and child behavioral adherence. Process evaluation data from the DECIDE-Children trial showed that several school-level fidelity components, such as delivery of health education sessions and implementation of school-based activities, consistently achieved high levels (>80%) with limited variability across schools and participants [14]. Therefore, these indicators were less suitable for explaining individual differences in obesity-related outcomes in the present analysis. Nevertheless, other potentially informative fidelity or engagement indicators were not fully captured, such as teacher implementation quality, children's direct participation in school-based activities, and children's engagement with intervention content. Thus, our findings should be interpreted as reflecting selected adherence-related processes rather than the full implementation fidelity of the intervention. Third, the temporal ordering between caregiver app engagement, child behavioral adherence, and child obesity-related outcomes could not be firmly established in this secondary analysis. Although adherence indicators were assessed during the intervention period and outcomes were evaluated over follow-up, caregiver engagement may both influence and be influenced by children's behavioral changes or weight-related progress. For example, caregivers of children who showed more favorable changes may have been more motivated to continue using the app, whereas caregivers facing greater difficulties may have disengaged over time. Therefore, reverse causality cannot be excluded, and the observed associations should not be interpreted as causal effects of adherence. Fourth, child behavioral adherence was measured using caregiver-child behavior monitoring reported through the app. Although caregivers were instructed to observe and/or inquire about their child's weekly behaviors and preferably complete the report together with the child, this measure remains proxy-reported and may reflect caregiver perceptions. In addition, caregiver app use and caregiver-reported child behavioral adherence were derived from the same respondent, which may introduce common-method bias and inflate the observed associations between caregiver and child adherence indicators. Caregivers who used the app more frequently may also have been more diligent in reporting children's behaviors, which could introduce reporting-related correlation. Future studies should incorporate more direct and multidimensional measures of child engagement, including school-level participation records, direct activity monitoring, and children's own reports where appropriate. Finally, because multiple statistical comparisons were conducted across several adherence indicators and obesity-related outcomes, individual statistically significant findings, particularly interaction terms, should be interpreted as exploratory and hypothesis-generating rather than confirmatory.

Implications and Future Research

Future studies should evaluate adherence to better interpret the true effectiveness of complex interventions. In our study, children with higher caregiver and child adherence levels showed more favorable changes, suggesting that intervention effects may be underestimated when adherence is not considered—an issue aligned with the concept of "type III error," in which poor implementation rather than ineffective intervention leads to null findings [31]. Evidence from prior childhood obesity interventions similarly shows that meaningful benefits emerge when implementation fidelity is moderate to high [32]. Therefore, routine collection of detailed adherence data and integration of implementation evaluation frameworks are essential for accurately assessing intervention impact and informing policy and practice [33].

Conclusion

In this secondary analysis of an mHealth app-assisted childhood obesity intervention, higher caregiver app-use adherence and children's behavioral adherence were associated with more favorable changes in weight status and physical fitness. These findings underscore the importance of coengagement in digital health programs and highlight the potential of app-supported, family-engaged strategies for childhood obesity prevention.

Acknowledgments

We thank all the children and caregivers in the diet, exercise, and cardiovascular health children's study for their participation. We also appreciate the teachers involved in the program and thank all the investigators for their help throughout this study.

Generative AI (ChatGPT, OpenAI) was used during manuscript preparation for language editing, improving clarity of expression, and assisting with responses during the revision and copyediting process. It was not used for data analysis, generation or interpretation of study results, or selection of references. All AI-assisted content was reviewed and verified by the authors, who take full responsibility for the accuracy, originality, and integrity of the manuscript.

Abstract

Background: Mobile mental health (MH) apps are increasingly promoted as tools for self-care. However, less is known about how users integrate them into everyday life and how they combine with other forms of support.

Objective: This qualitative study examined what motivates individuals to adopt MH apps and how these tools are used alongside other care practices.

Methods: We conducted semistructured interviews with 31 Czech MH app users aged 18‐56 (23 women), recruited through social media, researchers' networks, and snowball sampling. Eligible participants had used an MH app for at least 2 weeks; individuals currently experiencing a psychological crisis were excluded. Interviews were conducted online or face-to-face and analyzed using reflexive thematic analysis by Braun and Clarke. The analysis was inductive and informed by a critical realist epistemological stance. Initial analytic engagement was conducted independently, followed by collaborative theme development and refinement.

Results: We identified the following three motivational patterns for MH app use: (1) regular use to maintain well-being and support preventive self-care; (2) reactive use during periods of acute distress; and (3) temporary, problem-focused use aimed at understanding or addressing a specific difficulty. Beyond motivations for adoption, our findings revealed the following four distinct trajectories of app engagement and disengagement: (1) emancipation, with apps acting as ongoing support for self-care when therapy is reduced or ended; (2) independence, as techniques learned through apps are transferred into everyday life and used without the app; (3) reliance, where users persist with app-based self-care despite insufficient benefit, occasionally delaying or limiting other forms of help; and (4) episodic use, characterized by intermittent engagement during specific life periods. These findings extend existing research by showing that disengagement is not necessarily a marker of failure but can reflect successful self-care and the transfer of learned skills. We also identified tensions and unintended consequences, including the burden of sustaining engagement, risks of overreliance, emotional costs associated with sustained self-monitoring, and tensions between digital self-care and efforts to reduce screen use. Participants generally viewed self-monitoring as beneficial when guided by clear personal goals and embedded within a broader system of self-care.

Conclusions: Our findings suggest that appropriate disengagement can signal a successful step in self-care. App design and policy should acknowledge episodic use and strengthen connections to human support with clear guidance and accessible pathways to additional care when needed.

Introduction

Background

A growing number of studies point to a rising prevalence of mental health (MH) problems in the adult population [1-3]. In parallel, broader social processes of individualization in Western countries increasingly frame MH and well-being as an individual responsibility [4]. This orientation is reflected in the individualization of care, whereby individuals are expected to monitor their well-being and manage psychological difficulties largely on their own [5]. Recent technological advances have further reinforced this process through the rapid development

XSL•FO
RenderX

of stand-alone MH smartphone apps designed to improve users' well-being.

These trends matter most where formal care is hard to access. In Czechia, roughly 80% of adults meeting criteria for a current mental disorder receive no treatment, and over half of those seeking help encounter structural barriers [6]. Public stigma also remains high by European standards, with little recent change even as recognition of conditions like depression and anxiety has modestly improved [7]. In such contexts, MH apps may be adopted out of necessity rather than personal preference.

An expanding body of systematic reviews suggests that these digital tools may have moderate positive effects on reducing negative MH symptoms, improving well-being and emotional regulation [8-13], particularly with regard to depression and anxiety-related symptomatology. Despite this emerging evidence, numerous studies highlight persistent challenges related to low user engagement and factors that hinder the sustained use of MH apps [9,14,15]. Recent research therefore suggests that greater attention should be paid to personalization mechanisms within MH apps as promising strategies to enhance use of and perceived benefits from these digital tools [15,16]. However, significant gaps remain in our understanding of when and how apps benefit users and what role they play in broader self-care practices.

Users' Motivations and Experiences of MH App Use

Prior qualitative research has identified several factors motivating individuals to use MH apps. App properties that enable users to substitute emotional support usually provided by social interactions have often been highlighted. Chief among these is their immediate availability, which allows users to address psychological distress independent of the availability of social support. MH apps also provide a discreet space where users can address their MH needs. This privacy is particularly relevant in cases where stigma discourages the disclosure necessary for social support [17-19]. In addition to privacy, MH apps are often valued for their nonjudgmental stance. This provides some users with a sense of being understood and supported, mitigating feelings of loneliness and/or shame, while they remain aware of the app's nonhuman nature [17-19].

Beyond these substitutional properties, users are attracted by the diverse features (eg, breathing exercises and journaling) consolidated within single customizable platforms, which are often economically affordable [17,19-21]. This is an important factor for sustained app usage, particularly because MH apps have been found to be valuable for long-term MH maintenance and for allowing more precise and continuous tracking for mood and daily circumstances, thereby fostering self-awareness of the factors associated with changes in psychosocial functioning [15,18,22]

However, existing research indicates that engagement features, such as streaks and reminders, are often experienced ambivalently; while they may encourage routine for some, the perceived burden of continuous tasks can paradoxically discourage use [15,22]. Furthermore, concerns raised by MH app users relate to potential overreliance on app-based functions, particularly in the absence of complementary forms of support [19,23]. According to some users, this reliance contributes to the emergence of a new norm of independent coping, and failing to conform to this expectation leaves them with feelings of shame [24].

Current research also suggests that sustained, long-term use of MH apps for self-maintenance and health management requires a high level of self-initiative and intrinsic motivation [15]. These demands become compounded when users experience psychological distress, which may make it more difficult for them to familiarize themselves with app content or to effectively navigate available features [15]. In this regard, the involvement of external professional support from counselors and therapists to assist users in engaging with and interpreting MH app content has been identified as a potentially promising approach [19].

A recent qualitative study shifted the research focus from the sustained use of MH apps to macro-engagement, within which off-screen, goal-directed activities associated with behavioral change may continue beyond app use [25]. This study showed that on-screen interactions and off-screen, goal-directed practices often remained disconnected, which limited the extent to which behavioral change was supported in everyday life. The authors therefore argued that greater support for engagement beyond the screen was needed. However, aside from this emerging line of research, we know little about how people integrate MH apps into their broader MH care practices and how these digital tools interact with the other forms of support with which people engage.

Theoretical Framework for Self-Care

To examine the use of MH apps, we draw on the Middle-Range Theory of Self-Care of Chronic Illness (MRTSC) proposed by Riegel et al [26]. Within this framework, self-care is conceptualized as an ongoing process aimed at maintaining health and well-being in both healthy and ill states. The theory distinguishes the following three interrelated aspects: (1) *self-care maintenance*, which involves behaviors intended to preserve health and prevent symptom exacerbation; (2) *self-care monitoring*, which refers to the observation and tracking of bodily or psychological changes; and (3) *self-care management*, which encompasses responses to symptoms based on their detection and interpretation. This characterizes self-care as a decision-making process during which individuals reflect on their symptoms based on experience and contextual factors.

Although MH self-care differs from self-care in chronic illness in that needs and goals may fluctuate over time, the MRTSC framework provides a useful lens for understanding how individuals maintain well-being, monitor psychological states, and respond to perceived changes in their MH. The framework is particularly relevant for studying MH app use, as these apps can facilitate all 3 aspects of the self-care process. They support monitoring and reflection through features such as mood tracking or journaling; they enable self-care maintenance through guided relaxation or mindfulness practices; and they assist in self-care management through actionable coping strategies or crisis resources. Moreover, the MRTSC offers a process-oriented framework that is particularly suited to symptom-driven engagement and decision-making in MH self-care contexts. This perspective allows MH app use to be

XSL•FO
RenderX

understood as part of an ongoing self-care process alongside other forms of professional and informal support. In this respect, understanding the use of MH apps as part of self-care raises important questions about when, how, and for how long individuals integrate these tools into their everyday practices.

This Study

Existing research on MH apps remains largely descriptive and fragmented—motivations, user engagement, and disengagement are often examined in isolation. Moreover, disengagement is often interpreted as a negative outcome. Recent human-computer interaction research [27] offers an alternative perspective by conceptualizing disengagement as a natural cyclical phase of technology use that is driven by user agency and specific goals. Pausing or stopping use can be a deliberate positive decision rather than a breakdown in motivation or usability. Applying this framework may help explain how disengaging from MH apps may reflect successful self-care management.

Furthermore, while recent research has begun to highlight the disconnect between on-screen engagement and off-screen behavioral change [28], less attention has been paid to how MH apps are embedded within broader ecosystems of MH care and support. To address this gap, we draw on the MRTSC to examine how users engage with and disengage from MH apps and how these apps are embedded within broader MH self-care practices and support systems. To achieve this aim, the study addresses the following research questions (RQs):

- RQ1: What motivates individuals to engage with and disengage from the MH apps?
- RQ2: How are MH apps integrated into users' everyday lives and into broader ecosystems of MH care and support?

Methods

Participants and Procedure

We conducted 31 semistructured interviews with Czech users of mobile MH apps (aged 18 - 56, 23 women). Recruitment was initially conducted through a paid social media advertising campaign (Facebook [Meta] and Instagram [Meta]) targeting the general Czech-speaking population in Czechia aged 18 years and older. Owing to low response rates to the advertisement, recruitment was subsequently supplemented through the researchers' personal networks and further through snowball sampling. None of the participants had a prior relationship with the interviewers. We were transparent about the study's purpose, framing the conversation as an exploration of how people use these apps, their benefits, and the boundaries of their usefulness. We excluded individuals who were (1) 17 years old or younger, (2) currently in psychological crisis, or (3) survivors of a traumatic event within the preceding 12 months. The only inclusion criterion was having used a MH app for at least 2 weeks. Demographic data were collected before the interview (Table 1).

The semistructured interview guide was developed through a multistage, iterative process. Following agreement on the research objectives and questions, all the authors of this study independently proposed thematic domains and interview questions relevant to the investigated phenomenon. Through discussion and consensus, these suggestions were consolidated into 11 thematic areas such as participants' app use, motivations, perceived benefits and drawbacks, comparisons with other forms of MH support, trust, and long-term experiences with MH apps. The preliminary guide was further informed by a screening of MH apps available in major app stores and an analysis of user reviews, which helped identify salient user experiences and recurring concerns. Finally, the guide was pilot tested with three individuals (1 woman aged 26 y and 2 men aged 25 and 27 y) who had experience using MH apps. Based on participant feedback, several questions were reworded, alternative prompts were added, and items perceived as overly broad or insufficiently relevant to participants' experiences were refined. The full interview guide, including translations, is available in Multimedia Appendix 1.

