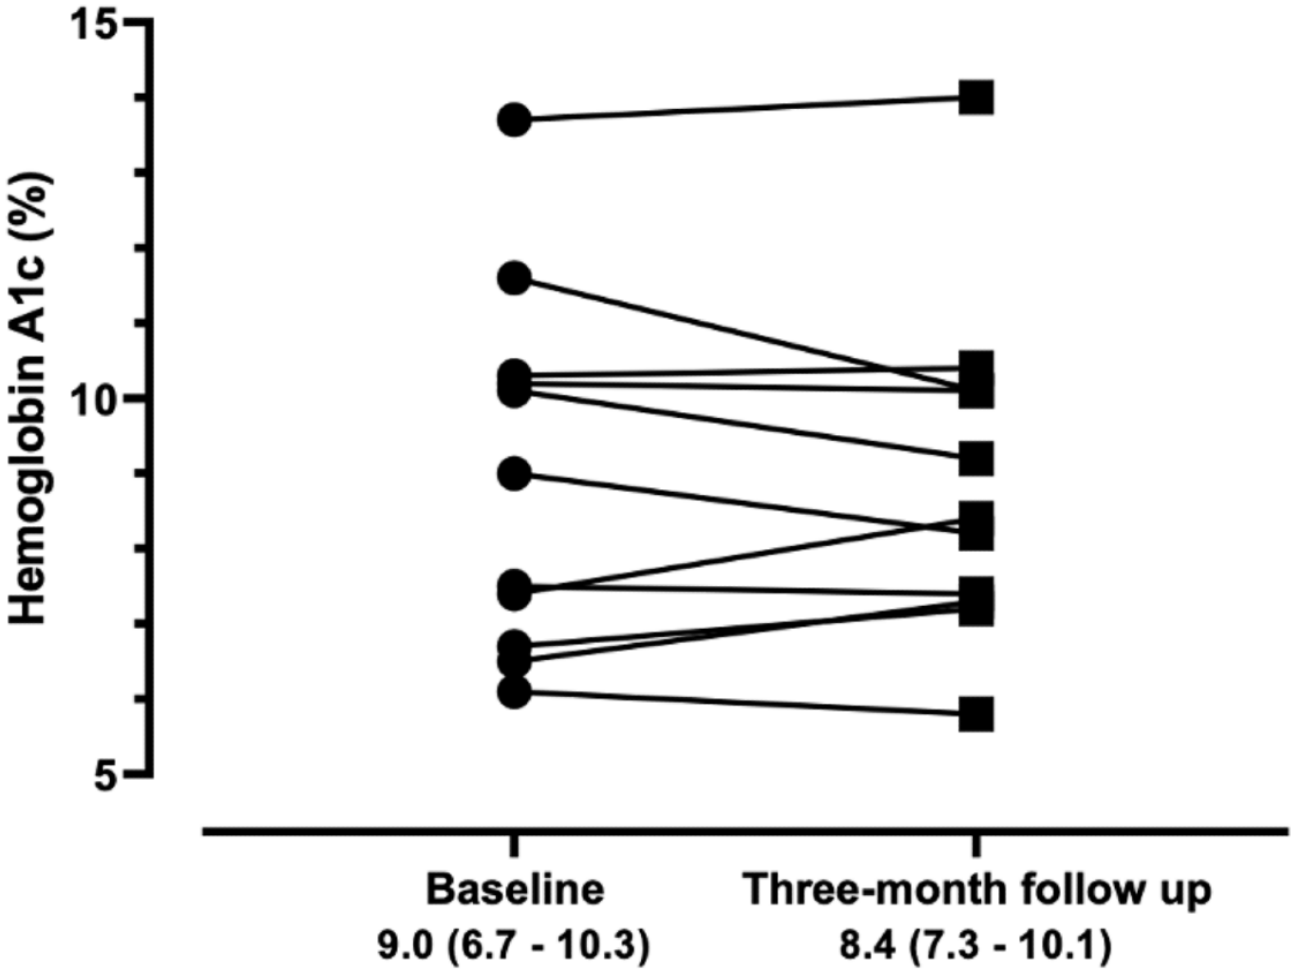


XSL•FO
RenderX

Glycated Hemoglobin

Glycated hemoglobin levels were measured in children and adolescents living with T1DM at the workshop and 3 months later. On the workshop day, the glycated hemoglobin level was 9.0% (IQR 6.7% - 10.3%), ranging from 5.4% to 13.7%. At the 3-month follow-up, the glycated hemoglobin level was 8.4% (IQR 7.3% - 10.1%), ranging from 5.8% to 14.0%, without changes in comparison to the baseline (*P*=.789, Figure 2).

Figure 2. Comparison of hemoglobin A_{1c} levels in participating children during the workshop and at the 3-month follow-up.



Quality of Life

Across all domains, scores were close to 60, with a slight increase in worry and a marginal decrease in diabetes symptoms, communication, and treatment-related aspects. The overall score showed a slight increase for both, but the changes observed from baseline to follow-up were not statistically significant (Table 4). On the other hand, no significant differences were found between the perception provided by children and adolescents living with T1DM and their caregivers (Table 3 in Multimedia Appendix 2).

XSL•FO
RenderX

Table . Quality of life reported by the children and by their parent/caregiver at baseline and 3 months later. Wilcoxon matched pairs test was used.

Characteristics	Baseline	3 months follow-up	*P* value
Children living with T1DM[a] (P25-P75)			
Diabetes symptoms	59.1 (56.8 - 77.3)	54.6 (50.0 - 72.7)	.35
Treatment I	56.3 (50.0 - 81.3)	50.0 (50.0 - 75.0)	.44
Treatment II	67.9 (50.0 - 82.1)	53.6 (50.0 - 78.6)	.27
Worry	41.7 (25.0 - 50.0)	50.0 (50.0 - 50.0)	.20
Communication	66.7 (33.3 - 91.7)	50.0 (50.0 - 75.0)	.95
Overall	60.5 (43.9 - 69.7)	61.0 (52.3 - 70.9)	.16
Parents/caregivers, median (P25-P75)			
Diabetes symptoms	65.9 (50.0 - 75.0)	50.0 (50.0 - 59.1)	.08
Treatment I	50.0 (37.5 - 68.8)	50.0 (50.0 - 75.0)	.56
Treatment II	60.7 (46.4 - 78.6)	50.0 (50.0 - 75.0)	.52
Worry	41.7 (33.3 - 50.0)	50.0 (50.0 - 58.3)	.11
Communication	54.2 (16.7 - 83.3)	50.0 (50.0 - 75.0)	.40
Overall	56.9 (42.6 - 68.9)	62.4 (56.4 - 75.8)	.11

[a]T1DM: type 1 diabetes mellitus.

Perception of knowledge

The perception of CC and T1DM knowledge, when compared with 3 months after the workshop, showed a significant decrease in median reported knowledge among both children and adolescents living with T1DM and their caregivers (Table 5).

Table . Difference in knowledge at 3-month follow-up in children living with type 1 diabetes mellitus and their caregivers. Wilcoxon matched pairs test was used.

Characteristics	Baseline	3 months follow-up	*P* value
Children living with T1DM[a], median (P25-P75)			
Carbohydrate counting knowledge	3 (3-4)	3 (2-3)	.03
Parents/caregivers, median (P25-P75)			
T1DM[a] knowledge	3 (3-3)	2 (2-3)	.02
Carbohydrate counting knowledge	3 (3-4)	3 (2-4)	.04
Insulin therapy knowledge	2 (2-3)	2 (2-2)	.75

[a]T1DM: type 1 diabetes mellitus.

Workshop Satisfaction

HCWs found that the workshops not only taught them about CC and the use of WebDia-Mundi but also allowed them to see T1DM from the perspective of children and adolescents living with T1DM and their caregivers. They expressed an understanding that there is no need to impose food restrictions when managing T1DM, and those with T1DM can lead normal lives if they practice CC. Some HCWs mentioned the following:

> *No need for prohibitions or excessive restrictions.*
>
> *Type 1 diabetics can lead a normal life.*

Regarding changes they plan to make in their practice after the workshop, HCWs expressed a commitment to active listening, considering patients' contexts, and practicing empathy. They mentioned intentions such as:

> *Listen and provide more support.*
>
> *Empathize and put myself in their shoes.*
>
> *Help caregivers understand it's not their fault, is a manageable condition.*
>
> *Show greater interest in their well-being and challenges.*
>
> *Empower them to manage the condition and live a normal life.*
>
> *Always prioritize the patient's feelings.*

HCWs found the most positive aspect of the workshop to be the valuable interactions with children and adolescents living with T1DM and their caregivers. On the other hand, the most negative aspect, as reported by HCWs, was the discomfort of self-administering glucose measurements and injections during the practical sessions. Their feedback included:

XSL•FO
RenderX

> *The hands-on experience was enriching, allowing us to experience it ourselves, administering NaCl and measuring glucose. It was a unique and fascinating practical course in my professional life.*
>
> *Living as a diabetic [person living with diabetes], understanding the effort required to measure glucose, calculate meals, and make injections, highlighted the time and dedication patients invest in normalising their glucose.*
>
> *Practising self-monitoring of glucose and experiencing it first-hand truly deepened our understanding of the patient's perspective.*

Finally, the comments and reflections of the HCWs underscored the workshop's significant influence on their perspectives and professional approaches. They emphasized the need to expand participation, sharing this knowledge with professionals from various health care organizations, expressing interest in specialized workshops, and proposing the creation of camps and activities for children and adolescents living with T1DM.

The caregiver also showed significant interest in the workshop. Most of them found the workshop duration suitable, and all reported valuable knowledge gained, resulting in a positive learning outcome. Their feedback emphasized the importance of CC and the usefulness of CC apps. Some comments mentioned were:

> *I gained a better understanding of carbohydrates.*
>
> *The carbohydrate counting app proved to be incredibly useful.*
>
> *Maintaining a positive outlook is crucial; it helps build confidence that things happen for a reason.*

In summary, the lifestyle changes considered by the children and adolescents living with T1DM and their caregivers were predominantly centered around dietary choices and the use of WebDia-Mundi (Table S4 in Multimedia Appendix 2).

Discussion

Principal Results

Our findings indicate a favorable response to the WebDia-Mundi app (an adaptation of the WebDia app tailored to the Peruvian context) among HCWs, children and adolescents living with T1DM, and their caregivers. The incorporation of popular local foods and an easy-to-use interface were key factors in ensuring the app's effective adaptation in Peru. Additionally, the app played an important role in enhancing users' understanding of CC, which is essential for better nutritional management and quality of life. The training provided to HCWs improved their knowledge regarding the care they deliver to individuals with T1DM. It is important to note that most HCWs are more familiar and comfortable providing dietary advice for individuals with type 2 diabetes and often feel less confident when counseling patients with T1DM. Moreover, children and adolescents living with T1DM, and their caregivers, exhibited a generally positive perception of their quality of life. While the use of WebDia-Mundi resulted in slight improvements in specific domains, these enhancements did not reach statistical significance. Furthermore, there were no notable changes observed in the levels of glycosylated hemoglobin among children and adolescents living with T1DM. In the management of T1DM in LMICs, having tools that alleviate the burden of self-managing glucose levels is crucial. One of the key challenges faced by people living with T1DM is understanding how to manage their meals effectively. Traditionally, many individuals with T1DM followed highly restrictive dietary patterns due to limited knowledge about CC. Providing an accessible and practical app empowers both patients and caregivers, while improving HCWs' understanding of CC contributes to better overall care.

Comparison With Prior Work

The general knowledge was low among the participants of the workshop. Other studies with physicians and nurses show similar results on the inadequate training in the treatment of T1DM [23-25]. A parallel scenario emerged among children and adolescents living with T1DM and their caregivers, highlighting a perceived inadequate knowledge concerning self-management and dietary practices [26]. It is noteworthy that enhancing the knowledge of CC has been proven to positively impact the self-management of the disease [27]. Nevertheless, 3 months into the training, there was a notable decline in the perceived knowledge regarding CC and T1DM. This decline could be attributed to diverse postintervention factors that might have adversely impacted self-perceived knowledge when attempting to implement the acquired skills from the workshops, especially in the practical application of CC in daily life, or they discovered there was much more to learn than they initially thought as they underwent the training [28,29].

Regarding the usability of WebDia-Mundi, HCWs expressed a positive attitude towards operability, ease, and satisfaction, emphasizing the practicality of the CC in the diet and the promotion of an unrestricted diet. Similarly, both children and adolescents living with T1DM and their caregivers initially shared a similar attitude. However, over the course of 3 months, this positive attitude decreased significantly by 24 and 20 percentage points for children and adolescents living with T1DM and their caregivers, respectively, resulting in an attitude close to neutral. Despite this change in attitude, there were no statistically significant differences observed in perceived operability, satisfaction, and ease. The lack of significance in these measures may be attributed to the small sample size, as numerical values are more vulnerable to minor fluctuations compared with relative frequency. Additionally, the observed lack of significance may be linked to a disinterest in using the app, given that a low proportion of adolescents have been reported to adhere to the use of such apps [30]. The mHealth adherence rate averages 56%, highlighting the necessity for enhancement through customization options and reminder notifications for improved usability [31].

Furthermore, our results show no significant changes in the mean glycosylated hemoglobin level of children and adolescents living with T1DM after 3 months. These findings are consistent with previous reports suggesting that while changes have been observed with CC support apps at 3 months in adults, no similar changes were found in the pediatric age group, possibly due to

XSL•FO
RenderX

the inherent difficulty in controlling diet in this population [32,33]. It is essential to note that the patient management approach in Peru exhibited clear restrictions, suggesting that introducing an alternative management style might necessitate an adaptation period for patients to assimilate the concept of CC, potentially extending beyond 3 months. While certain apps, such as the Swiss version (ie, WebDia), have explored the option of displaying insulin amounts to enhance user-friendliness [10,34], this was not implemented in Peru due to regulatory requirements and the need for supervised implementation by trained HCWs to mitigate potential clinical consequences [35]. Furthermore, there was limited awareness among patients' treating physicians about WebDia-Mundi, and the research team did not provide close follow-up.

Most existing mHealth apps for CC are free; however, their food databases are often generic, lacking cultural specificity [36,37]. The complexity of CC varies significantly depending on the dietary context of each country. One widely recommended feature in previous studies is the use of visual food representations, which was also preferred by participants in our validation process [38]. As a result, we incorporated more visual photos to enhance usability. While the original Swiss version included only 20 food images, the Peruvian version was enriched with 108 photos to better support users in estimating portion sizes and improve the app's practical utility. Furthermore, previous studies have not been conducted in LMICs, where challenges such as limited access to health care and medications can significantly impact outcomes related to quality-of-life improvements for people living with T1DM. However, despite the lack of changes in glycosylated hemoglobin, participants reported improvements in the management and control of their disease, citing increased self-confidence [39]. Some participants mentioned feeling more freedom in their dietary choices and greater confidence when deciding what to eat. Additionally, children were able to assist their caregivers and became more aware of CC, making the process less stressful for both. Consequently, our results on the perception of the quality of life of both children and adolescents living with T1DM and their caregivers, although not statistically significant, revealed a slight increase in the overall score.

A frequently suggested enhancement for WebDia-Mundi involves expanding the information provided for each preparation or food, such as displaying ingredients considered, carbohydrate typology, and comparisons with similar preparations. While this could enhance user decision-making, there's a potential trade-off, as it might increase the complexity of the app [34]. Access to technology also surfaced as a potential limitation, particularly for individuals residing in areas with restricted internet or smartphone connectivity. This is one of the most common challenges encountered in the implementation of digital health services or mHealth solutions [40].

Regarding the workshop, the results indicate a noteworthy increase in knowledge acquisition among HCWs. Beyond demonstrating improved understanding of CC and the use of WebDia-Mundi, they also expressed gaining insights into the lived experience of an individual living with T1DM. These workshops adhere to the basic education outlined in the principles of the National Assessment Framework, which is derived from the National Diabetes Services Plan in Australia [41]. This educational approach aims to advance knowledge and understanding, but to achieve significant behavioral changes in HCWs, it is essential to implement a comprehensive training program [41]. Similarly, children and adolescents living with T1DM and their caregivers provided positive feedback about the workshop, citing the acquisition of valuable knowledge, particularly in the realm of making informed food choices. The involvement of children and adolescents living with T1DM and their caregivers in these workshops facilitates a thorough assessment of the needs and expectations for enhancing educational programs tailored for individuals living with T1DM [42].

Public Health and Clinical Relevance

The adapted app, WebDia-Mundi, holds the potential to enhance access to diabetes management tools, especially in LMICs. By offering an adaptable tool for diverse cultural settings, it could contribute to reducing disparities in health care and improving equity in access to quality resources for T1DM control [40]. Additionally, the app can serve as a valuable tool for health promotion and education, as the integration of mHealth and health coaching for individuals with chronic diseases has demonstrated a positive impact on both the quality of life and self-management of the disease [43]. Facilitating CC and insulin management can empower individuals living with T1DM and their caregivers to make informed decisions about their treatment and enhance self-care, regardless of their location. However, the adaptation process posed significant challenges, highlighting the need for more agile and scalable approaches to effectively adapt mHealth tools to different countries. Cultural and linguistic differences, as well as variations in dietary habits and health systems, require a structured but flexible adaptation framework. Multistakeholder involvement was essential to ensure that the tool meets the needs of the target population. In addition, e-learning strategies could facilitate the implementation of WebDia-Mundi, improving its accessibility and ease of use for both HCWs and end users in a variety of settings. On the clinical side, WebDia-Mundi could be an effective resource for HCWs in clinical T1DM management by simplifying carbohydrate intake tracking and insulin dosing, ensuring that CC education remains accessible to a wide range of users, including those who are illiterate or speak a native language other than Spanish [44]. Furthermore, WebDia Mundi might be beneficial for caregivers by enabling them to better understand diabetes management and providing practical tools to support patients more effectively [10].

Limitations

This study has several strengths that significantly contribute to its impact and reliability. First, the successful adaptation of the WebDia app to the Peruvian context highlights the adaptability of WebDia-Mundi. Its potential to address and integrate diverse dietary and cultural needs highlights the possibility of scalability to other countries with no costs for the users. Second, the comprehensive approach, incorporating both quantitative and qualitative methodologies, offers a more complete assessment of the app's effectiveness. Additionally, the active involvement and collaboration among HCWs, children and adolescents living

XSL•FO
RenderX

with T1DM, and their caregivers throughout the study phases ensure validity and reflect a strong commitment to enhancing T1DM care within the Peruvian context. It is important to highlight that the collaboration among dietitians, endocrinologists, app developers, and the diabetes community throughout the study phases ensured that the adaptation process was user-centered and aligned with the real needs of the target population. The participatory approach ensured that WebDia-Mundi met the dietary and cultural needs of the target population. Furthermore, the inclusion of 3 distinct cities in Peru, each with its unique characteristics, although not exhaustive of Peru's geographical diversity, enhances the heterogeneity of our findings. However, it is important to acknowledge certain limitations. The absence of a control group in specific aspects of the study restricts direct comparisons with individuals who did not participate in the research. Additionally, the short follow-up period may have limited our ability to observe significant changes in HbA_{1c} and long-term behavioral adaptations. Another key limitation is the potential bias inherent in using a convenience and snowball sampling method and recruiting participants through social media. This approach may have inadvertently led to the inclusion of individuals already inclined towards undertaking the course due to their existing interest, potentially skewing our sample towards those with lower levels of knowledge. The lack of heterogeneity in education levels among caregivers may have influenced the feedback on the app's usability and accessibility, leading to different perspectives on its ease of use and practical applicability. Furthermore, this recruitment strategy could impact the external validity of our findings. However, it is important to highlight that recruiting people with T1DM presents significant challenges, even when using traditional recruitment methods. Based on our experience in patient recruitment, social media and community networks have proven to be among the most effective ways to engage participants in this context. Nevertheless, it is crucial to emphasize that this study serves as a pilot project, not intended to yield universally applicable results. Moreover, a technical barrier in LMICs is the potential existence of areas with lower mobile literacy levels or limited internet access. This might prevent widespread and equitable use of app-based tools, possibly excluding certain populations from fully benefiting from technological health solutions [45]. Finally, the initial sample size was not reached, and therefore, the power is lower, or the ability to detect small changes is lower.

Conclusion

WebDia-Mundi is a tool for enhancing the self-management of people living with T1DM, covering both children and adolescents. Although clinically significant improvements in glycosylated hemoglobin have not been achieved, the application has received favorable acceptance and demonstrated efficacy in increasing dietary education, enabling a life free from unnecessary restrictions. It is crucial to acknowledge that additional efforts are necessary to enhance implementation, which requires further pretesting. Nonetheless, this study serves as an example of how tailoring mHealth solutions to the specific context of LMICs can contribute significantly to enhancing the quality of life for individuals with T1DM. Future research is needed to assess the long-term impact of the app and explore its adaptation to other cultural settings and evaluate strategies to reach a more diverse population, including people with different languages, literacy levels, and educational backgrounds, to ensure equitable access and ease of use.

Acknowledgments

We would like to acknowledge the many individuals who were involved in this study. A special thanks to Maria Dextre Jauregui and Ursula Bonilla for their collaboration in this study. We would like to acknowledge the "Fond de Péréquation" from the Geneva University Hospitals and The Leona M and Harry B Helmsley Charitable Trust for granting the funds for this project. The database used for carbohydrate counting content in processed and ultraprocessed foods originated from a prior study conducted within the Food Policy Program, funded by Bloomberg Philanthropies (grants 46129 and 2019 - 71181). Additionally, support was provided by the SALURBAL project, funded by Wellcome Trust (grant 205177/Z/16/Z).

Data Availability

The datasets generated and analyzed during this study are available from the corresponding author upon reasonable request. Deidentified data supporting the findings of this study can be provided for research purposes in line with JMIR's data sharing policy.

Authors' Contributions

CAR collected the study data and contributed to manuscript preparation. KBA drafted and wrote the manuscript. DB provided overall guidance on the study design and manuscript development and contributed to study conceptualization and manuscript writing. JLM developed the WebDia application. LSG contributed to the carbohydrate estimation of processed foods. MJAB and MATG contributed to training activities. LAF and AL participated in the validation process during the first phase of adaptation. JZT and OH contributed to study conceptualization and manuscript writing. MLP coordinated the project, provided overall supervision, and contributed to study conceptualization and manuscript writing. MCP supervised the entire study process, provided critical guidance and training, and contributed to study conceptualization and manuscript writing. All authors reviewed and approved the final manuscript.

Abstract

Background: Mobile money–based cash transfer interventions are becoming increasingly utilized, especially in humanitarian settings. southern Madagascar faced a humanitarian emergency in 2021-2022, when the second wave of the COVID-19 pandemic and a severe famine affected the fragile region simultaneously.

Objective: This mixed-methods study aims to analyze the impact and factors influencing the success of a mobile money–based conditional cash transfer intervention for health care utilization at 4 primary and 11 secondary facilities in Madagascar.

Methods: We obtained quantitative data from 11 facility registers, detailing patient numbers per month, categorized into maternity care, surgical care, pediatric care, outpatient care, and inpatient care. An interrupted time series analysis, without a control group, was conducted using the end of the intervention in July 2022 as the cut off point. For qualitative data, 64 in-depth interviews were conducted with health care providers, NGO staff, policymakers, beneficiaries, and nonbeneficiaries of the intervention, and was interpreted by 4 independent researchers using reflexive thematic analysis to identify facilitators and barriers to implementation.

Results: The interrupted time series analysis showed a significant negative impact on health care utilization, indicating a reduction in health care–seeking behavior after the end of the cash transfer intervention. The effect was stronger in the slope change of patient numbers per month (defined as $P<.05$), which significantly decreased in 39 of 55 (70%) models compared to the step change at the end of the intervention, which showed a significant but lower change ($P<.05$) in 40% (22/55) of models. The changes were most pronounced in surgical and pediatric care. The key factors that influenced the success of the implementation were grouped across three levels. At the community level, outreach conducted to inform potential beneficiaries about the project by community health workers and using the radio was a decisive factor for success. At participating facilities, high intrinsic staff motivation and strong digital literacy among facility staff positively influenced the intervention. Confusion regarding previous activities by the same implementing NGO and perceptions of unfair bonus payments for health care providers included in the project negatively affected the intervention. Finally, at the NGO-level, the staff present at each facility and the speed and efficiency of administrative processes during the intervention were decisive factors that influenced the intervention.

Conclusions: The conditional cash transfer intervention was overarchingly successful in increasing health care utilization in southern Madagascar in a humanitarian setting. However, this success was conditional on key implementation factors at the community, facility, and NGO levels. In the future, similar interventions should proactively consider the key factors identified in this study to optimize the impact.

Introduction

Over the past decade, Sub-Saharan Africa (SSA) has seen a substantial rise in the number of people with access to digital technologies. Digital transformation has made a stark difference for previously disenfranchised communities, especially in the field of financial services [1].

One technology that stands out is mobile money, which allows the creation of bank accounts and enables financial transactions using unstructured supplementary service data codes without requiring an internet connection [1]. The use of mobile money has seen an unprecedented rise in SSA over the past years, with over 781 million users in 2022 [2].

Mobile money and digital payment services are increasingly used in providing humanitarian and development aid, including by large multilateral organisations such as the World Bank [3]. The COVID-19 pandemic has resulted in a boost in mobile money–based support schemes, aiming to ensure equitable access to health care during crises [4]. Mobile money–based interventions are particularly feasible in humanitarian settings as they are fast to implement, cost-efficient, and reach people who are structurally excluded or in hard-to-reach areas [1,5].

However, scientific evidence on the effectiveness of such programs in increasing access to health care is scarce. Similarly, research on implementation factors that influence their effectiveness is lacking.

Madagascar, with a population of 29 million [6], experienced two humanitarian crises in 2021 and 2022. First, the COVID-19 pandemic led to a reduction in GDP, increased unemployment, and poverty [7] Second, a severe drought and subsequent famine affected the southern regions of the island, where extreme poverty and malnutrition rates are particularly high [8,9]. Health care access in Madagascar—particularly in the south was already limited before these crises, due to a severely resource-constrained health system and high financial barriers to care [10]. In 2021 and 2022, the additional economic strain from the pandemic and famine put the financial viability of health facilities at risk, which rely on patients' out-of-pocket payments [11,12]. In response, the nongovernmental organisation (NGO), Doctors for Madagascar implemented a mobile money–based conditional cash transfer intervention to improve access to health care and financial stability of health facilities.

In this study, we aim to (1) analyze the impact of this intervention on health care utilization in a humanitarian setting, and (2) to identify factors contributing to its success.

We expect this research to provide evidence for policymakers and implementers of future health care interventions in humanitarian settings.

Methods

Study Setting

Madagascar is one of the least developed countries globally [13]. The country has a maternal mortality rate of 392 deaths per 100,000 live births, an under-5 mortality rate of 71 per 1000 live births, and an average life expectancy of 64 years [6]. Over 40% of health care expenses are paid out-of-pocket [14]. With over 80% of the population living in extreme poverty, financial barriers are a major hindrance to accessing health care [6,8].

This study draws on data from selected health facilities in 7 regions of Madagascar (see Multimedia Appendix 1), where extreme poverty rates range between 78% and 95% [8]. During the intervention, the region was hit by severe drought and famine, putting over 2 million people into acute food insecurity [9]. Simultaneously, the second wave of the COVID-19 pandemic affected the economy severely, leading to a 7% decrease in GDP and a nationwide recession [7,15].

Intervention Description

This study analyzed a mobile money–based conditional cash transfer intervention, aimed at increasing health care utilization; it was implemented from February 2021 to July 2022. The inclusion criteria for patients to benefit from the intervention were (1) presenting for care at a participating facility during the intervention timeframe, (2) belonging to one of the eligible patient groups (detailed below), and (3) registering on the digital mTOMADY platform with a mobile money account (support was available at the health facilities at point of care). The intervention covered 80% of patients' expenses for medications and medical consumables through conditional cash transfers. Patients qualified for the intervention if they sought care for (1) acutely life-threatening conditions, (2) accidents or injuries, (3) pregnancy, childbirth, or postpartum care, or (4) pediatric care. The decision to include an eligible patient in the intervention lied with the treating health care provider, and patients could decline participation at any point.

The costs covered by the intervention were limited to medical consumables and medication due to donor requirements. It did not cover consultation fees, laboratory fees (excluding laboratory consumables), hospitalization, or indirect expenses (eg, transportation costs).

Facilities could express their interest in participating with the implementing NGO, which selected facilities based on previous collaborative experience and geographical location, prioritizing those in underserved regions with high poverty rates. The NGO staff members were employed at each participating facility to support the administration of the intervention.

Once a patient completed treatment, the health facilities submitted claims for reimbursement through a digital platform for health care–related payments developed and provided by the German-Malagasy NGO, mTOMADY [16]. The claims were filed by a local employee, usually an administrative clerk at the health facility. Claims contained patient sociodemographic data (eg, age, gender, family size), medical information (diagnoses, symptoms, quantities of medication received, and consumables used), and cost data (eg, prices of each type of medication and medical consumables). All claims underwent scrutiny for accuracy by a team of registered doctors at the implementing NGO's central administrative level. Clarification was requested by this team in case of inconsistencies or missing data. Health facilities were reimbursed for approved claims using mobile money. Participating facilities received a small

XSL•FO
RenderX

bonus payment (approximately USD 0.50) for each approved claim.

Data Sources

Quantitative Data

The primary data sources for the interrupted time series (ITS) analysis were routine facility-level registers from January 2021 to December 2022. These registers were maintained by health facilities for reporting to the national health information system. The registers categorized patient numbers per month into outpatient, inpatient, surgical, maternity, and pediatric care. The register data were obtained from 11 of the 15 facilities that participated in the intervention; 4 facilities declined to share their data. One facility provided only total patient numbers per month rather than disaggregated data. The facilities compiled register data from paper-based registers into digital datasheets. We received these datasheets, which were screened for plausibility and outliers by an independent researcher. Clarification was sought from the facilities in case of inconsistencies. Cleaned data sheets from each facility were combined into one data sheet for analysis.

Qualitative Data

Qualitative data were collected through interviews with health care providers, project implementation staff, policymakers, beneficiaries and nonbeneficiaries (individuals who were eligible to participate in the intervention but who opted out) of the intervention . Interviews were conducted between September 9 and November 11, 2022. Tailored interview guides were developed for each participant group to capture their unique perspectives and experiences.

Health care providers were recruited through phone calls or direct visits. We sampled facilities across different regions, including a mix of primary, secondary, public, private, and faith-based providers. Project implementation staff were recruited through phone calls or emails. Policymakers were purposively sampled and contacted via telephone or email, with additional participants identified through snowball sampling. Beneficiaries and nonbeneficiaries were approached in person within their communities with the help of community health workers (CHWs). Communities were selected using a purposive sampling approach, to represent two communities each in proximity and farther from the 2 facilities where the intervention was implemented for the longest duration.

A Malagasy researcher fluent in local dialects and French, conducted the interviews after undergoing comprehensive training in qualitative research and ethics. The study's purpose and objectives were communicated to the participants in their preferred language, and written informed consent was obtained. Interviews were conducted in private settings chosen by participants, in either Malagasy or French, based on participant preference, and were audio-recorded with consent.

Data Analysis

We used a convergent mixed-methods design for this study, in which qualitative data were analyzed based on the findings from the quantitative analysis [17]. We analyzed qualitative data to explain the differences in the impact of the conditional cash transfer intervention on health care utilization at participating facilities.

Quantitative Data

We conducted an ITS analysis using segmented linear regression without a control group. To assess nonstationarity, we used the Durbin-Watson test to evaluate and adjust for autocorrelation [18]. We did not assess for seasonal trends in the data. Our dataset covered only 2 years, and this limited period and number of data points did not allow for a comprehensive analysis of seasonality. We used the month in which the intervention ended at each facility as the cutoff point and analyzed step and slope changes at that point. For all facilities, the preintervention period was defined as the time from when they joined the intervention until the end of May 2022 (except for one facility, which discontinued the intervention in September 2021). The postintervention period ranged from June 2022 to December 2022 (except for one facility, for which the postintervention period began in October 2021). The start date of the intervention was different for each facility, ranging from March 2021 to December 2021.

We developed separate models per facility for all patients and by patient subgroups (outpatient care, inpatient care, surgical care, maternity care, and pediatric care). As facilities were onboarded to the intervention on a rolling basis and one facility left the intervention early, we did not run a model encompassing all facilities. All statistical analyses were conducted using R Studio, (version 2023.06.1, R Foundation for Statistical Computing) [19]. A P value of <.05 was considered statistically significant.

Qualitative Data

For qualitative data, recordings were transcribed verbatim and translated into English by trained interpreters. To ensure accuracy, a native Malagasy speaker conducted random spot checks, comparing transcripts and translations to the original recordings. Researchers anonymized all identifying information before transcription.

Data were securely stored in a password-protected digital database. Four researchers independently coded all interviews using reflexive thematic analysis [20]. Regular meetings were held to ensure coding validity and consistency. We used NVivo (version 12, Lumivero) for all qualitative analyses [21].

Ethical Considerations

Ethical approval for all components of the study was obtained from the University of Heidelberg Ethics Committee (Heidelberg, Germany) under the registration number: S-982/2021. In addition, we obtained formal approval from the district health office, a regional subdivision of the Malagasy Ministry of Health, in each district in which data were collected. For all secondary analyses of patient data, the ethics committee waived additional informed consent as all data were anonymized before being forwarded to the research team. For primary data collection for qualitative interviews, written informed consent was obtained from each participant prior to the interview. All identifying data were removed from the interviews during transcription, and all interviews were pseudonymized before

XSL•FO
RenderX

analysis. Participants received no compensation for their participation in this study.

We referred to the STROBE (Strengthening the reporting of observational studies in epidemiology) and SRQR (Standards for reporting qualitative research) reporting guidelines in the preparation of this manuscript [22,23].

Results

Sample Description

We obtained register data from 11 out of 15 health facilities; 4 facilities refused to share their register data. Multimedia Appendix 2 contains details on these 11 facilities.

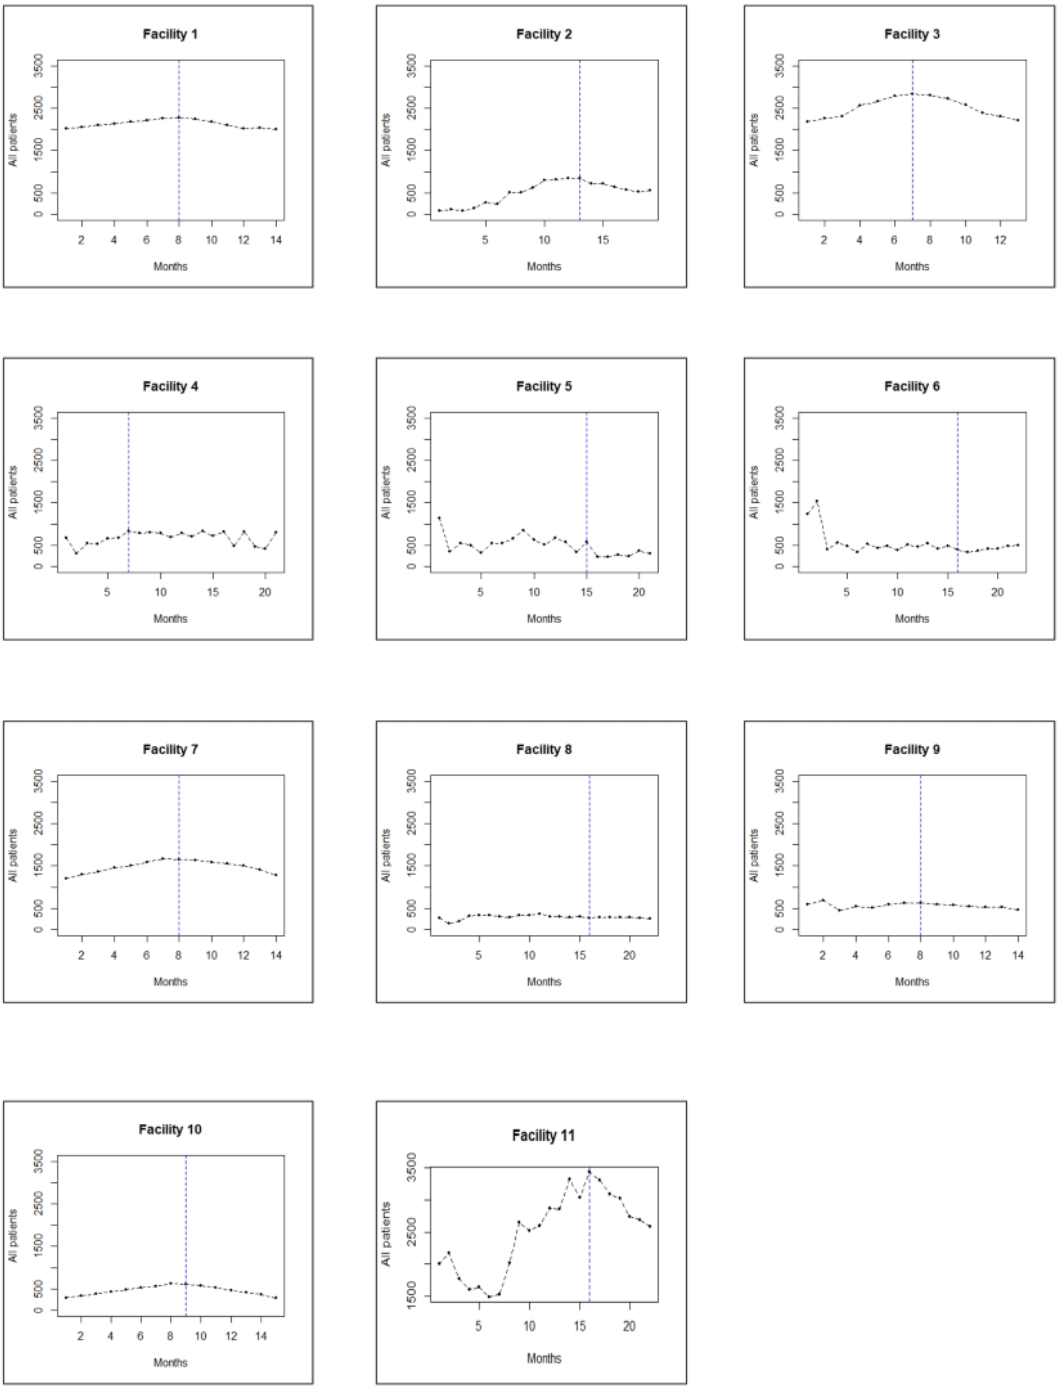
For the qualitative data, we analyzed data from 64 interviews, which lasted between 30 minutes and 1.5 hours, with an average interview duration of 47 minutes. Ten interviews were conducted with project implementation staff, 22 with health care providers, 17 with beneficiaries, 9 with nonbeneficiaries, and 6 with policymakers.

Effect of the Intervention on Health Care Utilization

Overall, health care utilization decreased significantly across most facilities after the end of the intervention. The end of the intervention had a more pronounced effect on patient numbers per month in the long term, which decreased significantly in 39 of 55 (70%) ITS models across separate facilities and patient groups. In comparison, the point effect in patient numbers only showed a significant decrease in 40% (22/55) of all models. Figure 1 illustrates total patient numbers per month at each facility.

XSL•FO
RenderX

Figure 1. Total patient numbers for all patient categories (inpatient, outpatient, surgical, maternity, and pediatric care, depending on services offered by each facility) at 11 health facilities in southern Madagascar that participated in a mobile money–based conditional cash transfer intervention for health care utilization between March 2021 and July 2022. The blue dotted lines mark the end of the intervention at each facility.



The facility with the most pronounced decrease in patient numbers after the end of the intervention was Facility 10, a private facility located in an urban area. Overall, the negative effects of the end of the intervention were most pronounced in maternity, pediatric, and surgical care; whereas, outpatient consultations were the least affected by the end of the intervention.

Table 1 shows the detailed results of the ITS models. The step change values indicate the immediate difference in patient numbers at the end of the intervention, whereas the slope change describes the change in patient numbers per month over time.

Explanatory Qualitative Findings

The qualitative interviews elucidated 7 key factors that differed between facilities where the ending of the intervention had a significant impact on health care utilization and those where it did not. These factors spanned across 3 levels: the community level, the facility level, and the level of the implementing NGO. Table 2 summarizes these factors, as determined in the qualitative analysis of in-depth interviews with key implementation stakeholders, sorted by factors and facilities, with and without significant changes in health care utilization after the end of the conditional cash transfer intervention.

Table . Key factors influencing the successful implementation of the digital cash transfer intervention..

Key factors	Facilities with significant effects[a]	Facilities without significant effects[b]
Community level		
Community Outreach	Where knowledge about the intervention was high, community members were more likely to seek care	A lack of knowledge about the intervention led to confusion and insecurity and a hesitation to utilize health care.
Facility level		
Facility staff motivation	Facilities where staff expressed high inherent motivation and altruistic mindset performed better and were more adaptive to programmatic challenges.	Facilities, where staff expressed lower intrinsic motivation, were less adaptive to programmatic challenges and performed worse.
Bonus payments paid by the NGO[c]	Bonus payments were perceived as useful to increase motivation.	Expressed that bonus payments were insufficient and demotivating, especially when unequally distributed among facility staff
Preexisting activities of the same implementing NGO	Facilities without previous interventions from the same NGO did not experience confusion about previous interventions which could thus not impact their work.	Confusion regarding the overlap and differences of the conditional cash transfer intervention with previous NGO activities led to a lack of clarity for health care providers.
Digital literacy of facility staff	High levels of digital literacy among facility staff positively impacted intervention uptake.	Low levels of digital literacy among facility staff negatively impacted intervention uptake.
NGO level		
NGO staff present at each facility	Presence of NGO staff at each facility was perceived as useful.	Challenges when NGO staff were absent, for example, on weekends or when they served multiple facilities
Speed and ease of the intervention's administrative processes	Facilities that were onboarded later in the intervention benefited from decreased challenges as frequent issues experienced during the first few months of the intervention had been resolved.	Delays and challenges in the programmatic process of the intervention (especially claims validation and reimbursement) were major barriers, especially for the first facilities onboarded.

[a]Facilities F1, F2, F3, F10, F11.

[b]Facilities F4, F5, F6, F8, F9.

[c]NGO: nongovernmental organization.

Community Level

Community Outreach

For beneficiaries, different perceptions of the outreach conducted as part of the intervention and their subsequent knowledge about the intervention influenced health care utilization. Outreach about the intervention was mostly conducted by CHWs, who held group discussions, mass outreach activities (eg, during market days), or conducted home visits and explained the intervention and its procedures to the population. These activities were usually combined with health education activities conducted by CHWs. Additionally, brief radio spots describing the intervention were broadcast in the intervention area. Additionally, at higher-performing facilities, patients expressed that hearing about the intervention through CHWs or on the radio encouraged them to seek care. Conversely, participants in proximity to lower-performing facilities expressed a lack of information about the intervention and often only heard about it once they had arrived at a health facility.

> *It was a community health worker who talked to me and explained the intervention. (He said,) that we have to go to the hospital when we are sick and not go anywhere (else) for care.* [Beneficiary 5]

> *There is no awareness (raising) here. I did not hear (about the intervention).* [Nonbeneficiary 7]

Facility Level

Facility Staff Motivation

The intrinsic motivation of individual health care providers was different between facilities. Facilities that actively sought to participate in the intervention and where health care providers had a strong interest in its success performed better. At these facilities, health care providers took considerable steps to ensure the functioning of the intervention, including covering patient copayments out of pocket or using personal phones to enroll patients.

> *For the facilities that received it involuntarily, we found several kinds of problems because like any project if there is no commitment from the people it is not possible to accomplish it. For the facilities that accepted it, these facilities welcomed it with their hearts, and we immediately saw that the project worked well and that it brought good to the whole facility.* [Project implementation staff 6]

XSL•FO
RenderX

Bonus Payments Paid by the NGO

With the intervention, facilities received a bonus payment for each claim. At some facilities, the bonus payment was perceived as useful to increase motivation among health care providers, while others expressed that the bonus payments were insufficient.

How bonus payments were distributed among staff members (ie, if everyone got a share or the money was kept by the individual responsible for filing the claims) further contributed to the frustration regarding the bonus payment and lower performance at some facilities.

> *The intervention's close collaborators benefited because they received indemnities, and they did their work well. I saw them running around doing their work and they did it perfectly.* [Health care provider 3]

> *At the time of the intervention, the work was voluminous; the indemnity for the agents is not sufficient. This is the problem. We work here; we work at night when there are many patients.* [Health care provider 15]

Preexisting Activities of the Same Implementing NGO

Overall, facilities where the intervention was more successful in increasing health care utilization were those that had not previously collaborated with the NGO. Facilities that had previously collaborated with the NGO expressed confusion about the differences between the new intervention and interventions implemented by the same NGO previously. The data further indicated an unwillingness to adapt to the new intervention's processes among some facility staff who had worked on these previous projects.

Digital Literacy of Facility Staff

The confidence and skills of health care providers and administrative clerks in using the digital tools required for the administration of the intervention equally influenced the success of the intervention. Facilities where staff had higher levels of digital literacy found the intervention easier to implement than those with lower digital literacy.

NGO Level

NGO Staff Presence at Each Facility

At high-performing facilities, active NGO staff members encouraged the uptake of the intervention by patients and aided the facilities in managing the intervention-associated workload. Because of this positive role of NGO staff, their absence was perceived as difficult. Some NGO staff served several facilities, which caused issues for facilities on the days when NGO staff were absent. Emergencies that occurred at facilities during the night or on the weekends were perceived as equally challenging because the NGO staff were absent.

Further, NGO staff placed at the facilities received a salary from the NGO, whereas the facility employees who also supported the intervention did not receive an additional salary, leading to dissatisfaction among some health care providers.

> *I encourage each patient who arrives there to discuss directly with the doctor and tell him that we have heard this and that. I did not also do a wait-and-see attitude, but I did everything, even if it is not my job, to win the hearts of these facilities, so that they recognise that I am enthusiastic about collaborating.* [Project implementation staff 7]

Speed and Ease of the Intervention's Administrative Processes

Facilities where the intervention had a significant impact on patient numbers tended to be those that joined later, likely benefiting from more established processes at the implementing NGO.

Issues related to the reimbursement of the facilities by the NGO significantly impacted the facilities, as delays in payout caused issues for the facilities related to paying their staff salaries or making prepayments for ordering medication and consumables. These delays were a significant source of frustration.

> *The payment made by (the NGO) was a bit delayed at the beginning. It was difficult for the hospital at that time. The hospital needs to run while the cash, the money was blocked there. It was settled later on, and everything was fine.* [Health care provider 11]

A key factor in causing the delay in the payout was the insufficient quality of the claims filed by the facilities, which was echoed by both health care providers and NGO staff. Health care providers expressed that additional training or guidelines on claim filing could have improved this situation.