Ethical Considerations

The study received ethical approval from the Masaryk University Research Ethics Committee (0198/2025) prior to data collection. All participants provided written informed consent and consent for the processing of personal data. Informed consent was obtained from all participants in writing and reaffirmed verbally immediately before the interview. Participation was voluntary, and participants could withdraw from the study without penalty before their data were anonymized. Interviews were audio-recorded and transcribed for analysis. Audio recordings were stored securely and deleted following transcription. Transcripts were anonymized prior to analysis, and access to study data was restricted to authorized members of the research team. Participants received CZK 500 (equivalent to US $23.23) as compensation for completing the interview. One participant described past suicidal ideation but indicated during the interview that these thoughts were no longer current. At the end of the interview, the interviewer returned to this disclosure, checked whether the participant wanted information about relevant support services, and offered to provide contact information.

Data Analysis

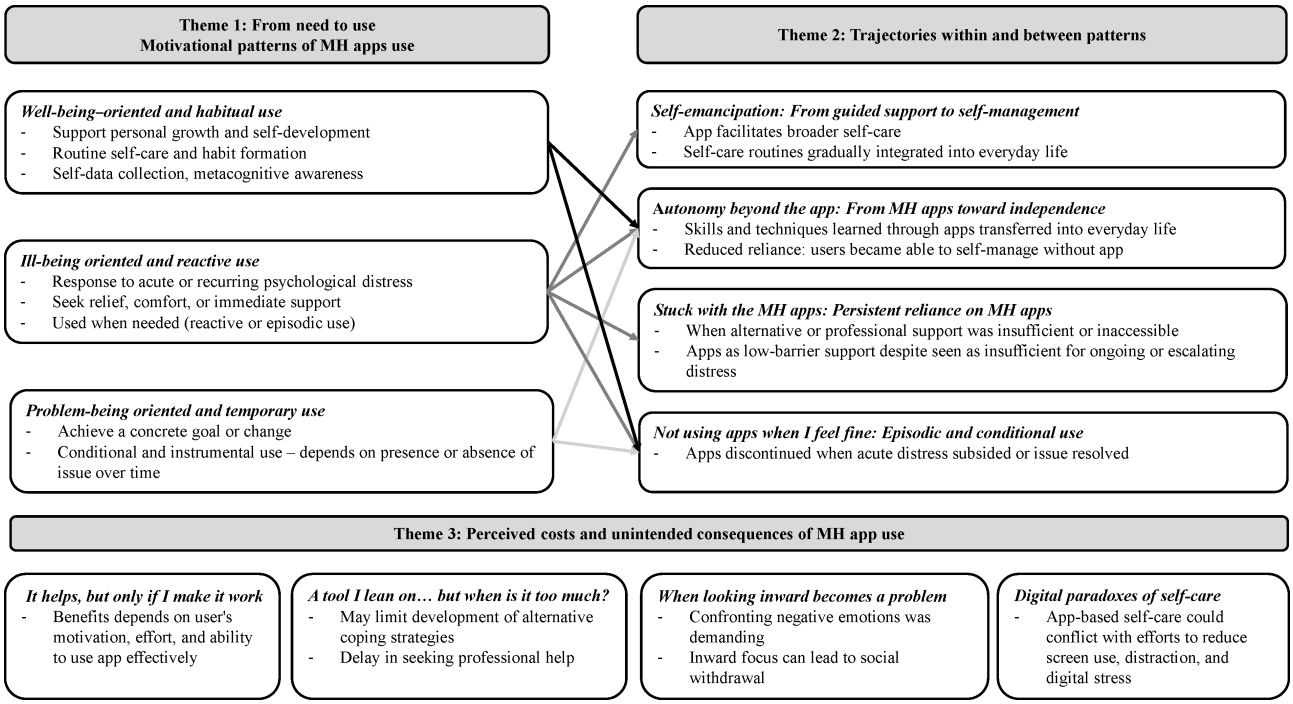
We conducted reflexive thematic analysis (RTA), following the 6-phase approach outlined by Braun and Clarke [29]. The MRTSC informed the broader conceptual framing of the study and was used as a lens through which the findings were subsequently interpreted. RTA is a flexible method suited to exploring patterned meaning across participant accounts. Our epistemological stance was informed by critical realism [30], which assumes that the participants' accounts provide access to real experiences and underlying mechanisms, while recognizing that these experiences are always mediated through language, context, and interpretation. The analysis was inductive and bottom-up, with themes developed from the data rather than imposed a priori. Consistent with RTA, data saturation was not used as a stopping criterion; instead, recruitment concluded after the project's predefined recruitment target had been reached and the dataset was judged sufficiently rich and varied to address the RQs [31]. Participants provided detailed accounts of their experiences, and the sample encompassed diverse patterns of app use, motivations, perceived benefits, challenges, and trust-related concerns, enabling the development of well-supported themes addressing the study aims. The adequacy of the dataset was assessed throughout the iterative process of data collection and analysis. Toward the end of recruitment, additional interviews continued to provide illustrative examples and nuances of participants' experiences but did not substantially expand the range of issues relevant to the RQs. Given the breadth, depth, and diversity of the dataset, the research team concluded that it was sufficiently rich to address the RQs. Only authors VS, ZS, and AŠ were involved in the analytic process; stages 1 - 3 (ie, data familiarization, initial coding, and early pattern identification) were conducted independently by each author to encourage diverse readings of the data, with regular consultation to discuss developing interpretations, while later stages of theme development, refinement, and definition were collaborative. This iterative and reflexive process allowed us to move between participant accounts and broader explanatory interpretations, attending both to surface meanings and to the underlying conditions that shaped app use and the consequences of app use. Further methodological specifics are reported in the accompanying COREQ checklist (Checklist 1).

XSL•FO
RenderX

Positionality

AŠ and VS approached the analysis from backgrounds in critical health psychology, with particular attention to the interplay between individual self-care and broader health and care contexts. AŠ had limited personal experience with MH apps, while VS had previously used meditation apps before transitioning to unguided practice. ZS approached the research from a critical psychology perspective, with particular sensitivity to the social contexts in which individual responsibility for MH and well-being is constructed. These differing positions informed reflexive discussions of developing interpretations throughout the analytic process. A more detailed description of each author's positionality is available in Multimedia Appendix 2.

Results



Sample Description

Regarding the duration of use, most of the sample had been using their apps of choice for over a year (n=21), followed by participants who had used them for 6 months to 1 year (n=6), and 2-6 months (n=4). Out of 31 participants, 10 disclosed MH issues that could be classified as symptoms related to a clinical disorder. Specifically, 5 participants reported panic attacks, 4 reported depressive mood, 3 reported anxiety, and 1 reported suicidal ideation. Clinical diagnoses disclosed during the interviews were attention-deficit/hyperactivity disorder (ADHD; n=2), bipolar disorder (n=1), and a history of alcoholism (n=1). For further sample characteristics, refer to Table 1.

Analytical Results

Our analysis generated 3 themes that capture the dynamic nature of MH app use. These themes illustrate how participants initially engaged with apps, how use was reshaped or interrupted over time, and how MH apps were integrated within broader self-care strategies. The themes are analytically distinct but closely intertwined, reflecting self-care decision-making processes (Figure 1).

Figure 1. Motivational patterns, trajectories, and perceived costs of mental health (MH) app use. The figure provides a visual representation of the thematic findings. Arrows illustrate relationships between patterns (theme 1) and trajectories of MH app use (theme 2) identified in participants' accounts. Theme 3 represents perceived costs and unintended consequences that cut across patterns and trajectories.

Theme 1: From Need to Use—Motivational Patterns of MH App Use

Overview

Throughout the interviews, participants described diverse motivations for downloading MH apps. We identified 3 overarching motivational patterns that reflected how participants understood their mental well-being and the role of digital self-care at the onset of MH app use—*well-being–oriented and habitual use*, *ill-being-oriented and reactive use*, and *problem-oriented and temporary use*.

Well-Being–Oriented and Habitual Use

Well-being–oriented use was typically described as proactive and oriented toward maintaining or enhancing psychological well-being over time. Participants who entered app use from this position often framed MH apps as tools for routine self-care, supporting habit formation and reflection, and structuring time devoted to oneself. Most commonly, it was associated with functions that enabled self-data collection (eg, emotion tracking and journaling) or supported the development of metacognitive awareness (through meditation) and general mindfulness.

For several participants, well-being–oriented use also involved tracking functions to facilitate long-term reflection on life events

XSL•FO
RenderX

and experiences. In these cases, participants wanted to document and preserve (mostly positive) personal life experiences over time:

> *...to analyze my states or situations I find myself in... so I'll be able to look back in history and analyze it, even learn from it, from mistakes or from what's repeating.* [P10_10_56M]

Importantly, well-being–oriented engagement did not always originate from a clearly articulated personal need. In some cases, app use began through contextual exposure, such as social media recommendations, employer-provided access, or professional curiosity among health and social care workers who sought to familiarize themselves with MH apps to assess whether to recommend them and which apps to recommend to their clients. What initially started as experimentation evolved into a meaningful self-care practice if participants experienced the app as beneficial.

The perceived value of habitual use often became particularly salient when use was interrupted. Some participants reported that during unintended breaks, most commonly due to lack of time, they felt less emotionally regulated or more scattered:

> *I miss it in the sense that I know I approach life differently and I'm less emotionally stable.* [P32_27M]

These experiences functioned as a feedback loop that reinforced motivation to resume regular self-care practices, with continued support from MH apps.

Ill-Being–Oriented and Reactive Use

By contrast, ill-being–oriented use was characterized by reactive engagement with apps in response to acute or recurrent psychological distress. Participants turned to apps because of anxiety, panic attacks, emotional breakdowns, mood deterioration, or periods of intense stress. In these situations, apps were valued primarily for providing rapid relief in the form of distraction (eg, breathing techniques and simple interactive tasks) or grounding when other forms of support were unavailable. One participant compared having an MH app on her phone to:

> *... [having] a pain killer in your medicine cabinet. One doesn't need it every day, but you know if your head hurts really bad, it's there.* [P29_23F]

A recurring context for reactive use involved situations in which participants felt trapped or unable to leave, with MH apps described as a "lifebuoy" during periods of severe panic because they interrupted escalating anxiety and validated emotional experiences:

> *...when the panic attack started to come on, I wasn't able to think rationally... And I really thought I was going to suffocate. And I knew there were some breathing exercises there, and different exercises to kind of redirect attention, or the app tries to stop the brain from thinking 'I'm dying, help, help...?'* [P29_23F]

Ill-being–oriented use was typically episodic, with participants reporting that they stopped using the app once the acute distress subsided. As one interviewee noted:

> *...the last time [I used the app] was about two weeks ago, so in terms of frequency now... maybe about once every two weeks. Honestly, I'm actually feeling quite well right now. Psychologically, I mean.* [P14_19F]

Although apps were often described as effective in reducing immediate distress, participants generally distinguished this form of use from longer-term psychological work. Apps were framed as first aid or temporary support, rather than substitutes for therapy or deeper interventions.

Problem-Oriented and Temporary Use

The third motivational pattern reflected a problem-oriented approach to MH app use. Participants did not turn to apps during acute episodes but when they sensed that "*something was not right*" and wanted to understand or manage a specific issue over time. Their use of MH apps was framed less as a tool for immediate emotional regulation and more as a resource for understanding the issue. For example, one participant described using a different app for mood tracking to evaluate the emotional impact of her work, explicitly framing the app as a way to *see* and confirm or deny what she had been sensing:

> *I was using [the app] because of work, because I wanted to find out whether that job was really affecting me emotionally so much, and how bad it actually was. ...I wanted to have it on paper and see to what extent it was the job and to what extent it was something else.* [P12_34F]

Engagement with the apps was typically conditional and instrumental. It fluctuated over time, based on the presence or absence of the issue. Participants described adjusting the frequency and intensity of app use in response to changing circumstances or perceived need. Rather than striving for daily use, they deliberately returned to the app during more demanding periods and disengaged when conditions improved. As one participant noted, regular use felt unnecessary outside of more difficult phases:

> *Now I only come back to [the app] when I feel like I need it. When there's a more difficult period, I feel that it's needed more to become more aware again.* [P18_31F]

These motivational patterns captured the distinct ways in which participants entered MH app use. They differed in urgency, temporal framing, and expectations for what the apps could provide. However, our data also showed some overlap between these patterns, and some accounts revealed movement between patterns over time. Rather than discrete categories, the patterns are best understood as orienting distinctions that shaped how participants integrated the apps into their lives and the roles the apps played. How these motivational patterns evolved was the focus of the trajectories described further in this study.

XSL•FO
RenderX

Theme 2: Trajectories Within and Between Patterns

Overview

Across interviews, participants narrated common variations in how they put the apps to use, reflecting shifting needs and life circumstances. We identified four trajectories to describe how participants moved within and between motivational patterns as follows: (1) the *self-emancipatory trajectory*, in which app use supported a shift from distress toward self-management; (2) the *trajectory from MH apps toward independence*, in which managing issues without the app was framed as a positive outcome; (3) the *persistent reliance trajectory*, characterized by continued or long-term use; and (4) the *episodic and conditional trajectory*, in which apps were used selectively, often only during periods of difficulty.

Self-Emancipation: From Guided Support to Self-Management

The first trajectory illustrates how MH app use could support a shift from distress management toward broader self-care routines. Here, autonomy was narrated not primarily as disengagement from the app, but as a gradual movement away from external support and toward more self-directed self-management. Specifically, some participants described transitions from ill-being- to well-being–oriented use, in which MH apps functioned as tools to facilitate the shift. Several participants described installing apps when they decided to reduce or terminate psychotherapy after reaching their initial therapeutic goals:

> *...I think I kind of felt that I didn't need [therapy] that much anymore, so maybe I perceived [the app] as some kind of replacement for therapy, that I still had some kind of certainty that, if something happened, it could maybe help me.* [P06_23F]

This excerpt illustrates how MH apps could function as a psychological safety net, facilitating the transition from psychotherapy to more autonomous self-management.

In this regard, MH apps were often perceived as tools that created a visually appealing and user-friendly space. They legitimized the time devoted to self-care practices and thereby supported the development of self-care management. One interviewee further described how self-care subsequently extended beyond therapy:

> *I'd say that actually [I do] a huge number of things that maybe aren't a priori, that one would normally say are good for mental health[...] So, when a person reflects on it once in a while, or even every day, it at least then leads me to the point where, at a minimum, I'm reminded every day that I should be doing something for myself.* [P18 _31F]

In this trajectory, MH apps supported the development of self-care routines that were subsequently integrated into participants' everyday lives. Participants described a broader reorientation toward caring for their MH on a day-to-day basis, with apps serving as scaffolding during periods of transition.

Autonomy Beyond the App: From MH Apps Toward Independence

Across both ill-being and well-being pathways, some interviewees described a gradual reduction in their reliance on MH apps as they learned and internalized skills and techniques introduced through app use. They subsequently applied them independently in everyday life:

> *[...] so it happens that I just tell myself, "Okay, I'm going to meditate for a few minutes even without the app."* [P16_52M]

For some interviewees, this transfer of skills into everyday life emerged as a positive side effect of MH app use, whereas others, such as the above-mentioned participant, described it as an explicit goal to become more mindful in daily life and to integrate techniques learned through the app beyond the app context.

Trajectories toward independence were characterized by an orientation toward transferring app-introduced skills into everyday life. For well-being–oriented users, this trajectory was motivated by a desire to integrate app-based practices more broadly into existing self-care routines. For those entering through an ill-being–oriented pathway, independence reflected an effort to avoid exclusive reliance on the app and to feel capable of managing situations without app-based guidance. For problem-oriented users, independence meant gaining sufficient understanding of a specific issue, allowing them to scale back or discontinue monitoring.

Stuck With MH Apps: Persistent Reliance on MH Apps

Not all trajectories led toward increased autonomy. For some users, the transition from MH app use as an emergency lifeline to the development of broader self-care practices did not materialize. These participants either maintained reliance on MH app techniques that had previously alleviated acute stress or continued to use MH apps as de facto substitutes for crisis helplines without further developing self-care practices. In both situations, they remained oriented toward MH apps not because the benefits were increasing, but because alternative forms of support were insufficient or perceived as inaccessible.

For 1 participant, escalating stressors eventually rendered app-based coping insufficient:

> *But even then, when I walk outside [after MH app use], the first thought just goes back to the original problem and I'm right where I was before, so basically it doesn't really work anymore. I don't want to bash the app. It's more that I'm currently experiencing much more stress, and in a more long-term way, and it's not just one isolated problem.* [P17_38M]

In this interview, seeking help from health care professionals was not considered, despite the perceived insufficiency of app-based support.

In cases where apps substituted for crisis intervention, especially free versions with limited functionalities, they functioned as low-barrier support for individuals experiencing psychological

XSL•FO
RenderX

distress and limited financial means while simultaneously attempting to access professional care:

> *[...] either calling the crisis hotline, which has happened to me several times when I couldn't get through... I definitely looked for [the app] myself, because I had long known that I needed psychotherapy. I couldn't afford that, so I tried to find free psychotherapy... I always see [MH apps] as a kind of substitute for situations when therapy or another person simply isn't available.* [P15_42F]

Although this interviewee dealt with her mental difficulties largely on her own, she perceived her difficulties as too severe to be addressed through MH apps alone. This perceived limitation was echoed by another participant, who explicitly stated:

> *When... or once it becomes long-term, an app on its own won't really help.* [P23_24F]

Taken together, these accounts suggest that persistent reliance on MH apps may reflect not only individual coping strategies, but also structural constraints that shape access to professional MH care.

Not Using MH Apps When I Feel Fine: Episodic and Conditional Use

Episodic and conditional use was most commonly associated with the ill-being pattern and was characterized by nonsystematic engagement with MH apps. Participants frequently reported that they stopped using the app once acute distress subsided. Unlike trajectories toward independence, episodic and conditional use did not involve internalizing app-based practices. Instead, participants described keeping MH apps available as resources to be reactivated during periods of psychological difficulty, while preferring other self-maintenance strategies during less demanding times.

Some interviewees indicated that their MH app use followed a seasonal pattern, triggered by episodic deteriorations in well-being, typically during autumn or winter. These interviewees expressed interest in seasonal subscriptions with flexible and user-friendly terms, reflecting how their engagement with MH apps was shaped by seasonal need:

> *I wouldn't want to pay for an expensive annual subscription, especially if I know I'm not using it on a daily basis.* [P22_23F]

This participant did not perceive daily MH app use as necessary and consequently was not interested in committing to a long-term subscription.

Theme 3: Perceived Costs and Unintended Consequences of MH App Use

Overview

While most participants described MH apps as helpful (eg, providing structure, calming guidance, and distraction during stress), they also reflected on tensions and unintended consequences arising from their use. We identified 4 interrelated subthemes that captured these perceived costs. First, "*It helps, but only if I make it work*" describes tensions that stem from the perceived responsibility for making app use effective. Second, "*A tool I lean on... but when is it too much?*" captures tensions around reliance on apps, including their use as substitutes for other forms of support and the potential delay of help-seeking. Third, "*Inward focus as a risk*" highlights how self-monitoring and reflective practices, while often stabilizing, can also intensify attention to internal states and become ruminative. Finally, "*Digital paradoxes of self-care*" describes conflicts between app-based self-care and attempts to reduce screen time or disengage from stressful technologies. Across these subthemes, tensions emerged not solely because of functional limitations, but through participants' active efforts to engage with digital self-care and their ongoing evaluations of the costs and benefits of app use.

It Helps, but Only if I Make It Work

Across interviews, participants repeatedly emphasized that, while MH apps offered accessible support, they could not generate the motivation required for consistent or effective use. Apps were commonly framed as passive tools whose benefits depended on users' own effort and willingness to engage:

> *[...] the apps will only remind you that this is important, but they won't do the work for you.* [P04_24F]

Similarly, another participant stressed that change stemmed from her own determination rather than the app itself, which merely provided a starting point:

> *It's not that the app directly forced me to take better care of my mental health. What actually pushed me to do something about it was mainly that [my mental states] were just burdensome.* [P21_24F]

Across accounts, participants recognized a certain level of agency as a prerequisite for benefit. For some, this responsibility was framed as a natural or even empowering aspect of app use; for others, it was experienced as a burden or source of tension.

This ambivalence was particularly visible in relation to reminders and streak-based features. While some participants appreciated the structure these features provided, others described actively protecting their autonomy by resisting notifications or streak mechanisms that induced guilt or created tension between disengaging from the app and losing accumulated rewards. As 1 participant explained, reminders were acceptable only as long as they did not make her feel bad for noncompliance:

> *If it made me feel bad for not doing something, I'd probably be done with this shit.* [P04_25F]

In such cases, perceived pressure was not motivational but instead led to disengagement.

Beyond motivation and effort, some participants emphasized that benefiting from MH apps also presupposed a certain level of competence (eg, understanding and appropriately applying the techniques offered). One participant noted that merely having access to coping strategies was insufficient; through therapy, she learned how to work with techniques she had previously encountered in the app:

XSL•FO
RenderX

> *[...] to get the right effect, you need to have the right techniques and know how to use them... thanks to therapy, I learned how to do that.* [P07_23F]

Again, this reinforced the idea that healthcare providers could play a crucial role in guiding some users to successfully leverage the apps' functions. Taken together, these findings indicate that the apps' effectiveness is not intrinsic, but negotiated through the users' engagement with them.

A Tool I Lean on… but When Is It Too Much?

Participants reported several unintended consequences related to growing reliance on MH apps, often framed as a tension between the benefits of immediate support and concerns about depending too heavily on the app. Apps were often described as psychological crutches that were helpful in moments of distress, yet accompanied by reflections on whether such reliance might limit the development or use of alternative coping strategies. One participant recalled how her partner explicitly raised this concern while observing her use of the app during anxiety-provoking situations on public transport, prompting her to consider what would happen if the app were unavailable:

> *...he came up with this interesting idea... what would I do if I didn't have my cell phone... that I actually rely on it a little bit... and so I become a little dependent on it.* [P21_23F]

Reliance on apps was also linked to reflections on help-seeking beyond the app. Participants frequently emphasized that they themselves were responsible for recognizing when app-based support was no longer sufficient and when professional help was needed. One interviewee articulated particularly clearly how short-term relief provided by apps could intersect with postponing professional help. She first framed this as a general risk:

> *...people often, instead of paying for care, reach for an app and think that it will replace therapeutic care.* [P07_23F]

The interviewer then asked:

> ***Interviewer:*** *Is that also your experience?*
>
> ***P07_23F:*** *Absolutely, yes. I was also that person who reached for the app first [...] but I didn't have any guarantee that it's actually helping me.*

In these accounts, the perceived risk concerned the way reliance on short-term app support could reshape judgments about when additional help was necessary.

When Looking Inward Becomes a Problem

Some participants worried that app use promoted an inward focus, which they found emotionally demanding rather than uniformly supportive, particularly when it involved confronting negative emotions or unresolved difficulties. As one participant described, reflective prompts were not limited to positive experiences but also required deeper engagement:

> *[...] that not only positive questions, but also deeper ones, where you really have to think about it and it hurts. It can hurt.* [P02_20M]

In a similar vein, others questioned whether repeated attention to negative emotional states might reinforce rather than alleviate distress:

> *If I kept feeling like shit and kept saying that I felt sick, I think I would have just continued to feel sick, because I would have kept repeating to myself that I feel sick.* [P04_24F]

In these accounts, self-monitoring was experienced as effortful and potentially counterproductive when not accompanied by sufficient support or resolution.

Others expressed concern that sustained inward engagement could lead to withdrawal from social interaction, noting that excessive self-focus might not be desirable:

> *...if I kept using it, I'd really withdraw into myself, which probably wouldn't be good.* [P12_34F]

Taken together, these accounts point to the double-edged nature of MH apps; while privacy and inward focus are central to digital self-care, they may also become emotionally demanding or socially isolating under certain conditions.

Digital Paradoxes of Self-Care

Finally, some participants reflected on broader digital paradoxes inherent in app-based self-care, highlighting tensions between the goals of mental well-being and the means through which support was delivered. Several respondents described a contradiction between using MH apps and their simultaneous efforts to reduce overall technology or screen use, particularly when digital environments themselves were experienced as stressful or overstimulating. As 1 participant noted:

> *I am trying to distance myself a bit from technology right now because I'm finding it's one of the triggers that stresses me out. Actually, meditating and using an app are perhaps a bit... maybe they go against each other a little. It just shouldn't feel forced, you know? Which technology often does.* [P30_43M]

Others similarly described discomfort with the necessity of keeping the phone close to access support, particularly when opening an app risked drawing them into other, unwanted digital activities:

> *...it bothers me that it forced me... that I have to keep it on me... once it's open, I start dealing with... other things there.* [P25_42F]

In response, some participants reported avoiding app use in certain contexts, such as at work or in overstimulating environments, acknowledging that the device itself could introduce distraction or exacerbate stress.

Discussion

Principal Findings

In our study, we explored why users adopt MH apps and how they integrate these tools into their lives and into broader ecosystems of MH care and support. Our findings highlight that user engagement is a continual negotiation between app functionalities and users' evolving needs. Importantly, we provide further evidence that disengagement can be a

XSL•FO
RenderX

meaningful outcome of MH app use, challenging engagement-centric assumptions that dominate current app design and evaluation.

Our results suggest that sustained MH app use is perceived as a goal only in a limited set of contexts. In other situations, MH apps are understood either as tools for temporary solutions or as instruments intended to foster the development of autonomous self-care practices that eventually become independent of MH apps. Our findings show that for some users, overcoming a difficult period or successfully integrating self-care practices into daily self-care maintenance resulted in what has been previously termed "positive disengagement" [27]. As users' goals were reached, they naturally decreased their app usage, showing that disengagement may follow individuals' own appraisals that the app is no longer needed. These reported experiences challenge the existing body of research on MH apps and the problem of low user engagement [9,14,15] by demonstrating that for some users, long-term sustained engagement is in direct conflict with their goals.

Beyond goal attainment, disengagement also emerged as a protective strategy in what we describe as the *digital self-care paradox*, whereby users intentionally reduce their engagement with digital tools to minimize the negative effects associated with prolonged technology use, such as overreliance on MH apps [19,23] or technology fatigue [15]. Moreover, usage discontinuation was often the result of successful substitution for off-screen self-care behaviors (eg, spending time outside). Therefore, "episodic" use or abandonment can often be a sign of a procedural recalibration of resources toward nondigital self-care, indicating successful self-care management.

This study showed that users varied considerably in their initial motivational patterns, which coincided with different self-care phases described in the MRTSC [26]. These patterns evolved along the following two dimensions: (1) intent, which referred to whether MH app use was oriented towards supporting well-being (emphasizing self-care maintenance), addressing ill-being (driven by self-care management), or understanding a specific problem (through self-care monitoring); and (2) engagement timing, which reflected when and how the apps were used, ranging from habitual and episodic to reactive use. Additionally, our findings showed that these initial patterns evolved over time into distinct trajectories shaped by the users' needs and resources, including enhanced self-care management supported by MH apps (self-emancipatory trajectories), the development of autonomous self-care without continued reliance on MH apps, increased reliance on MH apps as substitutes for human support, and episodic use limited to periods of perceived need.