Finally, early in the intervention, changes were required to the mTOMADY platform to adapt it for the intervention. These changes were perceived as confusing and challenging for facilities. However, the frequency of changes was reduced over the intervention's lifespan, meaning that facilities onboarded later were less likely to experience such issues.

Discussion

Principal findings

Our study aimed to describe the impact of a mobile money–based conditional cash transfer intervention on health care utilization in a humanitarian setting, as well as to identify key factors that influenced the success of the intervention. Overall, our study showed a significant decline in health care utilization following the ending of a mobile money–based conditional cash transfer intervention in southern Madagascar. Data from 11 facilities showed a marked reduction in patient visits, particularly in maternity, pediatric, and surgical services, with outpatient consultations being the least affected. The qualitative findings highlighted key factors influencing intervention outcomes across three levels. These factors included community outreach, facility staff motivation, ease of the administrative processes of the intervention, digital literacy of facility staff, and the presence of NGO staff at facilities.

Our analysis showed that health care utilization decreased at most facilities when the conditional cash transfer intervention ended. This ties in with other findings from Madagascar, which

XSL•FO
RenderX

demonstrated an increase in health care utilization when user fees were abolished [24]. This change was most pronounced for 3 patient categories: maternity patients, pediatric patients, and patients requiring surgery. Given that surgical care is particularly expensive and likely to cause catastrophic health expenditure in SSA [25-27], this is not surprising. Our findings indicate that patients might forgo necessary surgical care in the absence of financing methods for their care. The evidence on the costs of pediatric care is less comprehensive. However, several studies from SSA suggest that the costs associated with pediatric care for asthma, pediatric surgery, and pneumonia could be catastrophic for households [27-29]. Evidence on the impact of partial cost coverage or fee reduction for pediatric health services is however lacking.

Evidence on similar interventions using mobile money-based cash transfers for health care utilization in humanitarian settings is severely limited. Contrary to previous findings [30], our study revealed a significant decrease in health care utilization following the end of a cash transfer intervention. However, our study analyses a conditional cash transfer intervention, whereas previous studies examined unconditional cash transfers [30,31], in which the money may have been used for other purposes. Our findings do however align with evidence from nonhumanitarian settings, in which health care utilization increased in the presence of targeted cash transfer interventions [32,33], especially for maternity services [34]. Cash-transfer interventions in nonhumanitarian settings, especially in combination with other interventions such as health education or text-based reminders, have been shown to improve risky sexual behavior [35], and are perceived as useful in improving the adherence and management of patients with TB [36]. It must be noted that most cash transfer interventions used physical currency, limiting the comparability of our findings [30-34].

Despite an overarching impact of the conditional cash transfer intervention on health care utilization, the impact was not significant across all facilities. We identified 7 key factors that may explain these differences across facilities.

At the community level, differences in community outreach and thus the intervention-related knowledge of the population across communities was decisive. For this intervention community outreach was only conducted in certain communities. In facilities where the NGO implemented community outreach, this was done via CHWs and radio campaigns. CHWs are vital for improving health care-related knowledge, access to health care and health outcomes in the communities they serve [37,38]. As we did not interview CHWs for this sample, we cannot further elucidate the reasons behind the differences in community outreach they conducted; however, given the evidence on factors influencing CHW performance, including training, supervision, remuneration and workload [38,39], it stands to reason that similar factors were decisive in our setting.

At the facility level, facility motivation and mindset were key determining factors of the success of the intervention. Provider motivation has been described as a key factor in the implementation and adoption of new practices [38,39]. It is noteworthy that the described intervention may have impacted provider motivation and thus either positively or negatively reinforced preexisting motivation levels. For example, the intervention, leading to an increase in patient numbers at the facility, may have increased provider workload which, depending on its perceived manageability, has been identified to be a key determining factor of provider motivation [39]. Equally, the intervention required health care providers to take on additional tasks and may have negatively impacted provider motivation [39].

Bonus payments received for each claim filed, were perceived very differently across facilities. At some facilities where all staff members received benefits through bonus payments, they were perceived as motivating factors. This ties in with evidence from other contexts, which have shown that bonus payments can enhance provider motivation and potentially quality of care [40,41]. This effect is however conditional on how the distribution of bonus payments was perceived among health care providers. Bonus payments perceived as unjust or unfair decrease provider motivation [41-44 ,].

Another key factor was previous NGO interventions at the same facilities, which led to confusion at the facilities with the changes in the procedures of the new intervention. Given the sizeable percentage of public services that are delivered by NGOs in SSA [45], such negative effects of past NGO interventions on future interventions should be examined more closely.

Given the digital nature of the conditional cash transfer intervention, a lack of digital literacy at the facility level was a key factor hampering the intervention. This finding ties in with findings from other studies across SSA [46-51]. In the face of rising digitalisation of health care delivery, governments, NGOs, and multilaterals, should invest in improving the digital skills of health care providers to eliminate a key barrier to the implementation of digital health interventions in the future.

Two factors emerged as decisive at the implementing NGO level. First, NGO staff placed at each facility was perceived as an important success factor for the intervention. NGO staff alleviated health care provider workloads by supporting the intervention's administration [52]. Despite this positive effect, the fact that NGO staff were paid directly by the NGO, may have reinforced perceived inequalities in remuneration and thus furthered pre-existing frustrations [43].

Another noteworthy finding of our study is that facilities which appeared more successful were facilities, where the intervention was implemented later, and which thus benefited from more established and well-running processes. This echoes previous findings on public health interventions, which identified "implementation infrastructure," including robust administrative systems as a key success factor [40,41]. It is vital to consider these challenges for future, similar interventions, for example by incorporating piloting phases into implementation plans to establish robust administrative processes early on.

A key challenge for cash transfer interventions, especially in humanitarian settings, is sustaining the increases in health care utilization after financial support concludes. Based on the findings from our study we propose several strategies to enhance sustainability in similar interventions.

XSL•FO
RenderX

First, strengthening local health financing systems is essential for sustaining service utilization. Future interventions could partner with local governments, private, or non-profit health insurance schemes to transition conditional cash transfers into more permanent financial assistance for vulnerable populations. Developing mechanisms for partial subsidies through national health funds or community-based health insurance schemes can support continued access to essential services without relying solely on external funding.

Second, we observed that the increased health care utilization during the intervention period partly stemmed from targeted community outreach and health education efforts. Sustained CHWs in health promotion can maintain community awareness and perceived value of health care services. Future interventions should invest in CHW training and create resources to enable communities to make informed health decisions, encouraging health care utilization even without direct financial incentives.

Finally, the data analyzed in this study contained several indications that the intervention had a positive impact on the trust expressed by patients in health care providers and the health system. This was particularly observed at facilities where health care providers helped patients in signing up for the intervention, for example by allowing them to use their ID cards to obtain a SIM card, or where they supported patients who were struggling with copayments. This improved trust is crucial as it can lead to sustained improvements in health care-seeking behavior even after financial incentives end. Future implementers should prioritise trust-building measures—such as transparent communication, continuous outreach, and patient-centred care—to cultivate a health care environment where patients feel supported and motivated to seek timely medical assistance.

Limitations

We conducted an ITS analysis without a control group. Given the public health emergencies in southern Madagascar in recent years, which impacted health care utilization in the region, we opted against a historic control group. In 2020 the COVID-19 pandemic heavily impacted the Malagasy population and health system [7]. In 2018-2019, a severe measles epidemic [49,53] and in 2017, a plague outbreak affected the island [52,54]. Choosing control data from health facilities in a different part of the country was equally unreliable. Even though the health system is weak across Madagascar, the south of the island has particular challenges. Geographical access barriers are particularly pronounced [8], and facilities, human resources, and equipment are particularly scarce [10]. Equally, extreme poverty is more pronounced in the study regions than in the rest of the country [8,55]. Lastly, the severe drought and subsequent famine were specific to the study region and did not affect other parts of the country [9].

Four out of fifteen health facilities refused to share their facility registers with us for quantitative analysis. As facilities did not need to give a reason for refusing to share their data, we cannot eliminate the possibility that there is thus a selection bias in our final sample. However, we included facilities with varying levels of impact of the intervention on health care utilization, suggesting that the overarching results were not skewed. Our qualitative data draws on a convenience sample of facilities, which includes most but not all facilities for which a quantitative analysis was conducted, meaning we may not have captured all factors that influenced the success of the intervention.

Further, our qualitative data were collected in Malagasy and translated into English, which may have introduced translation errors. However, all data were translated by a trained interpreter with previous experience in qualitative research and spot-checked randomly for consistency between recording and translation by a native Malagasy speaker.

Conclusions

In conclusion, our study shows that a mobile money–based conditional cash transfer intervention led to an increase in health care utilization in a humanitarian setting, particularly in surgical and pediatric cases. This indicates that similar interventions could be useful for mitigating the effects of future humanitarian crises on health care utilization. Several factors influenced the success of the intervention. Designers and implementers of future, similar interventions should proactively mitigate these factors. Additional researchers should be invested in filling the remaining evidence gaps regarding the use of mobile money–based cash transfer interventions in humanitarian settings.

Acknowledgments

We want to thank everyone who participated in our interviews and shared their views, ideas, and thoughts openly and honestly. We would also like to thank the entire team at Doctors for Madagascar for their support of our research and for making this intervention possible. We further want to thank the local researcher who conducted the qualitative data collection for his dedication and for making this study possible. The German Cooperation for International Development (GIZ) sponsored the intervention analyzed in this study. A grant from the Theracur Foundation specifically supported the research activities. The French-translated version of the manuscript is available (See Multimedia Appendix 3).

Conflicts of Interest

None declared.

Multimedia Appendix 1
Location of health facilities in southern Madagascar that participated in a mobile money–based conditional cash transfer intervention for health care utilization between March 2021 and July 2022. Facilities located in urban areas offering secondary care are marked

Abstract

Background: Cervical cancer is currently the leading female cancer in Uganda. Most women are diagnosed with late-stage disease. Human papillomavirus (HPV) vaccination is the single most important primary preventive measure. While research regarding text message vaccine reminder use is strong in the United States, their use has not yet been demonstrated in a preteen and adolescent population in subSaharan Africa or other low- and middle-income countries.

Objective: The objective of this pilot randomized controlled trial was to assess the impact of vaccine reminders with embedded interactive educational information on timeliness of HPV vaccination in Kampala, Uganda.

Methods: In this randomized controlled trial conducted in 2022, caregivers of adolescents needing a first or second HPV vaccine dose were recruited from an adolescent clinic and three community health centres in Kampala, Uganda. Families (n=154) were randomized 1:1 into intervention versus usual care, stratified by dose (ie, initiation, completion) and language (ie, English, Luganda) within each site. Intervention caregivers received a series of automated, personalized text messages or automated phone calls based on family preference. Five messages were sent before the due date, including both static and interactive educational information, with five follow-up messages for those unvaccinated. Receipt of the needed dose by 24 weeks postenrollment was assessed by χ^2, regression, and Kaplan-Meier with log-rank test. All analyses were conducted using intention-to-treat principles.

Results: Overall, 154 caregivers were enrolled (51.3% for dose 1; 48.7% for dose 2) and 64.3% (n=99) spoke Luganda. Among individuals in the intervention arm, 62% (48/78) requested SMS text message reminders and 38% (n=30) requested automated phone reminders. There was no significant difference in requested mode by HPV vaccine dose or language. Intervention adolescents were more likely to receive the needed dose by 24 weeks (51/78, 65.4% vs 27/76, 35.5%; *P*<.001; RR 1.8; 95% CI 1.3 - 2.6). There was no interaction by dose or language. There was no difference in vaccination between those requesting SMS text message versus phone reminders (32/49, 65.3% vs 19/30, 63.3%; *P*=.86). The number needed to message for one additional vaccination was 3.4 (95% CI 2.2 - 6.8). Kaplan-Meier curves demonstrated more timely vaccination in the intervention arm (*P*<.001).

Conclusions: In this novel trial, SMS text message and automated phone reminders were effective in promoting more timely HPV vaccination in this population.

Introduction

Worldwide, human papillomavirus (HPV) infection is the most common sexually transmitted infection [1], with the highest prevalence in young adults [2]. The majority of HPV-associated morbidity and mortality is due to cervical cancer, which is the fourth most common cancer in women worldwide, with an estimated 604,127 new cases and 341,831 deaths in 2020 [3,4]. SubSaharan Africa overall, has the highest cervical cancer incidence and mortality rates in the world [4]. Cervical cancer is the leading cancer among women in Uganda [4]. Up to 72% of women are diagnosed with late-stage disease [5], and 80% die within 5 years of diagnosis [6]. The age-standardized cervical cancer incidence rate in Uganda is more than 4 times the global average, and the age-standardized mortality rate is nearly 6 times higher [4].

HPV vaccination is the single most important primary preventive measure for HPV [7-9]. A systematic review of HPV vaccine programs across 69 countries over ten years found estimated maximal reductions of 90% for HPV 6/11/16/18 strain infection (ie, the most common cancer-causing strains), 90% for genital warts, and 45% for low-grade and 85% for high-grade cytological cervical abnormalities [10]. HPV also plays an important role in anal, vulvar, penile, and oropharyngeal cancer [4]. HPV vaccines are most effective when adolescents are vaccinated before HPV exposure. HPV vaccination is currently recommended in Uganda for adolescent girls aged 9 - 14 years in a 2-dose series and as a 3-dose series for those aged 15 - 26 years.

However, despite high efficacy and a strong safety profile, global HPV vaccination coverage rates remain low compared to other routinely recommended vaccines [11]. Uganda added HPV vaccination to the National Extended Programme on Immunization in November 2015. However, among the adolescents who receive the first dose of the HPV vaccine, many do not receive the second dose they need to complete the series for full protection. Furthermore, among those who do not receive the second dose, many do not receive it in a timely fashion—that is, within the recommended 12 months—resulting in more days at-risk. In Kampala City, only 45% - 62% of girls in the target age range have received two doses of the vaccine [12]. Similarly, many girls (56.7%) had delayed completion of HPV vaccination [13].

Reminders are an evidence-based approach to improve vaccine receipt. In Uganda, the only current reminder available is a paper appointment card, which can easily be misplaced or destroyed. A countrywide evaluation of HPV vaccination in Uganda highlighted the need for caregiver engagement to improve HPV vaccination rates. It was also noted that there was an inadequate follow-up system for second doses [14,15]. Text messaging or SMS text messaging offers low-cost, scalable opportunities to foster vaccination across a population. A Cochrane review found that text messaging, as a single-method reminder, had the largest effect size with high certainty of evidence (risk ratio [RR] 1.29, 95% CI 1.15 - 1.44; six studies; 7,772 participants) [16]. Text message reminders for HPV vaccination have shown to be effective in several studies within the United States [17-19]. Such reminders have also been used for pediatric vaccination studies in African countries such as Kenya and Nigeria [20-25], and in three other non-African low- or middle-income countries (LMIC) [26-28], but not for adolescent vaccines including HPV vaccine. Adolescent vaccination patterns, knowledge, and perceptions differ from those for pediatric vaccination, and interventions in high-income versus low- or middle-income countries also differ [29]. Therefore, text message performance cannot be extrapolated from those targeted to parents of young children or to parents in high-income settings.

In this pilot randomized controlled trial, we assessed the impact of vaccine reminders with embedded interactive educational information on timeliness of HPV vaccination in Kampala, Uganda.

Methods

Setting, Recruitment, and Informed Consent

This randomized controlled trial RCT (clinicaltrials.gov: NCT05151367; 09/12/2021), funded by the National Institutes of Health (R21CA253604), was conducted in 2022. This study took place at three health centres—Kisenyi, Kawaala, and Kiswa—in Kampala, Uganda, overseen by the Kampala Capital City Authority (KCCA) and located in the suburbs of Kampala City, as well as the Makerere/Mulago/Columbia Adolescent Health Clinic at Mulago National Referral Hospital, the teaching hospital for Makerere University College of Health Sciences. The study health facilities were selected purposively in consultation with KCCA to ensure the inclusion of different city divisions. Each of the study health facilities provides HPV vaccination services to adolescent girls and has affiliated schools, although due to the pandemic, vaccination was not occurring in schools.

Caregivers were eligible to participate if they were (1) the adult parent of an adolescent girl aged 10 - 14 years due for a first or second HPV vaccine dose during the study period, (2) resided in Kampala or the surrounding districts, (3) had their usual care at a study site, (4) spoke English or Luganda, and (5) had a cell phone with text messaging capability. Only one child per family was included. Families were recruited by study staff, including village health teams, either through the health facilities or in the community. Informed consent was obtained from a parent or legal guardian for study participation. On enrollment, a demographic survey was completed.

XSL•FO
RenderX

Randomization

We used central randomization of parent-adolescent dyads with a 1:1 allocation, stratified by dose (ie, initiation, completion), and language (English, Luganda) within each site. The randomization lists, based on permuted blocks with varying block sizes, were prepared within REDCap (Research Electronic Data Capture) electronic data capture tools hosted at Columbia University [30,31]. The statistician and those collecting outcome data remained blinded to arm assignment until analyses were complete.

Intervention

On enrollment, parents randomized to the intervention were able to select if they wanted messages sent either via SMS text messages or as an automated phone call, as well as if they wanted messages in English or Luganda. Messages included both reminders about the needed dose as well as educational information about the importance of the HPV vaccine and were based on a successful previous study [17], as well as 85 key informant interviews with caregivers (n=30), adolescents (n=30), health care workers (n=11), school (n=10), and government officials (n=4). First, team members identified the key content, timing, and framing for each message based on the interviews. The final draft messages were first designed in English, then translated into Luganda by an independent professional translator, and then reverse-translated by a second independent professional translator, while ensuring proper linguistic and cultural equivalence. The Luganda and English messages were then pretested with 24 parents with small iterative changes.

Five messages before the due date and five follow-up messages were automatically sent centrally using a custom-designed SMS text messaging or phone reminder service. Charges were reversed such that no family was charged for sending or receiving messages. Messages included both static and interactive educational information such as the need for timely receipt of HPV vaccines and differed based on which dose was due. Messages for those who had not yet received any HPV vaccine dose began right after enrollment. For those who had received one dose but had not completed the series, messages began either 4 weeks before the dose was due (ie, for those for whom the dose was not yet due) or immediately (if the dose was overdue). Families who reported that their adolescent would be away at boarding school had their message timeline targeted to the next school break. Messages were personalized with the adolescent's first name. Parents randomized to usual care received no vaccine reminders and instead received their usual care.

Measures

Outcomes

The primary outcome was the receipt of the next needed HPV vaccination (dose 1 or dose 2) by 24 weeks postenrollment. Practice staff blind to study arm assignment abstracted vaccination data from the HPV vaccine registry within each enrolling site.

Analyses

For this feasibility pilot study, with a minimal sample size of 77 in each arm, a hazards ratio of 1.67 with 80% power was observed, allowing for a 5% type I error comparing time to next dose.

To assess the primary outcome, we assessed the difference in proportions using χ^2 tests and relative risk estimated from logistic regression. We also assessed for any interaction effects of doses due or language of messages (English or Luganda). The number needed to message for one additional vaccination was then calculated. In addition, the timeliness of vaccination was assessed using Kaplan-Meier analyses with log rank test. All analyses were intention to treat. All analyses were conducted using STATA (version 14.0 MP; STATACorp). A formal statistical analysis plan was drafted and agreed upon prior to the start of analysis.

Ethical Considerations

This study was approved by the Institutional Review Boards at Columbia University (AAAT1572) and Makerere University (Mak-SOMREC-2020 - 13) as well as by the Uganda National Council for Science and Technology, with written consent for study participation. Informed consent was obtained from a parent or legal guardian for study participation. All data were securely stored in a study-specific database. Those enrolled received Ugandan Shillings (UgX) 15,000 which is equivalent to approximately US $4 as compensation for their time at the initial interview.

Results

Overall, 274 families were approached and 181 were eligible; of those, 85.1% (n=154/181) were enrolled (Figure 1). Only 8 families were ineligible due to not having a cell phone. Of the 154 dyads enrolled; 51.3% (n=79) had not yet initiated the series and were enrolled to receive dose 1 reminders for initiation; 48.7% (n=75) had already received one dose and were enrolled for dose 2 reminders for completion. No family was ineligible due to not speaking English or Luganda. Nearly two-thirds of those enrolled (64.3%; n=99) spoke Luganda (Table 1), and there were relatively equal numbers enrolled by age group except for a smaller percentage of 14-year-olds. Over three-quarters (77.3%; n=119) were enrolled from the KCCA sites. There was an equal balance between arms for those in the intervention and usual care groups. Of those families randomized to the intervention, 62% (n=48/78) requested the reminders be sent as text messages, with the remaining 38% (n=30) requesting automated phone reminders. There was no significant difference in requested mode based on HPV vaccine dose or language (desired text messages for initiation reminders (22/39, 56%), versus for completion reminders (26/39, 67%; *P*=.35), desired text messages for reminders in English (21/28, 75%) versus in Luganda (27/50, 54%; *P*=.07).

[a]HPV: human papillomavirus.

[b]KCCA: Kampala Capital City Authority.

Characteristics of the Study Population

Most (130/154, 84.4%) of the caregivers were women; 13.2% (20/152) had no schooling, and 67.1% (102/152) had only completed a primary or ordinary level of education. Approximately 54.9% (84/153) had a regular (ie, not smart) cell phone. Of those with a smartphone, none preferred WhatsApp over text messaging to receive health reminders for their adolescent. Of all those surveyed, while most (136/152, 89.5%) were not worried at all about going over their text message limit, 76.6% (118/154) had run out of airtime or messages in the past 6 months. Most (125/154, 81.2%) received text messages daily. Nearly half (76/154, 49.4%) reported receiving most of their information about the HPV vaccine from a health care provider, 27.9% (n=43) from radio or television, 7.1% (n=11) from family or friends, and 2.6% (n=4) at their adolescent's school. Approximately 41.6% (64/154) knew their adolescent was due for an HPV vaccine dose, and of those 46.9% (30/64) knew when the dose was due. The HPV vaccine perceptions were generally positive, with 96.7% (147/152) reporting that the vaccine was very or somewhat safe, and 98.7% (151/153) reporting that it worked very or somewhat well. Only 44.4% (68/153) thought their adolescent would be protected with only one dose of the vaccine.

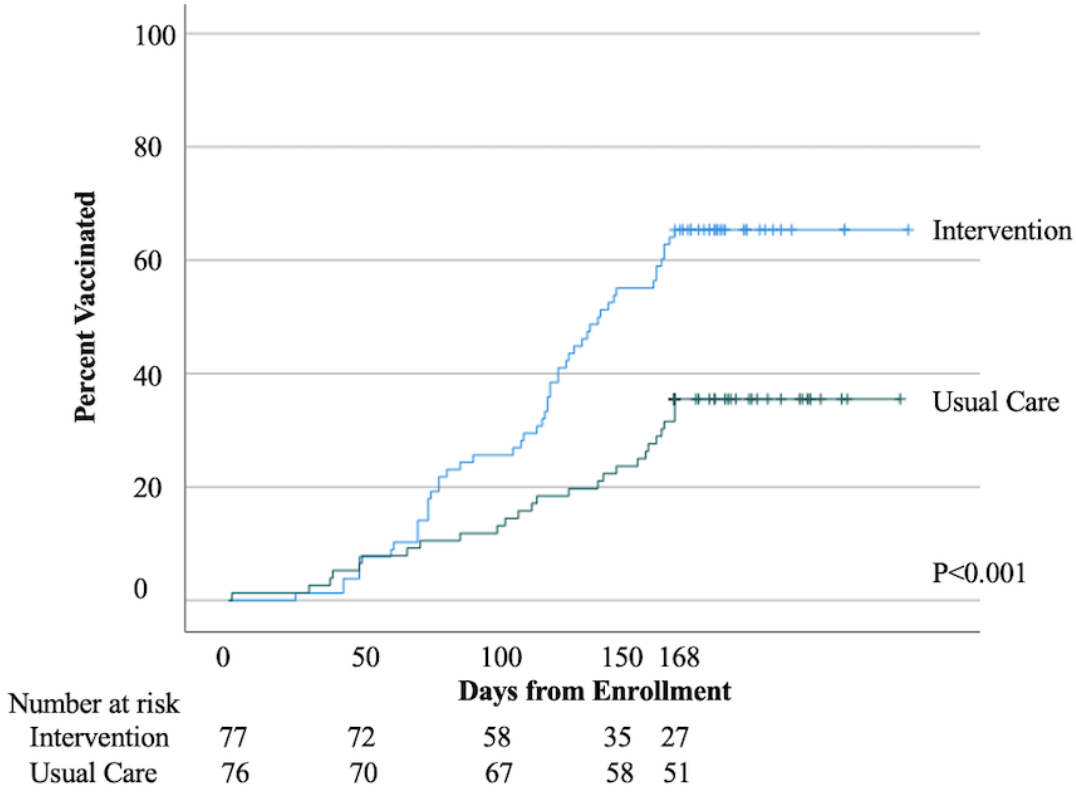
Intervention Effects

Overall, 95.5% (703/736) of text messages were delivered as expected and 90% (9/10) of replies were processed as expected.

XSL•FO
RenderX

In an intention-to-treat analysis, intervention adolescents were more likely to receive a needed dose by 24 weeks (65.4%, 51/78 vs 35.5%, 27/76; *P*<.001; RR 1.9 95% CI 1.3 - 2.6). As an exploratory analysis, there was no interaction by dose needed (*P*=.34) or language (*P*=.22). There was also no difference in vaccination between those who wanted the reminders sent as a text message or as an automated phone reminder (32/49, 65.3% vs 19/30, 63.3%; *P*=.86). The number of families needed to message for one additional girl to be vaccinated was 3.4 (95% CI 2.2 - 6.8). Kaplan-Meier curves demonstrated more timely vaccination (*P*<.001) (Figure 2). On post-hoc analysis, when split by dose, results were similar; the number of individuals who needed dose by 24 weeks for initiation was 66.7% (26/39) versus 27.5% (11/40; *P*<.001; RR 2.17 95% CI 1.34 - 3.52) and for completion was (25/39, 64.1% vs 16/36, 44.4%; *P*=.09; RR 1.54 95% CI 0.93 - 2.58).

Figure 2. Time from first message sent to receipt of next needed dose.



Kaplan-Meier estimates of time from enrollment to receipt of the needed HPV vaccine dose. The x-axis represents time in days since enrollment until receipt of the HPV vaccine dose. The y-axis represents the cumulative proportion of adolescents vaccinated. Follow-up of each child was censored at day 168 or 24 weeks, if the child had not yet received the needed dose.

Postintervention Interviews

We completed postintervention interviews with 30 parents from the intervention arm, including those in need of first versus second doses, those who requested text versus phone reminders, and those who spoke English versus Luganda. Overall, all study participants rated the reminders as highly acceptable and would recommend them to their friends. Some viewed the reminders as a demonstration of "special care" by health workers to have adolescent girls vaccinated and protected against cervical cancer. Participants noted the messages reminded them of when to take their girls for HPV vaccination and provided additional information on the safety and importance of HPV vaccine. A few participants expressed an inability to read messages on their own, receiving few messages, and having busy schedules—highlighting the continued importance of offering an option for automated phone reminders instead of solely text messages. All participants agreed that the intervention should be extended to other community members.

Discussion

This pilot trial demonstrated that SMS text message and automated phone vaccine reminders for HPV vaccination were feasible and acceptable for parents to use in a low-income country such as Uganda, with high user satisfaction. This pilot study also demonstrated effectiveness in a combined outcome of next needed dose—first or second dose—in both overall

vaccination at 24 weeks as well as timeliness of receipt of the needed dose. The overall number of families needed to message for one additional girl to be vaccinated was quite low at 3. Overall, our data suggest that integration of SMS text message vaccine reminders in LMICs is both feasible and accepted by parents and could improve HPV vaccination across a population.

Reminder strategies may be especially important for adolescents, who unlike young children in general have fewer visits with health care providers and therefore, may be less likely to be vaccinated or receive information about the vaccine. In a study conducted in Australia, SMS reminders to parents or guardians who had consented to their adolescent receiving the HPV vaccine within a school-based program led to higher HPV vaccine administration [32]. Similarly, text message reminders for HPV vaccination have been shown to be effective in several studies within the United States [17-19]. In our study, parents in the intervention arm received personalized, scheduled message reminders that included both a reminder about the needed dose as well as educational information about the importance of the HPV vaccine. This addition of information likely proved important, given that only half of the participants knew their adolescent was due for an HPV vaccine, and of those who did, only half of the participants knew when the dose was due. The countrywide evaluation of HPV vaccination in Uganda highlighted the need to increase awareness of the importance of HPV vaccination, as well as evidence-based education and outreach [14,15]. Perceived vaccine safety [5] and perceived benefits of vaccination—particularly cancer protection [33]—have all been noted before as important factors that may impact HPV vaccination in Uganda, all of which were included in our messages.

Some important lessons were learned in this pilot study that could be important for others wanting to use text message vaccine reminders. First, there was high user satisfaction, acceptability, and recommendation ratings, illustrating general interest in these sorts of reminders. Second, only 8 families were ineligible due to not having a cell phone, indicating the potential reach of such interventions. The Global System for Mobile Communications Association Intelligence data highlight that there were 30.55 million cellular mobile connections in Uganda at the start of 2023, which is equivalent to 63.8% of the total population [34]. However, other LMIC may have less cell phone penetration. Third, although a minority, some families opted to receive automated phone reminders, highlighting the potential importance of families being able to select their mode of reminder. There was also no effect on the intervention based on type of reminder selected. In a study of HPV vaccine reminders in the United States, text messages but not phone reminders were effective [18]. It is not clear if the difference here is that families had a choice in their reminder types. Another study, also in the United States but focusing on HPV vaccine series completion, had families choose the modality of the intervention and found completion rates were similar between different recall methods [35]. Of note, only half of the participants in our study had a smartphone, highlighting the continued importance of SMS versus multimedia messaging service or web-linked text messages for this population. Fourth, while most caregivers reported that they were not worried at all about going over their text message limit in a month, three-quarters of them reported that they did run out of airtime or messages in the past 6 months. In this study, we set up reverse billing. It is not clear if the parents would have opted to pay for their own messages. If such reminders were to be used across a larger population for future vaccination support, reverse billing may be needed. Of note, in previous studies in the United States, cost of messages was not highlighted as a concern [36]. Finally, we needed a long lead time to collaborate with a vendor and receive a code from the Uganda Communication Commission; therefore, others may need to keep a long lead time in mind. While not text message reminder-related, it may be important to note that only 44.4% of caregivers surveyed thought their adolescent would be very protected with only one dose of the vaccine. If Uganda moves to a one-dose HPV vaccine, as may be recommended [37], much education may be needed to reassure families that only one dose is now needed.

This study had several limitations. First, our participants were a convenience sample who agreed to take part in an HPV vaccine text messaging study and were from an urban and primarily literate population and therefore may not be representative of the larger population. Similarly, HPV vaccine perceptions regarding safety and efficacy were generally positive among participants. It is unclear if, among a population with more negative views, the intervention would be as successful. However, despite the positive views only one-third of the usual care group were vaccinated within the 24-week period. Third, not 100% of the text messages were delivered as expected. Since all analyses were intention-to-treat, this could have impacted our effect size. We were also not able to confirm delivery of automated phone calls. Fourth, we allowed participants to select text message versus automated phone reminders and therefore could not assess impact if we had not allowed selection and instead sent all participants text messages. Next, this trial took place during the COVID-19 pandemic which could have affected vaccine receipt. However, this should have affected both arms equally. Finally, this pilot study was designed for a combined outcome of next needed dose—first or second dose. Future work will involve conducting a larger, fully powered randomized control study. Despite these limitations, a key strength of this study is that it demonstrated feasibility, acceptability, and pilot effectiveness in over 150 families, recruited from different areas in Kampala, and included English and Luganda speakers. Luganda is one of the most spoken languages in Uganda.

In this novel trial, text message and automated phone vaccine reminders were effective in promoting more timely HPV vaccination. Such reminders could be considered to increase vaccination rates across a population.

Abstract

Background: Directly observed therapy (DOT) is the standard method for monitoring adherence to tuberculosis (TB) treatment. However, implementing DOT poses challenges for both patients and providers due to limited financial and human resources. Increasing evidence suggests that emerging digital adherence technologies, such as video directly observed therapy (VDOT), can serve as viable alternatives.

Objective: This study aims to evaluate the effectiveness of VDOT compared with usual care directly observed therapy (UCDOT).

Methods: Between July 2020 and October 2021, we conducted a 2-arm, parallel-group, open-label randomized trial with a 1:1 assignment to receive either the VDOT intervention (n=72) or UCDOT (n=72) for treatment adherence monitoring at public health clinics in Kampala, Uganda. Each group was further stratified to ensure equal numbers of males and females. Eligible patients were aged 18-65 years, had a confirmed diagnosis of TB, and were undergoing daily treatment. The VDOT group was provided with a smartphone equipped with an app, while the UCDOT group followed the routine monitoring practices outlined by the Uganda National TB Program. We tested the hypothesis that VDOT was more effective than UCDOT for monitoring medication adherence. The primary outcome was adherence, defined as having ≥80% of the expected doses observed during the 6-month treatment period. An intention-to-treat analysis was conducted, and multivariable logistic regression was used to estimate the effect of the intervention on adherence monitoring. Adjusted relative risk ratios and their corresponding 95% CIs are presented. Secondary outcomes included treatment completion, loss to follow-up, death, and reasons for missed videos in the intervention group.

Results: The intention-to-treat analysis included 142 participants, with 2 excluded due to discontinuation of medication within the first week after enrollment. The median age of participants was 34 (IQR 26-45) years. The median fraction of expected doses observed (FEDO) was significantly higher in the VDOT group compared with the UCDOT group (100, IQR 80-100 vs 30, IQR 10-60, respectively; P<.001). When using a FEDO cutoff of ≥80% to define optimal adherence, 63 of 142 (44%) patients met the threshold, with a significant difference between the VDOT and UCDOT groups (56/71, 79% vs 7/71, 10%, P<.001). After adjusting for confounders, VDOT users were significantly more likely to achieve ≥80% of their expected doses observed compared

XSL•FO
RenderX

with UCDOT users (adjusted risk ratio 8.4, 95% CI 4.16-17.0). The most common reasons for failing to submit videos of medication intake were an uncharged phone battery, forgetting to record videos during medication intake, and losing the smartphone.

Conclusions: Enhanced VDOT was more effective than UCDOT in increasing adherence monitoring among patients with TB in Uganda. This evidence highlights the potential of digital technologies to improve treatment adherence monitoring and support in high TB burden settings with limited human resources.

Introduction

The End TB Strategy envisions a world free of tuberculosis (TB), with zero deaths, disease, and suffering due to TB by 2035 [1]. In 2022, an estimated 10.6 million new cases were reported, while 1.6 million people died from TB worldwide [2]. Although effective treatments for TB disease have existed for over 50 years, nonadherence to medication remains a common problem among patients and poses a significant obstacle to achieving the goals of the End TB Strategy [1,3]. Nonadherence reduces cure rates, prolongs infectiousness, and results in poor treatment outcomes, including treatment failure, drug resistance, death, and relapse [4-7]. The emergence of drug-resistant TB and multidrug-resistant TB (MDR-TB) is partly attributed to patients not adhering to their medication properly [4]. Globally, an estimated 450,000 incident cases of MDR-TB were reported in 2021, marking a 3.1% increase from 437,000 cases in 2020 [2]. According to a recent meta-analysis that included 148 studies, the global pooled prevalence of MDR-TB was 11.6% (95% CI 9.1%-14.5%), significantly higher than previous estimates [8].

The World Health Organization (WHO) and US clinical practice guidelines recommend directly observed therapy (DOT) as the standard of care for TB treatment [9,10]. DOT involves a health care worker observing a patient in person while they ingest TB medications to monitor adherence and provide support as needed [10]. When implemented correctly, in-person DOT can facilitate high levels of medication adherence and successful treatment of TB disease. Additionally, DOT can aid in the early detection of adherence issues, adverse drug reactions, and worsening TB symptoms [11]. Previous estimates indicate that approximately 50% of patients on long-term treatment for chronic diseases often fail to adhere to their prescribed medication regimens in both developed and developing countries [12]. Several barriers hinder the effectiveness of DOT, including the inconvenience of daily in-person visits to health facilities, a shortage of health care workers, high transportation costs, TB-related stigma, and long patient waiting times at health facilities [13,14].

Digital adherence technologies have recently emerged as promising tools to address barriers to patient support and treatment monitoring at the health system, patient, and structural levels [15-18]. Video directly observed therapy (VDOT) is an innovative smartphone-based system that uses an app to record videos of medication intake, enabling remote monitoring of treatment adherence. VDOT reduces the need for frequent face-to-face meetings, thereby minimizing inconvenience to patients and lowering transportation costs [19,20]. Several observational studies have evaluated the feasibility and acceptability of VDOT, including 2 conducted in Africa [20-26]. Three randomized clinical trials (RCTs) in the United States, United Kingdom, and Moldova have assessed the efficacy of VDOT, demonstrating that it is feasible, acceptable, cost-saving, and convenient for patients [16,27-29]. A pilot study in Kenya found video-observed therapy to be both technically feasible and acceptable to patients and health care professionals [24]. Similarly, studies conducted among patients and health care providers in Uganda have shown that VDOT is feasible and acceptable for monitoring and supporting patients undergoing TB treatment [25,30,31]. A recent systematic review and meta-analysis found that VDOT is effective in improving medication adherence and bacteriological resolution compared with in-person DOT care [32]. However, none of the studies included in the review were conducted in Africa, as no RCTs comparing VDOT with in-person DOT have been published from the region. The aim of our study was to compare the effectiveness of VDOT and usual care directly observed therapy (UCDOT) in observing and monitoring treatment adherence among patients with TB in Uganda.

Methods

Ethical Considerations

This study was approved by the institutional review boards of the University of Georgia (ID PROJECT00000571), Makerere University (protocol 756), and the Uganda National Council for Science and Technology (HS656ES). All participants provided written informed consent in either English or Luganda, based on their language preference. The consent process included assurances regarding the privacy and confidentiality of the data collected during the study. Participants received approximately US $10 as compensation for transportation and the time spent participating in each visit.

Trial Design

The “DOT Selfie” study was a parallel-group, open-label randomized controlled trial involving 144 adult patients with TB at selected treatment clinics in Kampala, Uganda. Participants were randomized into a control group (n=72), which received UCDOT, and an intervention group (n=72), which received VDOT for adherence monitoring. Enrollment into the

XSL•FO
RenderX

RCT occurred between July 13, 2020, and follow-up continued through October 25, 2021. The details of the trial's design and methods were described in our published protocol [33].

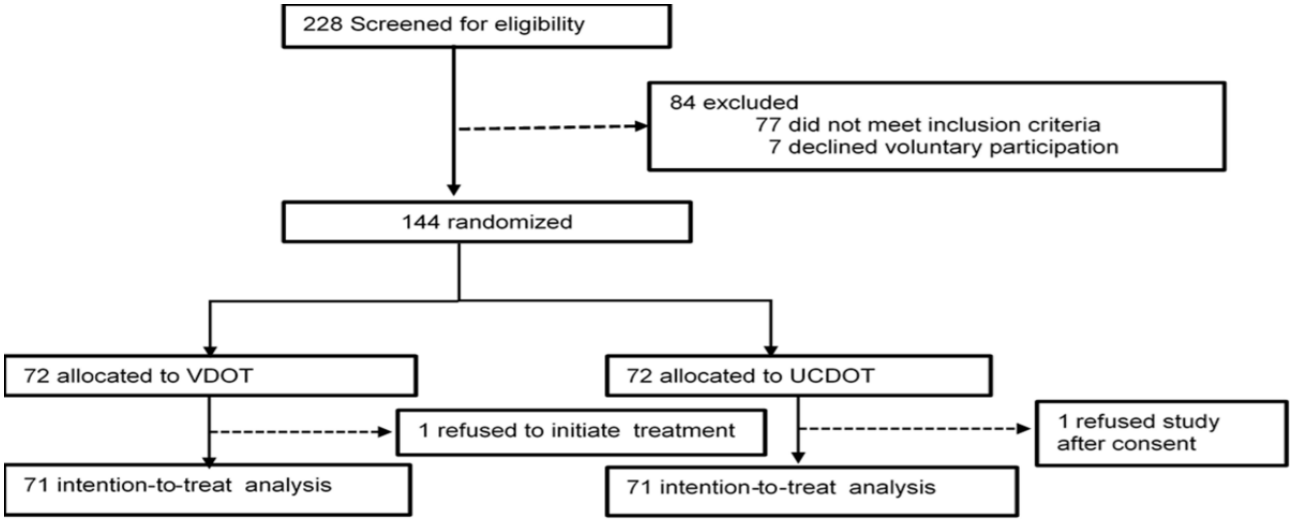
Eligibility Criteria

Eligible participants were adults aged 18-65 years with a confirmed diagnosis of drug-susceptible TB in the new or retreatment category, who had initiated treatment within the past month and planned to reside in Kampala for the entire 6-month treatment period to facilitate close study follow-up. Participants were excluded if they could not speak and read either Luganda (the local dialect) or English, were too ill to withstand the study procedures at enrollment, or had a self-reported motor, visual, hearing, or cognitive disability that would hinder proper use of a smartphone. Additionally, patients residing in areas without cellular network coverage or access to electricity for charging their smartphones were excluded.

Study Setting and Recruitment Procedures

The primary study site was the Lubaga TB clinic, with secondary recruitment sites being public clinics that provide free TB services in Kampala. All TB clinic sites are located about 10-15 km from the Kampala city center and collectively treat approximately 10,000 patients with TB annually. The study team worked closely with clinic nurses, who helped identify potentially eligible patients at the selected public clinic sites. Trained research assistants used a screening checklist to assess study eligibility, and then provided a brief description of the study. The details of the design and methods of the randomized controlled trial are described in our published protocol [33]. The baseline questionnaire was administered after consent, and a copy is provided in Multimedia Appendix 1. Participants were then randomized into the intervention or control study group. The study flow is shown in Figure 1.

Figure 1. DOT Selfie participant flow diagram. UCDOT: usual care directly observed therapy; VDOT: video directly observed therapy.



Randomization and Masking

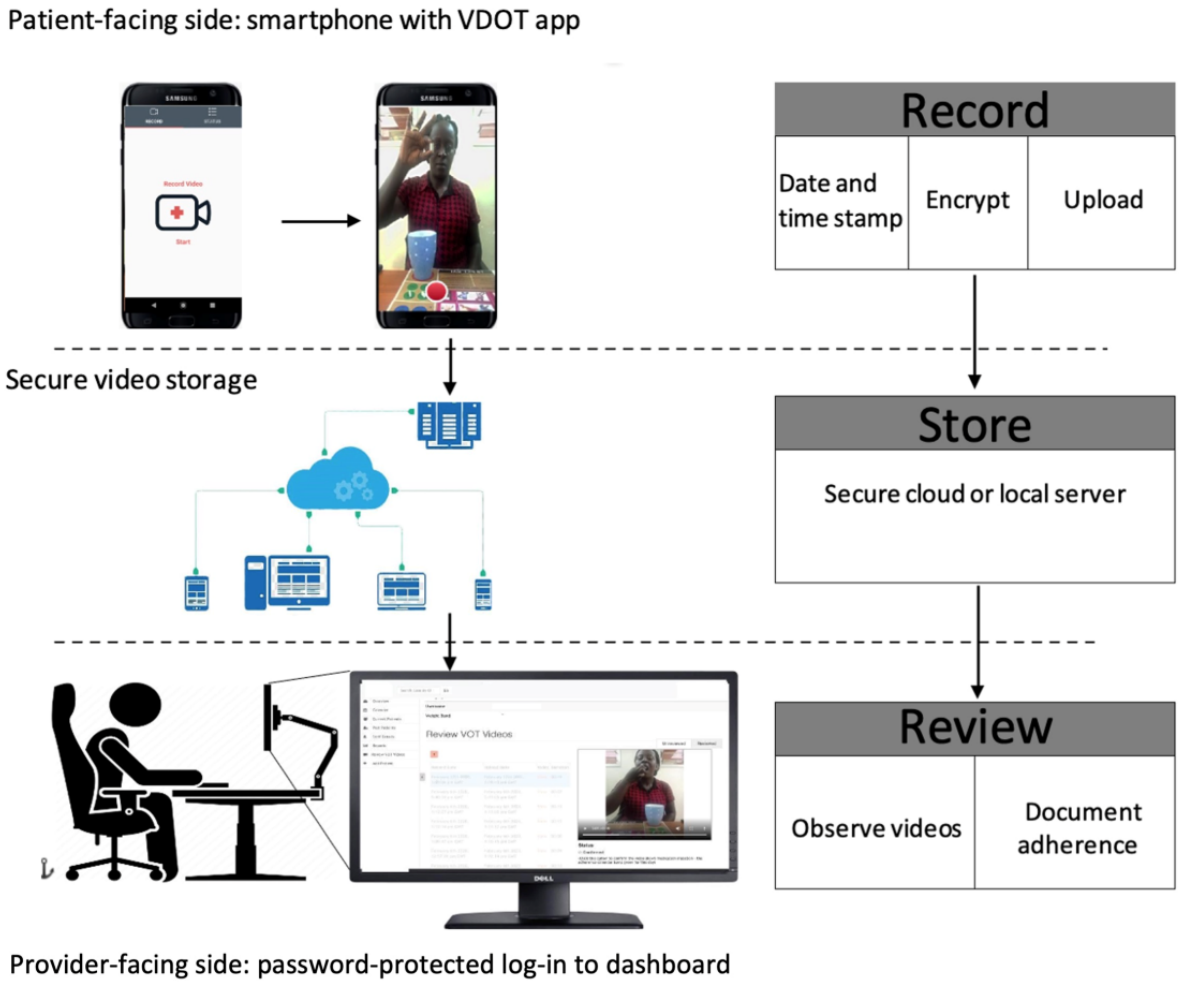
We randomized 144 participants in a 1:1 ratio to receive either VDOT or UCDOT, as shown in Figure 1. We chose equal allocation to optimize the power of the study [34]. Randomization was stratified by sex to ensure equal representation of men and women in each study group [34]. Sex stratification was justified because sex is a known factor associated with adherence to TB treatment [34,35]. Permuted block randomization with block sizes of 4 and 6 was used to ensure a balanced assignment of participants to the intervention or control groups and to minimize the predictability of study arm assignment. Each block contained a specified number of randomly ordered treatment assignments, as recommended in clinical trial methods by Friedman et al [34]. The detailed process followed during randomization is published in the protocol elsewhere [33]. Given the nature of the intervention, participants and study staff were not masked to study group assignment. Study investigators were not blinded to allocation information due to ongoing scientific reviews and the possibility of making clinical decisions about participants' treatment if it became necessary to withdraw them from the intervention. The trial statistician was blinded to study group assignment during the analyses.