Our findings provide further evidence of how MH apps enhance self-care maintenance, particularly through well-being–oriented and habitual use aimed at promoting psychological stability. Specifically, MH apps contribute to self-maintenance by legitimizing space for self-care, maintaining self-care routines, or supporting activities that reduce overall stress. The MRTSC suggests that the value of these digital routines lies in their cognitive economics. Ideally, apps offload the cognitive burden of daily maintenance, preserving users' psychological resources. However, our data reveal a critical tension—the digital mechanisms designed to support these habits (eg, notifications or streaks) may backfire. Instead of seamlessly integrating self-care into daily life, these intrusive features paradoxically increased technology fatigue, disrupting the very processes they aimed to facilitate.

Self-monitoring constituted a central component of the problem-oriented pattern of MH app use, although it was also present within the well-being–oriented and habitual patterns. While the MRTSC conceptualizes self-care monitoring as the observation and interpretation of changes, our findings illustrate that in the context of digital MH, this process extends beyond discrete symptom tracking. Some users engaged in detailed journaling and broader self-narrativizing. Here, the app facilitated a highly complex form of appraisal, allowing users to contextualize their psychological states or alternatively record positive experiences to counterbalance negative affect and keep a "life history." Crucially, however, the effectiveness and perception of this meaning-making depended on intentionality. When tied to a specific, personally meaningful goal, monitoring was beneficial. Conversely, when self-monitoring lacked clear intent, it was frequently experienced as burdensome or even depressing, which is consistent with prior research on the adverse outcomes of MH app use [10]. Ultimately, our data expand on this finding, suggesting that the value of digital self-monitoring hinges less on the mechanical act of tracking and more on the user's finding meaning in the process of recording data (ie, on their capacity to articulate why and how monitoring is meaningful for them).

Our study engages with the implications of stand-alone digital technologies designed for private and autonomous use by showing that MH apps were indeed largely managed by users themselves and rarely embedded in shared or professionally supported care practices. One strand of our findings illustrates how MH apps facilitated the processes of self-emancipation, supporting transitions from professionally delivered treatment to self-care. At the same time, our results show that external feedback on MH app use, whether from close others or health care professionals, often enhanced engagement, enabling users to refine their usage patterns or to apply skills acquired through the apps beyond the screen. Such external support proved especially vital for users who reported that in times of acute psychological distress, it was difficult to apply the techniques presented within the app. This finding resonates with the work of Villegas Mejía et al [25], who emphasized the importance of supporting engagement that extends beyond the MH app context.

Consistent with prior research [22], our interviews revealed numerous examples of MH app use enhancing self-care management by fostering skills and self-care habits that enabled some participants to transition from professionally delivered treatment to more autonomous management of their MH. However, this self-enhancement may have unintended consequences. For some users, greater perceived autonomy in self-management was accompanied by a heightened sense of personal responsibility for managing MH difficulties, leading them to hesitate to seek professional help, out of concern that they might burden health care providers or divert resources from

XSL•FO
RenderX

those in greater need. Viewed through the MRTSC, this hesitation is notable, as the theory positions consultation and seeking information as adaptive self-care management responses rather than departures from self-care. In treating help-seeking as a failure of autonomy, these users adopted a framing at odds with the MRTSC, in which turning to others is itself a legitimate self-care behavior. Our findings also resonate with the research of Van der Poll et al [24], who similarly described how MH app users may willingly assume personal responsibility for managing their own MH. Extending their work, our data suggest that this sense of responsibility can be accompanied by increased hesitation to seek professional help.

Moreover, our findings suggest that some users develop reliance on MH app–related practices as a primary source of immediate relief from negative emotional states. Although rapid relief may prevent symptoms from escalating, it may reduce the likelihood that users reflect on the seriousness of their condition and consider seeking professional help, potentially sustaining reactive crisis management. Unlike crisis hotlines, most stand-alone MH apps do not include mechanisms that actively encourage or facilitate seeking professional support.

We consider these findings especially concerning in populations where barriers to MH care are already high. In such contexts, promoting MH apps as a solution risks obscuring the problem in the short term while exacerbating it in the long term. Individuals who might otherwise seek professional help may instead rely on an app as a form of temporary relief, making symptoms more manageable while foregoing appropriate treatment. While this relief may reduce immediate distress, it can also prolong avoidable suffering and leave underlying needs for care unmet. What may appear to be a solution to limited access to MH services may, in fact, function only as a palliative response to a broader structural problem.

Limitations

This study has several limitations. First, the distinction between "well-being" and "ill-being" orientations may partly reflect processes of self-narrativization, whereby participants construct coherent accounts of their MH app use that align with identity work rather than their immediate psychological states. Second, the study relies on retrospective accounts of MH app use. Participants reconstructed the evolution of their engagement over time based on memory and subjective interpretation, which may introduce recall bias. Future research would benefit from longitudinal designs capable of capturing trajectories of MH app use as they unfold. Third, although our analysis focused on MH apps, some participants reported extending their digital self-care practices by consulting generative AI tools (eg, large language models) embedded in, or external to MH apps.

Finally, the sample was relatively homogeneous, consisting predominantly of young, female, Czech, digitally engaged participants, which limits the range of experiences represented and, consequently, the transferability of the findings to other populations and contexts. In addition, individuals currently experiencing a psychological crisis were excluded from participation. Our findings may therefore not fully capture experiences of MH app use during acute psychological distress. Future research should examine whether and how the identified patterns and trajectories manifest across more diverse demographic, cultural, and clinical contexts.

Recommendations

Similar to health care providers, MH app designers may consider "positive disengagement" as a legitimate outcome. Because some app designs discourage this through various mechanisms (eg, daily streaks), incorporating "pause" functions, allowing flexible payment plans, and avoiding punitive gamification mechanics may empower users to successfully integrate coping strategies off-app. MH apps could also be designed to promote connection rather than substitute for human support. Instead of functioning as self-contained solutions, apps might serve as intermediary or boundary objects that facilitate communication with professionals, counselors, or trusted peers. Moreover, apps with emotion tracking or crisis support features may integrate empathic prompts to direct users to low-barrier resources (eg, hotlines and MH professional directories) in response to the detection of sustained distress. Clear guidance to distinguishing between manageable distress and symptoms that warrant clinical attention, alongside normalizing help-seeking as a legitimate and responsible step, may reduce feelings of shame and prevent responsibilization for solving one's own problems. In this way, MH apps can function as bridges to care rather than barriers to professional support.

For clinicians, the practical task is to bring clients' motivations for autonomous app use into the conversation and help educate them about the limits of these tools. Clients prone to reactive use during acute distress warrant particular attention, as these apps rarely offer crisis plans. MH professionals should work with such clients on a crisis plan that does not depend on the app. Mood tracking and journaling should be encouraged only for clients who experience them as beneficial or connected to personally meaningful goals.

Conclusion

This study shows how MH apps are embedded within broader practices of care and support, and under which conditions they may be empowering or problematic. For some users, they foster autonomy, strengthen self-care skills, and enable the transfer of coping strategies beyond digital platforms and even beyond professional treatment. In such cases, discontinuing app use may reflect the successful integration of self-care into everyday life. For others, however, MH apps may reinforce app-based coping and contribute to reliance on digital tools. Overall, providing clearer distinctions between everyday emotional strain and clinically significant symptoms, while framing help-seeking as a responsible and legitimate course of action, may help alleviate shame and counteract the tendency to place excessive responsibility on individuals to manage their own MH.

Acknowledgments

We express our gratitude to the participants of our study for giving us their time and helping us understand digital mental health tools better.

The authors declare the use of generative AI (GenAI) in the writing process. The following tasks were delegated to GenAI tools under full human supervision: text reformulation (refinement of Introduction and Discussion sections of the manuscript), table formatting, proofreading and editing. The GenAI tools used were ChatGPT 5.5, Gemini Pro, and Copilot. All AI-generated suggestions were evaluated and revised by the authors, who take full responsibility for the final content of the manuscript.

Funding

This study comes from the project "On our own: Opportunities and Risks in the Individualization of Society (PRINS) CZ.02.01.01/00/23_025/0008710," which is co-financed by the European Union.

Abstract

Background: The use of electronic headache diaries via smartphone apps has several advantages over paper and pencil diaries. Still, adherence is not always satisfactory. One potential strategy to improve adherence is the implementation of daily reminders, but their effect remains uncertain.

Objective: The DMKG-App (the headache diary app of the German Migraine and Headache Society, DMKG) sends daily reminders to encourage user adherence. Due to a technical problem, reminders failed for a 14-day period in early 2023. This provided a unique opportunity to evaluate the effect of daily reminders on adherence to the headache diary in the form of a retrospective longitudinal observational cohort study.

Methods: The failure period was compared to 14-day prefailure and postfailure periods and to corresponding periods of the previous year. We evaluated effects on the number of daily entries, delay to make the daily entry, and attrition rate, using ANOVA and logistic regression (α<.05). The effect of age, gender, headache frequency, and previous adherence was investigated using interaction analysis.

Results: The DMKG-App had 4236 active users before reminders failed (females 81.6%, 95% CI 80.5 - 82.8), age 39.8 (95% CI 39.4 - 40.2) years. During the failure period, the number of daily entries fell by 11.0% (95% CI 9.2 - 12.8). More specifically, entries per 14-day period significantly declined from 10.2 (95% CI 10.1 - 10.3) prefailure to 9.1 (95% CI 9.0 - 9.2) during the failure period, followed by a rise to 10.2 (95% CI 10.1 - 10.3) during the postfailure period ($F_{2,11498}$=79.2; P<.001). The delay to make the daily entry increased by 46.3% (95% CI 45.8 - 46.8), from 1.90 (95% CI 1.89 - 1.90) days prefailure to 2.78 (95% CI 2.77 - 2.79) days during failure, and returned to 1.85 (95% CI 1.84 - 1.86) days postfailure ($F_{2,39}$=155.4; P<.001). In addition, there was a significant rise in attrition rate by 32.2% (95% CI 8.1 - 61.7) (from 4.0%, 95% CI 3.4 - 4.6, in the prefailure period to 5.2%, 95% CI 4.6 - 5.9, in the failure period, returning to 3.9%, 95% CI 3.4 - 4.5, in the postfailure period, z=3.10; P=.002). Interaction analysis revealed that the effect of reminder failure was larger in males than in females (regarding entry delay), in persons with lower compared to higher headache frequencies (regarding number of daily entries and entry delay), and in persons

XSL•FO
RenderX

with higher vs lower previous adherence rates (regarding number of daily entries, entry delay, and attrition). There was no interaction between age and reminder failure.

Conclusions: This is the first study investigating the effect of daily reminders in a digital headache diary app. Results suggest that reminders are an effective means to improve adherence. Males, persons with low headache frequencies, and those with high adherence during the presence of reminders seem to benefit most. These results are important additions to our knowledge on compliance with digital health apps.

KEYWORDS

headache; electronic headache diary; adherence; entry delay; attrition rate

Introduction

Headache diaries are important tools for diagnosis and treatment evaluation in primary headaches [1]. Indeed, it has been shown that self-reported retrospective estimations of headache frequency are highly unreliable. In a study from the Leiden Headache Center, for example, the average difference between retrospectively self-reported and diary-assessed monthly migraine days was 4.7 (SD 5.0) days per month, with both overestimation and underestimation occurring [2]. Paper-and-pencil diaries have been used for a long time and have the advantage of being simple and free from technical requirements. On the other hand, they can get lost, may not be at hand when needed, and patients may sometimes fill in missing days shortly before the appointment, resulting in recall bias [3,4].

While some patients prefer paper diaries, smartphone-based electronic headache diaries have gained popularity in recent years. At a time when most people carry a smartphone, and with the majority of headache patients being relatively young and comfortable with digital technology, smartphone apps have several advantages [4]. The smartphone is always at hand, recall bias can be reduced by allowing retrospective entries only for a defined period, and automatic summaries give a quick overview to be shared with the physician [5,6]. Patients can be guided through data capture, and automated data validation improves data quality [6]. It has been shown that electronic diaries are superior to paper diaries in several respects (better validity, less missing data, and larger patient satisfaction [4,7]). Data can also more easily be used for large-scale research, as recently shown in an analysis of acute medication rating based on more than 270,000 users [8]. In the future, data from headache diary apps might be integrated with other health data, with possible applications, for example, for attack prediction [9].

Still, adherence to the diary is key to headache evaluation, and prompt entries increase accuracy by decreasing recall bias [2]. One attempt to increase adherence to headache apps is to send users daily reminders.

Different behavioral or motivational theory approaches offer explanations of how reminders may improve the target behavior (making the daily entry) [10]. For example, the COM-B model focuses on capability (C), opportunity (O), and motivation (M) as conditions of behavior (B) [11]. Regarding a diary app, the person needs to be proficient in handling a smartphone app (C), must have access to a smartphone and internet connection (O), and needs the motivation to fill in the diary. In this model, reminders might make the original motivation salient again, increasing the frequency of the behavior. The behavioral model developed by Fogg [12] introduces an additional element by assuming that the building blocks of behavior are the combination of motivation, ability, and triggers. A reminder is a prototypical example of a trigger, prompting existing motivation and ability into behavior. There also is the traditional concept of intrinsic vs extrinsic motivation, with the former describing that behavior is motivated "because it is inherently interesting or enjoyable," and the latter behavior that is motivated "because it leads to a separable outcome" [13]. A well-designed reminder might make the daily entry enjoyable. On the other hand, it may help to achieve a goal (headache documentation), so reminders may act on both intrinsic and extrinsic motivation. The self-determination theory is a modern theory of intrinsic motivation [14] and emphasizes that specific psychological needs (ie, autonomy, competence, and relatedness) must be satisfied to motivate human behavior. Reminders may promote a feeling of autonomy, as participants can, but do not have to, act upon them. Reminders may increase the feeling of competence by making it easier to reach the goal. They could also be specifically designed to create a sense of social relatedness. Also, concepts from digital literacy research may be useful for understanding the function of reminders, as this research suggests that both the user's ability and the system's usability must be present for a digital tool to be used effectively. In this framework, reminders increase the usability of a headache diary, as they make the diary easier to use [15].