Description of the Enhanced VDOT System

VDOT is a licensed Health Insurance Portability and Accountability Act (HIPAA)–compliant system originally developed by SureAdhere Mobile Technology, an initiative that started at the University of California, San Diego [36]. It consists of 3 main components, as described previously by Garfein and colleagues [19] and in our published protocol paper [33]. The components include (1) the patient-facing part, which is the smartphone app used by the patient to record medication videos; (2) the secure cloud-based server, which stores the uploaded medication videos; and (3) the provider-facing part, which is the web-based browser accessed through a secure, password-protected log-in via a computer, laptop, or tablet to review the submitted videos and daily adherence reports [33]. At the end of each video recording, an automatic, encrypted, time-stamped video was uploaded to the secure cloud server for storage and playback (Figure 2). Upon submission, the video was removed from the smartphone, ensuring that patients could not retrieve it.

XSL•FO
RenderX

Figure 2. Schematic of the asynchronous video directly observed therapy system for monitoring tuberculosis treatment (adopted from Sekandi et al [33]).



Enhancement of the VDOT System for Contextual Adaptation

The VDOT system was adapted to the local Ugandan context in 3 ways. First, we expanded the English-based SMS text message reminders to include motivational messages encouraging patients to continue taking their medications and submitting videos. Second, we translated the SMS text messages into Luganda (a local dialect) to facilitate understanding for patients who did not speak English. The following are examples of the SMS text message reminders and motivational messages we used: “It’s time to take your pills and send a video” and “Taking your pills will help you to get better.” Third, an additional SMS text message reminder was sent automatically 8 hours after the standard SMS text message reminder, which was sent to participants at 6:00 AM, if a medication video had not been received in the VDOT system. After adapting the VDOT system to the local context, it was dubbed “DOT Selfie.”

Description of the VDOT System

Description of Standard Procedures

The trial procedures are described in detail in our protocol paper, which is published elsewhere [33]. All participants had an initial face-to-face TB education session, regardless of the assigned study group. The session provided information on TB medications, including dosage, timing, the importance of taking daily pills as prescribed, and what to do in the event of a missed dose or lost pills. In addition, patients received information on cough hygiene behaviors, such as covering their cough to minimize the risk of spreading germs. Lastly, the education emphasized the importance of reporting any issues related to TB medications, including common side effects, adverse events, or new symptoms.

Intervention: Asynchronous Video Directly Observed Treatment

We used an asynchronous VDOT intervention package, which included (1) a loaner GSM (Global System for Mobile Communications) Itel P15 Android smartphone (model W5005) with a preinstalled VDOT app and a preassigned SIM card with a unique phone number; (2) a prepaid weekly internet data subscription of 350 MB at local telecom commercial rates; and (3) automated daily SMS text message reminders to take medications. Participants in the intervention group were enrolled in the VDOT system using a unique log-in personal identification number to set up an account and secure patient information in compliance with HIPAA [33]. The personal identification number also prevented access to the VDOT app by nonstudy participants. The app includes a video feature that

XSL•FO
RenderX

allows patients to record themselves while swallowing their daily doses of medication. In addition, patients received weekly incentives equivalent to US $0.30 in the form of social bundles or airtime minutes, contingent on successfully submitting videos for 7 consecutive days. The weekly incentive was specifically linked to the VDOT intervention, meaning that participants randomized to this study group were eligible to receive the incentive. However, all participants, regardless of the study arm, received a transport refund and reimbursement for their time at each visit, equivalent to about US $10. On the day of enrollment, participants received detailed training on how to use the VDOT app to record and submit videos of medication intake. They also received an instructional guide with pictorial illustrations (pill mat) showing the systematic process of recording the videos, as well as a description of the most common side effects of TB medications. The "pill mat" served as a visual aid to facilitate easy reporting of medication side effects during the video recording session (see details in Multimedia Appendix 2).

At the clinic, a trained study staff member logged into the secure VDOT system via a computer or tablet to download and review patients' daily videos, document medication adherence, and record any self-reported side effects. The study nurse also tracked missed video recordings and took follow-up actions as predefined in the protocol (see details in Multimedia Appendix 3). These actions included a follow-up call to assess missed doses, address side effects, and resolve any other issues as needed. Other secondary methods used to monitor adherence included pill counts and tracking prescription refills at the clinic.

Control: UCDOT

UCDOT was delivered according to routine practice under the Uganda National TB Program guidelines updated in 2017 [37]. The guidelines specify that the TB treatment supporter may be a health care worker, a trained workplace or community health worker, or anyone the patient chooses to observe them swallowing the tablets. The in-person interaction between the patient and the treatment supporter during treatment should occur at least five times a week, with observed medication doses documented in the treatment card. According to the guidelines, DOT services must be organized to accommodate the patients' circumstances and provided as close to their homes as possible. Some patients may opt to take their medication at the health clinic if they live nearby. The patient and treatment supporter are expected to agree on a mutually convenient meeting place for treatment observation and support. However, there is considerable variation in how DOT is delivered across clinics and among patients in Kampala city. After a confirmed diagnosis, TB medications are prescribed, and patients return for biweekly refill visits during the first 2 months (intensive treatment phase). In the continuation phase, patients return monthly for refill visits and clinical evaluation.

In usual care, adherence is assessed using patients' treatment cards, self-reports, and pharmacy prescription refills during routine clinic visits. The study research staff collaborated with TB clinic nurses or staff, community linkage facilitators, and treatment supporters to collect information on DOT. The research team combined data from all available sources and cross-validated it to the extent possible. Patients in the UCDOT study group were followed up for missed routine visits according to the National TB Program guidelines. This included a follow-up phone call if a patient missed a routine visit to refill a prescription, as well as addressing any issues, such as side effects, as needed. The COVID-19 pandemic caused some disruptions, resulting in unintended modifications to the routine delivery of UCDOT.

Follow-Up of the VDOT Group for Missed Videos and Study Visits

A predefined follow-up protocol was used to contact study participants in case of missed doses or videos (see Multimedia Appendix 3). The research staff made 2 phone call attempts within the first 24 hours of a missed video to establish the dosing history and determine the reason for the missed videos. If there was no response from the participant within 72 hours, the research team escalated the follow-up to a field visit to trace the participant at home or at their workplace. After 2 weeks of active follow-up with no success, the study team waited for the participant to return to the clinic for a routine visit. If the patient failed to show up for the scheduled clinic visit, the study team notified the national TB program staff to seek additional support. According to the standard WHO guidelines, a patient is declared lost to follow-up if they do not return to the clinic for their prescription refills for 2 consecutive months [38].

Study Measurements

Primary Outcome

The primary outcome measure was adherence, defined as the fraction of expected doses observed (FEDO) over the months of prescribed TB treatment or by the end of the study following randomization. In the VDOT group, adherence was directly measured based on medication videos submitted and reviewed by the research staff to confirm medication ingestion. In the control UCDOT group, daily medication adherence was measured through self-reports. This was also supplemented with indirect measures, such as notes on the patients' treatment card and prescription refill visits, as additional indicators of adherence. Study measurements were collected using a questionnaire at baseline and at follow-up during months 2, 4, and 6 to ensure close monitoring of all patients during treatment.

Secondary Outcomes

The secondary outcomes we selected are considered unfavorable outcomes and are also relevant indicators of performance for national TB programs. These include treatment completion, loss to follow-up, death, and treatment failure. The definitions of these outcomes were based on the WHO [38] and Uganda National TB Program guidelines [37]. Treatment completion was defined as completing all medication doses as prescribed by the TB clinic, as confirmed by the clinic records. Loss to follow-up was defined as an interruption in TB treatment for at least two consecutive months. Death was considered any death during the treatment period, regardless of the cause. Treatment failure was defined as a patient with TB whose sputum smear examination is positive at month 5 or later during TB treatment [38]. Treatment failure was difficult to ascertain due to

XSL•FO
RenderX

incomplete clinic records. However, no cases of treatment failure were documented among the participants.

Sample Size Estimation

The trial was powered at 80% to detect a 22% difference in medication adherence, the primary outcome, between the 2 groups: VDOT (85%) and UCDOT (63%), based on a 2-sided significance level of 5%. The adherence levels for the comparison groups were derived from previous DOT and VDOT studies conducted in Kampala, Uganda [25,39]. To achieve a chi-square test with a difference of 0.22 and an odds ratio of 0.30, the estimated total sample size was 124. We assumed an attrition rate of 14%, based on a randomized controlled trial comparing usual care and digital adherence interventions in Kenya, where the overall loss to follow-up rate was 11.7% (9.9% in UCDOT and 1.76% in VDOT) [40]. The calculated final sample size was 144 participants, with 72 per group. When calculating power and sample size, we treated the response as binary (0 or 1), with a cutoff value for nonadherence as the FEDO <80%, and adherence as the fraction ≥80%. This binary response variable for adherence was used in the final regression analysis to facilitate comparison with previous clinical trials [16]. Sample size tables were used to estimate precision, as described in detail elsewhere in our protocol paper [33]. All calculations were performed using the SAS statistical software package, version 9.4 (SAS Institute).

Statistical Analyses

We conducted an intention-to-treat analysis according to the study group to which patients were originally randomized. Superiority was determined by a 22% difference in the proportion of patients achieving the primary outcome (63% vs 85%). VDOT treatment observation was classified as completed if patients' medication doses were observed via video. UCDOT treatment observation was classified as completed if the patient reported that a designated treatment supporter observed the ingestion of prescribed doses. Univariate analysis was performed to describe the baseline characteristics of the study population. Multivariable logistic regression analysis was conducted to test for significant associations between the study groups (as the main exposure) and the primary binary outcome of adherence (no <80%, yes ≥80%). Age and HIV status were selected as potential confounders and were adjusted for in all models. Other covariates considered for adjustment during the primary analysis included education level, income, and smartphone ownership at baseline. We did not adjust for sex because randomization was stratified by this variable. Crude and adjusted risk ratios with 95% CIs are presented, and statistical significance was considered at *P* values less than .05.

Results

Overview

Of the 228 patients with confirmed TB who were screened, 144 met the eligibility criteria and were randomized into 1 of the 2 study groups, each with 72 participants. Two participants were excluded from the intention-to-treat analysis (n=142): 1 participant in the VDOT group refused to initiate TB treatment shortly after study enrollment, and another participant in the UCDOT group declined participation after initiating treatment. The 2 participants were included in the baseline analysis but excluded from any further analyses because they did not have the study outcomes of interest (Figure 1 and Multimedia Appendix 4 [41]). The median age of the participants was 34 (IQR 26-45) years. There was a significant difference in median age (*P*=.005) between the study groups, with participants in the UCDOT group being older; 120 of 144 (83.3%) participants owned a cell phone, while 53 of 144 (36.8%) had smartphones. Within the VDOT group, 29 of 72 (40%) owned a smartphone. Overall, 46 of 144 (31.9%) participants were HIV positive. All the measured baseline characteristics were balanced between the study groups, except for age (Table 1).

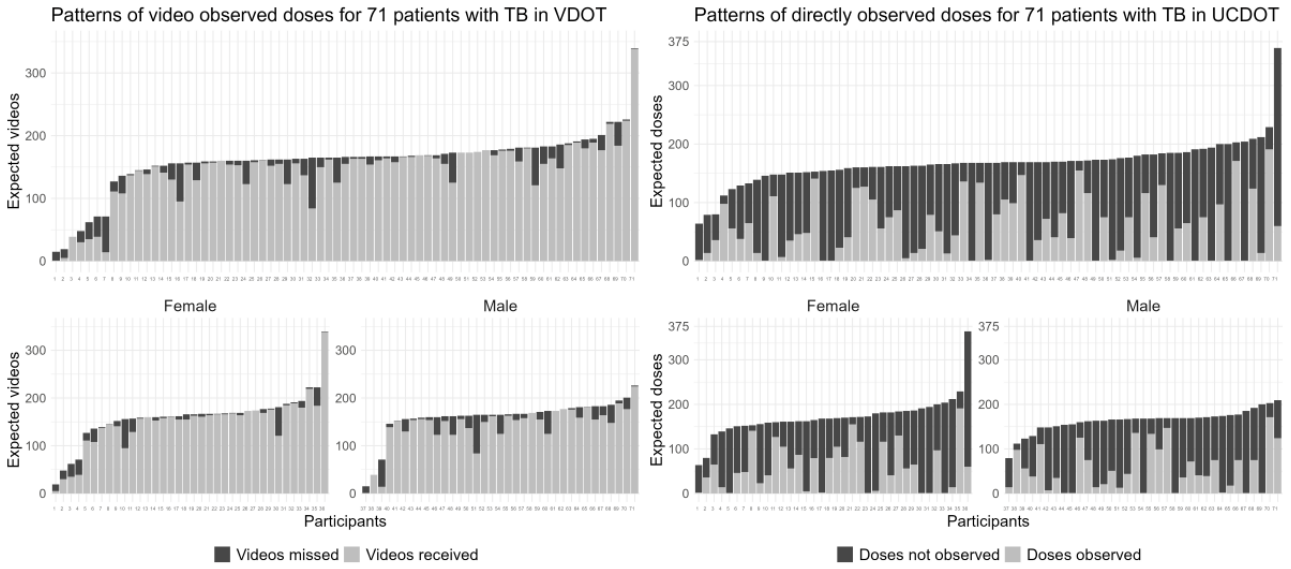
Patterns of Treatment Observation by VDOT and UCDOT Groups and by Sex

A visual illustration of the patterns of treatment observation among study participants is shown in Figure 3. For the VDOT group, the light gray bars represent the videos received via the technology system, while the dark gray bars represent the videos that were not submitted (ie, missed). For the UCDOT group, the light gray bars show the doses that were observed (as reported by the patients) and the dark gray bars show the unobserved doses. We observed clear differences in the patterns of observation between the 2 study groups. However, when the same data are further stratified by sex, there are no obvious differences in the patterns of doses observed between men and women within each group.

XSL•FO
RenderX

Figure 3. Patterns of treatment observation among participants in video directly observed therapy (VDOT) and usual care directly observed therapy (UCDOT). TB: tuberculosis.



Median Differences in Expected and Observed Doses by Study Arm and Sex

There was a significant difference in the median number of doses observed between VDOT and UCDOT (Table 2). However, there were no significant differences in the number of doses when comparing male and female participants within the same study arm (Table 3).

Table 2. Median number of expected and observed doses by study arm.

Doses	Total, median (IQR)	Video directly observed therapy, median (IQR)	Usual care directly observed therapy, median (IQR)	*P* value
Expected videos/doses	167 (158-177)	166 (158-177)	168 (158-178)	.40
Videos/doses observed	118 (39-157)	156 (134-168)	48 (14-98)	<.001
Videos/doses not observed	37 (7-105)	7(2-23)	105 (66-151)	<.001

Table 3. Median number of expected and observed doses within study arms stratified by sex.

Arm and doses	Total, median (IQR)	Male, median (IQR)	Female, median (IQR)	*P* value
Usual care directly observed therapy arm				
Expected doses	168 (158-178)	168 (158-172)	168 (158-184)	.49
Doses observed	48 (14-98)	41 (14-86)	56 (12-99)	.61
Dose unobserved	105 (66-151)	116 (68-151)	104 (64-148)	.96
Video directly observed therapy arm				
Expected videos	166 (158-177)	165 (160-178)	166 (155-175)	.57
Video observed doses	156 (134-168)	154 (134-164)	160 (135-170)	.37
Videos missed, doses not observed	7 (2-23)	10 (3-26)	4 (2-14)	.16

Differences in Adherence Measured by the Fraction of Expected Doses Observed

We evaluated adherence using the FEDO, expressed as a percentage, as shown in Table 4. The overall median FEDO was 80% (IQR 30%-100%), but the median adherence in the VDOT arm was 100% (IQR 80%-100%), which was significantly higher (*P*<.001) than that of the UCDOT group. When using a cutoff of ≥80% for FEDO to define optimal adherence and <80% for nonadherence, only 63 of 142 (44.4%) participants, on average, achieved optimal adherence with their expected doses observed. However, in the VDOT group, 56 of 71 (79%) participants achieved an optimum FEDO, which was significantly higher (*P*<.001) than in the UCDOT group. The median FEDO did not significantly differ by sex in either study arm (*P*=.16 for VDOT and *P*=.96 for UCDOT).

XSL•FO
RenderX

Table 4. Median adherence based on FEDO[a] by study arm.

Variables	Total	Video directly observed therapy	Usual care directly observed therapy	*P* value
Adherence (%), median FEDO (IQR)	80 (30-100)	100 (80-100)	30 (10-60)	<.001

No, n (%)	79 (66)	15 (21)	64 (90)	
Total, n	142	71	71	

[a]FEDO: fraction of expected doses observed.

Factors Associated With Treatment Observation as a Measure of Adherence

We performed a multivariable logistic regression analysis to evaluate the factors associated with optimal adherence levels (≥80% doses observed), as measured by the FEDO, with the results presented in Table 5. The results from the unadjusted regression models indicated that being in the VDOT group and identifying as Muslim were independent factors significantly (*P*=.03) associated with achieving adherence of ≥80%. We found that participants in the VDOT group were 8.4 times more likely to have ≥80% of their expected doses observed compared with those in the UCDOT group, after adjusting for confounding factors such as age, religion, current cell phone ownership, and HIV status. Current cell phone ownership was significantly (*P*=.04) associated with reaching the 80% adherence level, based on expected doses observed, compared with those who did not own a cell phone, after adjusting for the study group and other covariates.

In the intention-to-treat analysis of 142 participants, the secondary TB outcomes (Table 6) evaluated showed treatment completion at 90.1% (128/142) for all participants, with significantly higher completion rates in the VDOT group compared with the UCDOT group. The rate of loss to follow-up was 6.3% (9/142) overall, but 7 of 71 (10%) participants in the UCDOT group were lost to follow-up, compared with 2 of 71 (3%) in the VDOT group. Overall, there were 5 deaths; 4 of these were HIV coinfected and 3 were male (see details in Table 7).

Reasons for Missed Video Submissions in the VDOT Group

Based on the standard 6-month regimen of 168 doses and the enrollment date, we expected a total of 11,928 videos. Of these, 11,041 (92.56%) were successfully submitted by participants included in the intention-to-treat analysis over the study period. Of the 887 missed videos (7.44%), the most common reason reported by participants was a lack of a charged phone battery, accounting for 183 of the 887 (20.6%) missed videos. Technical or technology issues accounted for 450 (50.7%) of the missed videos. Patient-related issues accounted for 348 (39.2%) missed videos, with the most common reason (136/887, 15.3%) being forgetting to record the videos while swallowing the medication. Additional reasons for missed videos are provided in Table 8.

Table 8. Reasons for missed videos among VDOT[a] study participants in Kampala, Uganda.

Reasons for missed videos	Patients reporting (n=212), n	Videos missed (n=887), n (%)
Technical or technology-related issues		
Phone battery is not charged	39	183 (20.6)
Phone stolen/lost	6	98 (11.0)

Discussion

Principal Findings

In this study, we found that VDOT was significantly more effective in observing medication ingestion and monitoring adherence among patients with TB. Our findings align with a recent systematic review and meta-analysis that included studies conducted in Australia, China, Moldova, the United Kingdom, and the United States. The review concluded that monitoring treatment using VDOT was significantly associated with increased adherence and better microbiological outcomes compared with UCDOT [32]. Additionally, we found that cell phone ownership was significantly associated with a higher level of observed doses, regardless of the study group. Although VDOT was effective, some participants occasionally failed to submit their expected videos of medication intake. The most common reasons for missed videos were lack of a charged phone battery, forgetting to record the medication event, and loss of the smartphone. This finding is consistent with results from our previous pilot study conducted in Kampala, Uganda [25]. To our knowledge, this study is one of the few randomized controlled trials conducted to evaluate the effectiveness of VDOT in Uganda and Africa. More studies are needed to assess the effectiveness of VDOT in rural African contexts and other low-resource settings. Additionally, it is important to identify which subgroups of patients are most likely to benefit from this technology.

There are a few published randomized controlled trials that have compared various forms of VDOT intervention packages with in-person DOT thus far [16,28,29]. Story and colleagues [16] published the first multicenter trial evaluating the efficacy of video-observed treatment compared with usual care in 2019. The study was conducted in the United Kingdom and involved a larger sample of 226 patients from 22 centers. The sample was also highly diverse, with 58% of participants having a history of drug and alcohol abuse, homelessness, and incarceration. In the UK study, 70% of patients on VDOT achieved optimal (≥80%) scheduled observations during the first 2 months, compared with 31% in the UCDOT group. The difference observed in the VDOT arm could be attributed to the difference in the timing of the measurement of the primary outcome, which was 2 months versus 6 months after randomization. The Moldova trial by Ravenscroft and colleagues [28] compared patients assigned to VDOT and clinic-based DOT. The study measured the primary outcome as the observed medication adherence every 2 weeks for the entire 6 months of treatment. The study concluded that VDOT significantly decreased nonadherence compared with standard DOT and reduced the time and money patients spent during their treatment [28]. Although there were some differences in the delivery of the VDOT intervention package and the measurement of the primary outcome, the conclusions on the effectiveness of VDOT are quite similar across studies.

The UCDOT group had a low level (21/71, 30%) of reported observed doses of medication over the 6 months of treatment. This result is very similar to the findings from the UK trial, despite differences in the study populations, delivery of DOT, and treatment durations [16]. This finding further reinforces the fact that in-person DOT is generally difficult to implement, particularly in low-resource settings [39,42]. A Cochrane review of 11 clinical trials concluded that TB cure and treatment completion rates were not improved by DOT [13]. In South Africa, a recent study found that only about 25% of patients with TB received formal DOT support, either home-based or clinic-based [43].

Cell phone ownership was significantly associated with achieving optimal observation of the expected doses of medications, regardless of the study group. Moreover, we found that 120 of 142 (84.5%) patients owned a cell phone, while 53 of 142 (37.3%) had personal smartphones at baseline. This finding suggests that having access to a cell phone could serve as an indirect facilitator of adherence support for patients on treatment. In African settings, smartphone ownership and cellular networks are rapidly proliferating, presenting opportunities to leverage modern technology to improve health care and service delivery. According to the National Institutes of Health, “there is a need to stimulate research utilizing mHealth tools aimed at the improvement of adherence to treatment, effective patient-provider communication, and self-management of chronic diseases in underserved populations” [44]. There is increased utility and effectiveness of accessible mobile technologies in enhancing the monitoring of patients with chronic diseases, which can be attributed to the affordability and reliability of smartphones in both high- and low-income settings [45,46].

The main secondary outcomes, including treatment completion and loss-to-follow-up, were statistically better in the VDOT group compared with the UCDOT group. These findings are consistent with the conclusions of a recent systematic review and meta-analysis [32]. The notably higher percentage of TB/HIV coinfected individuals among the deaths aligns with epidemiologic trends [2]. Treatment failure is an important outcome, but it is often difficult to ascertain, especially with follow-up periods of less than 1 year. To determine treatment failure, we used the records at the end of treatment at 6 months, although it should be routinely assessed at 5 months. We relied on the TB clinic records of sputum results at month 5 because our study protocol included only follow-up visits at months 2, 4, and 6. The study team did not have direct control over the standard clinical evaluations that occur in routine TB management. The clinic records were grossly deficient; therefore, we cannot conclusively state that there were no treatment failures. Larger studies are needed to compare these outcomes across the groups to ascertain the true differences.

Reasons for Failure to Submit Videos

Overall, technical and technology-related issues were the most commonly cited reasons for failure to submit videos. The lack of a charged phone battery was the single most common reason for failure to submit videos, as sometimes phones turned off during video recording. This finding is consistent with results from our pilot study in Kampala [25,47]. To minimize the phone battery issue, patients were trained and encouraged to ensure that their phones were always charged at night or before recording videos. The loss of a smartphone occurred among a

XSL•FO
RenderX

few participants, resulting in a substantial number of missed videos. The study team mitigated the disruption in data collection by replacing lost phones as soon as they were made aware. Missing adherence records were filled using self-reports from patients or clinic records on prescription refills. However, the self-report method falls short because it lacks an objective way to validate the doses taken [48].

The main patient-related reasons that mostly prevented the submission of videos included forgetting to record the medication intake, traveling to locations without access to electricity to charge the phone, or being too ill to record videos. These findings were similar to those reported in our first pilot study [25] and in other studies elsewhere [19,26]. Typically, when patients travel to rural areas in Uganda, there is a high likelihood that they will not have access to electricity, further complicating adherence monitoring. When videos were missed due to travel, the research team followed up to gather the missing information using self-reported adherence. A small number of patients reported a lack of a convenient place to record videos, which was a concern similar to our previous study [25]. This could suggest an underlying stigma associated with TB treatment. However, a study done in Turkey, which compared the levels of stigma among patients with TB using in-person DOT versus VDOT, concluded that patients who received VDOT reported experiencing less stigma [49]. The role of VDOT in mitigating stigma among patients with TB warrants further research, especially in diverse contexts.

Strengths in the Context of Prior Work

First, we evaluated the enhanced VDOT intervention, which is the only digital adherence technology offering remote visual observation of doses taken, making it comparable to the UCDOT. Other commonly used digital adherence technologies for TB monitoring, such as 99 DOTS and digital or smart pillboxes, only provide indirect signals as proxies for doses of medication intake [18]. Second, we successfully evaluated a culturally adapted VDOT in a randomized controlled trial (RCT) within the context of a low-income setting. In our study, we demonstrated that more than one-third of the participants owned a personal smartphone, and these numbers are growing globally. Third, we conducted the study in Kampala, Uganda, where the TB rates are estimated at 250 cases per 100,000, which is much higher than in the majority of settings where VDOT has been previously evaluated [16,19,29]. Fourth, the study facilitated the delivery of a patient-centered approach that was more convenient and less intrusive during the critical period of the COVID-19 pandemic. This also catered to the public health mitigation measures aimed at curtailing the transmission of COVID-19. Lastly, the RCT results generated in our study provide a basis for the systematic evaluation of the implementation process of VDOT. Although there is no gold standard for using digital adherence technologies to monitor TB treatment, our study adds to the mounting evidence that supports the digital observation of pill-taking as an alternative to in-person DOT in usual care.

Study Limitations

First, the study was conducted during the COVID-19 pandemic; therefore, some unintended disruptions in the health system could have altered the practical delivery of usual DOT care in Kampala, Uganda. This may have led to an overestimation of the effect of VDOT. However, a study comparing VDOT and UCDOT before and during COVID-19 found significantly higher adherence to TB treatment when using VDOT during both periods [50]. It is possible that adherence in the UCDOT group could have been greater if not for social distancing mandates and lockdowns. The potential effect of the pandemic period may limit the generalizability of our findings. Second, our study did not specifically measure clinical endpoints, such as sputum conversion at follow-up visits. Although we attempted to extract this information from routine clinic records, the data were incomplete. Third, our study was conducted in an urban setting, which may limit its generalizability to rural settings due to differences in key factors such as cellular network availability, internet coverage, and access to electricity for charging phone batteries. Lastly, the enhanced VDOT intervention included multiple components; however, this study was not designed to isolate the effects of specific components that may have contributed to the differences in adherence observed. Future studies could use a factorial design to assess the impact of different intervention components. There are cross-cutting limitations common to all digital health technologies, such as technology infrastructure, cost, and access to smartphones, which will impact adoption, scale-up, and sustainability, particularly in low-income settings [18].

Considerations for Future Adoption, Scale-Up, and Sustainability of VDOT

We proposed several considerations for the broader adoption, scale-up, and sustainability of VDOT in low-resource settings. Our findings support the need to carefully address the known facilitators and barriers to VDOT acceptability, such as those highlighted in the qualitative exit study of patients who used VDOT in Uganda [30]. First, VDOT requires upfront investment in the health system and local technology infrastructure to facilitate scale-up. A robust system would include the hardware—computers or smartphones—and the software—access to the internet, cellular networks, and maintenance of the VDOT system. There is also an overarching need for adequate access to electricity. Second, national TB programs could leverage public-private partnerships with entities such as telecommunication companies that manage vital resources such as internet coverage for sustainability. Third, standardized training for health providers is essential to facilitate the effective use and adoption of digital technology. Fourth, there is a need to integrate the VDOT system into the general health management information system to ensure interoperability and the timely use of adherence outcome data to improve patient care. The VDOT system could eventually be optimized for monitoring treatment adherence across multiple diseases, such as HIV/AIDS, diabetes, and hypertension. Lastly, patients would need basic training in the use of the VDOT app to ensure ease of use. In our qualitative exit interviews with users, training in the use of the smartphone app was cited as a major facilitator of ease of use and acceptability for VDOT [30]. In general, we expect that health providers and patients will grow more experienced and comfortable with technology over time.

Ethical-Legal Issues and Areas for Future Research

Confidentiality, privacy, and stigma concerns are overarching issues that must be carefully addressed to alleviate fears of intentional or unintended disclosure of a patient's disease status. The flexibility of making video recordings at the patient's desired time and place greatly enhances privacy [51]. In a VDOT study conducted in the United States and Mexico, patients agreed that VDOT promotes autonomy and a sense of control over their health [19]. The ethical concerns related to digital technologies can vary widely, particularly in relation to collecting, securely storing, and accessing videos that contain personally identifiable information, such as patients' faces. These concerns may also have legal and sociocultural contexts that need to be considered [52]. A recent qualitative study focusing on digital health technologies in sub-Saharan Africa concluded that threats to scale-up include the lack of buy-in from both patients and providers, insufficient human resources and local capacity, inadequate governmental support, overly restrictive regulations, and a lack of focus on cybersecurity and data protection [53]. Further research is needed to evaluate the impact of VDOT on patient-centered outcomes, such as satisfaction, quality of life, user engagement with the technology, and retention to prevent dropout. Other important areas of research include the effect of VDOT on health system workflows and workload, as well as its costs and cost-effectiveness compared with usual care.

Conclusions

The enhanced VDOT was more effective in increasing adherence observation to treatment than UCDOT among patients with TB in Uganda. This evidence supports the potential of digital technologies to improve monitoring and support of treatment adherence in high TB burden settings with limited human resources. Further research is needed to evaluate which subgroups are most likely to benefit from this technology.

Acknowledgments

This study is funded by the United States National Institutes of Health (grants 1R21 TW011365 and 3R21 TW011365-02S1). The funders do not have any role in the study design; in the collection, management, analysis, and interpretation of data; in the writing of the report; or in the decision to submit the report for publication. The funders did not have any authority over the study activities. We acknowledge Drs. Christopher Whalen, Noah Kiwanuka, and Robert Kakaire for their scientific input during the implementation of the study. We acknowledge Dr. Richard Garfein at the University of California, San Diego, and Dr. Kelly Collins at SureAdhere Mobile Technology, Inc. for the technical support they provided in setting up the project. We thank the research assistants, Mitchell Geno, Daphne Kyaine, and Gloria Nassanga, who collected the data and mobilized the study participants for interviews at the Lubaga study site and other clinics in Kampala, Uganda. Lastly, we acknowledge Everwell Health Solutions for providing the VDOT mobile technology service, training the research team, and providing technical support to the project team.

Abstract

Background: Cataract is the world's leading cause of avoidable blindness. High-quality cataract surgery is a cost-effective procedure to restore vision. In low- and middle-income countries (LMIC), there are high rates of poor outcomes after surgery and inadequate follow-up, which makes it difficult to effectively monitor surgical outcomes. To address this issue, the Better Operative Outcomes Software Tool (BOOST Cataract app) assesses the final outcome on the first postoperative day and records the reasons for poor outcomes at 6 weeks postoperatively, offering specific advice to improve outcomes.

Objective: The aim of this study is to evaluate the real-world utility of the BOOST Cataract app for monitoring cataract surgical outcomes in Inhambane Province (Mozambique) and to analyze the data collected by the app during a surgical campaign conducted therein.

Methods: This prospective study of diagnostic accuracy included patients older than 50 years who underwent manual small-incision cataract surgery. The BOOST Cataract app was used to collect data on visual acuity (VA) on the first postoperative day and to assess surgical outcomes. The sensitivity and specificity (with their 95% CIs) and area under the curve of the BOOST Cataract app (index test) were calculated to identify suboptimal outcomes (moderate and poor) compared with outcomes 6 weeks after surgery (reference standard). The causes of poor outcomes after 6 weeks were recorded and evaluated using the app.

Results: A total of 141 patients who underwent surgery during a cataract campaign in Inhambane Province (Mozambique) between April 2022 and May 2022 were included in the study. The mean age was 70 (SD 10.2) years, and 48.2% (68/141) of the participants were women. Of the 141 patients, 8 (5.7%) did not complete the study. The BOOST Cataract app had a sensitivity of 94.44% and a specificity of 59% for detecting suboptimal outcomes. The area under the curve was 0.825. The campaign outcomes were as follows: good (VA ≥6/18) in 45.9% (61/133) of cases, moderate (VA <6/18 to ≥6/60) in 33.8% (45/133), and poor (VA<6/60) in 20.3% (27/133) of cases. The main cause of a poor outcome was surgical complication, while refractive error was the main cause of a moderate outcome.

Conclusions: The BOOST Cataract app is a valuable tool for assessing suboptimal cataract surgery outcomes without waiting for the completion of postoperative treatment in settings where postoperative follow-up is incomplete. In resource-limited eye care systems, the BOOST Cataract app provides an opportunity to assess outcomes and analyze results to develop specific strategies to improve quality at a local level.

cataract extraction; outcome assessment; health care; developing countries; visual acuity; software

Introduction

In 2020, cataracts remained the leading cause of avoidable blindness in people aged >50 years, followed by glaucoma and refractive error [1]. Although cataract surgery is a highly cost-effective procedure for restoring vision, only 60% of patients who undergo cataract surgery achieve visual acuity (VA) of 6/18 or better, whereas up to 18% fail to achieve a VA better than 6/60 [2,3]. Surgical outcomes are worse in low-income countries, with an estimated mean effective cataract surgical coverage of 13.9% in the African region [4].

In low- and middle-income countries (LMIC), the low rate of postoperative follow-up makes it difficult to obtain reliable surgical outcome data [5]. The first step toward improving surgical outcomes is to routinely monitor the extent and causes of poor outcomes [6]. In a prospective study conducted at Kikuyu Hospital in Kenya, prospective monitoring improved surgical outcomes [7].

The only known data on cataract surgery outcomes in Inhambane Province came from the Rapid Assessment of Avoidable Blindness (RAAB) study, which was conducted between October 2016 and November 2016. The RAAB study showed that cataract blindness and visual impairment were not controlled in the province, with only 29% of those with blindness (VA <3/60) and 20% of patients with severe visual impairment (VA <6/60) undergoing surgery. Furthermore, only 42.9% of the operated eyes had a good outcome (VA ≥6/18), and 37.5% had a poor outcome (VA <6/60) [8].

Efforts have been made to objectively evaluate surgical outcomes, particularly for residents [9]. Access to the internet in low-resource settings has prompted its use, and it has been suggested that tools such as the Better Operative Software Outcomes Tool (BOOST Cataract app) may facilitate data collection in countries with low postoperative follow-up rates and help improve surgical quality [2].

The BOOST Cataract app was launched in 2018 by a global consortium of leading eye health organizations (the Fred Hollows Foundation, Sightsavers, The International Agency for the Prevention of Blindness, ORBIS International, Aravind Eye Hospitals, and the International Council of Ophthalmology) to address the issues of surgical quality measurement and surgical data recording and to help improve cataract surgical outcomes in low-resource settings.

The BOOST Cataract app is a free and easy-to-use app that can be used for recording and analyzing surgical outcomes the day after surgery. The app does not collect personal patient data but assigns a number to each patient. There are 2 phases in the assessment process. In phase 1, postoperative uncorrected distance VA (BOOST VA) is recorded between 1 day and 3 days after surgery. The BOOST Cataract app estimates the final surgical outcome according to the World Health Organization (WHO) reference criteria, which defines a good outcome as VA ≥6/18 [10] (Table 1). The outcome estimation is based on the direct correlation between VA on postoperative day 1 and the final VA [5,11]. This overcomes the lack of postoperative follow-up, which makes outcome evaluation difficult.

Table 1. World Health Organization (WHO) cataract surgery outcome criteria according to postoperative visual acuity.

Snellen PVA[a]	Definition of distance visual impairment (ICD-11[b])	Standards for postoperative visual acuity according to WHO[c]
Good		
≥6/12	Not impaired	>80%[d]
<6/12 to ≥6/18	Mild visual impairment	>80%[d]
Suboptimal		
Moderate		
<6/18 to ≥6/60	Moderate visual impairment	<15%
Poor		
<6/60 to ≥3/60	Severe visual impairment	<5%[e]
<3/60	Blindness	<5%[e]

[a]PVA: presenting visual acuity.

[c]WHO: World Health Organization.

[d]Assigned to only one of the “Not impaired” or “Mild visual impairment” categories, not both at once.

[e]Assigned to only one of the “Severe visual impairment” or “Blindness” categories, not both at once.

Phase 2 consists of analyzing the possible causes of poor outcomes at 6 weeks postoperatively. For this purpose, the presenting visual acuity (PVA) and best-corrected distance visual acuity (BCVA) of 20 patients with poor outcomes at least

XSL•FO
RenderX

6 weeks after surgery are recorded, and the possible etiologies (selection, complication, and refractive error) are assessed. In very low-resource settings where refractive services are unavailable, VA obtained with pinhole (Pin VA) is accepted as an approximation of BCVA. Based on these data, the tool can then identify the main cause of poor outcomes and suggests specific interventions aimed at improvements [12]. The BOOST Cataract app has been used in several countries to monitor the quality of cataract surgery [13]. A study evaluating the app's effectiveness at predicting the final surgical outcome showed that the ability of the BOOST Cataract app to correctly categorize surgical outcome was dependent upon the presence of corneal edema on postoperative day 1. However, this study was retrospective and not based on an LMIC population [14].

This study aimed to evaluate the utility of the BOOST Cataract app (software version 1.1.2) in a surgical campaign conducted in Inhambane Province and to perform an in-depth analysis of the outcomes and causes of suboptimal results.

Methods

Participants and Settings

Consecutive patients presenting with cataracts, who were aged >50 years, and who attended the Provincial Hospital of Inhambane and the District Hospital of Zavala, Mozambique, between April 2022 and May 2022 were included. Patients with cataract were recruited using convenience sampling according to the hospital's inclusion protocol for cataract surgery: patients aged >50 years with VA ≤6/60 in 1 eye and NC5 or NC6 cataract. The exclusion criteria were the absence of a pupillary light reflex and retinal pathology demonstrated by fundoscopy (NC5 cataract) or ultrasound (NC6 cataract), corneal scars affecting the visual axis, and advanced glaucoma demonstrated by optic nerve examination when it was possible to obtain.

Ethics Approval

Informed written consent was obtained from all patients who underwent surgery. All data were anonymized. As the study was carried out in the setting of standard clinical practice, the patients did not receive any financial compensation. This study adhered to the tenets of the Declaration of Helsinki and was approved by the Institutional Bioethics Committee for Health of the Republic of Mozambique (CNBS; reference: 443/CNBS/23).

Preoperative Examinations

All patients underwent a complete ophthalmological examination, including PVA, slit-lamp examination, pupillary reflexes, Goldmann applanation tonometry, and fundus examination, if lens opacity allowed. The power of the implanted intraocular lens (IOL) was calculated using a keratometer (LGM OftalTech) and mode A ultrasound (Scan sw-1000; Suoer). Patients for whom keratometry or biometry could not be performed were assigned to the IOL of the contralateral eye, if possible, or a standard 21 D IOL, if not.

VA Assessment

PVA was assessed using Tumbling E charts for distance vision, with available correction. After correctly identifying the direction of more than one-half of the optotypes in the upper line, the patient moved to the next line then to the lower lines. The lowest line at which more than one-half of the optotypes were read was recorded as the patient's VA. The patient moved one-half the distance when the direction of any line could not be identified. If the patient was unable to identify the optotypes at that distance, the assessor's fingers were placed 3 meters, 2 meters, or 1 meter from the patient. If the patient was unable to see their fingers, a light source was placed to document light perception.

Surgery and Postoperative Treatment

All surgeries were performed under retrobulbar anesthesia by the same ophthalmologist with extensive experience in manual small-incision cataract surgery (MSICS). MSICS was performed using a superior scleral tunnel. A rigid PMMA biconvex posterior chamber IOL (S3550 Aurolens; Aurolab Inc) was implanted with capsular support. Eyes with zonulolysis or extensive capsular rupture were implanted with an A5520 anterior chamber lens (Aurolab Inc). At the end of surgery, all patients received perioperative prophylaxis with intracameral 0.1 mL cefazolin (2.5 mg/mL) or 0.1 mL vancomycin (0.1 mg/mL) if they were allergic to penicillin [15].

All patients followed the same postoperative treatment protocol at the hospital, consisting of tapering doses of MFLOX-DM (moxifloxacin 0.5% + dexamethasone sodium phosphate 0.1%; Aurolab Inc) for 4 weeks. Eyes with intraocular pressure higher than 25 mm Hg received acetazolamide (250 mg Diamox).

Assessment the Day After Surgery and Phase 1 of BOOST Cataract App

In phase 1, patients were examined the day after surgery, and VA was measured in the operated eye by an independent observer (BOOST VA). The BOOST VA was entered into the app, and the surgical outcomes were calculated according to the WHO criteria (Table 1).

Slit-lamp examination was also performed to detect corneal edema. Significant corneal edema was defined as >10 Descemet folds or stromal corneal edema affecting the visual axis.

Assessment After 6 Weeks and Phase 2 of the BOOST Cataract App

All patients were instructed to return for follow-up 6 weeks after surgery and received a telephone call 2 days before the visit as a reminder to ensure complete follow-up after surgery.

All patients who completed follow-up at 6 weeks had their uncorrected VA (PVA), BCVA, and PinVA (pinhole visual acuity) assessed by an optometrist masked to the BOOST VA. A biomicroscopic examination and autorefraction analysis were performed (LGM OftalTech).

The VAs obtained at 6 weeks were classified according to the WHO criteria (Table 1): without optical correction (PVA outcome) and with pinhole (PinVA outcome).

In phase 2 of the BOOST Cataract app, the cause of poor outcomes (VA <6/60) was identified and recorded as selection, complications, or refractive error. The same was done for patients with a moderate outcome (VA <6/18 to ≥6/60).

XSL•FO
RenderX

Statistical Analyses

Statistical analyses of the data were performed using SPSS Statistics v21 (IBM Corp). Absolute and relative frequencies were obtained for qualitative variables. For the quantitative variables, depending on whether the normal distribution criteria were met, the mean and SD, median, IQR, and minimum and maximum values were considered.

Regarding the different VAs collected, an equivalent in decimal notation was assigned to the VA that could not be expressed numerically (light perception, counting fingers) [16,17]. The decimal values were converted to a LogMAR (minimum angle-of-resolution) scale for subsequent statistical analysis.

To analyze the ability of the BOOST Cataract app to predict the final surgical outcome, the results obtained on postoperative day 1 using the app (BOOST outcome) were compared with those obtained 6 weeks postoperatively (PVA outcome). For this analysis, only cases with complete follow-up were included. Both variables were grouped into 2 categories (good and moderate/poor results). Using the 6-week results as the reference standard, the sensitivity, specificity, positive predictive value, and negative predictive value of the BOOST Cataract app as a tool for predicting a negative result (moderate or poor) were estimated. All estimates are presented with the corresponding 95% CIs. A receiver operating characteristic curve was generated, and the area under the curve was calculated.

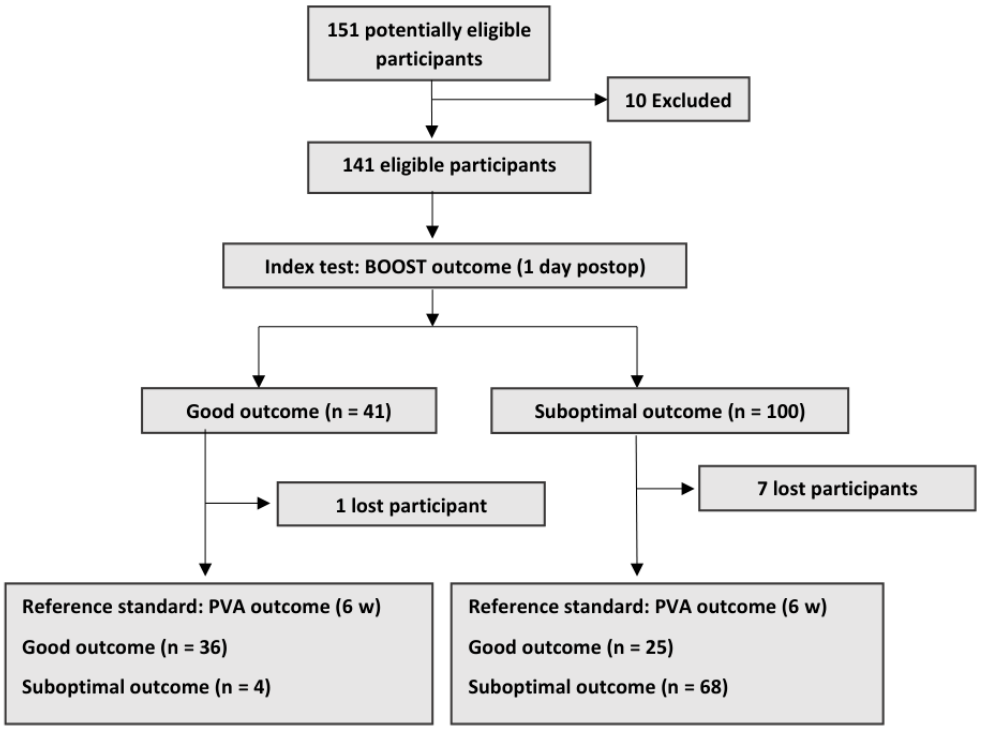
The presence of corneal edema on day 1 was tested as an independent predictor of moderate or poor outcomes at day 1 and at 6 weeks after surgery using a logistic regression model.

Results

Characteristics of the Campaign

We recruited 151 patients, and 10 were excluded because they did not meet the inclusion criteria for surgery. A study flowchart is presented in Figure 1.

Figure 1. Flow diagram of participants. BOOST: Better Operative Software Outcomes Tool; PVA: presenting visual acuity.



The study included 141 eyes of 141 patients who underwent surgery at the study site: 68 patients (68/141, 48%) were women, and 62 patients (62/141, 44%) were blind (VA <3/60 in the better eye; Table 2). This was the first eye operated on in 108 of 141 (76.6%) patients. In addition, 14 of 141 (9.7%) patients had a history of glaucoma, and 3 of 141 (2.1%) eyes had phacodonesis on biomicroscopic examination. In 123 of the 141 (87.2%) operated eyes, it was not possible to perform a fundus examination because of cataract density. Biometry could not be performed in 22 patients because of corneal irregularities or lack of fixation.