The electronic headache diary of the German Migraine and Headache Society (DMKG; the smartphone app is called "DMKG-App") uses daily reminders [16]. A technical problem in early 2023 resulted in a 2-week period during which no reminders were sent. This allowed us to analyze if the absence of reminders had an effect on (1) the number of days recorded in the app (daily entries), (2) the delay to record the daily entry (entry delay), or (3) a disproportionately high number of users stopping use of the app altogether (attrition rate). In addition, we investigated whether age, gender, headache frequency, and previous adherence influence the reaction to reminder failure.

XSL•FO
RenderX

Methods

Study Design

This is a retrospective longitudinal cohort study using data from a smartphone headache diary app that sends daily reminders to make the daily entry. For technical reasons, reminders failed for an approximately 2-week period in early 2023. We investigated how adherence was affected by reminder failure by comparing the failure period with 2 periods with intact reminders and with the analogous periods from the previous year.

Setting and Data Sources

The analysis used data from the smartphone headache diary app of the German Migraine and Headache Society (DMKG-App), available in Germany for Android and iOS since June 2020 for users aged at least 16 years. In the DMKG-App, users are asked to record every day either as “no headache” or “headache.” In the case of “headache,” additional headache characteristics are assessed, which were not analyzed here. A reminder to make the daily entry is sent as a smartphone push notification every day around 8 PM (fixed time), reading, “Don’t forget your headache diary. Your DMKG-App is ready for today’s entry.” Entries can be made retrospectively for a maximum of 14 days in the past as a compromise between reducing recall bias and maintaining app usability.

Participants

The DMKG-App is available in Germany for users aged at least 16 years who use the app either for their personal headache documentation or to support their headache treatment. We included participants fulfilling the criteria of being an “active user” during one of the periods of interest (see “Statistical Analysis” section below).

Ethical Considerations

The DMKG-App is part of the larger project “DMKG Headache Registry” [16] that has been approved by the ethics committee of the Ludwig-Maximilians-University Munich (Nr. 20 - 004), complies with European and German Data Protection laws, and is registered with the German Clinical Trials Register (DRKS 00021081). The DMKG-App is freely available for use by persons with headaches in Germany.

Each participant provided informed consent for the use of their data for headache research. As health data constitute a special category of personal data, participants provided explicit consent to the processing and scientific use of their data in accordance with Article 9(2)(a) of the General Data Protection Regulation (GDPR) [17]. The present analysis also includes data from adolescents aged at least 16 years. Article 8(1) of the GDPR provides that, where an information society service is offered directly to a minor, individuals aged at least 16 years may provide consent themselves [18]. Although European Union (EU) Member States may establish a lower age threshold, Germany has not adopted such a lower threshold. The German Data Protection Conference also addresses these requirements in its Short Paper No. 20 [19] on consent under the GDPR, which refers both to the requirement of explicit consent for the processing of special categories of personal data and to the specific conditions under Article 8 of the GDPR for children’s consent in relation to information society services. The consent procedure for DMKG-App use was designed on this legal basis. Accordingly, participants aged 16 or 17 years provided the required informed and explicit consent themselves, and no additional consent from a parent or legal guardian was obtained.

Only anonymized data were used for the present analysis, and only aggregated results are reported. Individual users cannot be identified from any part of this manuscript.

Analyzed Failure and Reference Periods

The failure to send reminders occurred following the release of a new app version (2.0.0) on December 17, 2022, and was corrected with version 2.0.4 released on February 10, 2023. However, after an entry in the app is made, reminders are preplanned for the next 6 (42 d) weeks and then work independently of the app version. This resulted in active app users experiencing failure of reminders only toward the end of January 2023. In addition, not all users updated to the new version immediately. Therefore, although reminders slowly started to fail beginning on December 17, a general failure occurred between January 28 and February 10, 2023. Therefore, we used this 14-day period for analysis. For comparison, we chose 14-day reference periods before December 17 (December 3-16, 2022) and in equal distance after the failure period (March 25 to April 07, 2023). We called these analysis periods the “prefailure,” “failure,” and “postfailure” period, respectively.

To exclude the possibility that circannual variations affected the results, we also analyzed the same time periods in the preceding year (ie, precontrol: December 3-16, 2021; control: January 28 to February 10, 2022; postcontrol: March 25 to April 07, 2022).

Variables

Users can record every day either as “no headache” or “headache,” or make no entry. Both “no headache” or “headache” days counted as recorded days. From this measure, we calculated 3 outcome parameters for each period: the number of recorded days (“daily entries”), the delay to make the daily entry (measured in days; the app allows making entries with a maximum delay of 14 d), and the attrition rate (users who had been active before the period but made no further entry during or after that period).

In addition, we used age, gender, headache frequency, and previous adherence categories to analyze if these variables modulated the effect of reminder failure. For age, 2 groups were defined by median split (younger <37 y and older ≥37 y). For headache frequency, categories were chosen according to migraine frequency categories [20] (low, medium, or high frequency: 0 - 7 d/mo; 8-14 d/mo; ≥15 d/mo, respectively) and determined from the entries in October 2022 (ie, before the prefailure period). Only participants who had made more than 70% of the possible entries in this time frame were included to reduce bias in headache frequency detection related to low adherence. For previous adherence, the number of entries in October 2022 was used. Most participants made daily entries (31 days, which we termed: “high previous adherence”), the

XSL•FO
RenderX

remainder was more or less evenly distributed between 0 - 14 entries ("low previous adherence") and 15 - 30 entries ("medium previous adherence").

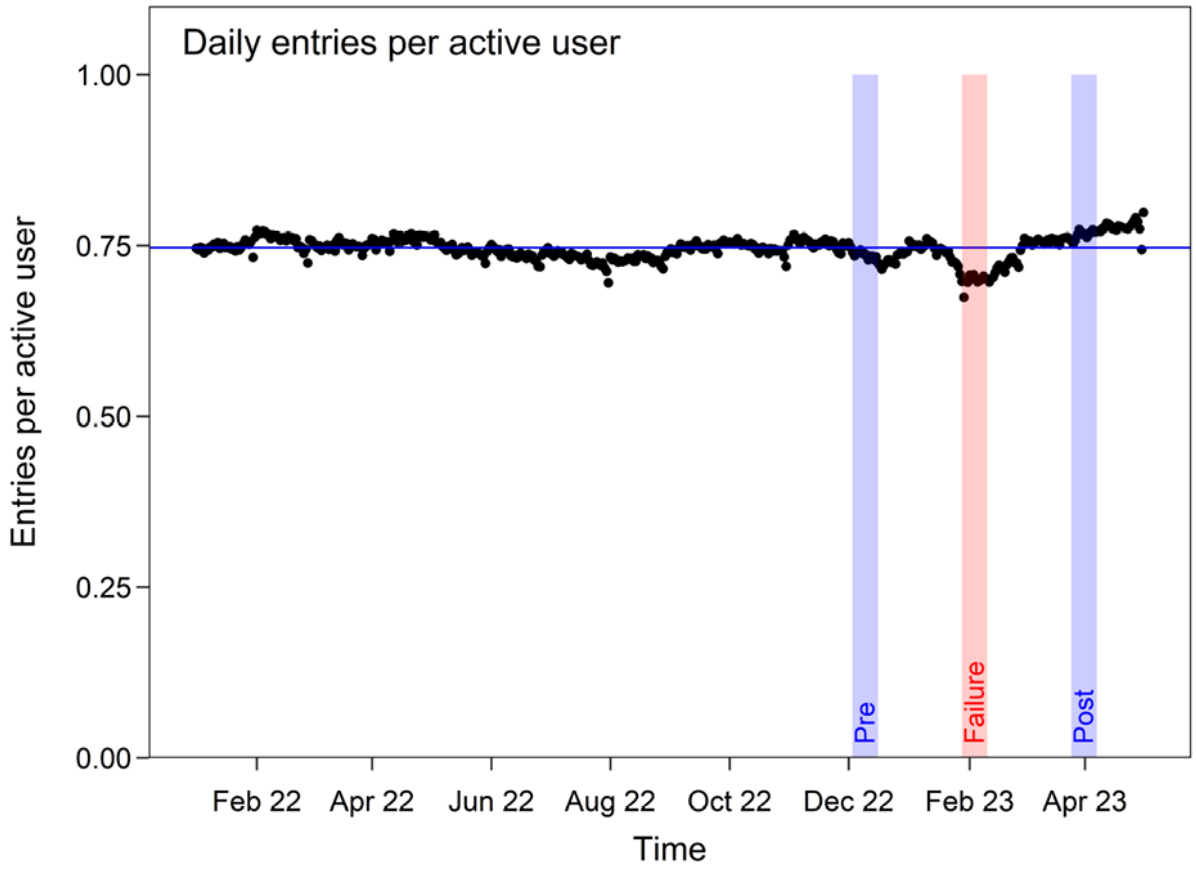
There were no missing data, as age and gender are mandatory entries in the DMKG-App, and the fact that some days were recorded and others not was the subject of our analysis.

Statistical Analysis

Statistical analysis was made in R (R Foundation for Statistical Computing; version 4.4.0). 95% CIs are given. $P<.05$ was considered significant. Post hoc tests comparing the 3 periods were corrected for 3 comparisons with Bonferroni Holm correction, and corrected P values (P_c) are reported [21].

As the number of app users changes continuously (new users joining and previous users ceasing to use the app; for the DMKG-App there currently is a net increase in users), we based our analysis on the number of active app users on a specific day, defined as users with at least 2 entries in the app, 1 before the analyzed day and 1 on or after the analyzed day.

To analyze the number of recorded days ("daily entries") during the different periods, we compared the number of entries within the respective 14-day period per active user between periods (prefailure, failure, and postfailure) using ANOVA followed by a Wilcoxon rank sum test with continuity correction. For a day-by-day graphical illustration, the number of entries on every day was set into proportion to active users on this day (Figure 1).



For the delay in recording the daily entry ("entry delay"), the number of days between the recorded day and the day the entry was made was calculated, averaged within periods and compared between periods using ANOVA followed by Welch t tests (2-tailed). If the entry was made on the day itself, the delay was 0. Only days with an entry were considered.

To analyze the proportion of users stopping app use ("attrition rate") during the different periods, all active users on the day before the start of the respective period were considered. For every day during the analyzed period, users that had not made any further entry on that day or any day after this (up to data closure on June 20, 2023) were considered to have stopped app use. Proportions of users having stopped app use at the end of the respective period were compared between periods using logistic regression.

To analyze if age, gender, headache frequency, and previous adherence modulated the effect of reminder failure on daily entries, delay, and attrition rate, categorical variables as defined above were included in the respective ANOVA or logistic regression.

XSL•FO
RenderX

Figure 1. Time course of the number of daily entries with respect to active app users. This was a longitudinal analysis of data from the Deutsche Migräne- und Kopfschmerzgesellschaft e.V. (German Migraine and Headache Society, DMKG) app, a headache diary app freely available in Germany, comparing a period where no daily reminders were sent with periods with reminders. A significant dip in the daily entry rate is seen during the period where no reminders were sent (failure). Each data point represents 1 day. Please note that the red bar denotes the absolute failure period. For some users, failure occurred earlier and/or lasted longer (see "Methods" section), explaining why the reduction of daily entries extended beyond the failure period. Prefailure and postfailure periods are marked by blue bars.

Results

The number of active users at the start of the reminder failure period was 4236. A total of 3460 (81.6%, 95% CI 80.5 - 82.8) were female, and the average age was 39.8 (SD 12.8, 95% CI 39.4 - 40.2) years.