[a]<3/60 in the better eye.

[b]≥3/60 to <6/60 in the better eye.

[c]<6/18 to ≥6/60 in the better eye.

[d]<6/12 to ≥6/18.in the better eye.

[e]≥6/12 in the better eye.

Outcomes of the Campaign: Phase 1 of BOOST Cataract App

Of the 14 intraoperative complications observed, 11 (7.8% of the 141 surgeries) were capsular ruptures. In addition, 10 (7.1%) anterior chamber IOL were implanted, and 1 case of aphakia was reported.

The outcomes of the BOOST Cataract app (BOOST outcomes) are presented in Table 3. Overall, 29% (41/141) of the operated eyes showed good outcomes. Of the 141 eyes, 74 (52.2%) had corneal edema on postoperative day 1. Corneal edema was associated with suboptimal (moderate and poor) BOOST outcomes (ρ<0.001).

The surgical outcome on day 1 (BOOST outcome) was worse than at 6 weeks. Of the 141 patients, 8 (5.7%) did not attend the 6-week postoperative visit. Of these, 6 underwent uneventful surgery. Of the patients who did not complete the follow-up period, 50% (4/8) had poor BOOST outcomes.

The final outcomes (PVA outcome) were good for 45.9% (61/133) of the eyes and remained poor for 20% (27/133) of the eyes. The PinVA outcomes were good for 73% (94/128) of the eyes and poor for 13% (17/128) of the eyes (Table 3).

Eyes that had a suboptimal outcome with the BOOST Cataract app were 21.44 (95% CI 6.35-72.35) times more likely to have a moderate or poor outcome at 6 weeks postoperatively compared with the eyes with a good outcome (ρ<0.001). Corneal edema was associated with the BOOST outcome (ρ<0.001) but not with the final PVA outcome (ρ=0.58).

Diagnostic Accuracy of the BOOST Cataract App

The sensitivity of the BOOST Cataract app for identifying suboptimal outcomes was 94%. The specificity was 59%. The area under the curve was 0.825 (Table 4).

Table 4. Diagnostic accuracy of the Better Operative Outcomes Software Tool (BOOST Cataract app).

Performance measures	Results, % (95% CI)
Sensitivity	94.44 (86.38-98.47)
Specificity	59.02 (45.68-71.45)
Positive predictive value	73.12 (66.69-78.70)
Negative predictive value	90.00 (77.24-95.98)

Reasons for Suboptimal Outcomes: Phase 2 of the BOOST Cataract App

Surgical complications (capsular rupture and zonulolysis with vitreous loss) were the main causes of poor final outcomes, while refractive error was the main cause of a moderate outcome (Table 5).

[b]VA <6/18 to ≥6/60.

Discussion

Principal Findings

The BOOST Cataract app was able to detect final suboptimal outcomes (VA <6/18) on the day after surgery with a sensitivity of 94%. Due to this sensitivity, it was possible, with reasonable confidence, to identify eyes that were moderately visually impaired or worse at the end of postoperative treatment.

Resource-poor LMIC are often characterized by a lack of equipment, high staff turnover, and frequent surgical campaigns where many surgeries are performed in short periods. In this context, the routine use of the BOOST Cataract app ensures that any decrease in quality is detected early in phase 1.

The specificity of the campaign in this study was only 59%. This low specificity did not provide sufficient certainty estimating the extent of good outcomes. Therefore, the BOOST Cataract app did not determine the center's local effective cataract surgical coverage. This is because it underestimated good outcomes in phase 1 by not considering transient corneal edema that occurs in the immediate postoperative period and usually resolves without sequelae.

At 6 weeks postoperatively, 45.9% (61/133) of the operated eyes had good outcomes, and just over 20% (27/133, 20.3%) did not achieve vision better than 6/60; with pinhole, 73.4% (94/128) had a good outcome, and 13.3% (17/128) had a poor outcome. These results do not meet the quality standards recommended by the WHO (Table 1).

In the 2016 RAAB study conducted in the province, 42.9% of patients aged >50 years who underwent cataract surgery had good outcomes, and as many as 37.5% had poor outcomes; among patients assessed using PinVA, only 55.4% had good outcomes, and 34.8% had poor outcomes [8].

The 2016 RAAB study collected information on surgeries performed before 2016 when the sutureless extracapsular technique was still being introduced. MSICS is now fully established, and surgical outcomes seem to have improved. However, the RAAB study showed outcomes over time, whereas our hospital-based study only observed outcomes at 6 weeks and may not have captured long-term surgical outcomes and complications. A new RAAB study in the province is required to demonstrate the improvement in surgical outcomes.

In phase 2 of this study, surgical complications were the main cause of poor outcomes (12/27, 44%). In Inhambane Province, as in other provinces of Mozambique, cataract surgery is performed in patients with a preoperative VA ≤6/60 [18]. It is common for cataracts to present at very advanced stages with a higher rate of complications (zonulolysis and capsular rupture), despite the use of MSICS, which has been shown to be a safe technique in LMIC [19-21].

These outcomes are comparable to those reported in other areas of the country. The RAAB study performed in Sofala Province reported good outcomes in 37.8% of the patients, which improved to 45.9% when considering PinVA [18]. The main causes of poor outcomes (VA <6/60) were selection errors (55.2%) and surgical complications (34.5%). The 2018 RAAB study conducted in the province of Nampula recorded 58.2% good outcomes and 22.4% poor outcomes in terms of PVA. The main causes of outcomes worse than 6/18 vision were a lack of optical correction (34%) and surgical complications (29%). The PinVA outcomes improved to 72.4% (good) and 16.3% (poor) [22].

The BOOST Cataract app does not collect data on moderate outcomes or their causes in phase 2. This is despite these outcomes representing a postoperative VA of <6/18 to ≥6/60, equating to moderate visual impairment (Table 1).

In this study, 33.8% (45/133) of the patients had a moderate outcome, and the main cause was refractive error. The magnitude of this finding seems to indicate that, in Inhambane Province, as in other LMIC, awareness of the causes of moderate outcomes is necessary to improve them [18,23,24]. Visual impairment due to residual refractive error may be reduced if stockpiles of IOLs in a range of powers and ocular biometry are accessible [25]. In our study, the mean postoperative spherical equivalent was higher than that in other studies [26,27], even though biometry was performed in 84.4% (119/141) of the eyes and 100% of the patients had undergone IOL implantation in the range of power accorded by biometry. Cooperation of patients with poor fixation of the operated eye may lead to errors when performing biometry.

XSL•FO
RenderX

The mean postoperative astigmatism was also higher than that reported in other studies [28]. In fact, 75.2% (85/113) of the eyes had astigmatism greater than 3D against the rule. The use of a superior scleral tunnel instead of a temporal tunnel may have produced astigmatism against the rule with a worse final VA outcome [29]. Additionally, the surgical material is often in poor condition due to excessive resterilization, which may lead to more superficial sclerocorneal incisions than desired, increasing induced surgical astigmatism risk [30].

Strengths and Limitations

Although the sensitivity and specificity obtained allow reaching relevant conclusions on the real-world utility of the app at the study site, due to the small sample size, it is not possible to generalize the diagnostic accuracy of the BOOST Cataract app in other low-resource settings. In settings with a lower prevalence of suboptimal outcomes, the negative predictive value might be lower. Therefore, the app, if confirmed in larger studies, has to be restricted to settings with poor-resource health systems.

Data on surgical outcomes in Inhambane are scarce and only available from the RAAB study conducted 8 years ago. This was the first study to analyze the causes of poor and moderate outcomes in such depth.

Surgical quality criteria have recently been revised, and VA ≥6/12, representing mild visual impairment, has been adopted as the threshold for a good outcome [2]. Due to the introduction of the MSICS technique and widespread use of biometry, surgical outcomes have improved. This new threshold places higher demands on the expected outcomes and implies an improvement in the visual expectations of patients undergoing surgery in LMIC.

To analyze the diagnostic accuracy of the BOOST Cataract app, moderate and poor outcomes were grouped into the suboptimal outcome category. From a public health perspective, it is of interest to know the number of eyes that do not achieve a VA >6/60 after surgery, which is the level of severe visual impairment that has the greatest impact on patient quality of life because it affects their ability to walk independently. Grouping moderate and poor outcomes into suboptimal outcomes encourages improvements in both outcome categories without focusing only on poor outcomes.

Conclusions

RAAB studies provide reliable data for planning eye health services and evaluating programs. These are the primary sources of information for measuring surgical outcomes at the population level in LMIC [31]. However, in settings with resource-poor eye health systems, the BOOST Cataract app offers the opportunity to assess outcomes at the local level; each center needs to analyze its surgical outcomes and develop specific strategies to improve quality.

Acknowledgments

This study was conducted as part of the Doctoral Program in Surgery and Morphological Science at the Autonomous University of Barcelona and as part of the Eyes of the World Foundation's project in Mozambique, aimed at strengthening eye health services.

This work received funding from the Universitat Oberta de Catalunya (UOC) e-Health Center Project 2022.

Data Availability

The data sets generated or analyzed during this study are available from the corresponding author on reasonable request. All relevant data are included in this article.

Authors' Contributions

ML conceptualized the study, provided resources, curated the data, contributed to the methodology, conducted the formal analysis, prepared the original draft, and supervised the research. VC assisted with data curation and resource provision. DM contributed to conceptualization and methodology. MMB contributed to conceptualization, methodology, and formal analysis. CLM conducted the formal analysis and supervised the research. All authors participated in reviewing and editing the final manuscript. No generative artificial intelligence was used in any portion of the manuscript.

Abstract

Background: In Lebanon, disadvantaged pregnant women show poor maternal outcomes due to limited access to antenatal care (ANC) and a strained health care system, compounded by ongoing conflicts and a significant refugee population. Despite substantial efforts to improve maternal health, the provision of maternal health services in primary health care centers (PHCs) still faces significant challenges. Mobile health (mHealth) interventions, particularly those using artificial intelligence (AI) and gamification, are proving effective in addressing gaps in maternal health services by offering scalable and accessible care.

Objective: This study aimed to evaluate the effects of an AI-based gamified intervention, Gamification and Artificial Intelligence and mHealth Network for Maternal Health Improvement (GAIN MHI), on maternal health outcomes and uptake of ANC services among disadvantaged populations in Lebanon.

Methods: The study was a community interventional trial with historical controls, conducted across 19 randomly allocated PHCs in 5 Lebanese governorates. Participants included pregnant women in their first trimester visiting PHCs. The intervention used mHealth tools, including educational mobile-based messages, appointment reminders, and the GAIN MHI app, which provided AI-driven and gamified learning for health care providers (HCPs). Data collected covered demographics, medical history, and maternal and neonatal health outcomes. Key outcome measures included uptake of health care services (eg, ANC visits, supplement intake, ultrasound completion, lab tests) and maternal and neonatal outcomes (eg, term delivery, normal delivery, abortion rate, neonatal morbidity, maternal complications).

Results: This study included 3989 participants, divided between a control group (n=1993, 50%) and an intervention group (n=1996, 50%). Regression models adjusting for demographics, health, and obstetric characteristics showed significantly higher odds in the intervention group for completing 4 or more ANC visits (odds ratio [OR] 1.569, 95% CI 1.329-1.852, *P*<.05), completing lab tests (OR 1.821, 95% CI 1.514-2.191, *P*<.05), 2 or more ultrasound screenings (OR 7.984, 95% CI 6.687-9.523, *P*<.05), urine analysis (OR 4.399, 95% CI 3.631-5.330, *P*<.05), and supplement intake (OR 3.508, 95% CI 2.982-4.128, *P*<.05). Regarding outcomes, the intervention group had 29.5% increased odds of a term delivery (OR 1.295, 95% CI 1.095-1.532, *P*=.002) and 58% increased odds of avoiding neonatal morbidity (OR 1.580, 95% CI 1.185-2.108, *P*=.002). However, both groups showed decreased odds of normal delivery (intervention: OR 0.774, 95% CI 0.657-0.911; control: OR 0.823, 95% CI 0.701-0.964) and

XSL•FO
RenderX

increased odds of maternal complications (intervention: OR 0.535, 95% CI 0.449-0.637; control: OR 0.586, 95% CI 0.474-0.723; $P<.05$).

Conclusions: The GAIN MHI intervention effectively improves uptake of ANC and maternal and neonatal outcomes. Our findings highlight the potential of mHealth interventions to enhance health care delivery. To sustain these improvements, future research should focus on integrating mHealth with other interventions that address socioeconomic and contextual factors. This approach will further optimize maternal and neonatal health outcomes among disadvantaged populations.

Introduction

Overview of Maternal Health in Lebanon

Women and girls, especially in conflict-affected and displaced communities, are highly vulnerable to poor sexual, reproductive, and maternal health (SRMH) [1-4]. Disadvantaged pregnant women in Lebanon encounter various maternal health complications and adverse pregnancy outcomes, including higher-than-usual cesarean section (C-section) deliveries due to pregnancy complications, preterm births, and hemorrhages, among others [5-7]. One key challenge is the limited access to antenatal care (ANC) services [8-10]. Recent investigations have underscored a remarkable decline in the use of ANC services among disadvantaged pregnant women in Lebanon, falling below the recommended threshold of 4 visits [1,6,11,12]. Barriers to accessing ANC include transportation issues, distance to primary health care centers (PHCs), shortage of skilled health care providers (HCPs), lack of awareness about available services, and the financial burden associated with seeking care [6,11,13-15]. Addressing these challenges and ensuring equitable access to maternal health care services are essential steps to improving pregnancy outcomes and reducing maternal mortality rates [16,17].

The Refugee Crisis in the Context of Lebanon

Addressing the identified barriers to accessing ANC services becomes particularly challenging in a fragile context, such as Lebanon, the country hosting the highest number of refugees worldwide. Around 1.5 million Syrian refugees, 489,292 Palestinian refugees, and 11,645 refugees from various other nationalities reside in Lebanon [18-20]. The continuous influx of refugees has strained the Lebanese health care system, resulting in medication shortages and high health care costs [21-25]. The country also faces a significant migration of health care professionals due to the protracted economic crisis it has witnessed over the past few years [22,26]. As a result, accessing basic health and social services has become particularly challenging for host communities, further exacerbating their vulnerability [27]. Among refugees, women of childbearing age face particular health care challenges, highlighting the importance of addressing women's health issues in Lebanon [28,29].

Primary Health Care Service Use Among Pregnant Women in Lebanon

To access essential medical services in Lebanon, disadvantaged Lebanese populations and Syrian refugees often resort to a network of PHCs, affiliated with the Ministry of Public Health (MOPH) [30,31]. The MOPH has established around 200 PHCs, managed by nongovernmental organizations (NGOs), municipalities, and governmental institutions and distributed across the country [32,33]. These PHCs provide affordable health care services for over 1 million disadvantaged Lebanese populations and Syrian refugees annually, with Lebanese patients benefiting from reduced out-of-pocket fees and Syrian refugees being supported by subsidies from the United Nations High Commissioner for Refugees (UNHCR) [31,34]. Alternatively, Palestinian refugees access health care services via a channel of 27 PHCs administered by the United Nations Relief and Works Agency for Palestine Refugees in the Near East (UNRWA) [30]. Both the MOPH and the UNRWA provide services related to reproductive health, including family planning, ANC, and postnatal care (PNC) services [35-37]. Recognizing the strains on Lebanon's health care system due to the influx of refugees and in alignment with its commitment to ensure universal health coverage, the MOPH collaborates with partners, such as the World Bank, the United Nations Populations Funds (UNFPA), and the European Union (EU), to implement projects aimed at strengthening primary health care services, including reproductive health care [23,31,32,38-41]. These initiatives provide wellness and sexual reproductive health (SRH) packages covering services such as screening, consultation, prescription medications, ANC, and PNC [39,40,42]. Similarly, to sustain its health care initiatives, the UNRWA relies on funding from member states of the United Nations, the EU, and various other states. Yet, despite the availability of these subsidized maternal health care services, compliance with standards continues to be a serious concern among disadvantaged populations in Lebanon [1]. To address the suboptimal maternal health services, mobile health (mHealth) interventions emerge as a potential solution to improve access to essential health care services [43].

Role of mHealth Interventions in Enhancing Maternal Health Outcomes

The proliferated usage of mobile devices has catalyzed the widespread adoption of mHealth initiatives, revolutionizing the landscape of health care delivery and empowering individuals

XSL•FO
RenderX

to actively engage in enhancing their well-being through accessible and innovative digital platforms [43-47]. mHealth emerges as a critical component for the worldwide effort to decrease maternal mortality and improve maternal health outcomes, mainly within disadvantaged populations [48,49]. By leveraging mobile technology, mHealth interventions offer scalable solutions to address maternal health challenges, providing vital resources, education, and support to pregnant women and new mothers, in remote or underserved areas [43]. mHealth interventions, such as Mobile Technology for Community Health (MOTECH), MOM Connect, and Mobile Alliance for Maternal Action (MAMA), highlight the effectiveness of strategies such as sending voice note messages and appointment reminders to expectant mothers and their spouses [50-52]. These interventions not only facilitate timely access to essential maternal health services but also promote greater engagement and support throughout the prenatal and postnatal journey. The integration of mHealth interventions extends beyond empowering the pregnant women and their spouses, by targeting their HCPs as well. Initiatives such as the Safe Delivery Application (SDA) show that such interventions have positively impacted HCPs' knowledge and skills, resulting in tangible improvements in maternal and neonatal outcomes.

As mHealth continues to advance, artificial intelligence (AI) innovations are being increasingly integrated into the health care sector to enhance the quality of care and address various health areas [53,54]. AI has been used in diagnostic support, as well as to enhance access to virtual health services in remote areas and address knowledge and skill gaps [55]. Building on these advancements, AI has shown significant promise in maternal health by predicting complications, such as preeclampsia, postpartum depression, gestational diabetes and anemia, stillbirths, and preterm deliveries [56]. Additionally, AI shortens the training time required for health care professionals in assessing preterm deliveries and improves access to maternal health care [57,58].

Moreover, the concept of gamification has been incorporated into mobile platforms to train HCPs and inform individuals about health and illness management [59-62]. For instance, the Maternal and Newborn Technology for Resilience in Rural Areas (MANTRA) app applies gamification to increase awareness regarding maternal and child health risk factors [63]. Users expressed satisfaction with the gamification approach, which led to improved maternal and child health knowledge and more informed decision-making [63].

These findings underscore the profound efficacy of mHealth interventions in maternal health outcomes and the accessibility of maternal health services [64,65].

mHealth Interventions for Maternal Health in Lebanon

In Lebanon, mHealth technologies have been incorporated to improve primary health care services for disadvantaged Lebanese and refugee populations [64,66]. These initiatives focus on using mHealth tools to manage noncommunicable diseases (NCDs) through interventions such as educational SMS messages and appointment reminders [67,68]. Other studies in Lebanon have investigated mHealth for weight management and the uptake of routine mammography [69,70]. In the realm of maternal health, the UNRWA electronic mother and child health (e-MCH) app represents a notable intervention. It integrates a comprehensive database on maternal and infant care and provides appointment reminders, thereby playing a critical role in ensuring the continuity of essential health care services [71].

Although certain countries in the Middle East and North Africa (MENA) region have effectively used mHealth solutions to enhance maternal health literacy and ANC visits, the focus on maternal health in Lebanon remains limited [72]. There is a scarcity of AI-driven solutions or gamified elements, highlighting a critical gap in leveraging technology to improve maternal health outcomes [73].

Study Aim

This study aimed to assess the effects of an AI-based gamified intervention, Gamification and Artificial Intelligence and mHealth Network for Maternal Health Improvement (GAIN MHI), on maternal health outcomes and uptake of ANC services among disadvantaged populations in Lebanon.

Methods

Study Design

This study was a community interventional trial with historical controls at distinct PHCs. Pre- and postintervention data were collected with the help of the assigned research assistant at each center. Data collected included demographics, medical and obstetric history, and maternal and neonatal health outcomes, including neonatal morbidities and maternal complications. The study comprised 3 distinct phases: preintervention data collection, intervention, and subsequent postintervention data collection. The preintervention phase spanned from July to December 2021. The intervention phase took place from September 2021 to December 2022. Finally, the postintervention phase extended from March to June 2023.

Center Selection

In total, 20 PHCs across 5 governorates in Lebanon—Beirut, Bekaa, North Lebanon, Mount Lebanon, and South Lebanon—were selected for this study. These centers serve disadvantaged Lebanese populations and refugees. Due to logistical constraints, 1 PHC was excluded, resulting in 19 (95%) centers. Of these, 10 (53%) were designated as control centers and 9 (47%) as intervention centers. Among the selected PHCs, 9 (47%; both control and intervention) are affiliated with the MOPH and serve Syrian refugees and disadvantaged Lebanese populations. The remaining 10 (53%) PHCs operate under the UNRWA and serve Palestinian refugees in Lebanon.

Study Population

Our target population in both pre- and postintervention phases consisted of pregnant women who presented at the selected PHCs during their first trimester and continued visiting the health centers for at least a year. All age groups were included. In the preintervention phase, pregnant women attended 1 of the PHCs for ANC during their first trimester between August 2018 and August 2020 and continued visiting the center until their delivery or termination of the pregnancy. However, in the

XSL•FO
RenderX

postintervention phase, pregnant women were already enrolled in the intervention and visited the PHCs during the period of the intervention. Controls were collected using the historical medical records of the patients at both timepoints.

The GAIN MHI Intervention

The GAIN MHI intervention (Figure 1) consisted of 2 different modalities: mobile-based messages (text and voice) and a mobile app (GAIN MHI app) aimed at enhancing maternal health outcomes (Figure 2).

Figure 1. Visual representation of the different components of the GAIN MHI intervention. ANC: antenatal care; GAIN MHI: Gamification, Artificial Intelligence and mHealth Network for Maternal Health Improvement; MOPH: Ministry of Public Health; PHC: primary health care center; UNRWA: United Nations Relief and Works Agency for Palestine Refugees in the Near East.

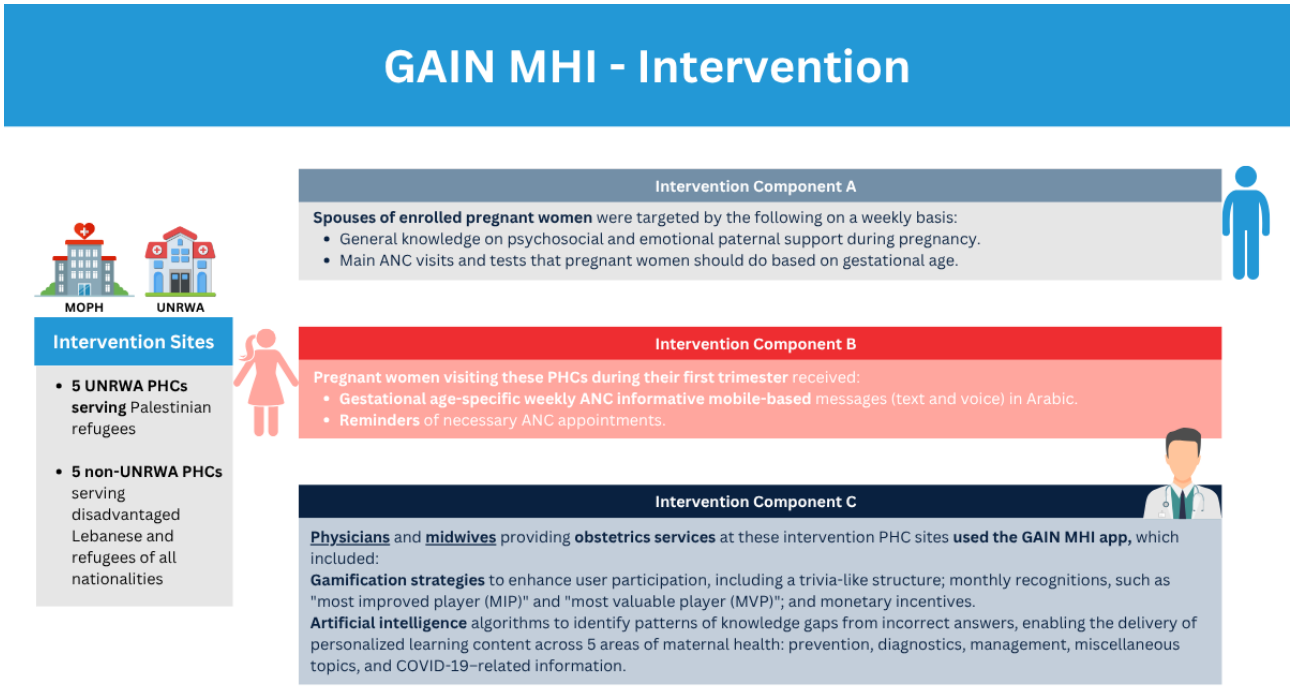

Figure 2. GAIN MHI theory of change. ANC: antenatal care; GAIN MHI: Gamification, Artificial Intelligence and mHealth Network for Maternal Health Improvement; HCP: health care provider; mHealth: mobile health; MOPH: Ministry of Public Health; OBGYN: obstetricians and gynecologists; UNRWA: United Nations Relief and Works Agency for Palestine Refugees in the Near East.

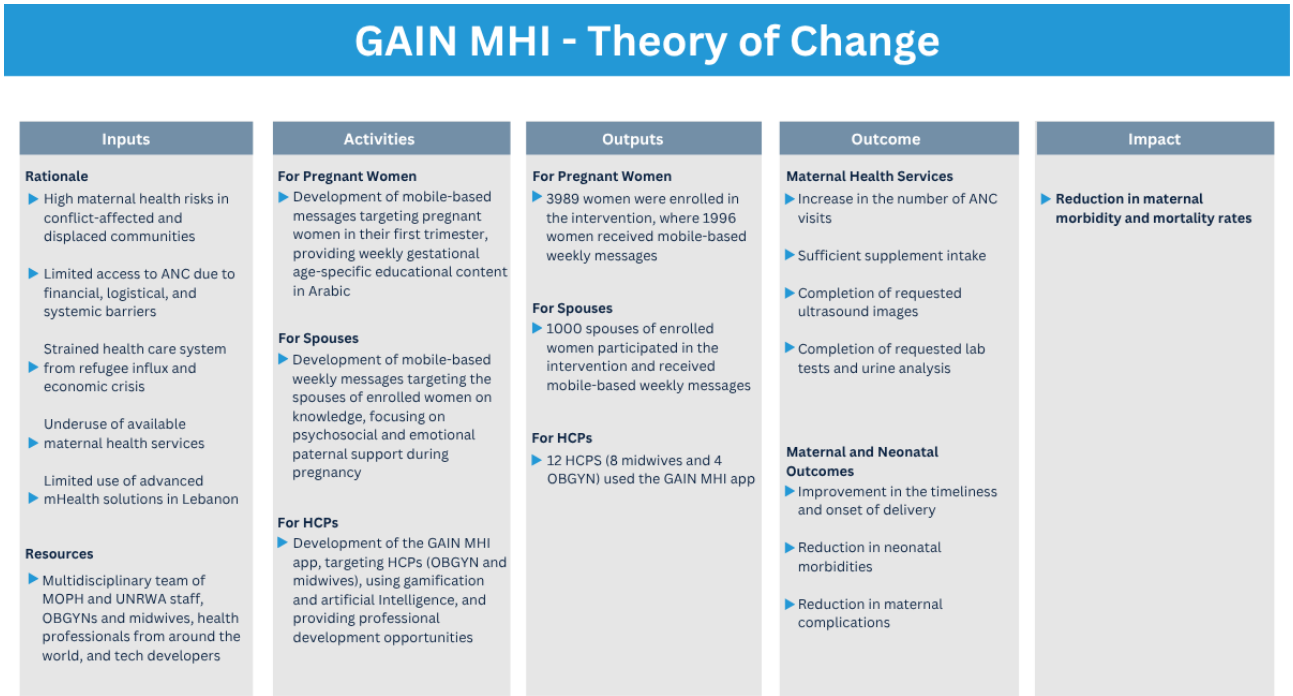

XSL•FO
RenderX

The mobile-based messages targeted pregnant women in their first trimester, including disadvantaged Lebanese populations and Syrian and Palestinian refugees, providing weekly gestational age-specific educational content in Arabic. The content covered pregnancy education, nutritional recommendations and supplementation, pregnancy danger signs, and postpartum care for 6 months after delivery, encouraging postpartum visits, breastfeeding, contraception, maternal mental health, and infant vaccinations. Reminder messages were also sent for upcoming ANC visits, vaccinations, tests, and medical examinations. Additionally, weekly messages were sent to the spouses of enrolled women on knowledge, focusing on psychosocial and emotional paternal support during pregnancy.

Although the focus was primarily on supporting pregnant women and their spouses, targeting HCPs was crucial. HCPs face various challenges, such as insufficient continuing education programs and career advancement, which hinder their work, notably in Lebanon [74,75]. To address these gaps, the GAIN MHI app, developed by the Global Health Institute at the American University of Beirut (AUB GHI), integrated gamification and AI concepts for the professional development of HCPs, particularly obstetricians and gynecologists (OBGYN) and midwives, working at the selected PHCs. This app features game principles such as a trivia-like concept, monthly recognition (most improved player [MIP] and most valuable player [MVP]), and monetary incentives to enhance learning engagement. These elements foster a sense of competition, motivation, and continuous improvement among HCPs. Additionally, the AI algorithms used in the app identify knowledge gaps based on the HCPs' incorrect answers, tailoring subsequent questions to individualize learning across 5 categories related to maternal health: prevention, diagnostic, management, miscellaneous, and COVID-19–related questions. For this purpose, a database of information on prenatal care was created. Topic modeling was used on this database to categorize the different topics of the stored content. Likewise, topic modeling was applied to the question bank, enabling the identification of topics linked to the incorrectly answered questions. Relevant information related to the identified topics was then retrieved and provided to the user. By leveraging AI, the GAINMHI app transforms traditional professional development into individualized efficient processes, minimizing the burden of standardized training programs that may not account for individual variability. In addition to this personalized learning approach, a randomized spin wheel is used for category selection, with each spin providing a question followed by explanations after the user answered. The app also includes a Knowledge Resource Center (KRC), and it communicates with users via automated WhatsApp messages, providing feedback on scores, answers, remaining attempts, monthly performance, and rewards. Available in both English and Arabic, the GAIN MHI app represents an innovative approach to advancing HCP education and maternal care.

Although the professional development of HCPs was an integral part of the intervention, it was not the primary focus of this research and is discussed in more detail in a separate paper.

Data Collection

In both pre- and postintervention phases, secondary data were collected from the medical charts of pregnant women who presented at the selected PHCs during their first trimester and continued visiting the centers for at least a year. In case a woman got pregnant more than once during the selected study period, her latest pregnancy charts were collected if they met the inclusion criteria of the project, while data on previous pregnancies were excluded. The data extracted from the medical charts of eligible pregnant women covered the following aspects: demographics, medical and surgical history, pregnancy history (supplements and ANC vaccinations taken, the first lab tests and ultrasound scans undergone, and any maternal complications encountered), neonatal complications, and breastfeeding history. Primary data on the knowledge, attitude, and practices (KAP) of women were collected before the intervention through quantitative surveys. The results of the KAP surveys will be discussed in a different paper. Primary data were also collected from pregnant women and their spouses participating in the intervention concerning their satisfaction with the mobile-based messages they were receiving. These data were collected through quantitative surveys at the end of the intervention; the results of these surveys are discussed in another paper. Satisfaction of HCPs with the GAIN MHI app was studied and captured through mixed methods surveys administered at the end of the intervention; the results of these surveys are discussed in a separate paper.

Ethical Considerations

Ethical approval was obtained from the Institutional Review Board (IRB) of the American University of Beirut (protocol number SBS-2020-0317) and the respective Ethical Committees at the MOPH and the UNRWA. Informed consent was obtained from all individuals participating in the intervention. Participants were informed of their right to opt out of the intervention at any point in time. The IRB approval covers secondary analysis without additional consent. All data were anonymized and deidentified. No compensation was received by participants.

Study Parameters

Study parameters were extracted and recorded for all pregnant women in the pre- and postintervention phases in all the centers. Table 1 shows the set of indicators that were selected to monitor the effectiveness of the intervention, along with their definitions. The selected parameters were categorized into 2 domains: uptake to health care and maternal and neonatal outcomes. Uptake of health care services included completing more than 4 ANC visits, having at least 2 ultrasound screenings taken, undergoing the available blood tests at the PHCs, undergoing the urine analysis test, and taking supplements during pregnancy. Onset of delivery on term, normal delivery, reduction in abortion, and reduction in any neonatal morbidity and any maternal complication were indicators constituting the domain of maternal and neonatal outcomes.

XSL•FO
RenderX

Table 1. Selected indicators to monitor the effectiveness of the interventions on uptake to health care and maternal and neonatal outcomes.

Domain and parameters	Definition
Uptake of health care services	
ANC[a] visits	Percentage of pregnant women who completed 4 or more ANC visits based on the World Health Organization recommendations
Supplement intake	Percentage of pregnant women taking the required vitamins that a women should take, including folic acid, iron, calcium, and magnesium
Ultrasound screenings	Percentage of pregnant women who underwent 2 or more ultrasound screenings during their pregnancy period
Blood tests	Percentage of pregnant women who underwent the available blood tests at their PHCs[b], including fasting blood sugar (FBS), blood group (+/–Rh), and the complete blood count (CBC)
Urine analysis	Percentage of pregnant women who underwent the urine analysis test
Maternal and neonatal outcomes	
Onset of delivery	Percentage of pregnant women who had a term delivery, delivering their latest child after week 37
Method of delivery	Percentage of pregnant women who had a normal delivery
Abortion	Percentage of women who had an abortion in their latest pregnancy before week 22
Neonatal morbidities	Percentage of pregnant women who faced any neonatal complications, including neonatal intensive care unit (NICU) admission, preterm delivery, Iatrogenic preterm birth injury, low birthweight, and neonatal early death
Maternal complications	Percentage of pregnant women who had any maternal complications, including gestational hypertension, gestational diabetes, perinatal depression, preterm labor, stillbirth, abortion, postpartum infection, postpartum hemorrhage, and postpartum depression

[a]ANC: antenatal care.

[b]PHC: primary health care center.

Statistical Analysis

Pregnant woman with a nationality other than Lebanese, Syrian, or Palestinian were excluded from the analysis. Sample baseline characteristics were calculated for the intervention and control arms using count and percentages or means (SDs). Chi-square (χ^2) and independent sample *t* tests were conducted to check for all possible differences in the baseline characteristics between the control and intervention arms. Given the fact that all the indicators are categorical, bivariate analysis was performed using the Pearson chi-square (χ^2) test to test the significant difference pre- and postintervention. To evaluate the impact of the intervention, separate logistic regressions were generated for each of the study indicators over the study period in each arm, while controlling for all the possible baseline differences between the control and intervention arms as age, nationality, history of chronic diseases, preterm delivery, abortion, C-section, gravida, and parity. Analysis was carried out at a .05 significance level using Stata SE software.

Results

Participants' Demographic Characteristics

Table 2 presents the baseline demographic and health characteristics of the participants in the control and intervention groups. The number of participants was almost equal between the control (n=1993, 50%) and the intervention (n=1996, 50%) group. At baseline, more than half of the sample was aged between 18 and 29 years in both intervention (801/1996, 54.3%) and control (806/1993, 53%) groups. The majority of the participants were Palestinians, constituting 71.3%(n=1423) of those in the intervention group and 63.5% (n=1267) of those in the control group. The rest of the participants were either Lebanese or Syrians. A higher number of patients in the intervention group (n=160, 8.1%) had a chronic disease. Regarding obstetric history, 6% (n=121) of participants in the intervention group had had a previous preterm delivery, 30.3%(n=605) had had a previous abortion, and 33% (n=664) had had a previous C-section delivery. In contrast, 4.3% (n=85) of participants in the control group had had a preterm delivery, 28.9% (n=575) had had an abortion, and 26.5% (n=529) had had a C-section previously. The mean gravida for the intervention and control groups was 2.98 (SD 2.02) and 3.12 (SD 1.86), respectively. There was a significant difference between the intervention and control groups in all the characteristics except for age.

Indicators Assessing Uptake of Health Care Services

Results of the bivariate analysis of the selected study indicators are presented in Table 3 across the 2 groups pre- and postintervention. Regarding indicators assessing uptake of health care services, during pregnancy, there was a significant rise in the percentage of women completing 4 or more ANC visits between the pre- and postintervention periods in both intervention and control groups. Specifically, the increase was higher in the intervention group, where the percentage of women completing 4 or more ANC visits increased from 71.9% (n=1436) preintervention to 79.9% (n=1251) postintervention (*P*<.001), while in the control group, the percentage increased from 68.6% (n=1367) preintervention to 74.5% (n=980) postintervention (*P*<.001). A similar trend was noticed in the percentage of women undergoing more than 2 ultrasound screenings, with a significant increase in the percentage from 44.2% (n=881) to 86.1% (n=1323) in the control group and from 46% (n=923) to 80.7% (n=1013) in the intervention group pre- and postintervention, respectively. Likewise, a significant increase was found in the percentage of women who received the intervention and completed lab tests (preintervention: n=1467, 73.5%; postintervention: n=1291, 82.5%; *P*<.001). On the contrary, in the control group, the percentage of women who completed the blood tests available at their corresponding PHCs decreased. Furthermore, there was an overall increase in the percentage of women undergoing urine analysis through their pregnancy, with a higher increase in the intervention group (preintervention: n=1276, 63.9%; postintervention: n=1379, 89.7%; *P*<.001) compared to the control group (preintervention: n=1746, 87.6%; postintervention: n=1161, 94.4%; *P*<.001). Additionally, there was an almost equivalent increase in the percentage of women taking their required supplements pre- and postintervention, respectively, in both intervention (n=906, 45.4%, to n=1162, 74.3%; *P*<.001) and control (n=768, 38.5%, to n=850, 64.6%; *P*<.001) groups.

[c]Not applicable.

Maternal and Neonatal Outcomes

Analysis of the data from the charts showed that the onset of delivery improved significantly in the intervention group but not in the control group. After the implementation of the intervention, the proportion of women who had a term delivery increased from 72.5% (n=1444) to 76.9% (n=1011) in the intervention group (*P*=.004). Similar results were observed in regard to neonatal morbidities, where the proportion of women decreased from 7.8% (n=159) to 5.4% (n=85) in the intervention group (*P*=.003). However, the proportion of women who had a normal delivery decreased in both intervention (preintervention: n=962, 51.9%; postintervention: n=652, 46.1%; *P*<.001) and control (preintervention: n=1072, 59.4%; postintervention: n=631, 54%; *P*=.004) groups, with a notable rise in the proportion of woman having C-section deliveries. Results of maternal complications were in the same direction of delivery and abortion, where a significant increase was detected in the proportion of women with maternal complications in both intervention (preintervention: n=309, 15.5%; postintervention: n=407, 26%; *P*<.001) and control (preintervention: n=311, 15.6%; postintervention: n=314, 23.9%; *P*=.02) groups.

Regression Models

Separate logistic regression models were generated for the control and intervention groups to quantify the intervention's impact over the study period (pre- and postintervention), while controlling for baseline characteristics that were different across the 2 groups (see Table 2). Each of the 2 models was adjusted for age, nationality, condition of existing chronic diseases, and obstetric history features (ie, previous preterm delivery, previous abortion, previous C-section, gravida, and parity). Tables 4 and 5 show the adjusted odds ratios (ORs) resulting from the logistic regression analysis of the selected indicators. Considering the domain of uptake of health care services, Table 4 indicates that there was a 56.9% increase in the odds of completing more than 4 ANC visits postintervention compared to preintervention (OR 1.569, 95% CI 1.329-1.852, *P*<.001), adjusting for the difference in the demographical, health, and obstetric characteristics. The OR of ANC visits was not statistically significant in the control group (*P*=.58). In contrast, concerning ultrasound images, participants in the intervention group had significantly higher odds (OR 7.984, 95% CI 6.687-9.523, *P*<.001) of having 2 or more images postintervention compared to the control group, where there was also a significant but lower improvement (OR 3.432, 95% CI 2.836-4.153, *P*<.001). A significantly high increase in the odds of pregnant women undergoing urine analysis was observed postintervention in the intervention group (OR 4.399, 95% CI 3.631-5.330, *P*<.001). Concerning lab tests, an 82.1% increase in the odds of pregnant women completing the required blood tests during their pregnancy was noted postintervention compared to preintervention (OR 1.821, 95% CI 1.514-2.191, *P*<.001).

[d]Significant at .05.

The analysis of the intervention's impact on maternal and neonatal outcomes revealed significant findings (Table 5). Specifically, the odds of experiencing a term delivery increased significantly by 29.5% (OR 1.295, 95% CI 1.095-1.532, *P*=.002) only in the intervention group. However, concerning abortion and delivery type, the study period was associated with decreased odds of normal deliveries (OR 0.774, 95% CI 0.657-0.911, *P*=.002) and decreased odds of not having an abortion (OR 0.702, 95% CI 0.657-0.911, *P*=.006). Table 5 also indicates that the odds of not having any maternal complication were 0.535 (95% CI 0.449-0.637, *P*<.001) in the intervention group and 0.586 (95% CI 0.474-0.723, *P*<.001) in the control group. In contrast, there was a significant increase of 58% in the odds of not experiencing any of the neonatal morbidities during the post- intervention period (OR=1.580, 95% CI 1.185-2.108, *P*=.002). Notably, this increase was detected as well in the control group but failed to demonstrate statistical significance.

Discussion

Principal Findings

This study assessed the impact of mHealth and AI-based gamified intervention on improving maternal health outcomes and enhancing the uptake of ANC services among disadvantaged Lebanese and refugee pregnant women. The study demonstrated significant improvements in maternal and neonatal health outcomes following the intervention. Pregnant women in the intervention group showed higher odds of completing 4 or more ANC visits (OR 1.569, 95% CI 1.329-1.852), undergoing urine analysis (OR 4.399, 95% CI 3.631-5.330), and completing required blood tests (OR 1.821, 95% CI 1.514-2.191) postintervention. Similarly, the odds of completing 2 or more ultrasound screenings were significantly higher in the intervention group (OR 7.984, 95% CI 6.687-9.523) than in the control group (OR 3.432, 95% CI 2.836-4.153). Supplement uptake also improved significantly in both groups, with a greater increase observed in the intervention group (from 45.4% to 74.3%, *P*<.05). The intervention significantly increased the odds of term delivery (OR 1.295, 95% CI 1.095-1.532) and reduced neonatal morbidities (OR 1.580, 95% CI 1.185-2.108). However, both groups showed decreased odds of a normal delivery and increased maternal complications, highlighting the need for continued efforts to mitigate these outcomes.

Uptake of Primary Health Care Services

Our study showed that there was an increase in the overall uptake of ANC visits among pregnant women in the intervention group compared to those in the control group. Such findings are in line with other studies demonstrating that implementing mHealth interventions, such as sending maternal health text messages to pregnant women, yields positive outcomes on the uptake of ANC and overall health [76-78]. Recent studies have suggested that sending reminders specifically for health care

XSL•FO
RenderX

appointments could be more effective than not sending any reminders at all [79-83]. The increased likelihood of attending at least 4 ANC visits could be explained by the additional maternal health information and psychosocial support provided by the message content generally and the ANC attendance reminder messages specifically in the GAIN MHI intervention. In a fragile context, such as Lebanon, where health care access is limited, such interventions are crucial for improving maternal and neonatal health [22]. Scalable and cost-effective mHealth solutions address systemic barriers in resource-constrained settings, ensuring better care continuity and health outcomes [43].

The higher odds of ultrasound use, completion of laboratory tests, adherence to supplements, and undergoing urinalysis among pregnant women in the intervention group emphasizes the effectiveness of mHealth interventions in promoting and actually improving ANC-seeking behavior. Our findings are consistent with other studies on mHealth and maternal health, where increased uptake of health care services was reported. A study in India demonstrated that the implementation of an mHealth intervention resulted in improved health behaviors among pregnant women, specifically by encouraging consistent adherence to supplementation. Another study in Bangladesh showed that receiving and listening to messages resulted in a significant increase in the rate of completion of laboratory tests [84]. The intervention's effectiveness might stem from its contextualized approach, which probably helped overcome logistical, linguistic, and geographical barriers, while also increasing awareness among pregnant women. It is important to highlight that substantial progress has been observed in both intervention and control groups, with notably greater improvements seen in the intervention group. This observation may be potentially due to the fact that PHCs in Lebanon benefit from external funding and ongoing projects, under the auspices of the MOPH and the UNRWA, aimed at enhancing overall health and maternal well-being [35-40,85]. The implementation of these projects at the selected PHCs may have contributed to the results obtained. In fragile contexts, such as Lebanon, mHealth interventions play a critical role in overcoming systemic barriers, improving ANC-seeking behaviors, and supporting maternal health outcomes [78]. By addressing logistical and awareness barriers, these interventions improve maternal health outcomes. Notably, progress in both intervention and control groups highlights the role of external funding and initiatives by the MOPH and the UNRWA in strengthening PHC services, further supporting maternal well-being.

Maternal Outcomes

Our study also showed a significant increase in term deliveries in the intervention group compared to the control group. One possible explanation for this could be that the increased overall uptake of health care services and supplement intake may play a potential role in decreasing the rate of preterm births. Notably, although the increase in the uptake of health care services was evident in both intervention and control groups, the likelihood was greater in the intervention group, possibly due to the encouragement provided by the GAIN MHI mHealth intervention. Additional research conducted by Gillespie [86] and Li et al [87] showed similar findings, suggesting that the rate of preterm births could potentially be decreased through the augmentation of supplement intake.

The increase in the proportion of pregnant women undergoing C-section deliveries in both intervention and control groups without a clear explanation is concerning, especially considering that the unnecessary use of C-sections may lead to negative health consequences and inefficiencies in resource allocation [88-90]. In Lebanon, understanding and addressing this trend is crucial to ensure optimal maternal health outcomes. The rise in C-section rates without medical indications is a worldwide concern and, unfortunately, is expected to persist with nearly a third (29%) of all births likely to take place by C-section by 2030 [91]. This alarming projection emphasizes the urgent need for a concerted effort to address the underlying factors driving this trend. It is essential to recognize that a singular mHealth intervention is insufficient to fully address complex maternal health challenges. This underscores the need for a comprehensive approach involving multiple stakeholders, including HCPs, policymakers, and communities. By prioritizing evidence-based practices and policies, there is an opportunity toward promoting vaginal births, when safe and appropriate, while ensuring that C-sections are reserved for cases where they are medically necessary. This should include providing continuous professional development for HCPs and implementing community education programs to raise awareness about the risks and benefits of different delivery methods. Such measures are essential for safeguarding maternal and neonatal health and reducing the burden of unnecessary surgical interventions.

In both intervention and control groups, there were no observed improvements concerning abortion and maternal complications among the disadvantaged Lebanese and refugee pregnant women. This absence of improvement underscores that maternal health outcomes are intricately influenced by various determinants that extend well beyond clinical interventions, encompassing social, economic, and environmental factors [92,93]. The disadvantaged status of the study population highlights the significant impact of socioeconomic disparities, particularly on women, which not only affect their own well-being but also shape the life prospects of their newborns. Financial constraints, in particular, may contribute to the decision to undergo abortion due to the substantial financial responsibilities associated with raising children. Although the GAIN MHI intervention has yielded promising results, it is evident that merely offering educational messages and appointment reminders is not sufficient when financial barriers and social determinants still hinder the uptake of essential maternal health care services, including addressing and treating maternal complications. Similar results were documented in a study on an mHealth intervention, the MatHealth app, indicating that financial challenges can impede the functionality of the intervention. As such, recognizing the broader determinants of maternal health outcomes, it remains important to address socioeconomic disparities and financial barriers alongside clinical interventions. By engaging in collaborative efforts, including comprehensive support, community empowerment initiatives, and adequate funding mechanisms, equitable improvements in maternal and neonatal health outcomes for

XSL•FO
RenderX

disadvantaged populations can be achieved. Persistent socioeconomic barriers, particularly among disadvantaged Lebanese and refugee women, limit the intervention's impact on maternal complications and abortion rates [22]. Financial constraints and social determinants remain significant obstacles to accessing essential care. Addressing these challenges requires a comprehensive approach that combines mHealth interventions with socioeconomic support, professional development for HCPs, and community education, ensuring equitable maternal and neonatal health outcomes.

Neonatal Outcomes

In terms of neonatal health outcomes, our study demonstrated a significant increase in the likelihood of not facing any neonatal morbidities postintervention. This aligns with the existing literature, such as the study by Bush et al [94], who found that the implementation of mHealth apps, such as the WYhealth Due Date Plus app, designed for pregnant women, resulted in a marked reduction in the incidence of low birth weight. Similarly, Nishimwe et al [95] observed an improvement in newborn outcomes with the sue of the Safe Delivery mHealth app targeting midwives. These findings underscore the multifaceted approach of the GAIN MHI intervention, which not only prioritizes support for expectant mothers but also extends its impact to their HCPs.

In light of these findings, it is essential to integrate mHealth solutions into the primary health care system, ensuring widespread uptake of maternal health information and appointment reminders. In practice, efforts should focus on contextualizing these interventions to address logistical, linguistic, and geographical barriers and include comprehensive support mechanisms to mitigate socioeconomic disparities, thereby fostering equitable maternal and neonatal health improvements. To effectively address the multifaceted nature of maternal health, it is recommended to integrate mHealth interventions within comprehensive maternal health programs. These programs should address both clinical and nonclinical factors that influence health outcomes, ensuring a holistic approach to maternal care. In fragile contexts, such as Lebanon, improving neonatal health is crucial. The GAIN MHI intervention significantly reduced neonatal morbidities, aligning with studies showing mHealth apps improve birth outcomes by enhancing maternal care and supporting HCPs [78]. Integrating mHealth solutions into primary health care, while addressing logistical and socioeconomic barriers, can foster equitable maternal and neonatal health improvements. A holistic approach that combines mHealth with broader maternal health programs is essential for sustained impact.

Equity and Gender Considerations

The GAIN MHI project prioritized equity and gender considerations across its design, implementation, and evaluation phases to ensure inclusivity and fairness in addressing maternal health challenges. All eligible women were recruited without discrimination based on race, ethnicity, nationality, religion, or socioeconomic status. The educational interventions were tailored to accommodate varying literacy levels and socioeconomic backgrounds, empowering women to make informed decisions about their health regardless of their educational or financial circumstances.

Recognizing the cultural and social dynamics of the MENA region, the project incorporated a participatory approach that engaged women and their spouses. Weekly educational messages targeted men to foster shared responsibility in maternal health, challenge traditional gender norms, and promote spousal support. This approach addressed critical barriers in underprivileged communities, where women often require the husband's consent to access health care services or purchase medications.

Additionally, the project leveraged AI and gamification through the GAIN MHI app to enhance the professional development of HCPs. By addressing knowledge gaps and tailoring training to individual needs, the app minimized inequities in access to continuing education for HCPs, particularly those serving disadvantaged populations. The integration of these innovative tools ensured that health care delivery was equitable, culturally appropriate, and responsive to the diverse needs of pregnant women and their communities.

Although the intervention aimed to promote equity, the potential for technology to exacerbate inequities was carefully mitigated. For example, the app was made available in English and Arabic to reduce language barriers, and the inclusion of automated feedback via WhatsApp ensured accessibility for users with limited digital literacy.

Limitations

Despite the positive outcomes of the GAIN MHI intervention, several limitations and potential biases must be acknowledged. The use of historical controls introduces selection bias, as differences between pre- and postintervention groups may reflect not only the intervention's impact but also other temporal changes, such as shifts in health care policies, provider practices, or patient demographics. Additionally, reliance on existing medical charts for data collection compromised data quality due to inconsistencies and missing information. Human errors in documentation and incomplete charts at PHCs, often caused by patients seeking care at private clinics or skipping appointments, posed challenges for tracking full medical histories. This fragmented documentation hindered comprehensive data collection and analysis, potentially reducing the reliability of the study's findings. The exclusive focus on objective data from medical charts also limited the study's ability to capture qualitative aspects, such as reasons for abortion or barriers to accessing health care, which are critical for understanding patients' experiences and decision-making processes. This underscores the need for complementary qualitative research to provide a holistic view of the factors influencing health care outcomes.

Cultural norms in the MENA region further complicated the intervention's implementation. Gender norms may have influenced the women's and their spouses' willingness to fully participate, and despite efforts to encourage spousal involvement through educational messages, varying levels of male engagement may have unequally affected maternal health outcomes. The study's focus on pregnant women attending

XSL•FO
RenderX

PHCs also limits the generalizability of its findings to the broader population, as women facing logistical, financial, or social barriers to accessing care were likely excluded, introducing another layer of selection bias.

Lastly, although the intervention aimed to reduce inequities by targeting underprivileged populations and incorporating AI-based tools for HCP training, reliance on technology may have inadvertently introduced disparities. Variations in access to smartphones or digital literacy levels among participants could have affected the intervention's reach and impact. These limitations highlight the need to interpret the findings with caution and emphasize the importance of further research to validate and refine the intervention for broader and more equitable.

Conclusion

In conclusion, this study highlights the effectiveness of the AI-based gamified mHealth intervention GAIN MHI in enhancing the uptake of ANC and improving maternal and neonatal outcomes. Although encouraging results were observed, the study highlights the need to couple the implementation of such interventions with other complementary interventions targeted toward addressing socioeconomic and context-specific factors that may contribute to the achievement of improved maternal and neonatal health outcomes among disadvantaged populations.

Acknowledgments

The authors would like to thank the staff and directors of the primary health care centers of the Lebanese Ministry of Public Health and the United Nations Relief and Works Agency for Palestine refugees in the Near East for their contribution to data collection and participation in the Gamification and Artificial Intelligence and mHealth Network for Maternal Health Improvement (GAIN MHI) intervention and the GAIN MHI app developer at the Global Health Institute at the American University of Beirut for designing and developing the mobile app. This project was funded by the International Development Research Centre.

Abstract

Background: Depression and diabetes are highly comorbid conditions and are significant causes of global disability, particularly among individuals with low income or those from racial or ethnic minority backgrounds. While digital interventions offer promise for managing these chronic conditions (such as via lifestyle modification), there is also emerging evidence suggesting that digital support may strengthen or complement existing health care relationships, particularly by improving patient perceptions of communication and connection with their health care providers.

Objective: This study aimed to examine the impact of an adaptive mobile health (mHealth) texting-based intervention on patient ratings of communication with their health care providers among individuals with diabetes and depressive symptoms.

Methods: This study used data from the DIAMANTE (Diabetes and Mental Health Adaptive Notification Tracking and Evaluation) trial, a prospective, randomized controlled trial that varied SMS text messaging strategies to encourage physical activity to support both mental and physical health for patients with diabetes and depression. Patients were recruited from safety-net clinics in San Francisco and through social media during the COVID-19 pandemic, and were randomized into three trial arms: (1) personalized SMS text messaging about physical activity via an adaptive learning algorithm, (2) randomly selected SMS text messaging about physical activity, and (3) a control group that received no SMS text messages. As a secondary outcome, we examined pre-post changes in patient-reported health care communication, assessed via surveys with the validated Consumer Assessment of Healthcare Providers and Systems (CAHPS) communication subscale. Bivariate comparisons examined changes in CAHPS scores, including age, gender, preferred language, race or ethnicity, nativity, marital status, and education. Our primary analysis used mixed-effects modeling within an intent-to-treat analysis to determine differences in CAHPS scores by trial arm.

Results: A total of 195 patients participated in the DIAMANTE trial from 2020 to 2022. After excluding patients who had incomplete or missing baseline or exit surveys, 156 patients were included in this secondary analysis. Overall, there was a substantive but nonsignificant decrease in the average CAHPS score over the 6-month trial period (−2.6; P=.11), with similar trends across patient demographic subgroups. Upon evaluating health care communication across the three randomized controlled trial (RCT) arms, there were no significant differences in patient-provider communication.

Conclusions: Digital health interventions are rapidly increasing in clinical practice and have the ability to reach historically underserved communities by overcoming barriers such as language, geography, and time constraints. However, RCTs have primarily focused on the clinical impact of these tools, rather than how the tools may impact patients' perceptions of their relationships with providers. While our study found no significant changes in patient-provider communication by RCT arm, the temporal implications of the COVID-19 pandemic during the DIAMANTE study period remain unclear and should be further studied. This study is the first of its kind to examine the influence of an adaptive mHealth intervention on patient-reported health care communication, with insights that may be important as digitally-enabled chronic care management rapidly expands.

Introduction

Treatment and care for depression and diabetes, two highly prevalent and often co-occurring conditions [1,2], are often siloed. Individuals with diabetes have an increased risk of developing comorbid depression compared to individuals without diabetes [3]. This comorbidity is often associated with a worse prognosis for both conditions [4], occurs at higher rates, and results in worse outcomes, particularly in marginalized communities, including individuals with low income, limited health literacy, or from racial or ethnic minority groups [5,6]. Management of chronic diseases such as diabetes requires self-management practices such as maintaining adequate physical activity and adhering to medications [6]. One important factor that affects self-management practices is positive patient-provider communication [7], which has been documented in many studies to increase trust and improve health outcomes among patients with chronic illness [8].

Mobile health (mHealth) interventions have the potential to effectively integrate with existing chronic health management plans. mHealth is defined as "medical and public health practice supported by mobile devices, such as mobile phones, patient monitoring devices, personal digital assistants, and other wireless devices [9]." The advent of cost-effective mHealth apps has been effective in helping patients engage in healthy behaviors, such as increased physical activity and lowered HbA_{1c} levels [10]. For instance, a diabetes SMS text messaging program improved HbA_{1c} scores as well as provided emotional support for patients [11]. Further, the COVID-19 pandemic has expedited the use of telehealth resources and SMS text messaging through secure platforms via electronic devices, which has improved access to health care [12].

The rapidly increasing number of chronic disease mHealth apps indicates the demand for self-management tools [7]; however, there must be a consideration of digital equity in terms of individuals' internet access, skills, and support related to these platforms and tools [13]. For example, mAdherence tools (ie, mobile health adherence tools) focusing on individuals with low income as well as those who are elderly and from racial or ethnic minority backgrounds were found to be effective and with high satisfaction ratings, although these required a strong baseline adherence program to begin with, as well as active encouragement from the clinical team [14]. Similarly, mHealth tools can be tailored for patients with non-English language preferences; with the addition of culturally concordant motivational messaging, mHealth tools have the potential to reduce health care disparities [15].

Recently, there has also been a surge in mHealth apps integrating artificial intelligence to address chronic health management needs and equity concerns via more personalized communication, such as adaptive learning which tailors messaging in response to an individual's behavior and characteristics [15,16]. Importantly, personalization of messaging could also reinforce and extend the patient-provider relationship that was already established during a face-to-face interaction. Previous observational studies have found that digital communication and remote monitoring could improve the quality and quantity of existing patient-provider relationships, leading to 'digital intimacy,' characterized by familiarity made possible by electronic devices in addition to in-person encounters [17]. This was true even when participants were aware that the digital communication was computer- or digitally-generated [13,17]. While this body of literature is growing, there is a lack of randomized trial evidence about the impact of these interventions on patient-provider communication outcomes.

Therefore, we sought to examine the impact of a personalized communication intervention on participants' ratings of provider communication during the study period. Specifically, this study is a secondary analysis of an existing RCT evaluating a digital health physical activity intervention using reinforcement learning algorithms among adult patients with depression and diabetes.

Methods

Ethical Considerations

This study was reviewed and approved by the Institutional Review Board (IRB) of the University of California, San Francisco (IRB #17-22608). All procedures performed in studies involving human participants were conducted in accordance with the ethical standards of the institutional and/or national research committee and with the WMA Declaration of Helsinki. Informed consent was obtained from all individual participants included in the study. Participants were provided US $110 for completion of the study and all data was deidentified. Further details of the study are described by Aguilera et al [18].

Study Design

The DIAMANTE (Diabetes and Mental Health Adaptive Notification Tracking and Evaluation) was a prospective, IRB-approved, RCT evaluating the effectiveness of a machine-learning-guided smartphone intervention on physical activity. In brief, the intervention sent SMS text messages to participants during a 6-month period to encourage physical activity to support both mental and physical health [19]. There were three arms of the trial: (1) the control arm received weekly messages to report their mood; (2) the random messaging arm received two additional daily text messages that were randomly selected from a message bank that provided feedback on step counts as well as a motivational message related to being physically active, and (3) the adaptive messaging arm used a reinforcement learning algorithm to personalize these daily feedback and motivational messages for each participant based on their demographics as well as their recent data (eg, their steps taken on the previous day, time elapsed since the previous message type that was sent to them) [19].

XSL•FO
RenderX

Development of the SMS text messaging system was designed using a behavioral theory, and the iterative design was completed with patients in a safety-net health care setting as well as via Amazon Mechanical Turk (MTurk) crowdsourcing [20]. For example, (1) the feedback messages were created to provide positive (eg, "Great job!"), neutral (eg, "You walked 4000 steps yesterday"), and negative (eg, "You can do better!") feedback and 2) the motivational messages were categorized within theoretical categories of capability (ie, knowledge and skills to be active), opportunity (ie, advice on strategies to be active, both independently and with others), and motivation (ie, cognitive messages about beliefs and emotions that impact health behaviors). The final DIAMANTE intervention tracked participant step counts from pedometers on smartphones, via an application designed in English and Spanish for both Apple App Store and Android Google Play [19]. Further details about the DIAMANTE application design process have been published elsewhere, including details about the reinforcement learning algorithm and the main RCT findings [18].

Recruitment

English- and Spanish-speaking patients aged 18 - 75 years, diagnosed with diabetes and had documented depressive symptoms (score >5 on PHQ-8), and who had an iPhone or Android smartphone were eligible for participation. Exclusion criteria included the inability to exercise due to physical disability, active psychosis or mania, active suicidal ideation, severe cognitive impairment, inability to read and write in English and Spanish, current pregnancy, and plans to leave the country for extended periods during the 6-month trial.

From 2020 to 2022, patients were first recruited from safety-net clinics in the San Francisco Health Network, the public health care system for the city and county of San Francisco. Due to the COVID-19 pandemic, the study team then expanded recruitment to individuals on social media (ie, Craigslist, Facebook, and Google) who met the same eligibility criteria and prioritized major metropolitan areas with diabetes and larger proportions of Spanish-speaking residents [20]. All patients in the San Francisco Health Network were recruited via their existing primary care provider, and all patients recruited online self-attested that their clinician had diagnosed them with diabetes; both parameters facilitated the focus on patient-provider communication in this paper. Patients received a compensation of $40 for participation in the baseline study and an additional $70 for completion of the 6-month active intervention follow-up. Both of the time points included a detailed 50-item survey with numerous validated scales and self-reported data.

Measures

We examined the impact of the randomized intervention on pre-post changes in patient-reported health care communication via participant surveys at baseline and follow-up, based on the validated Consumer Assessment of Healthcare Providers and Systems (CAHPS) communication subscale [21]. The CAHPS score is widely used across outpatient practices to assess the quality of communication and care processes, and is a well-documented 4-item measure of how often providers explained things well, listened carefully, showed respect, and spent enough time with patients (responses ranged from 'never' to 'always,' coded from 1 to 4). Using conventional scoring, response items were linearly transformed to aid in interpretation (eg, scores of 1, 2, 3, and 4 correspond to 25, 50, 75, and 100, respectively) and averaged across questions, resulting in a total possible score from 25 to 100, with 25 being the lowest possible score, reflecting poor communication between the patient and provider. This scale is one of the most widely used measures of patient-provider communication in routine clinical practice in the United States [22].

Covariates examined descriptively in this study included (1) age (tertiles of ≤45, 46 - 55, or ≥56); (2) gender (ie, man, woman, transgender, and gender queer), (3) education (≤ high school, some college, or ≥ college graduate), (4) race or ethnicity (Asian/Pacific Islander, Black or African American, Hispanic/Latino, White, or Multiethnic), (5) marital status (single, separated, widowed, married, or partnered), (6) born in the United States (US nativity: yes or no), and (7) preferred language (English or Spanish). Covariates were chosen based on previous evidence of their potential impacts on communication outcomes, in core domains of socioeconomic status (eg, education), potential communication barriers (eg, language, nativity), social support (eg, marital status), and other demographics previously associated with communication scores (eg, gender, race or ethnicity).

Statistical Analysis

We first examined the unadjusted descriptive associations between various demographic measures and changes in CAHPS scores from baseline to exit surveys using paired two-tailed *t* tests. These bivariate comparisons examined changes in CAHPS score based on participant age, gender, preferred language, race or ethnicity, nativity, marital status, and education.

Further, our primary analysis examined the changes in CAHPS scores by RCT intervention arm. As the data were from a randomized controlled trial, we did not adjust for the covariates. We used mixed effects modeling in an intent-to-treat primary analysis to determine any significant differences in the communication outcome based on the intervention arm.

Results

t Test Findings

Between 2020 to 2022, 195 patients participated in the DIAMANTE trial. After taking account of participants who dropped out (either due to incomplete data or missing baseline or exit survey), 156 patients were included in the analysis. Participants' mean age was 48.3 (SD 12.2) years and 62.2% (97/195) were predominantly female. A total of 76.3% (n=119) participants were predominantly English-language preferring, were born in the United States (64.1%, n=100), and represented Asian/Pacific Islander (7.7%, n=12), Black or African American (17.3%, n=27), White (28.8%, n=45), Hispanic or Latino (36.5%, n=57), and Multiethnic (9.6%, n=15) racial and ethnic groups. A large portion of participants were single (44.2%, n=92) or married (27.6%, n=64), and had at least some college education and beyond (68.6%, n=107).

XSL•FO
RenderX

As shown in Table 1, there was an overall decrease in the CAHPS scores from baseline to follow-up for most demographic subgroups, indicating communication measures declined during the DIAMANTE trial, although these differences were not statistically significant. This included all categories of gender, age, English and Spanish language, race and ethnicity, US and non-US nativity status, marital status, and most educational attainment levels. A few patterns emerged as well when descriptively comparing groups; greater raw decreases in CAHPS scores were observed among Asian or Pacific Islander and Black or African American participants. In educational attainment levels and age groups, there were larger raw decreases in those who had some college education and less, and those who were younger, respectively.

Table . Baseline demographic and clinical characteristics.

[a]CAHPS: Consumer Assessment of Healthcare Providers and Systems.

Paired Samples Results

Overall, there was a marginal decrease in the average CAHPS score over the DIAMANTE clinical trial period of six months. A mean decrease of −2.6 points (95% CI −5.9 to 0.6; *P*=.11) was observed across the 156 patients who completed both the baseline and exit surveys, which was not statistically significant.

Mixed-Effects Modeling Results

Further, in the primary intent-to-treat analysis, there were no significant differences in CAHPS scores between the three intervention arms (Figure 1). While not statistically significant, the largest decrease in CAHPS score was seen in the adaptive arm (−6.3 95% CI −13.8 to 1.3; *P*=.11) compared to the control arm.

Discussion

Principal Findings

Our study examined patient-reported health care communication using CAHPS scores over the course of a 6-month RCT study (DIAMANTE). There was an overall marginal decrease in communication scores reported by patients in the study, without any significant differences by intervention arm, suggesting that the intervention did not alter patient-reported communication over time. Findings varied across different demographic subgroups; however, these trends in decreasing communication were similar in most subgroups.

Our findings are contrary to some previous literature which may suggest improvements in communication by leveraging digital technology. Previous studies show that initiating mHealth apps in the context of an already established patient-provider relationship is vital in building effective communication channels [14,23]. Additionally, increased touchpoints and motivational behaviors from providers throughout the usage of the mHealth app have been shown to improve patient-provider communication [24,25] and cultivate a greater sense of connectedness compared to traditional clinical encounters [26]. However, to our knowledge, this is the first evidence specific to RCTs using personalized digital communication.

While our study found no significant relationships between the digital intervention and patient reports of communication, it uncovered overall decreasing trends in patient-provider communication. One major reason for this finding may be related to the influence of the COVID-19 pandemic on overall patient-provider communication. While patient-provider communication ratings measured by CAHPS at a national level have been steadily increasing through 2019, there was a decrease in hospital CAHPS scores over 2020 - 2021 period [27]; other findings have been mixed. For example, one previous study found that hospital CAHPS scores decreased across 3381 US hospitals during COVID-19 [28], whereas other studies found that CAHPS scores did not differ between in-person and telehealth visits, with one comparing scores before and during COVID-19 and the second study comparing CAHPS score variations between the two services during the pandemic [29,30]. Thus, it is unclear how the COVID-19 pandemic, which limited in-person interactions between patients and their providers uniformly, impacted the foundational rapport and trust between patients and providers.

Lastly, it has been documented that the pandemic exacerbated burnout among clinicians [28]. This is particularly important given the need for clinicians to have sufficient support and capability to invest in relationship-centered care, and this was particularly challenging in the context of the pandemic with many competing demands (ie, both mental and physical) in health care settings [31]. Additional research has also demonstrated the rapidly increasing digital communication channels and resulting workload on clinicians in recent years

XSL•FO
RenderX

[32]. Therefore, there may be potential for mHealth tools, particularly those that are more personalized, to impact patients' perceptions of their relationship with their health care team via physician workload pathways. Moving forward, more research is needed on how the role of digital communication, including personalized communication with machine learning can support both patient perceptions of their ongoing care as well as the relevance of the technology to the well-being and workflows of clinicians. Further, since many mHealth tools are used for chronic care management or educational support outside the confines of traditional clinical communication, it is important to distinguish the role of these tools on ongoing provider relationships, particularly for patients who have longitudinal care from the same providers.

Limitations

This study has several limitations. The study sample is limited due to the nature of the original RCT. Although CAHPS is a validated source of assessing patient-provider trust and communication, more granular measures of patient-provider communication, such as assessments of specific types and frequency of communication for chronic illness management, may have identified different patterns or mechanisms related to patient-provider communication. In addition, it was difficult to tease out the role of the COVID-19 pandemic and the multiple recruitment strategies for the DIAMANTE trial, particularly related to variation in the connection between each patient and their primary care provider. However, to our knowledge, this is the first longitudinal assessment of CAHPS communication scores examined within a randomized trial involving a digital intervention, which is an important base for future research. With the surge of artificial intelligence and adaptive learning technologies, there is a need for ethical research on how these techniques affect communication and the trust of the communities whose confidence in the health care system was already fragmented.

Conclusions

As the use of adaptive learning–based digital health apps have increased across health care facilities, it is important for technology to extend, not replace strong in-person relationships built on trust and evidence–based communication strategies. In-person communication skills will remain critical even as the pace of digital and adaptive technology implementation accelerates.

Abstract

Background: Major surgery is associated with significant morbidity and a reduced quality of life, particularly among older adults and individuals with frailty and impaired functional capacity. Multimodal prehabilitation can enhance functional recovery after surgery and reduce postoperative complications. Digital prehabilitation has the potential to be a resource-sparing and patient-empowering tool that improves patients' preoperative status; however, little remains known regarding their safety and accuracy as medical devices.

Objective: This study aims to test the accuracy and validity of a new software in comparison to the gold-standard electrocardiogram (ECG)-based heart rate measurement.

Methods: The PROTEGO MAXIMA trial was a prospective interventional pilot trial assessing the validity, accuracy, and safety of an app-based exercise program. The Prehab App calculates a personalized, risk-stratified aerobic interval training plan based on individual risk factors and utilizes wearables to monitor heart rate. Healthy students and patients undergoing major surgery were enrolled. A structured risk assessment was conducted, followed by a 6-minute walking test and a 37-minute supervised interval session. During the exercise, patients wore app-linked wearables for heart rate and distance measurements, which were compared with standard ECG and treadmill measurements. Safety, accuracy, and usability assessments included testing alarm signals, while the occurrence of adverse events served as the primary and secondary outcome measures.

Results: A total of 75 participants were included. The mean heart rate differences between wearables and standard ECG were ≤5 bpm (beats per minute) with a mean absolute percentage error of ≤5%. Regression analysis revealed a significant impact of the BMI (odds ratio 0.90, 95% CI 0.82-0.98, *P*=.02) and Timed Up and Go Test score (odds ratio 0.12, 95% CI 0.03-0.55, *P*=.006) on the accuracy of heart rate measurement; 29 (39%) patients experienced adverse events: pain (5/12, 42%), ECG electrode–related

XSL•FO
RenderX

skin irritations (2/42, 17%), dizziness (2/42, 17%), shortness of breath (2/42, 17%), and fatigue (1/42, 8%). No cardiovascular or serious adverse events were reported, and no serious device deficiency was detected. There were no indications of clinically meaningful overexertion based on laboratory values measured before and after the 6-minute walking test and exercise. The differences in means and ranges were as follows: lactate (mmol/l), mean 0.04 (range –3 to 6; *P*=.47); creatinine kinase (U/l), mean 12 (range –7 to 43; *P*<.001); and sodium (mmol/l), mean –2 (range –11 to 12; *P*<.001).

Conclusions: The interventional trial demonstrated the high safety of the exercise program and the accuracy of heart rate measurements using commercial wearables in patients before major surgery, paving the way for potential remote implementation in the future.

Introduction

Postoperative complications occur in 15%-40% of patients undergoing major surgery, potentially resulting in life-threatening conditions, a decline in quality of life, or reduced physical functioning [1-3]. Adverse events (AEs) associated with surgical procedures impose a significant financial burden due to additional costs from intensive care treatment, reoperations, or prolonged hospital stays [4,5]. Validated assessment tools, such as the Risk Analysis Index (RAI) score, the Eastern Cooperative Oncology Group (ECOG) Performance Status, and the Timed Up and Go Test (TUG), can accurately identify patients' individual risk factors and predict their surgical outcomes [6-9]. Importantly, the physical ability to recover from the physiological stress of surgery and the demands of an aggressive postoperative metabolism is strongly correlated with preoperative health status and physical functioning [10,11]. Accordingly, preoperative exercise interventions aim to enhance patients' aerobic capacity and muscle strength, significantly facilitating postoperative recovery.

Prehabilitation, an emerging field in perioperative care, addresses modifiable risk factors before surgery through interventions such as exercise training, nutritional support, and psychocognitive training [11]. Notably, moderate- to high-intensity programs combining aerobic and resistance training over 3-6 weeks have been shown in recent studies to significantly enhance cardiorespiratory reserve and the capacity to adapt to physical stress [11-13].

Digital health technologies have the potential to enhance health management and facilitate the large-scale implementation of personalized prehabilitation programs in clinical settings by offering cost-effectiveness, broad population accessibility, and high adherence to short-term exercise programs [14,15]. In particular, mobile health (mHealth) apps that leverage mobile wireless technologies and integrate with wearable devices are powerful tools for achieving health objectives through self- and remote monitoring, personalized goal setting, and gamification [16,17]. Wearable devices used for monitoring heart rate and activity are increasingly evaluated in accuracy validation studies [18,19]. The Prehab App has been developed as a platform linked to a wearable device, enabling individualized, risk-adjusted, home-based aerobic exercise training as prehabilitation before major surgery. The objective of the prospective interventional PROTEGO MAXIMA trial was to evaluate the accuracy of wearable measurements and the safety of the prehabilitation program compared with certified electrocardiogram (ECG) measurements in a supervised and controlled environment. Remote, independent, interventional, and risk-based exercising represents a novel, stand-alone approach in prehabilitation, necessitating regulated testing in compliance with the Medical Device Regulation (MDR) [20], the DIN (Deutsches Institut für Normung; German Industry Norm) ISO (International Organization for Standardization) 14155 [21], and the Medical Device Law Implementation Act (Medizinproduktedurchführungsgesetz; MPDG) [22]. This approach also holds first-mover status for real-time data capture. The hypothesis was that the software would demonstrate comparable accuracy and validity in heart rate measurement during a 6-minute walking test (6MWT) and a 47-minute interval training session, matching the performance of a certified ECG, which is considered the gold standard.

Methods

Study Design and Participants

The prospective interventional PROTEGO MAXIMA trial was designed to evaluate the validity, accuracy, and safety of a prehabilitation app. Reporting was conducted in accordance with the STARD (Standards for Reporting of Diagnostic Accuracy; Multimedia Appendix 1) reporting guidelines [23]. The trial included healthy students and patients scheduled for elective major surgery, conducted between March 25, 2022, and September 29, 2022, at the University Hospital Frankfurt [24]. The study protocol has been previously published [25]. In brief, the trial initially recruited 10 healthy students from the Sports Institute at Goethe University Frankfurt to establish a baseline data set from healthy volunteers. In the next phase, 65

XSL•FO
RenderX

patients (aged 18 years or older, capable of understanding and performing the endurance exercise program, and scheduled for elective major surgery) were recruited at the University Hospital Frankfurt. Eligible surgeries included gastrointestinal resections; resections of the hepatobiliary pancreatic system, endocrine glands, lung, or bronchus; splenectomy; abdominal wall hernia repairs; urological or gynecologic resections; or vascular surgeries excluding cardiovascular procedures. We did not exclude patients with chronic but compensated cardiovascular and pulmonary conditions, as these represented a key focus group for assessing risk. The main exclusion criteria were a history of pregnancy or breastfeeding, acute cardiovascular disease, or any acute noncardiopulmonary disorder that could affect or be exacerbated by exercise performance. All participants provided written informed consent. As this is a first-in-human-use pilot trial, we broadened the scope of data collection to include as many scenarios as possible, ranging from healthy students with anticipated textbook outcomes to normal and high-risk patients. At this stage, there was no control group as we needed to evaluate the validity and general safety of the interventional medical device, similar to a phase I study in drug development.

Ethical Considerations

The study adhered to the regulations of the DIN ISO 14155 [21], the MDR [20], and the MPDG [22]. The trial protocol was approved by the institutional review board of the University Hospital Frankfurt and by the Federal Institute for Pharmaceuticals and Medical Products (Bundesinstitut für Arzneimittel und Medizinprodukte; reference number 94.1.04-5660-13655) on February 7, 2022. The study was registered in the German Clinical Trial Register (DRKS00026985) on December 21, 2021, and in the European Database on Medical Devices (EUDAMED; CIV-21-07-0307311). Data from all patients were stored in an electronic case report form using the secuTrial system, a web-based data management application that complies with all required regulations. To assess the quality of the data and to audit the conduct of the trial, independent reviews were conducted by monitors following the monitoring plan of the clinical trial.

Aerobic Interval Training Using the Prehab App

The Prehab App is developed by Capreolos GmbH, a spin-off company from Goethe University, as a medical device class IIa according to the MDR. Currently, it is not yet CE-certified. The app is linked to a wrist-worn wearable (iOS- and Google Wear OS-based hardware) through a software app, providing an individualized, digitized prehabilitation program for patients undergoing major surgery to enhance their functional capacity using aerobic endurance exercise training. Based on the patient's risk factors (ECOG performance status, RAI score, TUG, hemoglobin values, and the presence of heart rate–changing medication), along with the resting heart rate, an individualized interval training program plan with a target heart rate range for moderate to vigorous training intensity (50%-80% of the maximum heart rate) is calculated using the Karvonen method (Multimedia Appendix 2) [26,27]. The predefined exercise program is then automatically uploaded to the patient's smartphone and is ready for use with a provided wearable. By measuring heart rate and distance during exercise, the app provides feedback on the patient's physical performance and potential alarms if the measured heart rate exceeds or falls below the suggested ranges (automated safety audit). Furthermore, the app used by the treating physician will be linked to the patient's app, allowing for supervision by receiving the same alarms as defined in the safety audit and derived from DIN ISO 14971–compliant risk management [28]. After completing the individual exercises, a patient-reported outcome form will collect symptoms during the exercise, which feeds into the safety audit in case of more than 2 reported symptoms. In the final intended use, patients will perform the training 3-4 times a week, selecting the type of exercise (eg, cycling, walking, running) at any time of the day, thereby facilitating a home-based, patient-empowering environment. A 6MWT at the beginning and end of the training period will measure baseline and endpoint fitness. The Quality-of-Life Questionnaire for patients with cancer, consisting of 30 questions (QLQC30), will assess the quality of life before and at the end of the training period.

A detailed overview of the risk assessment app interface and the flow diagram of the exercise training performed under controlled conditions is provided in Multimedia Appendices 2 and 3, respectively. Eligible participants underwent a structured risk assessment and were assigned to a predefined risk score (1-6) based on the ECOG performance status (ECOG 0=0 points, ECOG 1=1 point, and ECOG >1=2 points), TUG (0-7 seconds=1 point and >7 seconds=2 points), RAI-C score (≤25=0 points and >25=2 points), and hemoglobin values (>13 g/dl=0 points and ≤13 g/dl=2 points). Then, after a baseline 6MWT, participants performed 1 one-time endurance exercise program comprising a 47-minute interval training (5 minutes of warm-up, followed by alternating 2 minutes of high-intensity intervals and 3 minutes of low-intensity active rests for a total of 37 minutes, followed by a 5-minute cool down period) on a treadmill at the Institute of Sports Science of Goethe University Frankfurt. Participants wore 1 smartwatch on each wrist (1 iOS [Apple Inc.] and 1 Android [Google LLC/Alphabet Inc.] software combination), which was linked to the app on the complementary smartphone. Four different device combinations were assessed to extend the validity of the measurements: iPhone 13 + Apple Watch 7 (Apple 13), iPhone SE + Apple Watch 3 (Apple SE), Samsung A52 + Samsung Galaxy Watch4 (Samsung A52), and Google Pixel 6 + Samsung Galaxy Watch4 (Google 6). The rationale for choosing these wearables was straightforward: we aimed to provide the 2 major platforms used in smartphones and wearable technologies. As Google Wear OS was only recently introduced, the Samsung Galaxy Watch4 was the only compatible solution at the time of development. An extension to other wearable solutions can be easily performed later. Heart rates and distances were measured at different time points (6 time points during the 6MWT and 19 time points during the interval training) by the wearables and compared with a 12-lead gold-standard ECG (Custo diagnostic; Custo med GmbH) and the treadmill measurement. Participants' perceived intensity and pain during exercise were assessed using the Borg Scale and Visual and Numerical

XSL•FO
RenderX

Analogue Scale [29]. The maximum rate of oxygen consumption (VO_{2max}) in metabolic equivalent (MET) after the 6MWT was used to determine the baseline cardiorespiratory fitness [30,31]. Individual characteristics including wrist circumference, skin appendages, and skin humidity were assessed to evaluate their impact on the accuracy of measurements. As this is a fully regulated development process, the DIN ISO 13485 [28], the MDR [20], all applicable legislation such as the DIN ISO 27001 [32], and the recommendations for cybersecurity implemented by the Bundesamt für Sicherheit in der Informationstechnik (BSI [33]; Federal Office for Information Security) in Germany must be followed. This is done by a dedicated quality management program. Additionally, there is an external data safety and privacy officer within Capreolos GmbH who is responsible for monitoring this area. In brief, as the risk assessment is conducted by doctors on a separate app, all data are pseudonymized, and there are no personal data on the patient's app. There is only a study-specific number plus a log-in so that the patient can only be depseudonymized by the clinical institutions.

Safety Assessment of the Endurance Exercise Program

The aerobic exercise training was continuously supervised by a physician to ensure a safe environment. Secondary safety measures were based on blood samples—reported elsewhere—that were taken before and 15 minutes after the interval training (including creatine phosphokinase, creatine kinase-muscle-brain isoform, lactate dehydrogenase, glucose, sodium, potassium, chloride, C-reactive protein, blood carbon dioxide, lactate, and cell-free DNA). Moreover, the awareness of participants to specific alarm signals displayed on the wearable devices—by either color or haptic vibration—when exceeding or falling below the defined heart rate ranges was assessed. Symptoms, cardiac events, AEs, and serious AEs (SAEs) were assessed during the exercise and through structured telephone interviews or by visiting patients in the hospital (in case they had already undergone their planned surgery) on day 7 and 30 days after the exercise intervention [34].

Statistical Analysis

The sample size calculation was based on the assumption that a maximal irrelevant mean difference of ≤10 bpm (beats per minute) is regarded as acceptable [18,35]. An acceptable error rate using the mean absolute percentage error (MAPE) was defined to be +10% or −10% according to recommendations [36,37]. Considering a power of 80%, a 1-sided α of .05, and a dropout rate of 25%, a sample size of 75 patients was required. Categorical variables were summarized as numbers (percentages), and differences between groups were compared with the χ^2 test. Continuous variables were summarized with the Mann-Whitney *U* test or the Kruskal-Wallis test. Bland-Altman analysis, including calculations of mean differences and 95% limits of agreement (LoA), was used to compare heart rate and distance measurements. MAPE values were calculated as the error percentage between measurements. Outliers were not removed to prevent interference with assessing the accuracy of wearable measurements. Univariate and multivariate analyses were performed using a logistic regression model to assess the impact of different individual variables (eg, wrist circumference, skin humidity, skin appendices, risk scores) on the accuracy of heart rate measurement (odds ratio [OR] with or without 95% CI) and the impact of these variables on cardiorespiratory fitness was determined by VO_{2max}. Statistical tests were 2-sided, and *P* values ≤0.05 were deemed statistically significant. Statistical analyses were performed using SPSS software (version 28.0; IBM Corp.) and R (R Studio, version 4.2.2/R Foundation, version 2022.07.2).

Role of the Funding Source

The clinical trial was funded by the Else-Kroener-Fresenius Stiftung through the translational research program (number 2021_EKTP10). The funder had no role in study design, data collection, data analysis, data interpretation, or the writing of the manuscript.

Results

Baseline Data and Risk Factors

Of the 77 participants recruited, 75 were included (Figure 1). Two individuals were excluded on the training day after double-checking the exclusion criteria because they gave misleading information during the first interview. Finally, a total of 75 participants with 150 wearables-smartphone combinations were analyzed, of whom no one was lost to follow-up. The study population was divided into 3 subgroups: 26 (35%) participants with a risk score of 0, 38 (51%) with a risk score between 1 and 3, and 11 (15%) with a risk score between 4 and 6 (Table 1). The median age was significantly higher in the risk score 4-6 group (63 vs 46 and 57, *P*=.01), consisting of significantly more male participants (9/11, 82%, for risk score 4-6, vs 12/26, 46%, for risk score 0, and 29/38, 76%, for risk score 1-3, *P*=.02; Multimedia Appendix 4 [38]). No differences were found in terms of BMI or smoking. Importantly, high- and medium-risk patients more often suffered from chronic cardiovascular or pulmonary disease compared with the other groups. High-risk patients were most commonly from the visceral (5/11, 45%) and thoracic surgical specialties (1/11, 9%) undergoing hepato-pancreato-biliary and lung resections, while urological patients (23/38, 61%) were more often assigned to the medium-risk group, scheduled for radical prostatectomy and nephrectomy. Low-risk patients predominantly comprised gynecological (4/26, 15%) and vascular surgical (3/26, 12%) patients undergoing salpingo-oophorectomy, hysterectomy, or carotid endarterectomy. Consistent with the cardiopulmonary comorbidities, the structured assessment of risk factors revealed a significantly higher percentage of RAI scores ≥26 in the high-risk group (5/11, 45%) compared with the other groups (7/38, 18%, and 0/26, 0%, for moderate- and low-risk groups, respectively; *P*<.001). Similarly, TUG scores of 7-11 seconds were more prevalent in the high-risk group (10/11, 91%) compared with the other groups (18/38, 47%, and 8/26, 31%, for moderate- and low-risk groups, respectively; *P*=.004). By contrast, no differences were observed regarding ECOG performance status and hemoglobin levels.

VO_{2max}[b] (MET[c]), median (range)	3 (1-6)	3 (1-6)	3 (1-5)	2.4 (2-3)	.17

[a]N/A: not applicable.

[b]VO_{2max}: maximum rate of oxygen consumption.

[c]MET: metabolic equivalent.

Furthermore, by analyzing individual factors that impacted VO_{2max}, we found that age was a significant factor (*P*=.03) for cardiorespiratory fitness in the univariate analysis (see Multimedia Appendix 5). In general, the median VO_{2max} (in MET) for the 6MWT in all patients was 3.1 (range 1.2-6.0), indicating an overall low to moderate aerobic capacity.

Heart Rate Measurement Accuracy

The accuracy of the heart rate and distance measurement of The Prehab App software in combination with the wearables was compared with the measurement of the standard ECG and treadmill (Table 2). The mean heart rate differences for all devices were ≤5 bpm, ranging from 2.92 bpm (iPhone SE, LoA –21.0 to 26.8) to 4.48 bpm (Samsung A52, LoA –19.1 to 27.9) for the 6MWT and from 1.33 bpm (iPhone SE, LoA –19.3 to 22.0) to 2.61 bpm (iPhone 13, LoA –22.0 to 27.1) for the interval training. Consistently, MAPE values for all 4 devices were below the threshold of 10%, with lower values for the interval training (–0.3% [Google Pixel 6] to –1.8% [iPhone 13]) compared with the 6MWT (–1.6% [iPhone 13] to –2.9% [Samsung A52]; see Multimedia Appendix 6). Results showed MAPE values well below 5% and a mean heart rate difference under 5 bpm, indicating excellent reliability of iOS and Android heart rate measurements for The Prehab App software. Bland-Altman plots with 95% LoA are depicted in Figures 2 and 2. Interestingly, all 4 wearables exhibited a slight tendency to underestimate heart rates, which was generally greater for heart rate values over 100 bpm.

For a more detailed analysis regarding the accuracy of heart rate measurement, we subsequently assessed the impact of different individual characteristics, which was defined as an MAPE of <5% (Table 3). Multivariable analysis of individual variables assessed before the exercise training indicated that a low BMI (kg/m^2) (OR 0.897, 95% CI 0.822-0.980, *P*=.02) and a low TUG score (OR 0.122, 95% CI 0.027-0.546, *P*=.006) were independent predictive factors for high accuracy of the heart rate measurement.

VO_{2max}[c] (MET[d]), median (range)	3 (1-6)	1.54 (0.94-2.54)	.09	N/A	N/A

[a]N/A: not applicable.

[b]Accuracy of heart rate was defined as a mean absolute percentage error <5%.

[c]VO_{2max}: maximum rate of oxygen consumption.

[d]MET: metabolic equivalent.

Distance Measurements and Accuracy

Distance measurements of wearables compared with the treadmill revealed a higher variation, with mean differences ranging from –29.22 m (iPhone 13) to –104.28 m (iPhone SE) for the 6MWT (–31.67 m for Samsung A52 and –50.57 m for Google Pixel 6) and from –12.27 m (Samsung A52) to 208.15 m (Google Pixel 6) for the interval training (27.51 m for iPhone 13 and –24.15 m for iPhone SE). Consistently, the LoA were generally higher, with MAPE values exceeding 10% and a peak value of 30.61% for the iPhone SE.

Safety and Laboratory Assessments

The safety analysis of laboratory values, alarm settings of the app, and occurrence of AEs was conducted (Table 4). Lab analysis did not reveal any significant deviations in blood parameters, which remained within clinical limits. A detailed analysis from an exercise physiologist's view will be reported elsewhere. Awareness of alarm signals displayed on the wearables during the interval training was realized with a mean of 13.5 (SD 6.2) seconds. In total, 29 of 75 (39%) experienced an AE, of which 12 (16%) occurred during the interval training, comprising pain (5, 42%), skin irritation through ECG electrodes

XSL•FO
RenderX

(redness or vesicles; 2, 17%), dizziness (2, 17%), shortness of breath (2, 17%), and fatigue (1, 8%). During the follow-up at day 7, 3 of 15 (20%) participants still reported pain and 12 of 15 (80%) indicated skin irritations, which remained until the follow-up at day 30 in 2 cases. Notably, 14 events were related to the certified ECG (electrodes); however, these had nothing to do with the use of the software but had to be reported for regulatory reasons. There were no SAEs or device deficiencies that put the patient at an unacceptable risk. All AEs were periodically reported to the Bundesinstitut für Arzneimittel und Medizinprodukte according to the regulations of the MDR and the MPDG, and no AE lasted longer than 30 days. No SAE was reported during the trial, and no patient died until follow-up.

Table 4. Safety assessment of the app-based aerobic exercise training.

Discussion

Principal Findings

To the best of our knowledge, this is the first prospective trial report assessing the validity and safety of a risk-adjusted, app-based prehabilitation program using wearables for heart rate and physical activity monitoring. The analysis revealed a high accuracy of wearable heart rate measurement with a mean difference of ≤5 bpm and an MAPE of ≤5%, while distance measurement exhibited larger variations (mean difference ≤209 m and MAPE ≤31%), which can be explained through an impaired detection of patient's wrist movement during the exercise training on the treadmill and the lack of global positioning system trackers.

Prehabilitation in this context revealed a tremendous potential for improving modifiable factors in patients and thus increasing the safety and quality of surgical care. Perry et al [39] included 178 trials of heterogeneous quality on prehabilitation for patients undergoing major abdominal surgery, reporting prehabilitation to be superior to standard care in both length of hospital stay (1.81 days vs usual care) and postoperative pulmonary complications (risk ratio 0.55). This is consistent with the findings of the RCT by Barberan-Garcia et al [13] for postsurgical complications (31% vs 62%) in a cohort of 144 high-risk patients and with the meta-analysis of Moran et al [40] (OR 0.59, *P*=.03). Importantly, the study by Molenaar et al [12], which involved 251 patients undergoing resection of colorectal cancer, reported the benefit of a 4-week in-hospital multimodal prehabilitation program with significantly reduced severe postoperative complications (Comprehensive Complication Index>20: 17.1% vs 29.7%), medical complications (15.4% vs 27.3%), and enhanced functional capacity. At this stage, it seems that a resource-intensive prehabilitation program only works in clinical trials due to the enormous infrastructure requirements and costs associated with it, including patient travel over weeks, which seems hardly feasible. This suggests a real opportunity for a well-guided and safe remote approach that additionally fosters patient empowerment [41,42].