Number of Recorded Days in the Diary (Daily Entries)

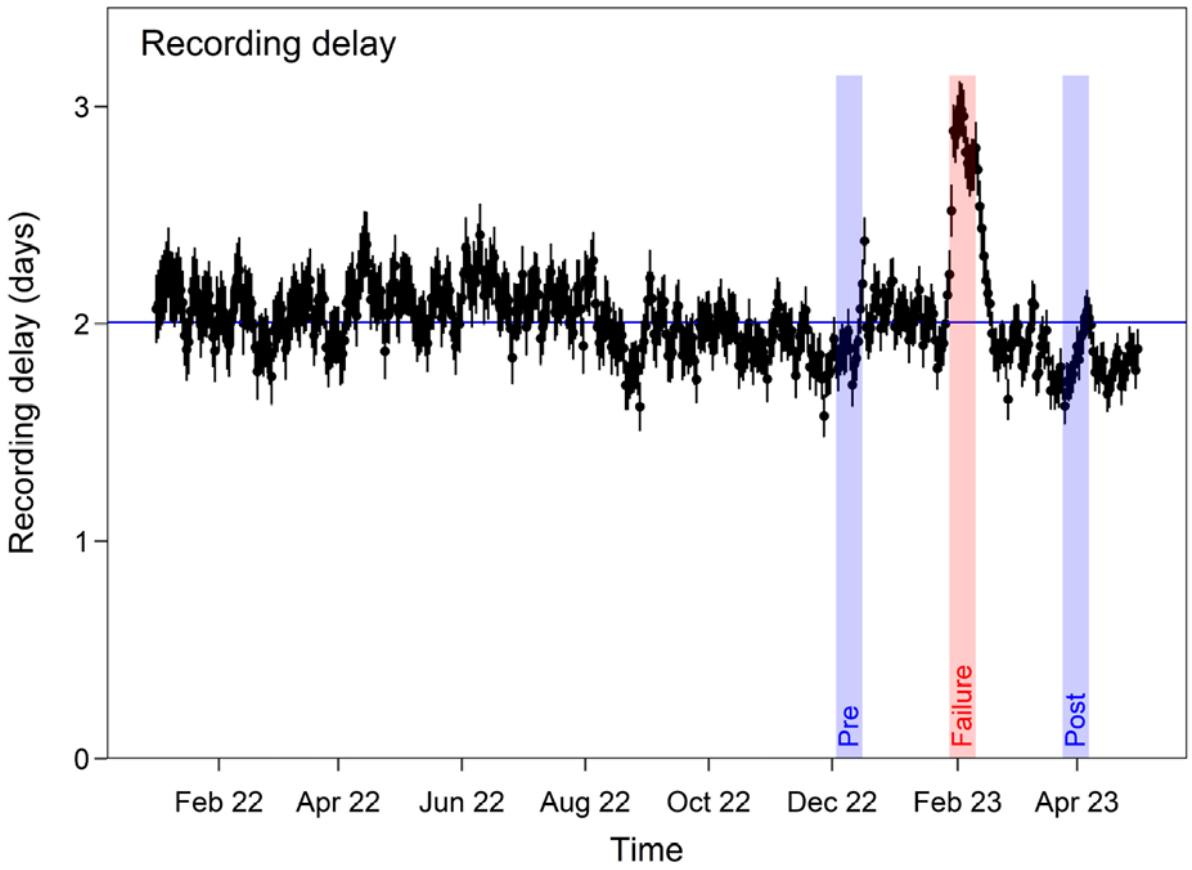
Figure 1 shows the course of daily entries in relation to active users, displaying a remarkable dip during the period where no reminders were sent. Active users made 10.2 (SD 4.3, 95% CI 10.1 - 10.3) of 14 possible entries during the prefailure period, 9.1 (SD 4.6, 95% CI 9.0 - 9.2) during the failure period, and 10.2 (SD 4.3, 95% CI 10.1 - 10.3) in the postfailure period. There was a significant difference between the 3 periods ($F_{2,11498}$=79.2; P<.001). Post hoc tests revealed significant differences between the prefailure and failure periods (z=11.9; P_c<.001) and between the failure and postfailure periods (z=12.5; P_c<.001) but not between the prefailure and postfailure periods (z=0.1; P_c=.90).

This was not an effect of time of the year, as no such effect was seen in the respective periods in the previous year (prefailure: mean 10.4 (SD 4.0, 95% CI 10.2 - 10.6) entries; failure: mean 10.5 (SD 4.1, 95% CI 10.3 - 10.7) entries; postfailure: mean 10.5 (SD 42, 95% CI 10.3 - 10.7) entries; $F_{2,5134}$<0.1; P=.91).

Thus, there was a reduction of daily entries per active user of 11.0% (95% CI 9.2 - 12.8, from 10.2 to 9.1 entries per 14-d period) from the prefailure to the failure period.

Delay to Make the Daily Entry

Figure 2 illustrates that the typical average delay in recording was around 2 days, which sharply increased to almost 3 days during the failure period. Specifically, average delays were 1.90 (SD 0.12, 95% CI 1.89 - 1.90) days in the prefailure period, 2.78 (SD 0.20, 95% CI 2.77 - 2.79) in the failure period, and 1.85 (SD 0.14, 95% CI 1.84 - 1.86) days in the postfailure period. This was highly significant between periods ($F_{2,39}$=155.4; P<.001). Post hoc tests revealed significant differences for comparison of prefailure to failure ($t_{20.5}$=−14.0; P_c<.001) and failure to postfailure ($t_{22.7}$=14.1; P_c<.001) but not prefailure vs postfailure ($t_{25.3}$=1.0; P_c=.24).



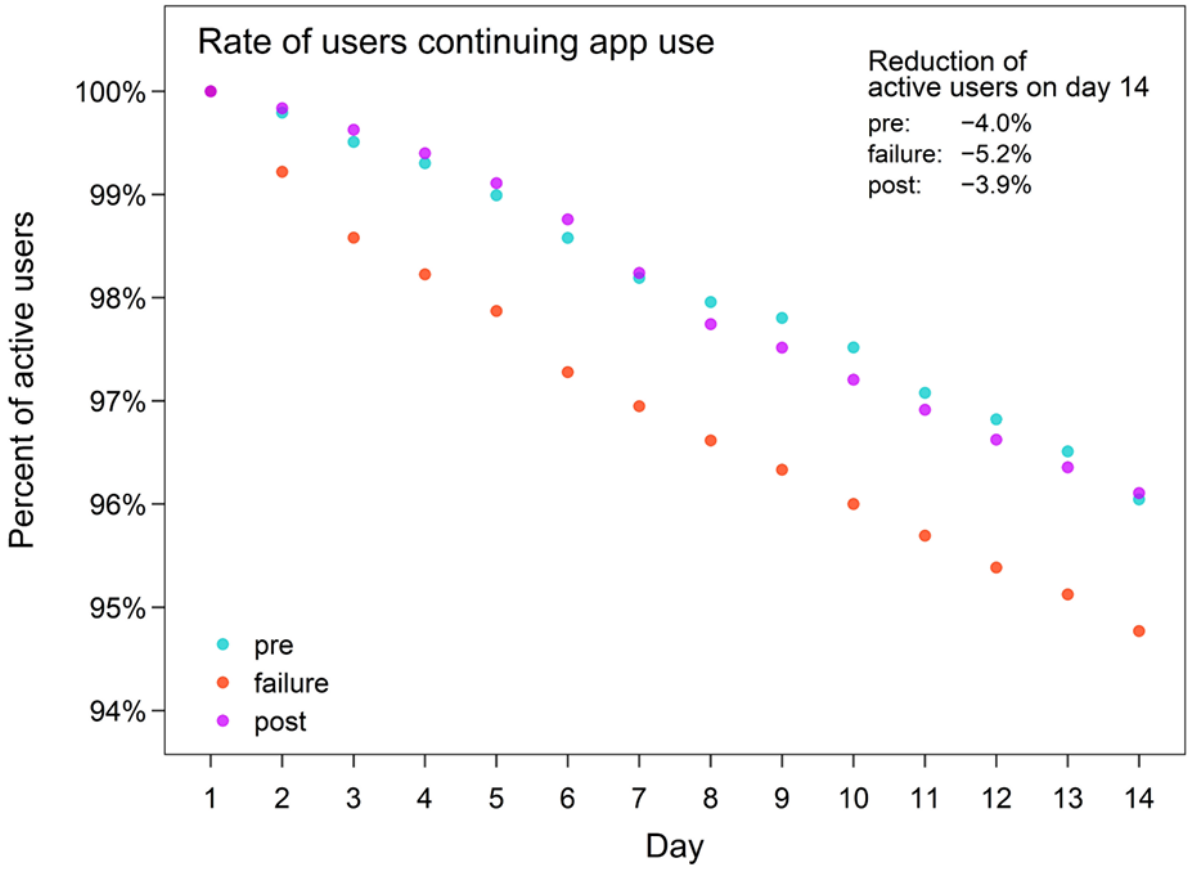
Again, this was not due to circannual variation, as the values for the respective periods of the preceding year were: precontrol

XSL•FO
RenderX

mean 2.08 (SD 0.07, 95% CI 2,08 - 2,08), control mean 2.03 (SD 0.10, 95% CI 2.02 - 2.04) and postcontrol mean 1.97 (SD 0.11, 95% CI 1.96 - 1.98). While ANOVA detected significant differences between periods ($F_{2,39}$=5.9; P=.006), the control period was not significantly different from either precontrol or postcontrol periods (precontrol vs control periods: $t_{23.5}$=1.68; P_c=.11; control vs postcontrol: $t_{25.8}$=1.72; P_c=.19). However, there was a small but significant reduction from precontrol to postcontrol ($t_{22.4}$=3.5; P_c=.002) that was not further explored.

The increase of recording delay from the prefailure period (1.90) to the failure period (2.78) corresponds to a relative increase of 46.3% (95% CI 45.8 - 46.8).

Figure 2. Time course of the delay in recording the daily entry. This was a longitudinal analysis of data from the Deutsche Migräne- und Kopfschmerzgesellschaft e.V. (German Migraine and Headache Society, DMKG) app, a headache diary app freely available in Germany, comparing a period where no daily reminders were sent with periods with reminders. A significant rise in delay is seen during the period where no reminders were sent (failure). Each data point represents 1 day; error bars correspond to SDs. Prefailure and postfailure periods are marked by blue bars.



Users Stopping App Use (Attrition Rate)

There is always a certain number of users stopping app use. From all users classified as active before the day where reminders failed, a total of 5.2% (220/4236 users, 95% CI 4.6 - 5.9) stopped using the app for good (ie, made no further entry after that). In comparison, in the prefailure and postfailure periods, 4.0% (155/3886, 95% CI 3.4 - 4.6) and 3.9% (189/4845, 95% CI 3.4 - 4.5) stopped app use (Figure 3). Logistic regression revealed significant differences between periods (prefailure vs failure: z=2.8; P=.006; postfailure vs failure: z=3.10; P=.002). Also, in the previous year, attrition rates were 2.8% (49/1735, 95% CI 2.1 - 3.7), 3.0% (58/1929, 95% CI 2.3 - 3.9) and 2.9% (64/2192, 95% CI 2.3 - 3.7) during the precontrol, control, and postcontrol periods, without significant differences (prefailure vs failure: z=0.1; P=.91; postfailure vs failure: z<0.1; P=.99).

XSL•FO
RenderX

Figure 3. Attrition rates during failure of reminders vs before and after failure of reminders. This was a longitudinal analysis of data from the Deutsche Migräne- und Kopfschmerzgesellschaft e.V. (German Migraine and Headache Society, DMKG) app, a headache diary app freely available in Germany, comparing a period where no daily reminders were sent (failure) with 2 periods with intact reminders (prefailure and postfailure). The rate of previously active users who continued using the app during the failure period compared to the prefailure and postfailure periods.

Thus, there was an excess loss of 1.2% (5.2% in the failure period vs 4.0% in the prefailure period) of active users within the period with notification failure, or, put differently, the loss of active users during the failure period increased by 32.2% (from 4.0% to 5.2%, 95% CI 8.1 - 61.7).

Interaction With Age

There was no significant interaction between age and period, neither for the number of recorded days nor for the delay to make the daily entry, nor for attrition rates (see Table S1 in Multimedia Appendix 1 for details).

Interaction With Gender

The increase of the delay to make the daily entry from the prefailure to the failure period was significantly lower in females than in males (+0.85, 95% CI 0.84 - 0.86) days vs +1.03 (95% CI 1.00 - 1.06) days; interaction between gender and period: $F_{2,78}$=5.0; P=.009). There was no interaction between gender and period regarding the number of recorded days or the attrition. Details are listed in Table S1 in Multimedia Appendix 1. In summary, females were less sensitive than males to reminder failure regarding the delay to make the daily entry.

Interaction With Headache Frequency

Results are summarized in Table S2 in Multimedia Appendix 1. For the number of recorded days, there was an interaction between period and headache frequency ($F_{4,5536}$=3.3; P=.01), with the prefailure to failure reduction being significantly larger in the low frequency group (−1.49, 95% CI −1.10 to −1.76 entries per 14 d) than in the 2 other groups (medium: −0.79, 95% CI −0.42 to −1.16; P=.004; high: −0.88, 95% CI −0.39 to −1.37; P=.04). For the delay to make the daily entry, there was an interaction between period and headache frequency ($F_{4,117}$=18.9; P<.001), with the prefailure to failure increase being larger with lower headache frequencies (low: +1.17, 95% CI 1.15 - 1.19; medium: +0.87, 95% CI 0.85 - 0.89; high: +0.60, 95% CI 0.58 - 0.62 days; all P<.001). For the attrition rate, there was no interaction between period (pre vs failure) and headache frequency (z=−0.64; P=.53).

In summary, patients with lower headache frequencies were more sensitive to reminder failure regarding the number of recorded days and the delay to make the daily entry.

Interaction With Previous Adherence

Results are summarized in Table S2 in Multimedia Appendix 1. For the number of recorded days, there was an interaction between period and previous adherence ($F_{4,6947}$=5.8; P<.001),

XSL•FO
RenderX

with the prefailure to failure decrease being larger in the high compared to the low previous adherence group (−1.21, 95% CI −1.44 to −0.98 d vs +0.13, 95% CI −0.60 to 0.86; P=.002). For the delay, there was an interaction between period and previous adherence ($F_{4,117}$=10.7; P<.001), with prefailure to failure increases of the delay being largest in the high previous adherence group (low: +0.77, 95% CI +0.73 to +0.81; medium: +0.81 (95% CI +0.78 to +0.84); high: +0.98 (95% CI +0.97 to +0.99) days; all 3 comparisons significant, Table S2 in Multimedia Appendix 1). For the attrition rate, there was a significant interaction between period (pre vs failure) and previous adherence (z=−4.22; P<.001). Excess attrition rates (pre vs fail) were highest in the high previous adherence group (low: −1.9% (95% CI −4.4 to +0.5); medium: −0.5% (95% CI −2.8 to +1.7); high: +2.7% (95% CI +1.6 to +3.8); both comparisons with high previous adherence were significant, Table S2 in Multimedia Appendix 1).