Studies on costs also suggest that an improvement in surgical outcomes, particularly the reduction in hospital length of stay, results in a significant reduction in hospital expenditures and the opportunity cost of surgery [4,5]. A more recent meta-analysis by Punnoose et al [43] of patients undergoing orthopedic surgery found a significant impact of prehabilitation on preoperative function, muscle strength, and reduction of pain. However, the current evidence on prehabilitation remains limited, characterized by broad heterogeneity between studies and a high risk of bias. Particularly, exercise regimens were not consistently reported in terms of the individual content of the exercises (ie, training type, intensity, duration) and a lack of compliance to high-intensity training substantially impairs the implementation of prehabilitation in clinical practice [11,15].

Recent studies evaluating digital prehabilitation models provide increasing evidence for their beneficial effects compared with conventional hospital-based in-person programs [14,15,44,45]. Moorthy et al [45] assessed the feasibility of a home-based supervised prehabilitation program involving 41 patients scheduled for esophago-gastric cancer surgery, revealing a higher program completion in the digital arm compared with the in-person cohort (84% vs 14%). Further, patients using the digital service exhibited increased cardiorespiratory fitness measured by the 30-second sit-to-stand test (*P*=.02) and the median heart rate recovery (10.5-15.5 bpm; *P*=.04). Similar positive effects on patients' adherence to digital exercise programs were found by Kadiri et al [46], who evaluated the efficacy of the "Fit 4 Surgery" app, which included 10 exercises for patients undergoing lung cancer surgery. Patients in the app cohort completed more exercise sessions (9 vs 2) in a shorter time (24 vs 45 days) before surgery and even during the postsurgical period (2 vs 0), compared with those attending hospital- or community-based classes. Importantly, a quality improvement study by Kimura et al [47] that assessed the impact of an online app-based prehabilitation program (SeamlessMD) on surgical outcomes after colorectal surgery demonstrated a significantly shorter length of hospital stay (adjusted estimates –1.15; *P*=.03), while there were no differences in terms of complication rates.

A remote prehabilitation program will empower patients' autonomy, alleviate pressure on health care workers and infrastructure, and eliminate unnecessary travel for patients. An oncologic diagnosis, coupled with the clear short-term goal of becoming the best version of oneself before a major surgical procedure, serves as a compelling motivator for patients and is a key driver of compliance and adherence to digital therapeutics [11]. Prehabilitation models incorporating remote monitoring with wearables for heart rate, physical activity, and progress tracking have been shown to support personalized goal setting, ensure safety through professional supervision, and enhance patient adherence to the program [15,17]. Various studies have assessed wearable heart rate accuracy by comparing them with the gold-standard reference method of ECG, indicating a low overall error, low mean difference SD, and acceptable agreement with ECG for consumer wearables (eg, Apple Watch or Fitbit) [18,48-50]. Wang et al [35] assessed the accuracy of 4 different wrist-worn wearables in 50 healthy students, showing median differences of ≤10 bpm, which were generally lower at rest compared with measurements during exercise. However, despite the acceptable accuracy in laboratory settings, real-time measurement in medical settings, including an assessment of Apple Watch 3 and Fitbit Charge 2 over 24 hours compared with ECG by Nelson et al [36], indicated that single heart rate observation could be inaccurate by significantly large margins, although aggregated values revealed high overall accuracy (<10% MAPE) [51].

The study has both strengths and weaknesses that will be addressed in the following. One of the study's strengths is that it follows a strict regulatory framework, supported by dedicated quality and risk management. All criteria assessed here were derived from risk management principles, explaining the stepwise approach that began with a first-in-human pilot study involving healthy students and patients within the intended use. The study was split into a pure usability part and an evaluation of the risk assessment, which will be reported elsewhere [26]. Another strength is the use of evidence-based risk calculation

XSL•FO
RenderX

tools. The RAI score emerged as the most suitable and user-friendly score, not requiring additional tools for assessment. It, combined with the TUG and ECOG scores, best met the requirements of a digital solution. Moreover, it is currently highlighted as the so-called surgical pause by the American College of Surgeons [52]. Other scores, such as the National Surgical Quality Improvement Program (NSQIP), require significantly more resources and have not demonstrated superiority in assessments, for example, within a German health care setting [53,54].

A weakness of the study may be that it is not a randomized controlled trial. However, given that we are establishing evidence in a young field of clinical medicine, safety and validity were the first steps in the stepwise approach. This was followed by a multicentric clinical trial that is currently underway. Comparability at this stage of remote prehabilitation is challenging due to the variety of methods used to implement it. van der Velde et al [55] performed a pilot randomized controlled trial in which they used a smartphone-based app to achieve behavioral changes before surgery. They found self-reported changes in alcohol use, nicotine cessation, and an increase in self-reported exercising. Wang and coworkers [14] developed an app to foster prehabilitation and assessed its usability. While they found promising usability results with their device, no efficacy data have been presented so far. Although the ideas of the 2 previously mentioned studies were only somewhat comparable to ours, the solutions lacked supervision of the exercises, making it unclear whether the patients engaged in light or moderate to vigorous exercise, which has significantly larger effects. Haveman et al [56] followed a similar approach to ours but differed by tracking individuals' activities and interpreting increases in heart rate and step counts 3 days before surgery as indicators of increased physical activity, without obtaining a specific readout from the assessed data. This shows that remote prehabilitation seems feasible, is being explored, and may be a hot topic for the next few years, as outlined in various arguments and discussion points previously [57].

Another challenge and critical endpoint measurement is compliance and adherence to the program provided. In this feasibility study and first-in-human use of a newly designed medical device, compliance was not an endpoint. However, the development of The Prehab App involved patients, doctors, and other experts from the very beginning [41]. The program was designed in a way that allows different risk groups to train within a general interval training framework, respecting their individual risk and adapting the individual thresholds of exercising to their profile [11,25,26]. During the randomized controlled trial, the Prehab App will reliably measure compliance using a traffic light system, as it documents every exercise in real time and provides precise information on how patients trained within their thresholds. Additionally, we will assess if the participants performed their exercises and if they took their supplementary nutrition using patient-reported outcomes. Reminders will be used to increase compliance and adherence.

All this together highlights the potential of digital prehabilitation interventions in achieving high levels of patient engagement, uptake, adherence, and usability satisfaction. App-based models provide a promising solution to overcome the limitations in scalability and sustainability seen with face-to-face programs in clinical practice. However, the application of digital prehabilitation models needs to be further assessed in multicenter randomized controlled settings to evaluate their effectiveness, particularly in terms of safety and efficacy in the final intended use, and to gain approval as a safe medical device [51,58].

Conclusions

This analysis presents the first pilot study assessing the validity and safety of a risk-stratified prehabilitation program for patients undergoing major elective surgery, utilizing an mHealth app linked to wearable devices for self- and remote monitoring of physical performance. The heart rate measurement was below the recommended threshold with an MAPE of ≤5%, demonstrating excellent accuracy. Laboratory analysis and assessment of AEs indicated that individually tailored exercise training can be safely performed in a supervised setting, justifying the remote testing of The Prehab App in a multicentric randomized controlled trial.

Use of Artificial Intelligence

No artificial intelligence has been used in the generation of the manuscript or any text presented here.

Acknowledgments

The Else Kroener Fresenius Foundation funded the clinical trial through the translational research program 2021_EKTP10, providing a total of €161,000 (US $168,821). JF was also supported by this grant for a different part of the clinical trial. The PROTEGO MAXIMA trial was a tremendous effort of many people. We must thank Mark Siller and his software development team at Seven D in Heilbronn, PD Dr. Georg Matheis for his support with medical device questions, and Jan von Hassel for his expertise and guidance in regulatory questions, including qualifying the whole team as MDR- and DIN ISO 14155-compliant investigators. Additionally, we extend our thanks to the Johner Institute team, especially Anne Arndt, for her support in MDR-compliant development and support. We also thank Claus Wuestenhagen for expert data safety and protection support. Our special thanks go to the Center for Clinical Trials at Frankfurt University Hospital, which supported us with independent monitoring conducted by Ina Müller. We also thank the Executive Department of Quality Management, led by Dr. Kyra Schneider, for their assistance with quality management questions. We are grateful to Professor Michael Behringer at the Institute for Sports Sciences at Goethe University for his cooperation. Finally, we are proud that the PROTEGO MAXIMA trial was the highest recruiting investigator-initiated trial in the Comprehensive Cancer Center Frankfurt/Main in 2022, with a total of 392 patients and participants across 3 modules.

Data Availability

Data can be accessed anonymously upon specific request and submission of the requesting group’s research question outline.

Authors' Contributions

Study conception and design were led by AAS, DZ, CD, JF, LM, JD, and NF. Data acquisition was conducted by SFFUZ, SS, AAS, JF, LM, CD, JD, FC, WD, and WS. Analysis and interpretation of data were carried out by SFFUZ, SS, AAS, NF, DZ, WOB, JF, FC, WD, and WS. Writing of the manuscript was done by SFFUZ, AAS, JF, LM, JD, and NF with input and final approval of all authors.

Conflicts of Interest

AAS, DZ, and CD are founders of Capreolos GmbH, a spin-off from Goethe University established to set up the regulatory framework for developing a medical device for prehabilitation. JF became a shareholder of Capreolos after the termination of the trial. All other authors declare that they have no direct or indirect conflicts of interest.

Abstract

Background: Minimally invasive thoracic surgery has improved lung cancer outcomes but requires enhanced postoperative care. Traditionally, the episodic care model has limited timely and multidimensional monitoring of patients. Recent technological advances in multimodal digital devices, including wearable devices and electronic patient-reported outcomes (ePROs), offer a promising solution to these challenges. However, current studies focus on only a few parameters and limited application in thoracic surgery.

Objective: This study aims to propose a self-controlled study to evaluate the feasibility and reliability of multimodal digital devices, including wearables and ePROs, for continuous perioperative monitoring to enhance recovery after thoracic surgery.

Methods: We included 288 patients with non–small cell lung cancer from the Guangzhou Medical University cohort, which includes 2757 participants with various lung diseases. Digital data were collected during hospitalization using a commercial smartwatch combined with an ePROs questionnaire, while clinical data were obtained from electronic health records (EHRs). Agreement between the digital device and EHR was evaluated via Bland-Altman analysis. Time-series data were normalized for continuous outlier monitoring, and threshold analysis of ePROs scores were used to explore associations across different modules.

Results: Throughout hospitalization, digital devices provided a subjective overview of the patients' recovery trajectories. Results of Bland-Altman analysis demonstrated a high level of agreement between the digital device and the EHR. For body temperature, the analysis revealed a minimal bias of 0.02 °C (95% CI –0.01 °C to 0.05 °C), the agreement for heart rate showed a bias of 0.26 beats per minute (bpm; 95% CI –0.49 bpm to 1.01 bpm), and the bias for oxygen saturation was –0.06% (95% CI –0.27% to 0.15%), indicating close alignment between the 2 measurement methods. Meanwhile, wearable devices demonstrate significant potential in outlier detection compared to the episodic care model, offering accurate and sensitive monitoring of outliers between traditional measurement intervals. Using a thresholding method, we found that wearable metrics were correlated with the severity of ePROs.

XSL•FO
RenderX

Conclusions: These findings highlight the reliability and clinical potential of digital device–based multimodal systems within the enhanced recovery after surgery framework, offering a novel approach for continuous perioperative monitoring.

Introduction

Background

Minimally invasive thoracic surgery (MITS) has significantly improved perioperative outcomes for patients with lung cancer, offering benefits such as reduced postoperative pain, shorter hospital stays, and quicker recovery times [1]. However, the success of MITS also demands higher standards for postoperative care, with a focus on early mobilization, increased physical activity, and personalized rehabilitation [2,3]. Building upon the foundation of smaller incisions, the enhanced recovery after surgery (ERAS) protocol further emphasizes both the speed and quality of recovery [4].

Currently, the commonly used perioperative monitoring model in clinical practice is episodic care, such as bedside monitoring, periodic assessment, and ward rounds. However, this care model limits patients' activities and timely feedback on subjective feelings. Moreover, some abnormal signs of intermittent attacks may be missed due to the discontinuity of monitoring. Therefore, a novel pattern to obtain multimodal, comprehensive, real-time, continuous, and reliable data of patient condition is urgently needed to achieve ERAS.

Recent technological advances in digital devices, including wearable devices and electronic patient-reported outcomes (ePROs) systems, offer a promising solution to these challenges [5,6]. Wearable devices, such as smartwatches and smart rings, can be used for continuous health monitoring, providing a more comprehensive assessment of an individual's well-being [7]. ePROs, in turn, can obtain real-time subjective feedback from patients. Previous studies have demonstrated that ePROs can reduce postoperative symptom burden and complications [8-10] and have shown their prognostic and therapeutic benefits [11].

Despite these advances, several challenges still remain. First, most studies focus on the continuous tracking of only a few parameters, predominantly heart rate (HR) and step count. Second, previous research has mainly concentrated on cardiovascular disease, as HR monitoring is relatively straightforward. Finally, there is a scarcity of studies combining wearable devices with ePROs for use in clinical practice, particularly in thoracic surgery.

Objective

To address the gaps mentioned earlier, we propose a prospective, self-controlled study to explore the feasibility and reliability of using multimodal digital devices, including wearable technology combined with ePROs, and provide a novel evidence-based approach to continuous perioperative monitoring for enhanced recovery after thoracic surgery.

Methods

Ethical Considerations

This prospective study received approval from the Ethics Committee of the National Center for Respiratory Medicine and the First Affiliated Hospital of Guangzhou Medical University (ES-2024-073-02) and was registered with the clinical trial registry (NCT06118229). All data incorporated in this study were deidentified. As compensation, participants in this study received regular follow-up visits and one-on-one counselling services provided by the medical team upon completion of the study. This study followed the Declaration of Helsinki.

Patients Selection

All patients were drawn from the Guangzhou Medical University cohort, a prospective, multicenter cohort designed to use multimodal data, including intelligent digital data, biospecimen data, and imaging artificial intelligence data from 2757 participants with various lung diseases, to assist in diagnosis, monitor treatment efficacy, and promote the rapid recovery of surgical patients. In this study, we prospectively and consecutively recruited patients with non–small cell lung cancer, one of the study arms within the Guangzhou Medical University cohort, aged ≥18 years, who were scheduled to undergo thoracic surgery between March 2023 and December 2023.

Detailed exclusion criteria were as follows: (1) patients unable to wear the wearable device or have poor compliance; (2) patients with a previous history of trauma, infection, or tumor; (3) patients without a smartphone equipped with an Android (Google LLC) or iOS (Apple Inc) operating system; (4) patients with other systemic inflammatory or neurological diseases; and (5) pregnant or lactating women.

All eligible patients provided informed consent after receiving detailed written information about the study, including the purpose of the study and use of wearable devices. Both verbal and written informed consent was obtained.

Wearable Device

The HUAWEI WATCH D (Huawei Device Co, Ltd) is a wrist-worn class II medical device approved by the Chinese National Medical Products Administration and certified under the EU Medical Device Regulation; it combines a micromechanical air pump, the TruBP pressure module, and temperature, photoplethysmography (PPG), and electrocardiography sensors to deliver continuous perioperative monitoring of body temperature, HR, oxygen saturation, and blood pressure. To limit motion- and wear-related artifacts, the watch uses an upgraded TruSeen 5.0+ optical system with 8 circumferential photodiodes and dual LEDs, a Fresnel film, and

XSL•FO
RenderX

a curved 2.5-D sapphire back with physical vapor deposition electrodes that improve skin contact; abnormal strap loosening or compression triggers an automatic hardware repeat-measurement and refusal protocol. Raw signals were processed in real time by a HiFi-Encoder deep learning pipeline that performs multichannel enhancement and concurrent time and frequency noise suppression, discarding any frame whose signal-quality index falls below 0.8; under vigorous movement, this yields 98% accuracy for HR deviations ≤10 beats per minute (bpm) and 95% for deviations ≤5 bpm, and the same signal-quality index filter is available to downstream analyses via Huawei Health Kit. Device accuracy had been confirmed against ANSI/AAMI/ISO 81060-2:2018 criteria, while the "Huawei Heart Study" (>3.2 million participants) demonstrated a 92.8% positive predictive value for atrial fibrillation (AF) detection, a result incorporated into the 2020 European Society of Cardiology AF guidelines, collectively supporting the WATCH D's capability to identify and suppress artifacts and to provide clinically reliable physiological data.

Collection of Wearable Data

The data recorded by the wearable device included body temperature, skin temperature, HR, oxygen saturation, sleep quality score, shallow sleep duration, deep sleep duration, dream duration, awake duration, daytime sleep duration, total sleep duration, step volume, distance movement, and calorie consumption. For safety considerations, the blood pressure measurement function on the wearable device was disabled by technicians from the backend.

Each participant was assigned a unique application account to access HUAWEI's developer application programming interface. Measurement data were transmitted to the application via Bluetooth, aggregated through the application programming interface backend, and deidentified before being stored on a secure network drive within the Tianhe-2 supercomputer, supported by the National Supercomputer Center in Guangzhou.

Collection of Electronic Health Record

Patients baseline characteristics, tumor characteristics, surgical information, and perioperative characteristics were included. Baseline characteristics comprised age, sex, BMI, smoking status, and consumption history. Tumor characteristics included pathological type, tumor location, tumor size, and tumor-node-metastasis stage. Surgical information encompassed American Society of Anesthesiologists grade, operation time, surgical procedures, anesthesia method, lymph node dissection, and intraoperative bleeding.

Postoperative characteristics included length of hospital stay, duration of chest tube placement, pleural drainage volume, body temperature, oxygen saturation, HR, amount of postoperative pain medication, frequency of pain medication, administration via pain medication, administration method, and visual analog score for pain and postoperative complications.

Collection of ePROs Data

ePROs included 9 symptoms, which is described in a former study [12], related on a scale from 0 (no symptom) to 10 (the most severe symptom). These symptoms were pain, cough, shortness of breath, restless sleep, fatigue, drowsiness, walking difficulties, and limitation of activities and distressed.

A link to the survey was sent each night at 7 PM during hospitalization. Automatic reminders were sent every 30 minutes thereafter if the questionnaires were not completed. If the survey was not completed by 10 PM, the investigator would remind the patients to complete it. All collected data were aggregated and stored using the same strategy as described earlier.

Time-Series Data Processing

Given the considerable variations in the duration of wearing the wearable device during the perioperative period among different patients, we normalized the time scale. Specifically, we set the start time of surgery as the origin time, with the preoperative period as negative time and the postoperative period as positive time.

A large amount of time-series data could be obtained using wearable devices, including body temperature, skin temperature, HR, and oxygen saturation. Multiple measurements could be recorded within a single minute to enhance the analyzability of the time-series data, and to further reduce the likelihood of potential false positives and false negatives arising from spurious signals, we averaged all measurements obtained within each minute and used these aggregated values in downstream analyses.

Statistical Analysis

Mean and SD or median and range were used to describe continuous data, while categorical data were presented as numbers and percentages. The agreement between the reference method and the wearable device was assessed using the Bland-Altman analysis [13]. To evaluate the feasibility and reliability between the wearable device and the reference method, Bland-Altman analysis was conducted, which is widely regarded as the gold standard for consistency assessment. This method quantifies the systematic bias and limits of agreement between 2 quantitative measurement methods, thereby providing statistical support for evaluating the reliability of the wearable device system. Subgroup analyses evaluating the reliability and feasibility of the digital device were conducted among patients with and without significant postoperative complications. Threshold analysis based on the ePROs score was used to evaluate relationships between different modules data.

Wearable devices can bridge gaps in patient monitoring within the traditional episodic care model. We analyzed the occurrences of outlier detections during periods lacking nursing supervision and visualized these occurrences as line graphs. After aggregating the raw high-frequency measurements into 1-minute averages, we defined outliers on the basis of these minute-averaged values: a minute-averaged body temperature >37 °C or <36 °C; a minute-averaged HR >90 bpm or<60 bpm; and a minute-averaged oxygen saturation <95%. Differences between groups were compared using Student *t* test (2-tailed), chi-squared test, or Fisher exact test.

All data preparation, analyses, and visualization were performed using R (version 4.0.5; The R Core Team, R Foundation for

XSL•FO
RenderX

Statistical Computing). We deemed *P* values <.05 were considered statistically significant.

Results

Participant Demographics and Baseline Data

A schematic overview of the study is presented in Figure 1. As presented in the flowchart diagram in Figure 2, 288 patients consented to participate in the study, including 174 female patients and 114 male patients with a median age of 56 (range 24-82) years. Baseline characteristics of the participants were presented in Table 1. At baseline, most patients underwent segmentectomy (n=203, 70.5%), while 85 (29.5%) underwent lobectomy. In total, 37 (12.8%) patients were former smokers, and 27 (9.4%) patients had a history of alcohol consumption. A total of 83 (28.8%) patients reported preoperative comorbidities, including hypertension, diabetes mellitus, chronic obstructive pulmonary disease, arrhythmia, coronary artery disease, and valvular heart disease. No intraoperative complications or surgical conversions were reported.

Figure 1. Schema of overall study design. A total of 288 patients were prospectively involved in this study. Multimodal data, including electronic health records (EHRs), wearable devices, and electronic patient-reported outcomes (ePROs), were collected, and multimethod statistical analysis was applied. ERAS: enhanced recovery after surgery. See Multimedia Appendix 1 for a high resolution version of this figure.

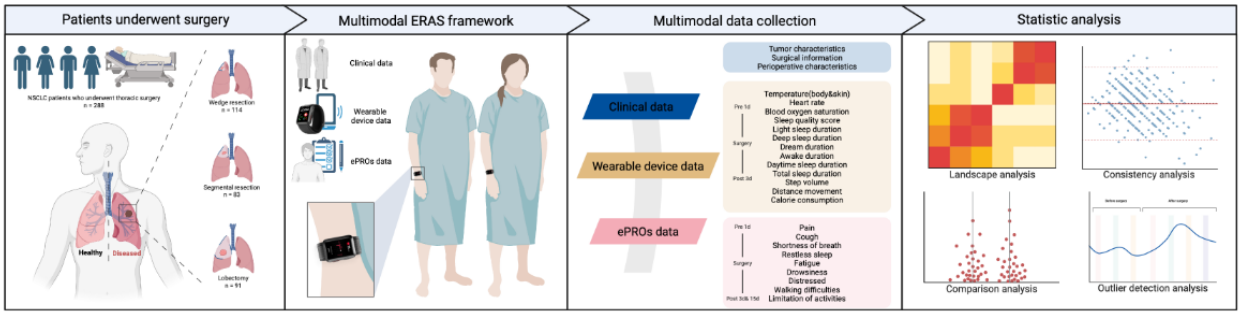

Figure 2. Patient recruitment. The flowchart illustrates the recruitment process and inclusion and exclusion criteria, and included participants underwent multimodal digital device monitoring. ePRO: electronic patient-reported outcome. See Multimedia Appendix 1 for a high resolution version of this figure.

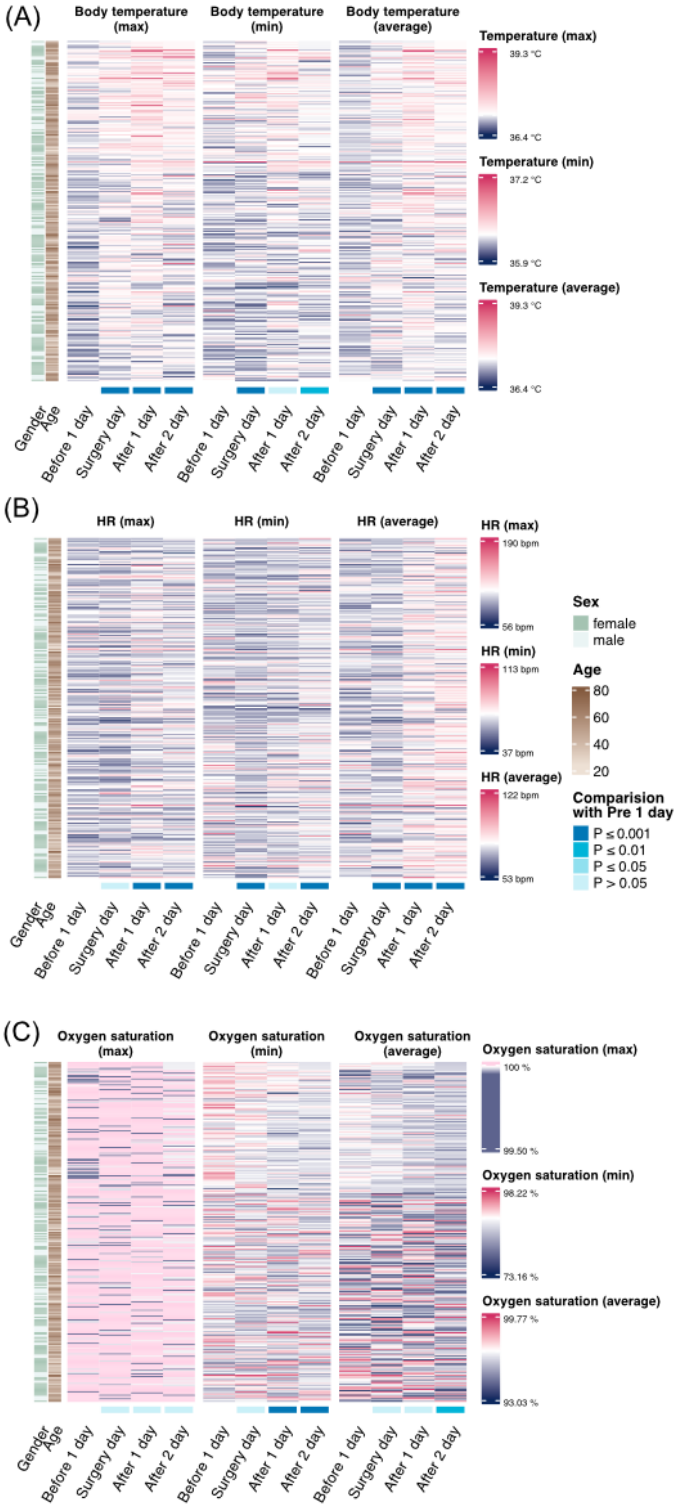
Mapping Patient Vital Status and Recovery During Perioperative Vital Signs and Recovery

Figures 3 and 4 demonstrate the utility of integrating wearable device data and ePROs to provide a comprehensive, real-time assessment of perioperative recovery. This analysis highlights the advantages of continuous monitoring in detecting critical physiological changes and tracking patient-reported symptoms during thoracic surgery recovery.

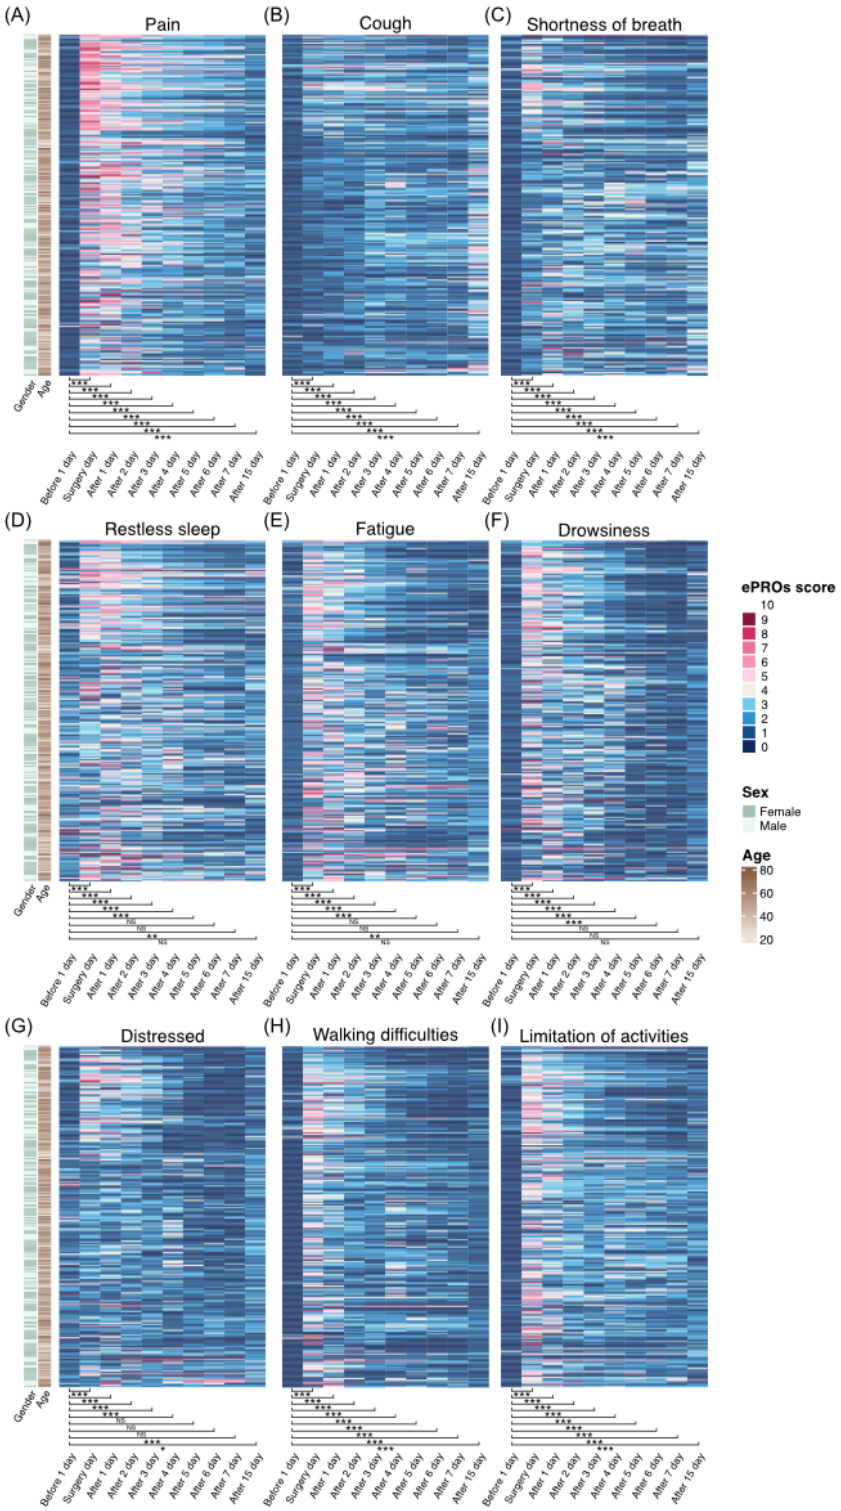
XSL•FO
RenderX

Figure 3. Heatmap illustrates the patients' perioperative body temperature, heart rate (HR), and oxygen saturation using wearable device data. (A) body temperature, (B) HR, and (C) oxygen saturation. Each parameter is displayed with its maximum, minimum, and average values. The sex and age of each patient are annotated and displayed alongside the heatmap. NS: not significant. See Multimedia Appendix 1 for a high resolution version of this figure.



XSL•FO
RenderX

Figure 4. The heat map illustrates the patients' perioperative recovery status using electronic patient-reported outcomes (eRPOs) data. (A) Pain, (B) cough, (C) shortness of breath, (D) restless sleep, (E) fatigue, (F) drowsiness, (G) distressed, (H) walking difficulties, and (I) limitation of activities. NS: not significant. See Multimedia Appendix 1 for a high resolution version of this figure.



In the analysis of wearable device data, both body and skin temperatures showed consistent increases after surgery, indicating inflammatory or healing responses (Figure 3A and Multimedia Appendix 2). HR demonstrated a clear upward trend, with statistically significant increases in maximum and average HR on the first and second postoperative days, highlighting the physical stress of surgery (Figure 3B). Oxygen saturation levels displayed a significant overall decline, especially in minimum and average values during the perioperative period, suggesting potential postoperative respiratory compromise that warrants close monitoring (Figure 3C). Early improvements in physical mobility, as evidenced by significant increases in step count, exercise distance, and calorie expenditure on the first postoperative day (Multimedia Appendix

XSL•FO
RenderX

2), underscore the rapid physical recovery promoted by ERAS protocols. Importantly, sleep quality significantly deteriorated on the day of surgery and the first postoperative day, reflecting the immediate postoperative impact on psychological recovery (Multimedia Appendix 2).

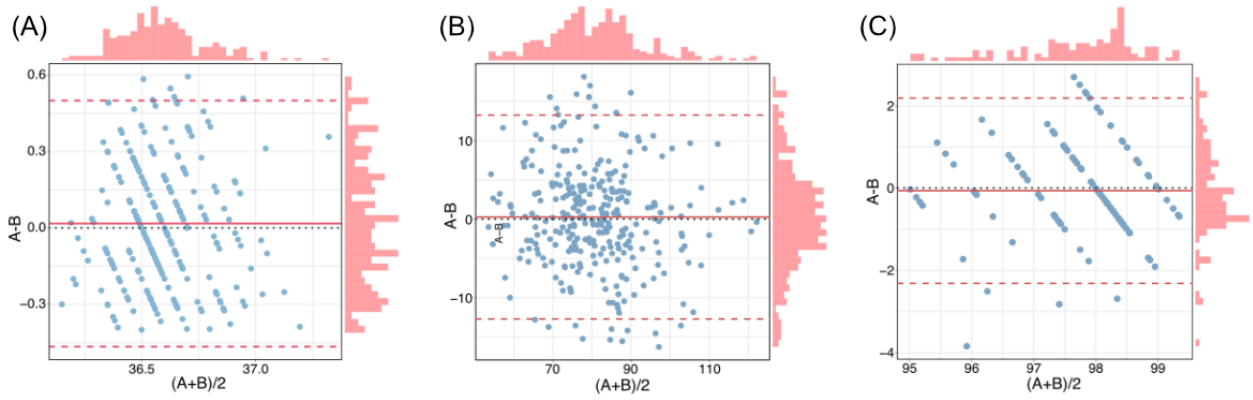
A total of 288 ePROs questionnaires were collected and analyzed. Figures 4A-4I showed that symptoms such as pain, cough, shortness of breath, and activity limitations peaked on the day of surgery and significantly improved within the first week and by day 15. This gradual symptom alleviation aligns with the expected recovery timeline, but the persistent challenges with sleep and fatigue underscore the need for tailored recovery interventions. The combination of wearable devices and ePROs provides a robust framework for perioperative monitoring, offering both objective physiological data and subjective patient feedback.

We also calculated the median and IQRs of ePRO scores during the perioperative period. The results suggested a pattern consistent with the objective trajectory of postoperative recovery. Taking pain as an example, the median pain score and IQR were 0 (IQR 0-0) on the day before surgery. The score peaked on the day of surgery, with a median of 5 (IQR 3-7), and gradually decreased starting from the second postoperative day, remaining at a low level. By the seventh postoperative day, the median pain score was 1 (IQR 1-2), and it further decreased by the 15th postoperative day, with a median of 1 (IQR 0-2; Multimedia Appendix 3).

Evaluation of Agreement Between Wearable Devices and Electronic Health Record

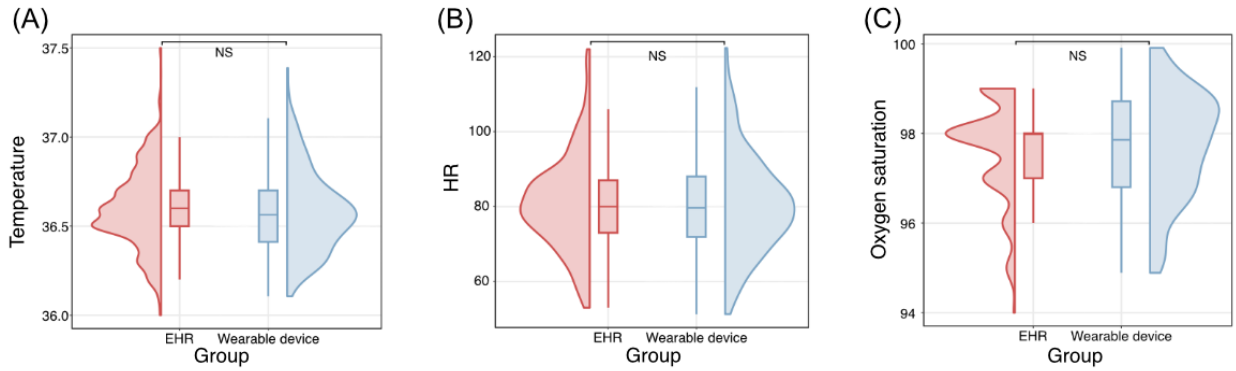
A Bland-Altman analysis was conducted to assess the agreement between wearable device data and electronic health record (EHR; episodic care model) for body temperature, HR, and oxygen saturation. For body temperature, the analysis revealed a minimal bias of 0.02 °C (95% CI –0.01 °C to 0.05 °C), with limits of agreement ranging from –0.47 °C (95% CI –0.52 °C to –0.41 °C) to 0.50 °C (95% CI 0.45 °C to 0.55 °C), indicating strong consistency between the 2 methods (Figure 5A). The agreement for HR showed a bias of 0.26 bpm (95% CI –0.49 bpm to 1.01 bpm), with limits of agreement between –12.71 bpm (95% CI –14.00 bpm to –11.43 bpm) and 13.24 bpm (95% CI 11.95 bpm to 14.53 bpm), reflecting slightly broader variability but overall reasonable alignment between the wearable device and EHR (Figure 5B). For oxygen saturation, the bias was –0.06% (95% CI –0.27% to 0.15%), with limits of agreement from –2.31% (95% CI –2.68% to –1.95%) to 2.19% (95% CI 1.83% to 2.56%), indicating close alignment between the 2 measurement methods (Figure 5C). Paired sample *t* tests confirmed a high level of agreement in the mean values for body temperature (Figure 6A), HR (Figure 6B), and oxygen saturation (Figure 6C), further supporting the reliability of wearable devices in perioperative monitoring. This analysis highlights that wearable devices provide accurate and clinically relevant measurements.

Figure 5. Bland-Altman plot shows the agreement between digital devices and electronic health records (EHRs) in all participants. (A) Body temperature, (B) heart rate (HR), and (C) oxygen saturation. See Multimedia Appendix 1 for a high resolution version of this figure.



XSL•FO
RenderX

Figure 6. Raincloud plot shows the comparison between digital devices and electronic health records (EHRs) in all participants. (A) Body temperature, (B) heart rate (HR), and (C) oxygen saturation. See Multimedia Appendix 1 for a high resolution version of this figure.



Continuous Vital Signs Monitoring: Bridging Gaps in Perioperative EHR Systems

Perioperative records in EHR systems often suffer from discontinuities, with significant temporal gaps in vital sign data. To address this issue, we conducted a systematic review to evaluate the benefits of wearable devices for continuous, 24-hour monitoring of vital signs. Table 2 summarizes the comparative performance of wearable devices in this context.

Table 2. Comparative performance and outliers between electronic health records (EHRs) and wearable devices.

	EHR	Wearable device	*P* value
Body temperature (times)			
Total number per patient	10.00	14,219.04	<.001
Total number per patient per day	3.08	4440.69	<.001
Outliers number per patient	0.23	2707.47	<.001
Outliers number per patient per day	0.07	845.56	<.001
He art rate (times)			
Total number per patient	10.19	4293.75	<.001
Total number per patient per day	2.65	1339.16	<.001
Outliers number per patient	2.08	964.96	<.001
Outliers number per patient per day	0.54	300.96	<.001
Oxygen saturation (times)			
Total number per patient	6.83	6924.67	<.001
Total number per patient per day	1.77	2057.24	<.001
Outliers number per patient	0.17	2644.67	<.001
Outliers number per patient per day	0.04	785.70	<.001

During hospitalization, body temperature, HR, and oxygen levels were measured an average of 3.08, 2.65, and 1.77 times per patient per day, respectively, during ward rounds, leading to 10.00, 10.19, and 6.83 measurements per patient over the course of their stay. In contrast, wearable devices recorded these parameters continuously, providing an average of 4440.69, 1339.16, and 2057.24 measurements per patient per day, with total readings reaching 14,219.04, 4293.75, and 6924.67 times.

The difference in detection sensitivity was particularly notable when comparing outlier detection. For body temperature, the ward rounds identified 0.07 times outliers per patient, per day, whereas the wearable devices detected significantly more outliers, averaging 845.56 times per patient per day. Similarly, HR outliers were recorded at a rate of 0.54 times per patient per day through ward rounds, compared to 300.96 times detected by the wearable devices. For oxygen saturation levels, ward rounds captured 0.04 times outliers per patient per day, while wearable devices identified 785.70 times outliers.

This comparison underscores the advantage of wearable devices in providing continuous, real-time vital sign monitoring, filling the gaps left by intermittent EHR-based records, and enabling earlier detection of critical physiological changes.

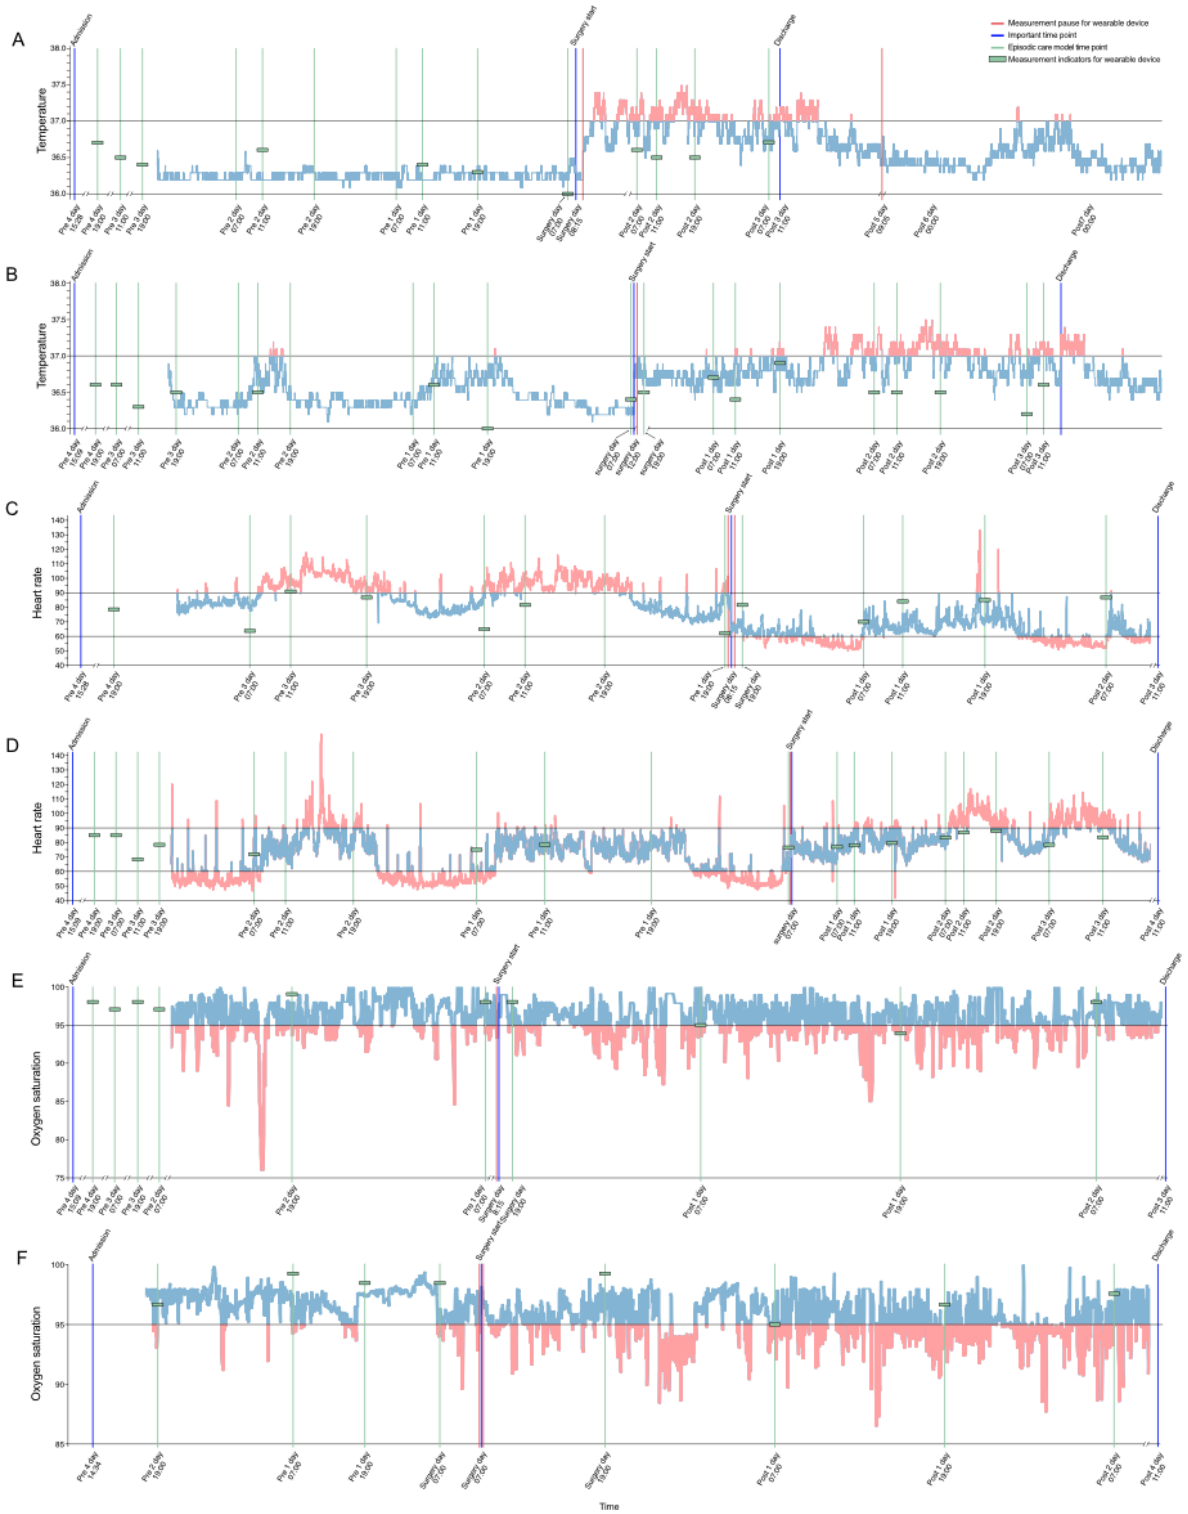
Typical Case Presentation and Comparison

To provide a clearer and more intuitive comparison between episodic care methods and digital devices, we sampled 2 typical cases and visualized their perioperative body temperature, HR, and oxygen saturation levels.

XSL•FO
RenderX

Figures 7A and 7B illustrated the perioperative body temperature trends for both patients. Preoperatively, the medical team assessed body temperature 11 and 17 times, respectively, for each patient, with all readings within normal ranges. Wearable device data closely mirrored these values, with most preoperative measurements also falling within normal limits. Notably, patient #1 maintained a more stable body temperature compared to patient #2, who experienced 2 transient spikes. However, the wearable device detected additional outliers that were missed by conventional monitoring, particularly in the intervals between routine checks.

Figure 7. Typical case presentation of perioperative continuous monitoring and comparison between episodic care method and digital device. (A) Perioperative body temperature trends of case 1, (B) perioperative body temperature trends of case 2, (C) perioperative heart rate (HR) trend of case 1, (D) perioperative HR trend of case 2, (E) perioperative oxygen saturation trend of case 1, and (F) perioperative oxygen saturation trend of case 2. See Multimedia Appendix 1 for a high resolution version of this figure.



XSL•FO
RenderX

Figures 7C and 7D depict the perioperative HR monitoring. The medical team recorded HR 12 and 16 times for each patient, respectively, and noted one outlier in the male patient. In contrast, the wearable device revealed time-specific fluctuations in HR that were not captured by conventional monitoring. Activities such as departmental visits occasionally led to missed measurements, an issue addressed by the continuous monitoring of the wearable device. For instance, in the selected female patient, measurements were missed at 11 AM and 7 PM on April 12, 2023, during which significant HR fluctuations occurred, as revealed by the wearable device.

Figures 7E and 7F show paired perioperative oxygen saturation monitoring. The medical team measured oxygen saturation levels 10 and 8 times for each patient, again noting an outlier in the male patient. The wearable device data showed high consistency with these traditional measurements while also providing continuous, uninterrupted data.

Assessing the Correlation Between Wearable Metrics and ePROs Scores

To explore the potential association between data from wearable devices and ePROs, we conducted a threshold analysis comparing wearable parameters between 2 subgroups, categorized based on the overall ePROs score and 9 subindexes.

Multimedia Appendix 4 summarizes the results of the threshold analysis based on the overall ePROs score. Notably, patients in the high-score group exhibited significantly higher extreme and mean values of HR, as well as lower minimum and mean oxygen saturation levels, compared to those in the low-score group. In addition, the high-score group showed elevated maximum body temperature and poorer sleep quality during the perioperative period. These findings suggest a strong association between elevated physiological stress, as detected by the wearable device, and higher self-reported symptom burden from ePROs.

Further analysis based on the 9 subindexes, detailed in Multimedia Appendix 5, revealed significant differences in extreme and mean values of body temperature, HR, and oxygen saturation levels between subgroups. These results underscore the association of wearable metrics in reflecting the severity of ePROs, providing valuable insights for more personalized perioperative management.

Reported Feasibility and Acceptance of Digital Device

Upon completing the study, all patients were interviewed to assess their experience with the ePROs and wearable devices. Table 3 presents the summarizations of their feedback. Overall, patients reported a positive experience, stating that both the wearable device and the ePRO questionnaires were easy to use, and the device was comfortable to wear and simple to maintain. The primary feedback centered on enhancing the functionality of the wearable device. Patients suggested improvements to the software interface for better usability and recommended adding a blood pressure monitoring feature to further expand the device's capabilities.

Table 3. Feedback regarding the digital device from patient and medical team interviews.

Themes	Interview response
Overall experience	• "It has a positive effect on my preoperative status assessment and postoperative recovery." • "It is non-invasive, I just need to wear the watch as usual and complete the electronic questionnaire." • "It is waterproof, I can even keep wearing it while taking a shower." • "I don't need to charge it frequently, once or twice a week is sufficient, which is very convenient." • "I'm satisfied, medical team can better understand my condition through the wearable device and ePROs, which makes me feel valued."
Device comfort	• "It looks like a watch for daily wear." • "There are different types of watchbands to choose, offering a comfortable, barely noticeable wear." • "It is very lightweight, and I wear it while sleeping without any impacts." • "I can easily fill the questionnaires on my phone, simply selecting options based on my condition. Only takes a few minutes to complete." • "The questionnaire comes with reminder notifications on my phone, ensuring that I don't forget to complete it."
Problems and improvements to the device	• "Plastic watchbands tend to cause swearing when worn outdoors in the summer." • "Is it possible to add a blood pressure monitoring feature?" • "Is it possible to use an infinitely adjustable watchband?" • "Is it possible to combine the wearable device's software with the questionnaire app into one? Download multiple apps can be quite frustrating."
Useful for the medical team?	• "Yes, it would greatly assist the medical team in supplementing critical data amidst their busy work schedules." • "Yes, it can be more objectively reflect the patient's perioperative vital status." • "Yes, it also serves as a motivation for patients. When patients wear the device and complete the ePROs questionnaires, it encourages them to be more proactive in order to achieve feedback and outcomes."

XSL•FO
RenderX

Evaluation of the Digital Device in Patients With and Without Postoperative Complications

Postoperative complications were recorded in 25 (8.7%) out of 288 patients. Of these 25 patients, 13 (52%) experienced air leaks, 6 (24%) developed sustained high fever, 5 (20%) had persistent pleural drainage, and 1 (4%) exhibited poor lung re-expansion. The remaining 263 (31.3%) patients did not report any recordable postoperative complications. The baseline characteristics of patients with postoperative complications were summarized in Multimedia Appendix 6.

Therefore, we performed the subgroup analyses based on patients with postoperative complications. The results of the Bland-Altman analysis demonstrated consistency with the overall findings. The body temperature revealed a minimal bias of –0.02 °C (95% CI –0.33 °C to 0.29 °C), with limits of agreement ranging from –0.33 °C (95% CI –0.44 °C to –0.22 °C) to 0.30 °C (95% CI 0.18 °C to 0.40 °C; Multimedia Appendix 7). The agreements for HR showed a bias of 1.65 bpm (95% CI –1.21 bpm to 4.51 bpm), with limits of agreement between –11.95 bpm (95% CI –16.66 bpm to –7.24 bpm) and 15.24 bpm (95% CI 10.53 bpm to 19.95 bpm; Multimedia Appendix 6). For oxygen saturation, the bias was 0.27% (–0.24% to 0.78%), with limits of agreement from –2.14% (95% CI –2.98% to –1.31%) to 2.68% (95% CI 1.85% to 3.52%; Multimedia Appendix 8). The results of the paired sample *t* test demonstrated a high level of consistency between digital device and EHR measurements in patients with postoperative complications (Multimedia Appendix 7).

We also conducted a subgroup analysis of patients without postoperative complications; their baseline characteristics were summarized in Multimedia Appendix 9. The results demonstrated a high degree of agreement between digital devices and EHR measurements (Multimedia Appendices 10 and 11).

In summary, the results of the subgroup analysis demonstrated a high level of consistency with the overall findings, thereby confirming the robustness of the study's main results. Furthermore, these findings reinforced that the digital device was capable of effectively capturing clinically relevant vital information even in complex clinical settings, supporting its broad feasibility and reliability for clinical application.

Discussion

Principal Findings

This is the first study to investigate the feasibility and reliability of using digital devices, including wearable devices and ePRO questionnaire, in the perioperative management of patients with lung cancer who underwent thoracic surgery. In this study, perioperative recovery was monitored through digital devices. Our results indicated that multimodal data could reflect patients' perioperative status objectively and provide rapid, sensitive outlier detection. This innovation can assist the medical team in optimizing recovery trajectories and achieving the goals of ERAS in the context of the MITS era.

Using prospectively collected data, we systematically mapped the perioperative recovery trajectory of patients with lung cancer who underwent thoracic surgery. Comparison across days revealed significant improvements in the vast majority of parameters, underscoring their critical role in recovery. Notably, the duration of shallow sleep, deep sleep, dreaming, total sleep, and day sleep, as recorded by the wearable device, showed no significant differences across days. However, the sleep quality score significantly improved during hospitalization. This discrepancy aligns with the restless sleep and drowsiness reported via ePROs, which reflect patients' subjective experiences, suggesting a higher level of accuracy [14,15]. Possible explanations include improved sleep structure, fewer sleep-cycle disruptions, enhanced subjective wakefulness and sleep experience, and gradual environmental adaptation. In addition, psychological changes after surgery, such as anxiety and distress, also play a role, as reflected in other ePROs-derived measures.

Although this is a noninterventional study, its potential impact on nursing care and therapeutic procedures holds significant clinical importance. Through the recovery trajectories monitored by wearable devices and ePROs, we were able to capture real-time vital signs and subjective experiences of patients, thereby providing more comprehensive information for clinical decision-making. As a self-reported tool, ePROs effectively reflect patients' subjective experiences, such as anxiety, pain, and activity limitations, and changes in their scores can serve as triggers for interventions. Specifically, when a score in a particular ePROs measure exceeds a set threshold, the nursing team can immediately implement corresponding interventions based on the patient's reported concerns. For example, if a patient reports high pain levels, the nursing team can provide a pain management plan according to the assessment results; if a patient's anxiety score exceeds the threshold, a psychological evaluation and consultation can be arranged. This precision-based intervention model using ePROs enables more individualized care, preventing both overintervention and undercare, thereby more effectively supporting the patient's recovery process. In addition, digital devices can promptly alert nursing staff when vital signs deviate from normal ranges, enabling timely interventions. The integration of ePROs and digital device monitoring data significantly enhances nursing efficiency, optimizes resource allocation, and reduces unnecessary interventions. Future interventional studies will further explore how these monitoring data can be integrated into routine clinical workflows to improve perioperative recovery outcomes and enhance nursing care quality.

Wearable devices are gaining attention in monitoring patients, and the health population has garnered significant attention. These devices are equipped with various sensors and chips designed to track a wide range of data, including HR sensors, accelerometers, gyroscopes, temperature sensors, oxygen saturation sensors, electrode sensors, and ambient light sensors. While their convenience is widely recognized, concerns regarding reliability and data security remain [16,17]. In this study, we conducted pairwise comparisons of body temperature, HR, and oxygen saturation obtained from EHR and wearable devices, respectively. Bland-Altman agreement analysis and

XSL•FO
RenderX

paired sample *t* test analysis demonstrated a high degree of consistency between the 2 modules' data, supporting the reliability, validity, and clinical utility of wearable devices. Subgroup analysis in patients with and without postoperative complications also showed consistency between overall results, further confirming the feasibility and reliability of the proposed digital device approach in this study. This is consistent with previous studies [18-21], including a systematic review by Germini et al [22], which confirmed the accuracy and acceptability of wrist-wearable activity trackers. This review included 65 studies, assessing 14 accuracy-related outcomes. Step count, HR, and energy expenditure were the most frequently evaluated. Fitbit Charge and Fitbit Charge HR (Fitbit Inc) showed the highest accuracy for step counts, while the Apple Watch (Apple Inc) performed better for HR. Acceptability, measured by data availability and wearing time, revealed that Fitbit Charge HR, Fitbit Flex 2, and Garmin Vivofit (Garmin Ltd) had the highest data availability, whereas GENEActiv (Activinsights Ltd) and FuelBank (Nike Inc) had the longest wearing time. Although previous studies, as mentioned earlier, have extensively demonstrated the accuracy and reliability of wearable devices, we acknowledge that in this study, we accepted the credibility of data collection provided by Huawei Technologies and did not conduct further independent validation of these data. Nevertheless, it is important to emphasize that quality assurances provided by manufacturers are not fully equivalent to rigorous independent data validation conducted in academic research. Therefore, the interpretation of our results should consider this specific limitation.

In this study, the wearable device estimated core body temperature by measuring peripheral skin temperature at the wrist. During the development phase, the research team established a mapping model by simultaneously collecting data on both core and skin temperatures. This model was further optimized using physiological and environmental parameters such as HR and ambient temperature. After the stability of the model was validated, it was integrated into the device's algorithm, enabling accurate real-time estimation of core body temperature based on skin temperature readings. In addition, the temperature sensor underwent calibration and performance testing under various environmental conditions to ensure measurement accuracy.

Continuous monitoring offers distinct advantages in perioperative management. In contrast to traditional EHRs, which capture vital signs at discrete time points, wearable devices provide real-time, continuous monitoring and reduce the likelihood of missing critical clinical changes. A key advancement in this area is the development of PPG technology, which has made HR monitoring a reliable and established feature of wearable devices [23,24]. A recent review in the *New England Journal of Medicine* summarized and provided an outlook on wearable digital health technologies for monitoring cardiovascular conditions. The gradual integration of wearable devices into cardiovascular care can support continuous monitoring of patients' vital signs and other physiological parameters, enabling rapid remote monitoring and management. This approach aims to facilitate early detection of disease deterioration, improve perioperative management, and reduce readmission rates [25]. Guo et al [26] evaluate the effectiveness of PPG technology integrated into wearable devices for detecting AF in a large population-based cohort across China. This study included 187,912 participants who monitored their pulse rhythm using a HUAWEI smartwatch for at least 14 days. Results showed that 0.23% (424/187,912) of the participants received a "suspected AF" notification, with 87% of cases confirmed as AF through clinical evaluation, yielding a positive predictive value of 91.6%. The study concluded that continuous home monitoring with PPG-based wearable devices is a feasible and effective method for early AF detection, enabling timely interventions to reduce AF-related complications. On the basis of these findings, wearable digital health technologies have been recommended for cardiovascular monitoring in the 2020 European Society of Cardiology guidelines [27].

In the perioperative management within the surgical community, wearable devices have shown promise across various surgical disciplines. Beqari et al [28] conducted a pilot study with 56 patients who had undergone cardiothoracic surgery to evaluate the effectiveness of the "NightSigal" algorithm. Patients were asked to wear a Fitbit watch for at least 1 week preoperatively and up to 90 days postoperatively to collect biometric data. The algorithm detected 17 out of 21 postoperative events, with a median detection time of 2 days before symptom onset. Sensitivity and specificity were 81% and 75%, respectively. Ghomrawi et al [29] assessed the use of Fitbit to monitor the postoperative complications in patients who have undergone pediatric appendectomy. The combined predictive ability for complex appendicitis was an area under the curve of 0.80, compared to 0.70 for simple appendicitis. Kane et al [30] examined activity monitors for predicting 30-day readmission by tracking activity levels before and after surgery. Readmitted patients showed lower return to baseline activity compared to nonreadmitted patients. After adjusting for cofounders, multivariable analysis demonstrated that returning to baseline activity was associated with a reduced risk of 30-day readmission. The model had a sensitivity of 75% and a specificity of 74%.

Despite the advances seen in other surgical fields, the utility of wearable devices in patients with lung cancer undergoing thoracic surgery remains underexplored. Our findings revealed that outliers in vital signs, such as fluctuations in body temperature, HR, oxygen saturation levels, and other key metrics, occurred between the time points of EHR monitoring. Implementing robust continuous monitoring and alarm mechanism could enable the medical team to better track patients' baseline vital signs, thereby facilitating ERAS protocols.

Effective outlier detection in this study relied on a 2-tier strategy that integrated device-embedded safeguards with protocol-level quality control. First, at the hardware–algorithm tier, the wrist-worn HUAWEI WATCH D combined (1) an upgraded TruSeen 5.0+ optical module—8 circumferential photodiodes, dual LEDs, a Fresnel film, and a curved 2.5-D sapphire or physical vapor deposition back—plus the TruBP pressure system [31], and (2) a HiFi-Encoder deep learning pipeline that discards frames whose signal-quality index is <0.8; together these

XSL•FO
RenderX

measures cut motion-related signal loss to one-quarter of that in the previous generation and yielded HR accuracies of 98% (≤10 bpm) and 95% (≤5 bpm) during vigorous movement. A dual-mode PPG-electrocardiography architecture driven by a high-performance chip was trained on large baseline datasets collected in rest, exercise, commuting, sleep, heat, and underwater conditions; it has already demonstrated a 92.8% positive predictive value for AF detection in >3.2 million participants and is cited in the 2020 European Society of Cardiology AF guidelines [27], while independent testing confirmed full compliance with ANSI/AAMI/ISO 81060-2:2018 [32]. The device is further supported by class II approval from China's National Medical Products Administration and European Union Medical Device Regulation certification. Second, at the study-design tier, intensive patient training and ward-level adherence checks led to exclusion of 13 poorly compliant participants; temperature, HR, and oxygen-saturation readings were cross-validated against EHR values to confirm accuracy; and continuous data were aggregated into 1-minute maxima, minima, and means, with outliers defined as minute-averaged temperature >37°C or <36°C, HR >90 or <60 bpm, or oxygen saturation <95%. This minute-level preprocessing attenuated sporadic spikes and focused analyses on sustained, clinically meaningful deviations. Collectively, the 6 elements—noise-reduction hardware, real-time AI filtering, extensive algorithm training, external validation and regulation, adherence management, and time-series preprocessing—provided a robust framework for distinguishing true physiological outliers from artifacts, thereby reinforcing the reliability and clinical applicability of our perioperative monitoring results.

The benefits of integrating EHRs with wearable devices are gradually becoming more apparent. Building on this foundation, we further incorporated ePROs to develop a multimodule perioperative monitoring network. Previous studies have demonstrated that patient reported outcomes (PROs) can effectively capture various aspects of a patient's perioperative status, such as sleep, fatigue, and drowsiness [33]. Dai et al [8] conducted a multicenter, randomized controlled trial demonstrating the feasibility and effectiveness of PROs-based symptom management in patients who underwent lung cancer surgery. In the early recovery phase, PROs-based groups experienced significantly fewer symptom threshold events at discharge within 4 weeks after discharge, with a lower incidence of complications, highlighting their potential to reduce symptom burden and complication rates. Earlier this year, Dai et al [9] updated the long-term follow-up results, showing that ePROs groups had a lower symptom burden and higher physical and emotional function scores over a follow-up period of 1 to 12 months compared to usual care.

In this study, we introduced a threshold analysis to stratify patients based on the ePROs overall score and subindexes. Most vital signs and physiological parameters measured by the wearable device showed statistically significant differences between the high and low ePROs score groups, suggesting a potential relevance between various digital device modules. This highlights the advantages of using multimodal data to comprehensively assess the perioperative recovery status of patients who underwent lung cancer surgery.

Our study also highlighted the potential economic benefits of the digital device–based continuous monitoring system. By enabling early detection of complications and timely interventions, the system may shorten hospital stays and reduce associated costs. Its integration into perioperative workflows can also alleviate nursing workload and improve resource efficiency. Furthermore, the use of the HUAWEI WATCH D, a certified medical-grade wearable device covered by the National Medical Products Administration, enhances the feasibility of large-scale clinical implementation.

The acceptability, usability, and comfort of digital devices are crucial determinants of their successful clinical implementation [25]. In this study, feedback from both patients and medical staff was largely positive, with participants acknowledging the ability of digital devices to gather detailed perioperative data without disrupting daily activities or routine care. Concerns were raised regarding the stability of the devices and the potential influence of external factors, such as physical movement, on data accuracy. Addressing these challenges through future technological advancements will be essential to ensuring the reliability of wearable devices in clinical practice.

To address these limitations and further enhance the robustness of digital perioperative monitoring, our study integrated ePROs as a complementary data modality alongside wearable devices. While wearable devices continuously captured objective physiological parameters such as HR and oxygen saturation, ePROs provided direct insights into patients' subjective symptoms and functional status, including pain, fatigue, and sleep quality. The design of combining sensor-based and self-reported data improved the overall reliability and interpretability of perioperative monitoring. Moreover, this integration supported seamless, minimally burdensome data acquisition and enabled more individualized recovery profiling. In future applications, this multimodal framework may also contribute to the development of more accurate and generalizable predictive models for surgical recovery.

There are several limitations in our study that warrant acknowledgment. First, this was a single-center, prospective, self-controlled study conducted among patients undergoing thoracic surgery, which limited the generalizability of the results to other populations. However, our findings provide a foundation for future multicenter clinical trials. Second, all patients enrolled were required to own and operate a smartphone and to have a basic understanding of the functions provided by the wearable device; while the research team made every effort to provide technical support and detailed assistance to all potentially eligible patients, we acknowledge that individuals with limited technological literacy, including some older adults, may have been excluded, which highlights the importance of future research into the usability and compliance of wearable technologies across diverse patient demographics. Third, although the 2-tier strategy of device-embedded safeguards coupled with protocol-level quality control used in this study could identify and manage most potential artifacts in the wearable-device data, we acknowledge that residual false

XSL•FO
RenderX

positive and false negative readings may still have influenced the study's results and conclusions. Fourth, although the wearable device used in this study was the first wrist-worn wearable device to receive class II medical device certification, the blood pressure measurement function required the patient to perform the measurement autonomously. This could potentially lead to frequent measurements that might affect blood circulation or result in missing or reduced data quality if measurements were not taken according to the study protocol. After careful consideration, to avoid interfering with the normal treatment process of the patients, we ultimately decided not to include blood pressure as one of the planned measurement outcomes in this study. Previous studies have demonstrated the safety and feasibility of using the HUAWEI Watch D for blood pressure measurement, which could compensate for the lack of blood pressure monitoring data in this study [21]. In the future, we will explore the clinical application of dynamic blood pressure monitoring for patients who underwent thoracic surgery using this device within a safer clinical framework. Fifth, individualized perioperative nursing interventions may have introduced outliers in the digital device–recorded data. For example, postoperative pain and the use of analgesics may have affected HR readings. Although this study used a multimodal monitoring approach to objectively reflect patient recovery from multiple perspectives and conducted a subgroup analysis to further verify the robustness of the findings, achieving real-time consistency and alignment between individualized perioperative clinical management and the parameters monitored by digital devices remains one of the key challenges for future research.

Conclusions

Within the perioperative management of patients with lung cancer under the ERAS framework, the digital device composed of wearable devices and ePROs demonstrated feasibility and reliability in the continuous perioperative monitoring of patients who underwent lung cancer surgery. Our study offered a novel approach for multimodal, continuous perioperative monitoring, thereby laying the foundation for future research.

Acknowledgments

The authors express their appreciation to all participants in this study; they also sincerely appreciate the technical staff from HUAWEI for generously answering their questions regarding the technical details of the devices. This study was supported by the R&D Program of Guangzhou National Laboratory (grant SRPG22-017). The writing and visualization in this study were entirely completed by the research team without the use of generative artificial intelligence for text or figure generation. ChatGPT was consulted for suggestions regarding code modification and error handling, and the final implementations were independently conducted based on the advice provided.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to institutional regulations concerning patient data but are available from the corresponding author upon reasonable request.

Authors' Contributions

JH is the co–corresponding author and can be reached at hejx@vip.163.com. RW, WG, and HL were responsible for the conceptualization. JZ, HH, WG, Y Li, ML, and QZ were responsible for data curation. RW, WG, Y Lin, and YF were responsible for the formal analysis. JH was responsible for funding acquisition. RW, HH, YC, and HL were responsible for the investigation. RW and YJ were responsible for the methodology. YH, JH, and HL were responsible for the project administration. KC was responsible for software. YC, JH, and HL were responsible for resources. WG, JH, and HL were responsible for the supervision. JZ, HH, and YF were responsible for validation. RW, LH, and ZY were responsible for visualization. RW and QW were responsible for writing—original draft. HD, YH, and HL were responsible for writing—reviewing and editing.

Abstract

Background: Surgical procedures and their potential complications place substantial strain on patients, clinicians, and health care systems. These strains are driven by the anticipated morbidity and mortality, so that there is resource-intensive postoperative inpatient management. Given the concentration of surgical services within hospital settings, current standard levels of care have limitations such as communication gaps, time lapses before evaluation, and investment of resources, which limit accessibility and generate disparities in delivery of care. However, recent advances in digital health, including telemedicine platforms, mobile health (mHealth), and wearable technologies, present an opportunity to decentralize and extend perioperative care into community settings. This review explored how established mHealth technologies are being integrated into the perioperative pathway and their impact on surgical care delivery and outcomes. It also highlights possible emerging models of remote physician and patient interaction where benefits seem to be outweighing the risks.

Objective: The aim of this narrative review was to present collected evidence for the use of established mHealth technologies in the surgical pathway of patients and highlight their readiness and potential in models of standard care.

Methods: A comprehensive literature search was conducted across MEDLINE (via PubMed), Web of Science, and Scopus databases between October 2022 and May 2024. Additional sources were identified through reference list screening of relevant systematic reviews. Data were extracted and analyzed based on surgical specialty, type of mHealth intervention, cost-effectiveness, and ethical considerations. Findings were summarized in tables to illustrate key trends and variations across studies. The extracted data were tabulated and described qualitatively to highlight similarities, differences, and possible emerging trends across the studies.

Results: A total of 28 articles published between 2008 and 2022 were included for qualitative analysis, with most (n=21, 75%) originating from the United States, Germany, and the United Kingdom. The study designs were predominantly randomized controlled trials (n=9, 32%) and observational studies (n=8, 29%). Collectively, these studies involved 6344 patients undergoing mHealth-based perioperative interventions primarily in general surgery, orthopedics, and oncology. Interventions frequently used smartphones (n=10, 36%) and wearable devices, often in combination with other tracking and measuring systems. Applications included wound monitoring, postoperative follow-up, and patient education. Data collection was multimodal and typically conducted daily, yet only 36% (10/28) of the articles reported defined follow-up periods. Cost-effectiveness was rarely assessed, with only 4% (1/28) of the articles reporting per-patient savings. Overall, 64% (18/28) of the articles were rated as low quality due to methodological limitations.

Conclusions: mHealth- and telehealth-based interventions show promise in enhancing aspects of perioperative care by enabling remote monitoring, patient engagement, and improved care continuity. Future research should focus on scalable implementation,

XSL•FO
RenderX

true cost-effectiveness analysis, equitable access, and integration into clinical workflows to ensure broad applicability in current models of care.

Introduction

Background

Surgical procedures and associated complications impose a significant burden on patients, treating teams, and health care systems that are related to the associated morbidity and mortality of the illness and treatment [1,2]. Consequently, there is a need for surgical management and follow-up to be conducted as inpatient care, where there is a wide availability of resources to attend to the circumstances in the patient surgical pathway. As procedures and aftercare are delivered at focal points (hospitals) where patients and resources are located, the number of patients assessed and treated is limited, and available resources vary greatly among institutions, cities, and countries, which places an important limitation on the standard of care worldwide [1-3].

The rapid progression of digital technology and artificial intelligence and the creation of new wireless wearable devices in recent years has initiated a transformation across numerous industries, and health care is now experiencing firsthand a transformation of its own [4]. Advances in mobile health (mHealth) technologies have allowed components of the care for patients to be adequately conducted away from the traditional hospital settings [5]. Telemedicine, mHealth, and similar technologies are a rapidly growing area where existing mobile technology is applied to aspects of standard care so that the same service can be provided in the community in a safe and tailored environment [5,6]. Despite innovations in digital technology, the surgical domain has understandably approached the integration and implementation of new and potentially revolutionary technologies with caution given the immediate and direct implications for patients' safety [7]. There is an increasing overwhelming need for community-based postsurgical care to be provided in settings where there is a higher level of patient comfort and convenience and be tailored to the individual's needs.

Given that the current standard of care for most surgical patients following hospital discharge does inherently present limitations such as communication gaps, time lapses before evaluation, and investment of resources, strategies in the perioperative setting can be analyzed at many levels to improve their efficiency and effectiveness. In this sense, mHealth strategies applied to the surgical patient pathway display great diversity in goal setting and applications, with hypothesized consequential improvements in patients' perioperative well-being and management of health changes [8-10]. In addition, the redistribution of the service burden can inherently impact the health economic budget distribution positively by redirecting inpatient hospital resources to those in most need [8,10].

There is already a great deal of technologies used in the community setting that can be accessed for health needs [4-6]. Data networks already exist to create, access, and securely transfer data remotely from individuals or care centers. The ubiquitous use of smartphones and wearable devices already offers the opportunity for medical data to be collected and stored in a more reliable, agile, and effective way [11]. These technological conditions paired with the good digital literacy in the community enable digital education, transition, and uptake rates to be more feasible. There is some available evidence that demonstrates that highly complex tasks within the hospital, such as performing a surgical procedure and monitoring patients with acute complex conditions, can now be performed remotely in a safe manner [12]. Mobile technologies can also provide the technological link to a remote group of medical experts, increasing the interconnectedness and globalization of health care as well as access to specialist care in remote areas [13].

Objectives

Given the readiness of the existing technologies and their potential, it is worth evaluating their application within the perioperative field. In this narrative review, we aimed to answer the questions of how already established mobile technologies (mHealth) can assist in the perioperative care of surgical patients, what their potential is for change in management, and what the different implementation possibilities are within the physician-patient interaction model. We collated research in which innovations were applied as interventions and outcomes were qualitatively analyzed.

Methods

Search Strategy

A comprehensive literature search was conducted between October 2022 and May 2024 across 3 electronic databases: MEDLINE (via PubMed), Web of Science, and Scopus. The search strategy was developed collaboratively by the study investigators and an academic research librarian to ensure methodological rigor.

The search combined controlled vocabulary terms (eg, MeSH [Medical Subject Headings]) and free-text keywords related to surgical specialties, general surgery, postoperative and preoperative care, ambulatory monitoring, telehealth, telemonitoring, telemedicine, remote consultation, mHealth, and digital health interventions. Synonyms and related terms were used in combination with Boolean operators (AND and OR) to broaden retrieval sensitivity. The search was limited to English-language publications from January 1, 2000, onward. The detailed search strategy for MEDLINE is provided in Multimedia Appendix 1. The search terms and syntax were

XSL•FO
RenderX

adapted to Scopus and Web of Science using database-specific indexing systems and search functions.

In addition to database searching, the reference lists of relevant systematic reviews were screened to identify additional studies meeting the inclusion criteria.

Study Selection

This narrative review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. After duplicate removal, titles and abstracts were independently screened by 2 reviewers (HT and MCS) to attain the final cohort of studies. Full-text articles were then retrieved and assessed against predefined inclusion and exclusion criteria (Textbox 1). In cases in which abstracts were unavailable or the available data were insufficient to determine relevance, the full article was reviewed and cross-checked against the research question and the predetermined eligibility criteria. Disagreements during the screening process were resolved through discussion between the 2 main researchers or consultation with a third reviewer (JS) when deemed relevant.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- English-language studies
- Human participant studies
- Original (new) data presentation and analysis

Exclusion criteria

- Studies that required the clinical team to be present in real time for the device to function
- Articles in languages that were not English
- Studies that involved patients with chronic illnesses
- Literature review articles
- Animal studies
- Studies on intraoperative interventions
- Study protocols
- Conference abstracts for which data could not be obtained
- Studies on telementoring
- Studies on remote monitoring by clinicians rather than remote monitoring performed by the patients

Eligibility Criteria

Eligible articles were required to be original research papers published in English reporting studies involving human participants and presenting primary data analysis. Studies were excluded when the publication was in a language other than English, involved populations with chronic illnesses, or based their research on animal models. Other types of evidence such as literature reviews, study protocols, or conference abstracts lacking accessible data or studies that focused mainly on intraoperative interventions were also not deemed appropriate for data analysis. Articles that described telementoring or studies that involved remote monitoring by clinicians rather than patients were also excluded. This review was restricted to publications made from the 2000s onward to capture advancements in mHealth technologies (Textbox 1).

Quality Appraisal

Although this is a narrative review, quality assessment was conducted to evaluate the strength and rigor of the evidence within the domains of mHealth and telemedicine. This step was deemed essential due to the emerging nature of these technologies and their growing relevance to contemporary models of care and intervention. Quality appraisal was undertaken independently by the researchers using criteria such as study design, risk of bias, potential confounding, allocation concealment, selective outcome reporting, loss to follow-up, early study termination, and imprecision of results. The appraisal was conducted under the framework and principles outlined in the article *Grading quality of evidence and strength of recommendations in clinical practice guidelines* [14]. Any discrepancies in quality rating were resolved through discussion. In accordance with the PRISMA guidelines and standards for reporting, transparency, and reproducibility, a summary of the quality assessment is provided in Multimedia Appendix 2 [10,15-41].

Data Extraction

Data were extracted from full-text articles using a standardized extraction form developed specifically for this review to ensure consistency throughout the data collection process. Extracted data included publication details, surgical subspecialty, study design, sample size, technology used, metrics assessed, data collection frequency, and follow-up duration. Additional data points included patient satisfaction, safety outcomes, complication rates, cost analyses, and ethical considerations.

Data extraction was carried out independently by the 2 primary reviewers (HT and MCS) using Microsoft Excel. Any

XSL•FO
RenderX

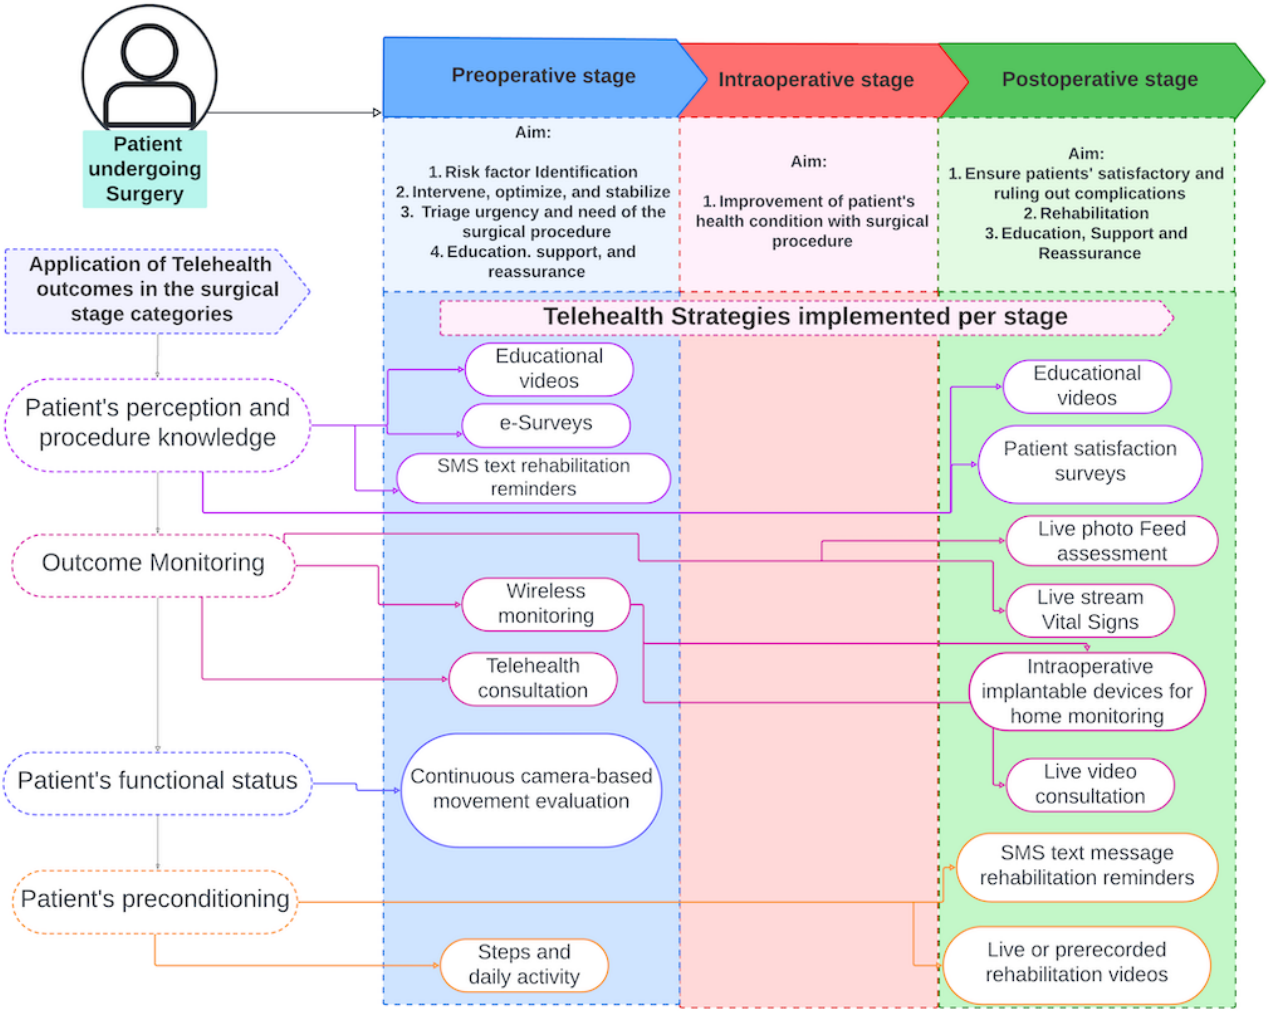
discrepancies were addressed through discussion. No automation tools were used for data extraction purposes.

Synthesis of Results

A narrative synthesis was undertaken to summarize the findings of the included studies. Results were grouped thematically based on surgical specialty, type of mHealth or telemonitoring technology used, cost-effectiveness, and ethical considerations. The extracted data were tabulated and described qualitatively to highlight similarities, differences, and possible emerging trends across the studies.

No meta-analysis was conducted due to the heterogeneity of study designs, outcome measures, and interventions. Where applicable, illustrative examples were provided to contextualize the findings and support interpretation (Figure 1).

Figure 1. Patient surgical pathway (preoperative stage, intraoperative stage, and postoperative stage).



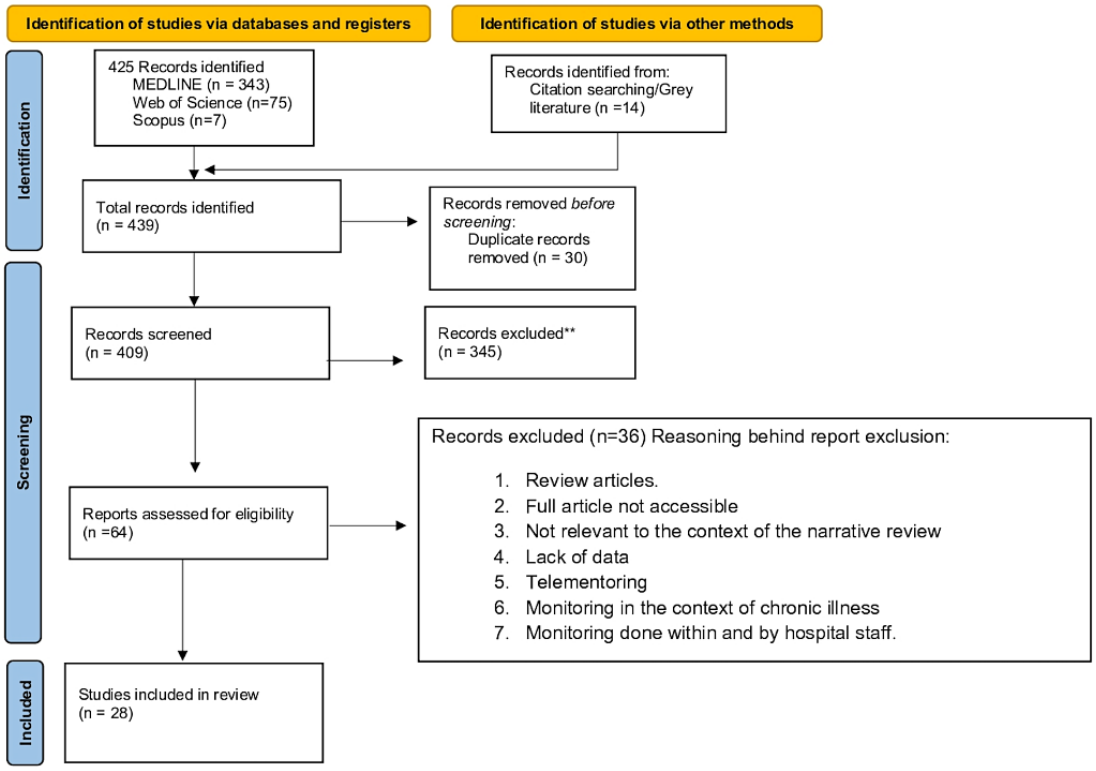
Results

Study Selection

A total of 439 records were initially identified through database searching (n=425, 96.8%) and gray literature (n=14, 3.2%). After removal of 6.8% (30/439) of duplicates, 409 articles remained for title and abstract screening, from which 64 (15.6%) publications were deemed potentially relevant and underwent full-text review, as exemplified in Figure 2. Following eligibility assessment, 56% (36/64) of the articles were excluded due to lack of relevance to the narrative review, lack of accessible full text, insufficient data, focus on telementoring, or focus on monitoring in the context of chronic illnesses. A final selection of 44% (28/64) of the full-text articles was retained for data extraction [10,15-41]. A table with full disclosure of the selected references can be found in Multimedia Appendix 3 [10,15-41].

XSL•FO
RenderX

Figure 2. PRISMA flowchart describing the screening methodology for the articles selected for this review. **No automation tools were used; all references were screened by title and abstract by the two main researchers (MCS and HT). These articles were not deemed relevant based on the title and abstract. Image adapted from Page et al [42].



Study Characteristics

The 28 included articles for data extraction were published between 2008 and 2022, and more than half (n=21, 75%) predominantly originated from the United States, Germany, and the United Kingdom. These countries had a publication upsurge from the year 2013 onward (Table 1).

Of the 28 included publications, 9 (32%) were randomized controlled trials, representing the highest level of evidence. Observational studies accounted for 29% (8/28) of the articles, and prospective and retrospective cohort studies each accounted for 4% (1/28) of the articles. Table 1 exhibits a trend toward higher levels of evidence in publications from 2018 onward when compared to previous years.

The included articles predominantly reported mHealth and telemonitoring strategies across 3 main specialties: general surgery, orthopedics, and oncology (Table 1). The most represented specialty was general surgery with 25% (7/28) of the studies, followed by orthopedics with 18% (5/28) of the studies and oncology with 11% (3/28) of the studies. Other specialties, including vascular surgery, obstetrics, procedural dermatology, and plastic surgery, each accounted for 7% (2/28) of the studies. Additional fields such as urology, transplant surgery, and nursing were each represented by 4% (1/28) of the studies.

Study Populations and Sample Sizes

Across the 28 studies, a total of 6344 patients participated in mHealth-related surgical research. Study cohorts varied widely in size, ranging from ≤50 patients to ≥1000 patients. As shown in Table 2, most studies had small sample sizes, with 46% (13/28) including ≤50 patients. In contrast, only 7% (2/28) of the studies recruited sample sizes as large as ≥1000 patients. Studies with intermediate sample sizes (51-500 patients) were the second most common type encountered in the collected evidence, representing 36% (10/28) of the selected studies.

Of the 28 articles deemed relevant, 14 (50%) reported the use of multidevice strategies for patient monitoring. These strategies combined smartphones, computers, tablets, smartwatches, and other unique wearable devices for outcome measurement (Table 2). Figure 1 provides a visual summary of the strategies assessed and implemented across the patient surgical pathway.

[a]SSI: surgical site infection.

Devices and Outcome Measurement

Several studies (5/28, 18%) focused on unique wearable devices for functional outcome measurement. Kayaalp et al [20], Chiang et al [26], and Calliess et al [32] validated new wearable-based gait kinematic analysis systems to assess functional recovery, implant longevity, and quality of life after total knee arthroplasty. Kayaalp et al [20] demonstrated that a new wearable system for knee function monitoring in healthy individuals showed comparable accuracy to that of motion capture systems, enabling postoperative mobility monitoring without restricting daily activities. Chiang et al [26] and Calliess et al [32] further supported the feasibility of wearable devices for continuous, objective assessment of functional outcomes.

The second most frequently reported mHealth strategy was the use of smartphones alone. Their use was reported in 36% (10/28) of the articles. Most smartphone-based interventions (10/28, 36%) revolved around web-based wound care and early detection of surgical site infections through photographic monitoring (3/28, 11%).

Henarejos et al [16] evaluated the effectiveness of an mHealth wound care education program in low- and middle-income countries using photographic monitoring to capture wound images during a 30-day follow-up. The images were shared with surgical teams via a digital exchange platform for timely intervention based on a color-coded classification system. The intervention resulted in a 19.1% reduction in surgical site infections despite study limitations associated with small sample size, loss to follow-up, and challenges related to health care infrastructure.

McLean et al [17] and Gunter et al [33] investigated smartphone-based models as assessment tools for early wound care, diagnosis, and intervention applied in the postoperative stage. McLean et al [17] focused on emergency abdominal surgery outcomes, including time of diagnosis, wound review attendance, and infection severity, whereas Gunter et al [33] focused on user satisfaction and validated a smartphone-based model as a wound monitoring system in vascular surgery. Both studies concluded that a smartphone-based model enabled postoperative follow-ups, early postoperative interventions, triage to appropriate care levels, and patient satisfaction.

Similarly, Hee Hwang and Mun [39] and Engel et al [15] explored smartphone-based models for remote free flap monitoring. Hee Hwang and Mun [39] demonstrated that smartphone-based flap assessment improved early diagnosis of flap compromise, increasing flap salvage rates from 96.2% to 100% and reducing reintervention times to 1.4 hours compared to a baseline of 4 hours. Engel et al [15] further validated the use of smartphone-based models as assessment systems and provided comparable accuracy rates, with shorter response times than those in in-person examinations.

Smartphones were also evaluated in the collection of data relevant to patient-centered outcomes, including rehabilitation, compliance, patient satisfaction, wound care reminders, and adherence to postsurgical rehabilitation programs. The studies by Hawkins et al [21], Segura-Sampedro et al [24], and Chee et al [28] appraised patient acceptance of smartphone-based models for follow-up. Segura-Sampedro et al [24] found that telemedicine-based follow-up services had a high sensitivity and specificity, supporting their feasibility and safety. Collectively, these studies reported reduced patient anxiety, improved postsurgical care understanding, and high acceptance of a self-monitoring program.

Although tablet-based interventions were less common, they were primarily used for patient satisfaction assessment and symptom tracking. Ertel et al [30] analyzed the feasibility of a video-based educational program and a telehealth monitoring model for post–liver transplantation care, including postoperative care management and readmission rates. The study concluded that the intervention was feasible, improved vital statistic maintenance, and enhanced patient awareness of preoperative and postoperative care management.

No articles identified in the literature search reported the use of artificial intelligence–based data capture, analysis, or monitoring.

Data Collection and Metrics

As shown in Table 2, the studies used a wide and variable range of data collection methods, including surveys, questionnaires, photos, rating scales, and scoring systems. In total, 50% (14/28) of the studies used a combination of these metrics to assess patient-reported outcomes, satisfaction levels, attitudes toward mHealth interventions, home monitoring, and pain or disability.