In summary, patients with high adherence during the presence of daily reminders were most sensitive to failure of these reminders.

Discussion

Principal Findings

This study demonstrates that daily reminders can significantly contribute to the adherence to electronic headache diaries. Absence of reminders during a 14-day period resulted in a measurable decline in daily entries by 11% and an increase of daily entry delays by 46% and attrition rates by 30%. Moreover, males, participants with lower headache frequencies, and with higher previous adherence showed a larger decrease in adherence in reaction to the reminder failure, while age groups did not differ in reaction to reminder failure.

The present results show that daily reminders indeed improved adherence to the DMKG-App electronic headache diary. From the different behavioral and motivational theories, Fogg's model may be best suited to understand the effect of reminders. In accordance with this model, smartphone reminders serve as external triggers, sometimes also called signals or nudges, to perform the desired behavior and can be seen as elements of persuasive technology [12,22]. Behavioral model developed by Fogg additionally lists ability and motivation as prerequisites for behavior and the digital literacy literature emphasizes that both ability and usability must come together for a digital tool to be used effectively [15]. In the DMKG-App, reminders are implemented as push notifications taking the user directly to the daily entry. Failure of reminders would be supposed to reduce usability [15] by making the daily entry more difficult, as the user has to locate and open the app, and choose the correct day. In addition, in the DMKG-App, the timing of the reminders (8 PM) is chosen to increase the salience of the original motivation [23,24] at a time when the ability of the users to perform the behavior is high (if a headache occurs this day, it will most probably already have occurred; most participants will be back from work but not yet too tired). This effect could be further improved by personalizing the time of the reminder based on the time of previous entries, as personalization is a well-established persuasive design principle [25].

Motivation may also decrease with reminder failure, as it becomes more difficult to reach the desired goal (having a good headache documentation) [22,23]. Reminders offer additional possibilities to increase motivation (not implemented in the DMKG-App), for example, making the response to the daily reminder enjoyable by including elements of gamification (like receiving points or seeing interesting animations). Regarding self-determination theory [14], DMKG-App reminders use language emphasizing user autonomy ("Your DMKG-App is ready for today's entry" instead of "You need to make your entry now" or "Your entry for today is still missing"). The feeling of autonomy could be further increased by allowing the user to choose the timing of the reminders. Up to now, the DMKG-App does not build on social relatedness, which might be an additional possibility to increase the effect of reminders according to self-determination theory [14]. Relatedness could be promoted by including the user's name in the reminders, by including information like "xxx DMKG-App users have already made the entry for today," or by using chatbot elements starting a reminder with "Can I help you to make your entry for today," possibly with personalized reactions like "I am sorry that you had a strong headache today." However, this carries a risk of bias, so that the effect of such an intervention on data quality would need careful evaluation.

While the reduction of daily entries and the excess attrition of users during the failure period may seem modest, the delay to perform the daily entry increased from 1.90 days in the prefailure period to 2.78 days in the failure period. This is a large effect that will likely increase recall bias. The exact clinical significance of a +0.9 day shift in entry delay is difficult to estimate, as most recall bias research in headache compared headache diaries to retrospective ratings after longer periods such as 1 - 3 months [2,26,27]. Results from time-diary research suggest that a 24 hours delay can result in an error of approximately 10% [28]. Our results therefore may have implications for both clinical headache care and scientific use of these data as both rely on data quality. Our data suggest that persons with low headache frequencies and those with high previous adherence are most sensitive to the reminder failure. The first relation seems reasonable as the headache itself might serve as a trigger to make the entry (within theory by Fogg [12]) and motivation (within Fogg or COM-B frameworks [11,12]) may be higher with more frequent headaches as headache-related disability is larger. Indeed, there is some previous evidence that adherence to a headache diary is better on headache days than on headache-free days [29].

On the other hand, in participants with low adherence despite receiving daily reminders, reminders seem to be largely ineffective anyway, possibly explaining why participants with higher adherence in the presence of reminders had a larger drop in adherence when reminders failed. However, there is no literature to support this speculation. In our data, there was also a small effect of males having a larger increase in recording delay with reminder failure than females. There is evidence that women are more socialized to engage in preventive health care and more readily integrate health behavior in their daily routines [30], most likely pointing toward an increased motivation for the behavior. Some (but not all) previous studies on mobile

XSL•FO
RenderX

health apps showed better adherence in females than in males [31], and such a relation has also been reported in a headache diary study [32], but the specific effect of reminders has not been investigated. In addition, there is some evidence that males may respond more to gamification elements than women in the health context (eg, [33]). Reminders may be regarded as a basal level of gamification. Further studies are needed to assess gender differences in adherence and personalized interventions may result from this.

One result from our study needs further comment. The attrition rates were generally lower in the previous year (2.8% - 2.9% in the precontrol and postcontrol periods) than in the year where the failure occurred (3.9% - 4.0% in the prefailure and postfailure periods). This is likely due to the fact that the DMKG-App was made freely available in Germany between these 2 time points. Before that, its use was limited to users being treated at a center participating in the DMKG Headache Registry, likely leading to lower attrition rates.

Comparison to Prior Work

There are not many recent studies investigating adherence to an electronic headache diary, and it is difficult to compare results because of different approaches. An analysis of 1561 users of the Curelator / N1 headache app showed that adherence strongly depended on the setting, being highest for a paid version, intermediate after physician recommendation using a download coupon, and lowest for a free version. In the Curelator / N1 headache analysis, 90-day adherence (proportion of entered days) was 66%, 44% and 34% in the 3 settings, respectively [34]. These values cannot be directly compared to our results showing 70% - 75% adherence, as we included only "active users" in the analysis (see "Methods" section). On the other hand, in a study including 1009 patients of the Leiden Headache Center using the headache center's e-diary for a minimum of 2 weeks and a median of 181 days, adherence was very high with only 10.8% of the daily entries missing [32]. This is likely due to this study being based on patients from 1 tertiary headache center who were explicitly asked to use the e-diary for their clinical follow-up or study participation. A study with adolescents treated at a tertiary headache center found that over 90 days, 68.7% of the entries within an internet-based headache diary were made on the same day. This rate was higher for headache days with acute medication intake [29]. A study using a headache diary app also providing progressive muscle relaxation that recruited participants at a tertiary headache center found an average of 51 days entered during the first 90 days (adherence 57%), but adherence sharply declined over time [35].

It has been emphasized that there are many factors influencing health-related electronic diary use, including app design (usability, content, feedback on entered data, technical reliability) and user factors (age, gender, digital skills, and symptom load) [4]. Regarding the effect of reminders on diary adherence, there are some reports suggesting that reminders increase use of health-related diaries, but there is a lack of formal investigation and no specific data on headache diaries [4]. Early studies on pain (not headache) diaries showed that reminders increased compliance with a paper diary (ie, entry within ±15 min of assigned time, 3 times daily) from 11% to 29% and use of an electronic diary with reminders further increased compliance to 94% over a 21-day study period [3,36].

Daily entries in headache diaries are crucial for obtaining accurate and reliable data, in both clinical practice and research. Consistent daily tracking enables the identification of patterns, triggers, and treatment effects, allowing for more personalized treatment strategies [2]. Regular use of an electronic headache diary was associated with significant improvements in headache and migraine frequency, intensity, and use of acute medication over a 6-month period [37]. These findings underscore the potential of electronic headache diaries to not only enhance data quality but also to actively support standard headache care by raising awareness for the individual headache disorder. The use of reminders likely can further promote adherence to daily entries and more effective treatment adjustments [37].

Strengths and Limitations

Strengths of the present study are the large sample size and the comparison with the same periods in the previous year. There also are some limitations. First, the failure period was relatively short, so it remains open if adherence would have deteriorated further or leveled out during a longer period. Because reminders arrived regularly before the failure period, users may have been relying on reminders for their daily entry, and it cannot be excluded that they would have started regular use of the app without reminders after a while. Indeed, the delay to perform the daily entry was mitigated somewhat after the first few days (Figure 2); however, a return to previous values only occurred after the end of the reminder failure. These questions could only be answered by a dedicated study, for example, comparing different reminder failure periods.

Second, total adherence rates determined within the present study may not be generalizable as we included only active users in the analysis. This was necessary to perform a meaningful analysis of the effect of the reminder failure. However, we have performed an additional analysis of the effect of previous adherence on the reaction to the reminder failure, showing that persons with high previous adherence (during a period with reminders) were more sensitive to reminder failure than persons with lower previous adherence. In future, dedicated studies might investigate the effect of reminders on new users specifically within the first weeks of app use–one could speculate that these initial reminders could help users engage in regular entries. It would also be interesting if sending reminders to users after a period of inactivity can bring them back to regular use.

Third, although the present study showed that daily reminders increase adherence to an electronic headache diary, it remains an open question what type of reminder would have the largest effect on adherence, a question that has also been discussed in other mobile health apps [38]. Future research could further refine understanding of reminders in headache diaries by comparing groups randomly assigned to different conditions, for example, receiving reminders vs no reminders from the beginning of app use vs reminders ceasing after a fixed time of app use with a longer follow-up period without reminders. They could also compare different types of reminders directed at

XSL•FO
RenderX

different effects, for example, increasing ability and/or motivation in addition to serving as a prompt according to behavioral theory by Fogg [12].

Conclusion

This is the first study on the effect of daily reminders in a digital headache diary app. Present results suggest that daily reminders are an effective means to improve adherence to electronic headache diaries, specifically by increasing the number of documented days and by decreasing the delay to make the daily entry. Males, persons with low headache frequencies, and high previous adherence were more sensitive to reminder failure. These results contribute to our knowledge on compliance with digital health apps and point out means to improve adherence and groups especially benefiting from reminders.

Acknowledgments

We wish to thank all DMKG-App users. No generative AI has been used in writing this manuscript.

Funding

The DMKG Headache Registry is funded by the German Migraine and Headache Society and by unrestricted grants or funding of specific analyses from companies with an interest in headache research (up to the time of submission of this work, Lilly, Teva, Novartis, Pfizer, and Lundbeck have made contributions). Supporting companies were given the opportunity to comment on the research protocol, and their comments were considered and judged to be scientifically relevant. Apart from that, supporting companies did not influence the study design.

Data Availability

The datasets analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Background: Approximately 2.5 billion adults worldwide were living with overweight or obesity as of 2022, highlighting the need for comprehensive weight management solutions. Digital nutrition platforms have emerged as an accessible solution that can be implemented at scale. Nutrium Care is an employer-sponsored program delivered via the Nutrium platform, facilitating dietitian-led nutrition counseling through consultations and in-app communication, while also enabling users to track food intake, water consumption, and physical activity.

Objective: This study set out to characterize longitudinal weight changes among active users of the Nutrium Care program and estimate associations between program engagement and weight loss.

Methods: This retrospective cohort study analyzed deidentified data from adult users with overweight or obesity enrolled in the Nutrium Care program. Users were included if they were taking action to manage their weight and had at least 3 months of follow-up data available; these users were referred to as active users. The primary outcome was weight loss after 3 and 6 months, estimated using piecewise linear mixed-effects models. To estimate the association between engagement and weight loss, more- and less-engaged users were matched on sociodemographic characteristics. Engagement was defined by the number of dietitian appointments, days of active platform use, and logging of food, water intake, and physical exercise.

Results: The study included 10,288 active users, predominantly female (n=6887, 66.9%) and aged 18 to 49 years (n=9741, 94.7%), who contributed a median of 6 (IQR 4 - 9) months of data to the cohort. In the first 3 months, active users lost 2.0 kg (2.4% of baseline body weight; 95% CI 1.9-2.0 kg) on average, increasing to 2.3 kg (2.8%; 95% CI 2.2-2.4 kg) by 6 months. Higher program engagement was associated with more weight loss, with the strongest association estimated for at least 1 dietitian appointment every 2 months, corresponding to 0.8 kg (95% CI 0.7-1.0 kg) additional weight loss after 3 months.

Conclusions: This retrospective cohort study addresses a critical research gap in hybrid nutrition interventions integrating professional dietitian support with an employer-sponsored digital nutrition program. Active users achieved weight loss, and regular contact with a dietitian was the strongest engagement factor associated with improved outcomes, supporting the potential role of professional support in digital weight management programs.

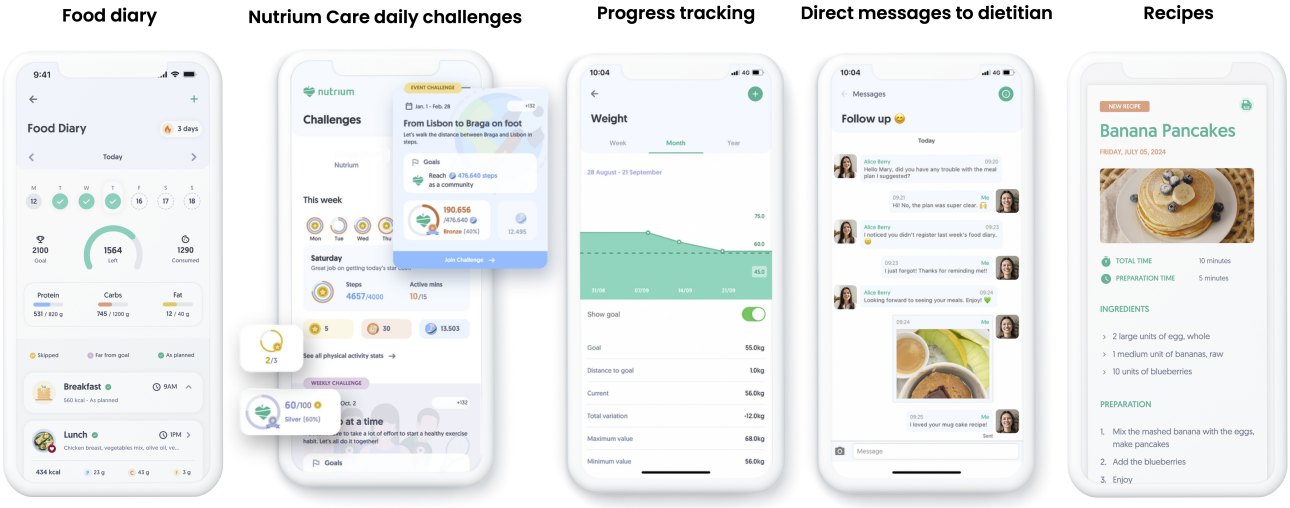
Introduction

The global prevalence of adult overweight and obesity has risen in recent decades and now represents one of the most significant public health challenges worldwide [1]. As of 2022, a total of 2.5 billion adults were living with overweight or obesity globally [2]. Obesity substantially increases the risk of chronic diseases, including type 2 diabetes, cardiovascular disease, and certain cancers [3], and contributes to an estimated 4 million deaths annually [4]. The associated economic burden was estimated to reach US $2.5 trillion in 2025 [5,6], highlighting the urgent need for scalable and sustainable solutions to weight management.