For instance, Khoshrounejad et al [25] investigated the impact of an SMS text message–based rehabilitation program after corrective hand surgery using questionnaires and rating scales to measure variables such as pain, disability, physiotherapy adherence, and patient satisfaction. The intervention demonstrated increased motivation for self-directed rehabilitation. Nevertheless, reduced rehabilitation session attendance was noted.

The studies by Schramm et al [22], Sun et al [27], and Card et al [38] all used combined metrics for patient-centered outcomes using clinical measures. The study conducted by Sun et al [27] demonstrated that wireless monitoring programs involving real-time symptom tracking and mobility and quality of life assessment could be applied effectively among patients with cancer undergoing major abdominal surgery. Furthermore, wireless monitoring programs facilitated early intervention, enhancing perioperative care when applied across the patient surgical pathway (Figure 1) by detecting real-time changes in symptom severity, mobility, and quality of life.

Data collection frequency varied, with 50% (14/28) of the articles reporting near-daily data collection (Table 2), whereas 11% (3/28) of the articles reported medium-term data collection (more frequently). Measurement duration variability was dependent on the parameters measured; for example, symptom burden, disability, rehabilitation progress, and patient satisfaction were commonly assessed over longer follow-up durations.

XSL•FO
RenderX

Despite frequent data collection being reported in most articles, 29% (8/28) of the articles did not report a follow-up period, leading to the assumption that data collection ended at patient discharge. Among the 36% (10/28) of the articles that specified a follow-up time frame, monitoring ranged from 72 hours to 1 month after surgery.

Economic Outcomes and Cost-Effectiveness

Only 7% (2/28) of the studies attempted to evaluate cost-related outcomes, with the study by Rosner et al [37] being the only one to systematically assess the financial impact of mHealth strategy application. The multicenter observational cohort study examined cost reductions in a 90-day period associated with an automated digital patient engagement platform in patients undergoing hip and knee arthroplasty. The intervention led to mean cost savings of US $656.52 per patient along with a relative reduction in 90-day readmission rates, hospitalization costs, and postoperative complications.

Barber et al [41] assessed telemetric intracranial pressure monitoring systems, which enabled home-based prolonged and safe intracranial pressure monitoring in neurosurgical patients. The system provided early reporting of combined outcomes across the preoperative and postoperative periods in the patient surgical pathway. Outcomes assessed included detection of clinical positive patient experiences, financial outcomes related to the outlay during pre- and postimplantation, and patient events. Clinical outcomes such as clinical events and associated complications were also deemed relevant for assessment. The system implementation yielded cost benefits by reducing unnecessary investigations.

Quality of Evidence

The quality assessment of the selected studies is detailed in Multimedia Appendix 2. This was conducted by the main researchers individually, and 64% (18/28) of the selected studies were classified as low-quality evidence. Common methodological limitations included study design issues, lack of blinding, publication and selection bias, and small sample sizes, which limited the strength of associations. mHealth research is concentrated within certain surgical specialties and typically limited to a single stage of the patient's pathway, mostly the postoperative period. As a result, its generalizability is limited, since findings cannot be easily applied across other specialties or the entire surgical pathway in different models of care.

Discussion

Principal Findings

Overview

Digital health care technologies, including mHealth strategies and telehealth, represent a rapidly evolving area where technology and health care intersect across the perioperative surgical care continuum. This narrative review highlights the significant opportunities that these technologies offer to enhance perioperative surgical care, particularly in the context of increasing health costs, limited inpatient resources, and the complexity of modern surgical procedures [43,44].

While telemedicine and remote consultation are already well integrated and show established benefits in clinical settings such as clinics, emergency departments, and rural trauma systems [15,45,46], this review demonstrated how successful digital health care technology implementation across the patient surgical pathway can be, impacting areas such as communication, patient convenience, and cost-effectiveness and care outcomes. The implementation of these technologies could streamline follow-up care and rehabilitation and significantly impact gaps in traditional surgical care, with the potential to substitute some components of inpatient care in a community setting.

Devices and Outcome Measurement

mHealth interventions often leverage common consumer technologies such as smartphones, tablets, smartwatches, and computers without requiring specialized or complex infrastructure. For instance, McGillicuddy et al [18] demonstrated how smartphones combined with wireless blood pressure monitors and medication trays supported postoperative care in patients undergoing transplants. Innovative approaches in the orthopedic field also showed promise, with 7% (2/28) of the studies developing and validating technologies for motion assessment in orthopedic care. These systems provided a cost-effective alternative to the gold-standard camera-based gait analysis systems using mobile technology, offering greater accessibility to patient condition assessment.

In the preoperative stage of the surgical patient journey, mHealth interventions improved new measuring strategies for patient engagement, assessment, and consistency and facilitated prehabilitation, as well as encouraging new modalities to provide informed consent and education. They also aided and positively influenced patients' behavior, expectations, and compliance, aspects that highly influence the postoperative stage, potentially leading to future complications or truncated recovery if not handled adequately. Hawkins et al [21] found that tailored educational videos reduced procedural anxiety and improved wound care understanding. Similarly, Migden et al [47] reported that preconsent video education enhanced consultation efficiency and patient satisfaction. Furthermore, preoperative SMS text messages were shown to support medication adherence and treatment continuity [48,49]. The implementation of these strategies demonstrates how digital tools can positively influence patient outcomes and impact surgical ones.

Postoperative applications focused on remote monitoring, rehabilitation, and complication detection. Studies demonstrated benefits in patient-led rehabilitation, early complication detection through virtual wound care, functional recovery tracking via wearables, enhanced symptom reporting and triage, assessment of return to function and quality of life, and supporting patient education and self-management.

Considering the potential for communication gaps between patients and care teams during the first 2 to 3 weeks after patient discharge, interventions that facilitate detection of complications within the patients' journey toward recovery, as well as early communication of rehabilitation modifications and recommencement of individual daily life activities, offer an opportunity for mHealth systems and groundbreaking

XSL•FO
RenderX

technologies to be explored and applied. Several studies (18/28, 64%) highlighted the effectiveness of mHealth in this matter [50,51]. For instance, Khoshrounejad et al [25] found that SMS text message–based rehabilitation systems improved short-term hand function following tendon repair, whereas Chen et al [52] reported improved rehabilitation adherence and range of motion in patients with frozen shoulder who received motivational SMS text messages.

Wearable devices were particularly useful when assessing functional monitoring during early rehabilitation by offering synchronous and objective data collection. This approach addressed the often poor correlation between subjective self-report and actual physical activity, laying the groundwork for mHealth interventions to assist in more accurate, patient-centered recovery monitoring [29].

Wound care has emerged as a promising area for virtual monitoring, leveraging mobile device use to detect early complications and escalate standard care practices accordingly. Studies have shown that smartphone-based imaging models for wound assessment are equivalent to in-person examination even for complex wounds such as pressure ulcers [53]. Data highlight benefits such as travel time reduction, time-efficient triage, and greater health care provider productivity [53-55]. These findings support the plausible and potentially efficient integration of digital photography into standard wound care protocols [33].

Data Collection and Metrics

Multidevice systems improve measurement accuracy and response timeliness of patients to clinicians. McGillion et al [34] found that, although remote automated monitoring technology did not increase *days alive at home* after surgery, it enabled early identification and correction of medication errors, reduced pain levels, and lowered readmission and emergency visits within 30 days. These outcomes underline the acceptability of technological implementation in the context of virtual care by patients and physicians, as well as the potential cost-effectiveness of remote automated monitoring technology in postoperative care [34].

Finally, mHealth system implementation has also proven to positively impact quality of life and return to baseline function. Basch et al [35] demonstrated that web-based symptom reporting in oncology patients led to more timely interventions, improved symptom control, fewer emergency visits, and enhanced survival. This emphasizes how mHealth may augment clinician awareness and symptom management.

Despite the many promising findings, several challenges persist within this area of research. Many studies lacked standardized outcome measures, long-term follow-ups, or cost-effectiveness analyses. For example, Goode et al [36] reported no significant effects of mHealth interventions on postprostatectomy incontinence. This highlights the need for further and more robust research on the role of digital interventions in specific clinical contexts, particularly where in-person services are unavailable.

Economic Outcomes and Cost-Effectiveness

In terms of the cost-effectiveness of mHealth systems in surgery, it is clear that there is limited direct analysis available. Most of the existing data stem from inferred associations linking the benefits of mHealth systems to improved surgical outcomes rather than providing concrete cost-effectiveness evaluations. Notably, the study by Rosner et al [37] stands out as the only one in this review to directly explore and quantify the cost-effectiveness of mHealth application within the surgical context. Their findings revealed that patients using an automated digital patient engagement platform following hip and knee arthroplasty experienced a 54.4% reduction in potentially avoidable complications. This had direct financial implications, with the study reporting an average saving of US $656.52 per patient at 90 days after surgery [37].

Quality Assessment and Evidence Strength

mHealth systems and implementation of new technologies have several challenges to overcome as universal access and targeted assistance become a pressing priority within the field. This system implementation should be able to facilitate the creation of protocols that respond to the needs of diverse population groups, such as people with less digital literacy than the average population and people with special needs or difficulties when handling new devices due to their lack of familiarity with new technology. In this era of interconnectedness, stringent data security in mHealth apps and telemedicine is imperative, protecting patient security and private data. The implementation of these systems requires new strategies for patient confidentiality and data safeguarding to be optimized and improved. The creation of tools, wireless wearable devices, and other elements for mHealth and telemedicine application requires the active participation of health care professionals to direct objective assessment and fully fulfill the aims of the strategies, where protocol compliance should be top priority. Inherently, a formal cost-utility analysis is necessary as reimbursement for non–face-to-face care continues to be problematic under traditional fee-for-service payment models that may not yet include virtual assessment implementation [31].

While conducting this review, some gaps in the literature were identified. These included limited discussion on ethical and safety considerations regarding mHealth system implementation in the patient surgical pathway and few articles discussing how to upscale and roll out their interventions, as well as the implementation in different models of care. Furthermore, the data did not provide evidence suggesting the integration of mHealth systems into standard hospital-level care and operations, which, in conjunction with lack of devices, standardization, and follow-up timing standardization, jeopardizes the immediate implementation of these devices at a larger scale within the surgical field.

Regardless of the vast number of publications on the use of telemedicine, wireless wearable devices, and mobile apps in surgical specialties, the available data collected in this narrative review still need to be read and evaluated with caution as the collective impact continues to be varied and there seem to be substantial questions regarding the quality appraisal of the

XSL•FO
RenderX

available evidence. When reading the available data, one must consider that studies are being conducted on a very small scale, compromising the possibility of establishing strong associations, which is a persistent limitation noted. Such limitations stress the need for multicenter trials and inclusive research that considers diverse health care contexts and infrastructure.

From the evidence gathered, none of the studies explored ethical considerations or system-level integration, making result generalizability an important aspect to consider in future research. Considering that the mHealth and telemedicine landscape is complex and varies from country to country, it is worth highlighting that most published articles and guidelines available are based on expert opinions, with evidence coming from high-income countries where strategies are applied to very specific scenarios and in highly controlled situations. Data then fail to provide insights on the challenges that may arise for low- and middle-income countries, where there is a substantial difference in circumstances, infrastructure, resource availability, and digital and educational literacy.

Conclusions

Considering the context of a changing health care delivery system with a shift to community-based care, mHealth is aiding more creative patient monitoring methods in the outpatient setting. mHealth and telemedicine can be effectively implemented to actively engage patient populations, making individuals active participants in the process of monitoring their own conditions and actively involving them in the decision-making processes, which overall improves the experience, efficiency, and outcomes of care.

There is an increasing body of evidence pointing toward mHealth and telemedicine demonstrating significant promise across the surgical care field, but this evidence should be interpreted with caution. Many interventions have been evaluated in small, highly controlled studies, which limits generalizability. In addition, further research is needed to address implementation barriers; validate cost-effectiveness; and develop scalable, standardized frameworks applicable across health care systems in multiple settings and contexts. Future work should prioritize inclusive design, robust ethical safeguards, and equitable access, ensuring that digital solutions are effective, acceptable, and sustainable across diverse patient populations and care environments.

Despite the highlighted limitations, digital health technologies, including mHealth and telehealth interventions, show a considerable potential to improve perioperative surgical care. These tools' strengths lie in enhancing patient education, enabling remote monitoring, supporting rehabilitation, and reducing unnecessary hospital visits, contributing to improved outcomes and system efficiency. Equally, there is evidence suggesting that mHealth technologies seem to have the potential to improve outcomes, reduce costs, and address gaps in perioperative care, particularly if future efforts prioritize equitable access, robust evaluation, and seamless integration into clinical workflows.

Acknowledgments

The authors would like to acknowledge the support of the Monash University and University of Melbourne library services for providing access to databases and literature search resources. They kindly thank Lorena Romero, librarian, for her assistance in providing material and guidance to support a well-structured research strategy, including input to refine the search strategy. The authors extend special thanks to the JMIR editorial team and assigned peer reviewers for all the input provided for this manuscript to be as complete as possible. During the preparation of this manuscript, generative artificial intelligence tools such as ChatGPT by OpenAI were used to assist with language refinement and formatting guidance for publication purposes. Threads have been provided in Multimedia Appendices 4 and 5. Despite the use of generative artificial intelligence tools, all outputs were critically reviewed, verified, and edited by the authors to ensure accuracy, clarity, and integrity. All authors take full responsibility for the content of this publication.

Data Availability

Data sharing is not applicable to this article as no data sets were generated during this study. All data analyzed during this study is included in this published article and can be found in Multimedia Appendix 6 [10,15-41].

Authors' Contributions

MCS and HT conceptualized and designed the narrative review. HT assisted in the process of article screening, quality appraisal, and data extraction. MCS led the process of article screening, quality appraisal, and data extraction and drafted the manuscript, with substantive revision from HT and JS. All authors contributed to the final version of the manuscript and approved it for final submission.

Conflicts of Interest

None declared.

Abstract

Background: Parkinson disease (PD) is a progressive neurodegenerative disorder characterized by motor and nonmotor symptoms that worsen over time, significantly impacting quality of life. While clinical evaluations such as the Unified Parkinson's Disease Rating Scale (UPDRS) are standard for assessing disease severity, they offer somewhat limited temporal resolution and are susceptible to observer variability. Smartphone apps present a viable method for capturing detailed fluctuations in motor and vocal functions in real-world settings.

Objective: This study aimed to use a smartphone-based app to quantitatively evaluate the interaction effect between time and disease severity on motor and vocal symptoms in individuals with PD.

Methods: This was an exploratory, cross-sectional pilot study. Disease severity in persons with PD was assessed using the modified Hoehn & Yahr Scale, Voice Handicap Index, and UPDRS. We used a custom smartphone app to administer finger-tapping tasks, sustained phonation (/a/ and /i/), and rapid syllable repetition (/dadada/ and /pa-ta-ka/). The total tap counts, tap-to-tap variability, and vocal parameters (loudness, jitter, shimmer, repeat counts, and their variability) were analyzed. Each task was divided into 5 equal time frames to analyze performance changes over a short duration. Time-severity interactions were examined using linear mixed models.

Results: In total, 20 persons with PD and 20 healthy adults were included in this study. Persons with PD showed worse motor and vocal performance compared to healthy adults, with higher dysrhythmia; worse jitter, shimmer, and jitter and shimmer variability; and fewer repeat counts. During finger-tapping tasks, individuals with PD showed an earlier onset of dysrhythmia than their healthy counterparts. While a higher UPDRS part III score was associated with greater finger-tapping variability, there was no significant time-severity interaction for this motor task. However, linear mixed model analysis revealed significant time-severity interaction effects for vocal tasks, including /a/ loudness (P=.001), /a/ jitter (P=.01), /a/ shimmer (P=.001), /i/ loudness (P=.001), /i/ jitter (P<.001), /i/ shimmer (P<.001), and /pa-ta-ka/-variability (P=.04). This indicates that individuals with higher UPDRS part III scores experienced a more rapid decline in vocal control during the assessment period. All measured smartphone-based characteristics showed a significant correlation with UPDRS part III scores, with finger-tapping variability having the strongest correlation.

Conclusions: This study demonstrates that a smartphone-based assessment, conducted over just a few minutes, can detect subtle temporal changes in fine motor and vocal control. The app successfully captured the earlier onset of dysrhythmia in individuals with PD and, importantly, identified significant time-severity interaction effects in vocal performance. This suggests that such digital tools can provide sensitive, dynamic insights into symptom progression, potentially enabling more precise monitoring and timely clinical interventions for individuals with PD.

Introduction

Background

Parkinson disease (PD) is a progressive neurodegenerative disorder characterized by the degeneration of dopaminergic neurons in the substantia nigra, a critical region of the basal ganglia [1,2]. This neuronal loss causes a marked decrease in dopamine, a neurotransmitter essential for regulating motor control [3]. Therefore, patients with PD experience motor symptoms such as bradykinesia, rigidity, resting tremor, and postural instability, progressively impairing their ability to perform daily activities. PD is further associated with a range of nonmotor symptoms that often precede motor symptoms. These include autonomic dysfunction [4], sleep disturbances [5], neuropsychiatric symptoms [6], sensory deficits [7], and gastrointestinal issues [8]. These symptoms highlight the broad impact of PD beyond large motor impairments that complicate disease management.

Of particular relevance to this study is the impact of PD on speech and fine motor control, which are closely linked to disruptions in basal ganglia–thalamocortical circuits [1,2,9]. As the disease progresses, patients often develop hypophonia and dysarthria that significantly impair their ability to communicate effectively [10]. These symptoms, combined with motor impairments, underscore the complexity of PD and highlight the need for comprehensive diagnostic and therapeutic strategies.

Finger tapping is a widely recognized assessment tool for evaluating motor dysfunction in PD [11]. The bradykinesia and decreased motor coordination associated with PD result in reduced total tap counts, increased variability in tap frequency, and impaired rhythmicity [12,13]. Recent studies have reported dysrhythmia or increased tap-to-tap variability as the main diagnostic features of PD using smartphone app [14-16]. Voice characteristics such as loudness, jitter (frequency variability), and shimmer (amplitude variability) are often altered in persons with PD owing to the rigidity and bradykinesia of the vocal muscles [10,17]. Vocal function tasks, such as producing sustained vowel sounds (/a/, /i/) and rapid syllable repetition (/dadada/, /pa-ta-ka/), can reveal subtle changes in voice control and coordination, making them valuable for assessing dysdiadochokinesis (difficulty with rapid alternating movements) and interval variability [18,19].

Traditionally, the diagnosis and assessment of disease progression of PD have relied on clinical observations of motor symptoms [2]. However, these methods can be subjective and may vary among clinicians, making episodic assessments during clinic visits inadequate for capturing day-to-day symptom variability, particularly in the early stages when symptoms may be subtle and fluctuating [19].

In addition to clinical observations, recent advancements in diagnostic methodologies have broadened the spectrum of tools available for the diagnosis of PD. Neuroimaging techniques such as dopamine transporter single-photon emission computed tomography and neuromelanin-sensitive magnetic resonance imaging have shown utility in supporting clinical diagnosis by visualizing nigrostriatal degeneration and related pathophysiology [1]. Furthermore, genetic testing is increasingly recognized as a valuable tool, particularly in patients with early-onset or familial PD. Mutations in genes such as *LRRK2*, *GBA*, and *SNCA* have been linked to specific subtypes of PD and may inform not only diagnosis but also prognosis and therapeutic selection. Recent commentary emphasizes the importance of integrating genetic testing into routine clinical care for patients with PD [2]. These evolving diagnostic modalities complement traditional clinical assessments and support the need for objective, technology-based tools for earlier and more precise characterization of PD symptomatology.

Such technological needs have paved the way for more accessible and continuous monitoring solutions, such as smartphone-based apps [20,21]. These apps leverage the sensors and processing capabilities of smartphones to perform real-time assessments of motor and vocal functions, offering a noninvasive, continuous monitoring tool that can be used in natural environments [17]. Smartphone-based assessments enable millisecond-level quantitative evaluation of dysrhythmia without observer biases [14]. Furthermore, the integration of smartphone-based monitoring into the diagnostic process for PD offers several advantages, including frequent symptom tracking in the patient's natural environment, providing a more comprehensive picture of disease progression [19,22]. This approach may improve diagnostic accuracy, particularly in the early stages of PD when traditional clinical assessments may miss subtle symptoms [23,24]. Furthermore, by enabling remote monitoring, these apps can enhance patient care by providing real-time feedback to clinicians and enabling timely adjustments to treatment plans [19].

Objectives

In this study, we developed a smartphone app to monitor PD-related motor and vocal symptoms. Using this app, we evaluated the finger-tapping and voice characteristics of individuals with PD and healthy adults. This study hypothesized that individuals with more severe PD would experience earlier onset of decline in vocal and fine motor control. Therefore, this study aimed to identify the differences in vocal and fine motor control function deterioration among persons with different levels of PD severity and confirm the time-severity interaction effect on finger-tapping and vocal assessments. In doing so, the authors expect that this study investigation would provide additional insights into the time-lapse perspective on PD diagnosis and severity assessment, leading to more precise diagnostic criteria and severity stratification.

Methods

Study Design and Participants

This was an exploratory, cross-sectional pilot study. The inclusion criteria for healthy adults were as follows: (1) age >19 years and (2) those who voluntarily consented in writing and agreed to participate in the study. The exclusion criteria were as follows: (1) history of neurological or orthopedic conditions that could impair upper limb function, (2) history of neurological or otolaryngological conditions that might impact voice and speech, (3) presence of facial paralysis, and (4) individuals considered unsuitable due to other concurrent conditions. The inclusion criteria for patients with PD were as follows: (1) age >19 years, (2) clinical diagnosis of idiopathic PD according to the UK Parkinson's Disease Society Brain Bank Diagnostic Criteria, and (3) modified Hoehn and Yahr (H&Y) scale stage 1 - 3. The exclusion criteria were as follows: (1) history of neurological or orthopedic diseases other than PD that could affect upper limb function; (2) history of neurological or otolaryngological diseases other than PD that could affect voice and speech; (3) presence of facial paralysis due to conditions other than PD; (4) a diagnosis of PD dementia based on the Korean Montreal Cognitive Assessment (K-MoCA), with the following cutoff scores [25]: <7 points: illiterate, <13 points: education duration of 0.5 to 3 years, <16 points: education duration of 4 to 6 years, <19 points: education duration of 7 to 9 years, and <20 points: education duration of 10 years or more; (5) presence of severe dyskinesia or on-off fluctuations; and (6) any comorbid conditions deemed to make study participation difficult [25]. Participants were recruited from an outpatient clinic at Seoul National University Hospital between January 2023 and January 2024, with the last follow-up date being January 23, 2024. Evaluations for patients with PD were conducted in the "on" state, representing the peak effect of PD medication. The "on" state refers to a self-perceived period of optimal physical function following antiparkinsonian medication. In this study, most assessments were performed approximately 1 to 1.5 hours after medication intake, when participants commonly reported being in their optimal functional state.

Ethical Considerations

The study protocol was approved by the institutional review board of Seoul National University Hospital (2211-048-1377; approved on December 16, 2022). Written informed consent was obtained from all participants. All study data were anonymized before analysis. This study was conducted in accordance with the principles of Good Clinical Practice and the Declaration of Helsinki. All participants received monetary compensation covering transportation to and from the study site. The participant pictured in this study provided written consent to publish the deidentified photograph for academic purposes.

Experimental Design

An in-house smartphone app was developed to quantify the fine motor control and vocal functions (Figure 1A). The app collected data on finger-tapping and various voice parameters using the built-in touch screen, microphone, and camera of an Android (Google LLC) smartphone. Access to the app was secured using an ID and a password. During registration, participant information such as name, date of birth, sex, and year of PD diagnosis was collected. Before each assessment session, participants were prompted by the app to input the time of their most recent antiparkinsonian medication intake. The app automatically recorded the start time of each assessment, allowing calculation of the elapsed time between medication intake and task performance.

For the finger-tapping assessment, participants were instructed to alternately tap 2 squares displayed on the smartphone screen as quickly as possible using the index and middle fingers for 20 seconds (Figure 1B). Separate menus were provided for the right and left hands. The voice assessment comprised 4 tasks: 2 phonation tasks and 2 speech tasks. In the phonation tasks, participants were required to sustain the vowel sounds /a/ and /i/ for 10 seconds without interruption. Each task was performed 3 times, with a 3-second rest between trials, and the transitions between the tasks and rest periods were automated. The speech assessment included alternating motion rate and sequential motion rate tasks. The alternating motion rate tested participants' ability to rapidly and repeatedly articulate the same phoneme, with instructions to say /dadada/ for 5 seconds. This was repeated 3 times with a 3-second interval between repetitions. The sequential motion rate evaluated the capacity to articulate different phonemes in sequence, where participants were instructed to say /pa-ta-ka/ for 5 seconds and repeat 3 times with 3-second breaks. Voice recordings were made using a smartphone microphone. To ensure consistent audio levels, the camera detected the participant's face and initiated recordings only when the face was within a specified distance from the device (Figure 1C). If the participant moved outside the predefined range either before or during the rest period, the test did not proceed.

The participants, including both healthy adults and persons with PD, underwent a single session of finger-tapping and vocal function evaluation using a smartphone app. All evaluations were conducted in a controlled hospital environment using a Galaxy S10 (Samsung) provided by the research team, with the investigator present to ensure standardized administration. Each participant completed all assessments twice. For healthy adults, only the age and sex were recorded. The baseline characteristics of persons with PD, including age, sex, disease duration, H&Y stage, Movement Disorder Society-Unified Parkinson's Disease Rating Scale (MDS-UPDRS) score, K-MoCA score, and Voice Handicap Index-10 (VHI-10), were collected. The MDS-UPDRS was developed to assess the impact of PD on activities of daily living and overall disease burden, allowing for the evaluation of both motor and nonmotor symptoms [26]. The MoCA assesses 8 cognitive domains to screen for cognitive impairment [27]. The VHI-10 is a self-assessment tool that measures the perceived severity of voice disorders and is categorized into functional, physical, and emotional domains [28]. It is widely used in adult patients with various types of voice disorders.

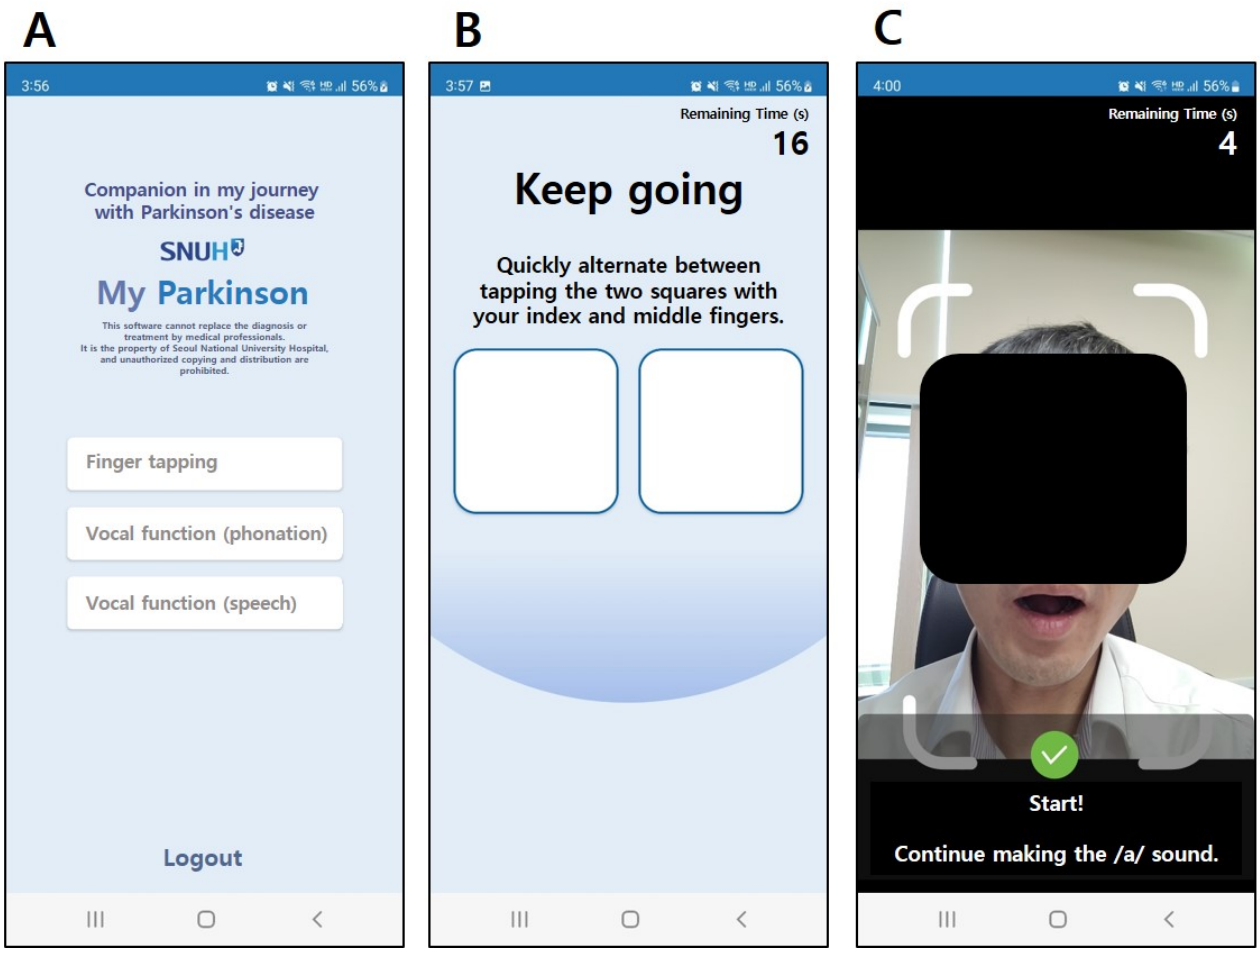
RenderX

Figure 1. Screenshots of the smartphone app: (**A**) main menu, (**B**) finger-tapping task, and (**C**) phonation task. For the convenience of readers, the text in the figure was translated into English (originally in Korean).



Data Extraction

In the finger-tapping task, data were collected using a mobile app that recorded the frequency of participants' alternating button taps on the screen. Only taps in which the participants alternated between the left and right buttons were included in the analysis. Instances in which a single button was pressed consecutively without alternating were excluded. To assess the variability in the tapping frequency, the SD of the time intervals between consecutive taps was calculated.

For voice analysis, we used the OpenSMILE for Python toolkit version 2.5.0 (audEERING®) [29] to extract specific acoustic features from the eGeMAPSv02 feature set [30]. The extracted features included loudness, jitter, and shimmer, which are commonly used in speech analysis to quantify variations in voice quality. To assess the variability of jitter and shimmer, the coefficient of variation, a normalized measure of variability that represents the ratio of the SD to the mean, was calculated. This approach allowed quantification of the relative variability in these acoustic features, providing insights into the participants' voice modulation patterns. In addition, during the speech tasks in which participants produced the /dadada/ and /pa-ta-ka/ sounds, variability in the frequency of speech production was calculated as the SD of the time intervals between consecutive sounds. This measure helped to evaluate the consistency of sound production, offering further insight into the participants' speech motor control and temporal coordination during these tasks.

Statistical Analysis

Data are expressed as means and SDs for continuous variables and as frequencies (percentages) for categorical variables. Each recorded entry of finger-tapping (20 s on each side) and vocal tasks (10 s for phonation and 5 s for speech) was divided into 5 equal time frames (TFs), with the first TF being TF1, and the last being TF5 (ie, for finger tapping: TF1=0 s-4 s, TF2=4 s-8 s, TF3=8 s-12 s, TF4=12 s-16 s, and TF5=16 s-20 s; for phonation: TF1=0 s-2 s, TF2=2 s-4 s, TF3=4 s-6 s, TF4=6 s-8 s, and TF5=8 s-10 s; and for speech: TF1=0 s-1 s, TF2=1 s-2 s, TF3=2 s-3 s, TF4=3 s-4 s, and TF5=4 s-5 s). ANOVA was conducted to determine whether there were significant differences between the different TFs and groups [31]. A linear mixed model (LMM) was applied to examine the time-group and time-severity interaction effects within each data group [32]. Statistical significance was set at $P<.05$. All statistical analyses were performed using SPSS (version 26.0; IBM Corp).

Results

Study Participants

In total, 20 individuals with PD and 20 healthy adults without a history of neurological disorders were enrolled in this study.

XSL•FO
RenderX

The patient group comprised 85% (17/20) female participants with a mean age of 68.30 (SD 6.30) years. The H&Y scale was distributed as follows: 1.5 (4/20, 20%), 2 (5/20, 25%), 2.5 (7/20, 35%), and 3 (4/20, 20%). The mean MDS-UPDRS part III score was 22.10 (SD 10.64), the mean VHI-10 12.05 (SD 9.59), and the mean K-MoCA 25.25 (SD 2.40). The healthy adults group comprised 50% (10/20) female participants with a mean age of 33.55 (SD 7.85) years. The demographic information of the study participants is presented in Table 1.

Table . Demographic characteristics (N=20 for each group).

	Persons with PD[a]	Healthy adults
Age (years), mean (SD)	68.30 (6.30)	33.55 (7.85)
Sex (female), % (n/N)	85 (17/20)	50 (10/20)
H&Y[b] scale, % (n/N)		
1.5	20 (4/20)	N/A[c]

Overall Characteristics of Finger Tapping

The patient group demonstrated a lower total number of taps (mean 76.250, SD 35.932 vs mean 199.263, SD 32.600; *P*<.001) and a notably higher tap frequency variability (mean 0.158, SD 0.144 vs mean 0.0288, SD 0.0101; *P* <.001) than the healthy adult group. This phenomenon was consistently observed across all TFs when the total experimental time was evenly divided into 5 segments (TF1-TF5). The results of the mean total number of taps and tap-to-tap variability are presented in Table 2.

Table . Time frame (TF)–wise analysis of tap-to-tap variability.

	Healthy adults, mean (SD)	Persons with PD[a], mean (SD)	*t* value (df)	*P* value
Total taps	199.263 (32.600)	76.250 (35.932)	22.678 (38)	<.001
Mean variability	0.0288 (0.0101)	0.158 (0.144)	–8.017 (38)	<.001
TF 1	0.0238 (0.0100)	0.101 (0.0803)	–8.563 (38)	<.001
TF 2	0.0238 (0.0100)	0.113 (0.0744)	–10.657 (38)	<.001
TF 3	0.0258 (0.0109)	0.130 (0.0920)	–10.067 (38)	<.001
TF 4	0.0284 (0.0128)	0.134 (0.0860)	–10.897 (38)	<.001

[a]PD: Parkinson disease.

Time-Group Interaction Effects on Finger Tapping

Both groups experienced increasing tap-to-tap variability as the TF progressed (*P*<.001). Furthermore, the LMM analysis revealed a significant time-by-group interaction during the finger-tapping task (*P*=.02), implying that the effect of time on increasing tap-to-tap variability was experienced differently by persons with PD and healthy adults (Table 3).

XSL•FO
RenderX

Table . Interaction effect of time and group on finger tapping.

	Coefficient (SE; 95% CI)	*t* value (df)	*P* value
Intercept	0.021 (0.012; –0.002 to 0.044)	1.815 (38)	.07
Time frame	0.072 (0.017; 0.040 to 0.105)	4.372 (38)	<.001
Group	0.002 (0.003; –0.003 to 0.007)	0.683 (38)	.50
Time frame: group	0.009 (0.004; 0.002 to 0.016)	2.388 (38)	.02

The positive coefficient in the TF:group row in Table 3 indicates that the patient group exhibited greater early-onset variability compared with the control group. This finding was further supported by the ANOVA and post hoc analysis of interval variability.

To assess whether the tapping intervals in both groups remained consistent or if fatigue was observed, an ANOVA was conducted on the interval variability across TF1 to TF5, which revealed a significant difference in the mean interval variability across the 5 TFs (P=.001 for healthy adults and P=.02 for persons with PD). Post hoc analyses found that while the interval variability of the control group significantly increased starting from TF3 (P=.01), that of the patient group did so earlier, starting from TF2 (P=.05). Together with the findings in Table 3, this implies that there was a meaningful interaction between time and group. More specifically, the patient group started to experience increasing variability earlier than the controls. The results of the ANOVA and post hoc analyses are described in (Tables S1-S4 in Multimedia Appendix 1).

Interaction of Time and Disease Severity on Finger Tapping in Persons With PD

While a higher UPDRS part III score indicated higher interval variability (P=.001), there was no significant interaction effect between time and disease severity (Table 4).

Table . Interaction effect between time and disease severity.

	Coefficient (SE; 95% CI)	*t* value (df)	*P* value

Overall Characteristics of Voice

The persons with PD group demonstrated significantly louder volumes (P<.001 for both /a/ and /i/) and higher mean jitter (P<.001 for /a/ and P=.006 for /i/), jitter variability (P<.001 for both /a/ and /i/), mean shimmer (P=.008 for /a/), and shimmer variability (P<.001 for both /a/ and /i/) in sustained phonation. For repeating speech tasks (/dadada/ and /pa-ta-ka/ sounds), the persons with PD group showed lower total repeats (P<.001 for both /dadada/ and /pa-ta-ka/), with elevated interval variability (P<.001 for /dadada/). Voice characteristics are presented in Table 5. There was no significant time-group interaction in the voice analysis (Table S5 in Multimedia Appendix 1).

[a]PD: Parkinson disease.

Interaction of Time and Disease Severity on Voice Characteristics in Persons With PD

A significant time-severity interaction effect was observed in many aspects of voice analysis. Specifically, time and UPDRS part III interaction effects were present in /a/ loudness (P=.001), /a/ jitter (P=.01), /a/ shimmer (P=.001), /i/ loudness (P=.001), /i/ jitter (P<.001), /i/ shimmer (P<.001), and /pa-ta-ka/-variability (P=.04). These results suggest that individuals with different disease severities exhibit significantly different performance trajectories over time. Participants with higher UPDRS part III scores showed greater declines in vocal and fine motor control over time, reflected by larger increases in jitter and shimmer and higher repeat variability in later time frames compared with those with lower scores. It is noteworthy that the time-disease severity interaction effect was significant in dependent variables where the independent time or independent disease severity effect was not statistically significant. This will be explored in greater depth in the Discussion section. The detailed results of the LMM analysis are described in Table 6.

Correlation and Linear Regression Analyses of Disease Severity on Finger Tapping and Voice Characteristics

All voice characteristics and finger tapping were significantly correlated with the UPDRS part III scores. Linear regression analysis revealed that finger tapping had the strongest correlation with the UPDRS part III score (r=0.35; R^2=0.123; P<.001). The results of the correlation and linear regression analyses are presented in Table 7.

Discussion

Principal Findings

This study investigated chronological differences in vocal and fine motor control deterioration among individuals with varying levels of PD severity, with the goal of discovering the interaction effect between time and disease severity on finger-tapping and vocal assessments. Voice analysis demonstrated significant time-severity interaction effects in many aspects. Persons with higher UPDRS part III scores showed greater increases in /a/-loudness, /a/-jitter, /a/-shimmer, /e/-loudness, /e/-jitter, /e/-shimmer, and /pa-ta-ka/-variability. Such time-severity interaction effects were present even in the dependent variables where the independent time or independent disease severity effect was not statistically significant. Finger-tapping performance was significantly affected only by UPDRS part III scores, with no evident time-severity interaction.

In recent years, there has been growing interest in using smartphone-based apps to provide objective and continuous monitoring of PD symptoms [13,17,19-21,23,24]. Unlike traditional assessments, a smartphone app can continuously and quantitatively monitor finger-tapping performance and detect subtle changes in motor function that might not be evident during a physical examination [33]. By capturing tap-to-tap variability in finger tapping down to milliseconds and analyzing the data across 5 TFs, it became possible to examine both the time effect and the time-group interaction effect in individuals with PD and healthy adult groups. This continuous data collection allows for the detection of variability and subtle symptoms that might otherwise go unnoticed, thereby providing a more comprehensive understanding of a patient's condition over time [19]. The group effect between the patient and healthy adult groups was evident, as shown in Table 2. Further intriguing was the time-group interaction effect observed in finger tapping, as shown in Table 3 and Tables S1-S4 in Multimedia Appendix 1. This suggests that the temporal worsening of dysrhythmia develops differently, even among persons with PD, depending on the disease severity.

In addition to motor symptoms, PD also affects vocal function, presenting in symptoms such as hypophonia (reduced speech volume) and dysarthria (difficulty articulating speech) [6,17,34]. These symptoms are linked to the rigidity and bradykinesia of the vocal muscles, which are also controlled by the basal ganglia–thalamocortical circuits [35]. In this study, vocal characteristics such as loudness, jitter, and shimmer were significantly impaired in persons with PD compared to healthy adults. The increased interval variability observed during fast-alternating vocalization tasks (/dadada/ and /pa-ta-ka/)

XSL•FO
RenderX

further indicated impaired articulatory control in patients with PD [19].

Statistical analysis revealed significant time-disease severity interaction effects for nearly all the voice characteristics examined. Notably, this interaction effect was observed even when the individual effects of time or UPDRS part III scores on the voice characteristics (eg, loudness, jitter, and shimmer) were not significant. This phenomenon highlights an important insight often seen in statistical analysis: the main effects may be non-significant, yet the interaction effect can still be meaningful. In such scenarios, while the UPDRS part III scores may not show a significant impact on vocal function when averaged across all TFs, their effect may vary significantly across different periods. For instance, a patient might experience minimal vocal changes during sustained phonation in the early stages of the disease. However, as the condition progresses, the impact on vocal changes could become more pronounced [35]. This underscores the importance of considering interaction effects within the model, as they can reveal critical dynamics that are not captured by the main effects alone.

The time-disease severity interaction within the patient group further suggests that the progression of vocal symptoms varies according to disease severity over time, emphasizing the need for dynamic, longitudinal evaluations of vocal function in individuals with PD. As PD advances, the impact on vocal symptoms fluctuates depending on the severity at different stages, with those experiencing mild disease severity initially showing minimal changes, which may later intensify as the disease progresses [23,35,36]. This variability highlights the need for the regular monitoring of vocal function to allow timely adjustments in treatment strategies. Longitudinal assessments are essential for capturing the nuanced progression of symptoms and tailoring interventions to meet the evolving needs of patients [19,24,35].

The time-severity interaction effect observed in vocal function suggests that individuals with higher UPDRS part III scores experience greater vocal fatigue over time. Increased inhibition of the thalamus leads to a significant reduction in the ability of the motor cortex to generate and sustain precise, coordinated movements required for normal speech. Therefore, these individuals experience greater vocal fatigue, characterized by earlier and more severe reductions in vocal loudness and increased variability in pitch (jitter) and amplitude (shimmer). Over time, the continued loss of dopamine exacerbates these issues, resulting in a progressive decline in vocal function. While the correlation coefficients in Table 7 are modest, this may reflect the difference in temporal resolution and scope between app-based metrics and clinical rating scales. Smartphone measures capture specific, moment-to-moment performance, whereas clinical scores aggregate broader symptom impressions over time.

The earlier and greater exacerbation of dysrhythmia and vocal control deficits in individuals with higher disease severity reflects progressive degeneration of the basal ganglia–thalamocortical circuits [9,37]. Finger-tapping dysrhythmia is linked to the dysfunction of direct and indirect pathways, particularly those involving the degeneration of dopaminergic neurons in the substantia nigra pars compacta. As the substantia nigra pars compacta dopaminergic output to the striatum decreases with advancing disease, the inhibitory-excitatory balance within the striatonigral (direct) and striatopallidal (indirect) pathways is disrupted [16]. This imbalance exacerbates motor dysrhythmia, especially in higher-severity cases, due to increased subthalamic nucleus burst firing, which contributes to abnormal motor rhythms [14].

Conversely, vocal control deficits, which are more dependent on sustained muscle activity and coordination, are further compromised by advanced PD owing to greater degeneration in the pathways responsible for fine motor control, particularly the hyperdirect cortico-subthalamic pathway [22,24]. This pathway plays a crucial role in coordinating the speech muscles. In individuals with higher disease severity, the progressive loss of dopaminergic input leads to earlier fatigue and diminished motor precision, resulting in worsened vocal control [9].

Importantly, the strength of smartphone-based assessment lies not only in its accessibility but also in its capacity to quantify time-sensitive symptom trajectories with high granularity. Although this study did not observe a significant time-severity interaction in fine motor control (finger tapping), such effects were clearly evident in vocal characteristics. This discrepancy highlights the potential of vocal metrics as sensitive indicators of progression and suggests that certain domains may respond differently to disease burden over time. The ability to detect these nuanced changes through a smartphone app underscores its utility in capturing progression patterns that may elude conventional assessments, reaffirming the clinical value of mobile technology in PD monitoring.

Beyond the interpretation of statistical findings, this study contributes meaningfully toward broader clinical goals in the management of PD. By demonstrating that a smartphone-based assessment can detect time-severity interaction effects in both fine motor and vocal symptoms, this study supports the feasibility of dynamic, real-world monitoring of disease progression. Furthermore, the ability to capture subtle, early-onset symptom fluctuations using accessible digital tools aligns with the long-term objective of improving diagnostic accuracy, particularly in the early or prodromal stages of the disease. Ultimately, by facilitating more personalized, timely, and continuous monitoring, this approach holds the potential to enhance patient care through earlier interventions and more responsive treatment strategies.

Limitations

This study has several limitations. First, the healthy adult group and the persons with PD group were not adequately matched for age and sex, and the demographics of the control group did not accurately represent those of the general population with PD. Future studies should ensure better age-sex matching. However, it is important to note that the significant results observed in both the group effect and within-group time-disease severity analyses were obtained regardless of this mismatch. Second, although smartphone monitoring is useful for collecting real-world data, in this study, data collection through the app was conducted in a controlled research setting rather than in a natural environment. Future research should explore the use of

XSL•FO
RenderX

smartphone apps in home settings to better capture real-world data in persons with PD. Finally, the findings of this study warrant large-scale research to evaluate the diagnostic accuracy and reliability of smartphone apps. While this study focused only on finger-tapping and voice characteristics, future research should include other variables such as gait functions, blinking, and natural language analysis.

Conclusions

This study highlights the potential of smartphone-based time-lapse assessment of symptoms to discern disease severity in persons with PD. With only a few minutes of dynamic assessment, this approach can detect subtle temporal fluctuations in dysrhythmia and vocal control deficits, providing novel insights into the severity of PD.

Acknowledgments

We would like to thank Gyumin Lee for mobile application development, Heewon Min for partial contribution to voice analysis, and Hyeonsu Kim for mobile application design.

This research has been conducted by the Excellent researcher support project of Kwangwoon University in 2023 and was supported by a grant (03-2022-2210) from the Seoul National University Hospital Research Fund.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to the sensitive nature of human data (eg, age, sex, and diagnosis) but are available from the corresponding author on reasonable request.