Multiple strategies have been used to support weight loss, including bariatric surgery, prescription medication (ie, appetite suppressants), and lifestyle interventions [7]. Recently, pharmacotherapy, particularly glucagon-like peptide-1 (GLP-1) receptor agonists, has gained significant attention due to its demonstrated effectiveness in reducing body weight [8]. However, long-term use of these drugs has not yet been well studied, and there are potential concerns related to loss of muscle mass and other health effects that warrant ongoing monitoring

XSL•FO
RenderX

[9]. Lifestyle interventions that combine dietary modification with physical activity remain a cornerstone of obesity management and are particularly effective when delivered with guidance from health care professionals, such as registered dietitians (RDs) [10,11].



Despite their effectiveness, lifestyle interventions delivered through in-person counseling are difficult to scale to large populations. The emergence of digital health and nutrition platforms offers an alternative scalable approach to supporting weight management. These platforms typically combine individualized nutrition counseling with tools for dietary self-monitoring, educational resources, and behavioral prompts designed to encourage sustained lifestyle change. Although these platforms vary in their specific content and features, initial evidence suggests that mobile and web-based health technologies can effectively support improved diet quality and weight loss among adults with overweight or obesity [12-14].

However, digital nutrition platforms differ substantially in their design, level of professional involvement, and behavioral support mechanisms [15]. Evaluations of digital nutrition platforms consistently identify motivation, education, and support features as core user needs [16,17]. User engagement with specific digital intervention features is an important component of achieving weight loss outcomes. Use of self-regulation techniques has been identified as a predictor of successful weight loss among users of digital nutrition platforms [18,19]. A recent meta-analysis of digital food-focused interventions found positive effects on food consumption, particularly if the intervention used prompts or cues [20]. Positive cues that reinforce healthful behaviors can help to combat the "food noise" (persistent thoughts about food) many individuals report as a barrier to successful weight management [21]. Indeed, many GLP-1 users attribute the reduction in "food noise" to their weight loss [22]. However, the specific types and intensity of engagement associated with optimal weight outcomes remain unclear, particularly in dietitian-led platforms.

Inclusion of tailored feedback or individualized counseling has been demonstrated to enhance participant success in digital interventions focused on changing eating behavior [23-25]. An evaluation of a web platform in Brazil concluded that use of the platform in combination with coaching from a dietitian led to greater weight loss and significant changes in eating behavior (more fruits and vegetables, less ultraprocessed food) compared with users who only accessed the platform on their own [26]. Although limited in scope, these results suggest a high level of effectiveness when digital nutrition platforms include access to a dietitian. While the overall utility of digital nutrition platforms is generally positive, the heterogeneity in features, including the level of dietitian support, underscores the need for platform-specific evaluations. This allows for identification of individual components that best enhance weight management outcomes.

Nutrium is a digital health platform designed to facilitate hybrid nutrition interventions through integrated asynchronous and synchronous communication between users and RDs. Unlike automated or self-guided nutrition applications, which rely on algorithmic feedback [27], this model centers on practitioner-led care. The platform integrates scheduled teleconsultations with continuous in-app messaging, allowing RDs to develop personalized nutritional interventions, monitor real-time dietary intake, and provide iterative feedback throughout the care continuum. By digitizing the dietitian user interface while maintaining professional oversight (Figure 1), the Nutrium platform aligns with behavioral frameworks that prioritize engagement and therapeutic adherence as primary drivers of long-term health outcomes, such as weight management [28].

Figure 1. Examples of the in-app user interface.

Nutrium Care is one delivery model for the Nutrium platform, implemented via employer-sponsored health and wellness programs. Through this model, employees gain access to professional dietetic consultations and sustained nutritional support through the Nutrium platform. This study aimed to provide the first evaluation of the Nutrium Care delivery model by quantifying longitudinal weight loss outcomes among program users and assessing the relationship between weight loss and user engagement with the program. Specifically, the study aimed to (1) characterize absolute weight loss among active Nutrium Care users after 3 and 6 months; (2) describe the proportion of active users achieving weight loss thresholds of 3%, 5%, and 10% of baseline body weight in the action phase; and (3) estimate the association between user engagement with

XSL•FO
RenderX

the program and weight loss across multiple engagement metrics, including dietitian appointments, days of active platform use, and logging of food, water intake, and physical exercise.

Methods

Study Design

This study was a retrospective analysis of secondary observational data from users of the Nutrium Care program, specifically examining user weight outcomes and engagement with the app. The study was completed in 2 parts. First, we examined longitudinal weight data to estimate weight outcomes 3 and 6 months after users joined the Nutrium Care program. Second, we quantified the difference in weight outcomes at 3 months between more and less engaged users.

This evaluation considered users' readiness to engage with behavior change. The transtheoretical model (TTM) conceptualizes behavior change across 5 core stages: precontemplation, contemplation, preparation, action, and maintenance [29]. The action phase reflects individuals who have moved beyond intention into active, committed behavior change. Here, users who attended at least 2 dietitian appointments, with the second occurring within 6 months of baseline, were classified as action phase users [30,31]. This study therefore restricted its evaluation to users whose platform engagement was consistent with active behavior change, rather than incidental or exploratory use, by considering only users in the action phase. This restriction was applied during revision to ground the analysis in the TTM, rather than being prespecified. For the remainder of this manuscript, we refer to users in the action phase as active users.

To estimate differences in weight outcomes by engagement, we compared more and less engaged users matched on sociodemographic characteristics. For each engagement metric, we had 2 groups: one that included users who met the threshold for engagement (more engaged users) and one that included users who did not (less engaged users). Engagement metrics and their thresholds were appointments with dietitians (≥1 appointment at least every 2 months), days of active use (DAU) of the platform (≥10 DAU per month), and logging of food, water intake, and physical exercise (≥1 time per week on average). As no established thresholds exist across the included engagement metrics for digital nutrition platforms, the thresholds applied were exploratory and defined a priori by the research team.

Study Population

The study population included Nutrium Care users aged 18 to 65 years with overweight (BMI 25 - 29.9), obesity (BMI 30 - 39.9), or morbid obesity (BMI ≥40) at baseline. Baseline was defined as the date of the first available weight measurement. Users were excluded if they did not have a valid baseline weight, which we defined as a weight measured within 30 days of their first appointment with a dietitian, had missing data on age or sex, reported using weight loss medications (ie, GLP-1 agonists), or reported a pregnancy. Implausible weight (<30 kg or >300 kg) and BMI (>60) data were filtered out before applying the inclusion and exclusion criteria [32]. Users needed to be in the action phase and have at least 3 months of follow-up data to be included in the primary analysis. Results for an unrestricted sample without action phase and follow-up restrictions are presented alongside the primary analysis.

Data

The data consisted solely of information that was originally generated during ordinary, routine use of the Nutrium Care program. Participants were not prompted to enter data for research purposes. Instead, all information was submitted voluntarily in the normal course of platform operation and service delivery. The data were entered by dietitians as well as self-reported by users. Data extracted from the Nutrium database included sociodemographic variables (age and sex), anthropometrics (weight and height), and engagement with the Nutrium application (including the number of dietitian appointments, exercise, food and water intake logging, DAU, and dietary goals). Users recorded weight by either entering a value manually in the application, reporting it to their dietitian during a consultation for entry into the user's record, or synchronizing a connected smart scale with user permission, which transmitted the weight automatically each time users weighed themselves. All datasets were deidentified prior to analysis. The research team had access only to pseudonymized or anonymized records containing no direct identifiers, and no attempt was made to re-identify individuals.

Outcomes

The primary outcome was weight loss in kg and as a percentage of baseline body weight at 3 and 6 months. Secondary outcomes included the proportion of users achieving any weight loss as well as weight loss thresholds of 3%, 5%, and 10% of baseline body weight at each time point.

Statistical Analysis

Weight Outcomes at 3 and 6 Months

To estimate average weight change at 3 and 6 months compared with baseline, we fit piecewise linear mixed-effects models. Time was represented with piecewise linear terms with break points at 3 and 6 months, allowing for different rates of weight change over time. We chose these time points based on the hypothesis that dietary behavior changes would be most intensive initially (0 to <3 months), continue at a slower rate (3 to <6 months), then stabilize (≥6 months). The model included random effects for the intercept and the overall time slope to account for between-user variation in baseline weight and weight change over time. Weight loss at 3 and 6 months was estimated by computing linear combinations of the fixed effects from the piecewise linear terms. We stratified the analysis by sex, age group, and baseline BMI category.

Weight Loss Thresholds

For the proportion of active users who achieved weight loss thresholds at each time point, we identified the weight measurement closest to each respective time point and compared it with the user's baseline weight. Users with no measurements within 30 days of a given time point were excluded from the primary threshold analysis for that time point. All users recorded a weight at or beyond 3 months, so exclusions at the 3-month

XSL•FO
RenderX

time point reflect measurement timing rather than absent outcome data. At 6 months, approximately half the cohort had no recorded weight at or beyond that point. We therefore report the 6-month thresholds as a range, with the measured-only proportion as the upper bound and a lower bound assuming that every user without a measurement near the time point did not reach the threshold, using the full analyzed cohort as the denominator. Additionally, as a sensitivity analysis, we repeated the threshold analysis using the last nonbaseline weight observation carried forward for excluded users. Users with no eligible prior measurement remained excluded.

Weight Outcomes by Engagement

To quantify the difference in weight change by engagement status, we first created a matched sample for each engagement metric. We used coarsened exact matching (CEM) [33] to balance groups of more engaged users with less engaged users on the following criteria: age group (18-29, 30-49, or 50-65 years), sex, country of residence, and BMI at first appointment (25 - 29.9, 30 - 39.9, or ≥40). Then we fit weighted piecewise linear mixed-effects models to the matched datasets. The model included an interaction term between engagement status and time for each of the 3 time intervals (0 to <3, 3 to <6, and ≥6 months). Because all included users had measurements until at least the 3-month time point, we estimated differential rates of weight change between more and less engaged users at this time point only. The models were weighted by applying the CEM weights to account for any residual imbalance between engagement groups after matching. Separate models were fit for each included engagement metric.

All analyses were conducted independently by the lead author. A coauthor reviewed the data processing pipeline against the inclusion and exclusion criteria for data quality issues. All analyses were completed in R (version 4.4.0; R Foundation for Statistical Computing) [34].

Ethical Considerations

The study received an exempt determination from the Syracuse University Institutional Review Board (protocol number 26 - 018). During account registration, users must review and consent to Nutrium's privacy policy before creating an account or providing any personal data. The policy explained how personal data may be processed in connection with platform use and informed users that data may be deidentified and aggregated for research and analytical purposes. For this study, only deidentified data were used, and no directly identifiable personal data were accessed by the research team. Users did not receive any compensation for participation in this study.

Results

Study Sample

The population considered for this study included 27,689 adults with overweight or obesity using Nutrium Care (Figure 2). The unrestricted sample, after excluding users with no baseline weight measurement (2745/27,689, 9.9%), reported GLP-1 agonist use (1296/24,944, 5.2%), reported pregnancy (611/23,648, 2.6%), or missing data on age or sex (13/23,037, 0.1%), included 23,024 users. The sample analyzed for the primary action phase population included 44.7% (10,288/23,024) of eligible users from the unrestricted population, after excluding 3647 (15.8%) users who were not in the action phase (<2 appointments in the first 6 months), 1544 (6.7%) users who joined within 3 months of the end of the observation window and had no opportunity to accrue 3 months of follow-up, and 7545 (32.8%) users who had fewer than 3 months between their first and last recorded data points.

Two-thirds of included users were female (6887/10,288, 66.9%), and most were aged 18 to 29 years (4584/10,288, 44.6%) and 30 to 49 years (5157/10,288, 50.1%; Table 1). The study included 61.2% (6293/10,288) of users with overweight, 34.3% (3531/10,288) of users with obesity, and 4.5% (464/10,288) of users with morbid obesity at baseline. Most users in this sample joined the platform in 2024 or 2025, contributing a median of 6 (IQR 4 - 9) months of data and 5 weight measurements to this study (Table 1). Follow-up duration was the number of months between a user's first and last recorded weight measurements. During the first 6 months, users had a median of 3 (IQR 2-4) dietitian appointments and 25 (IQR 14-44) days of platform app use and logged food, water intake, and exercise a median of 6 (IQR 2-25), 3 (IQR 1-14), and 3 (IQR 0-21) times, respectively (Table 1).

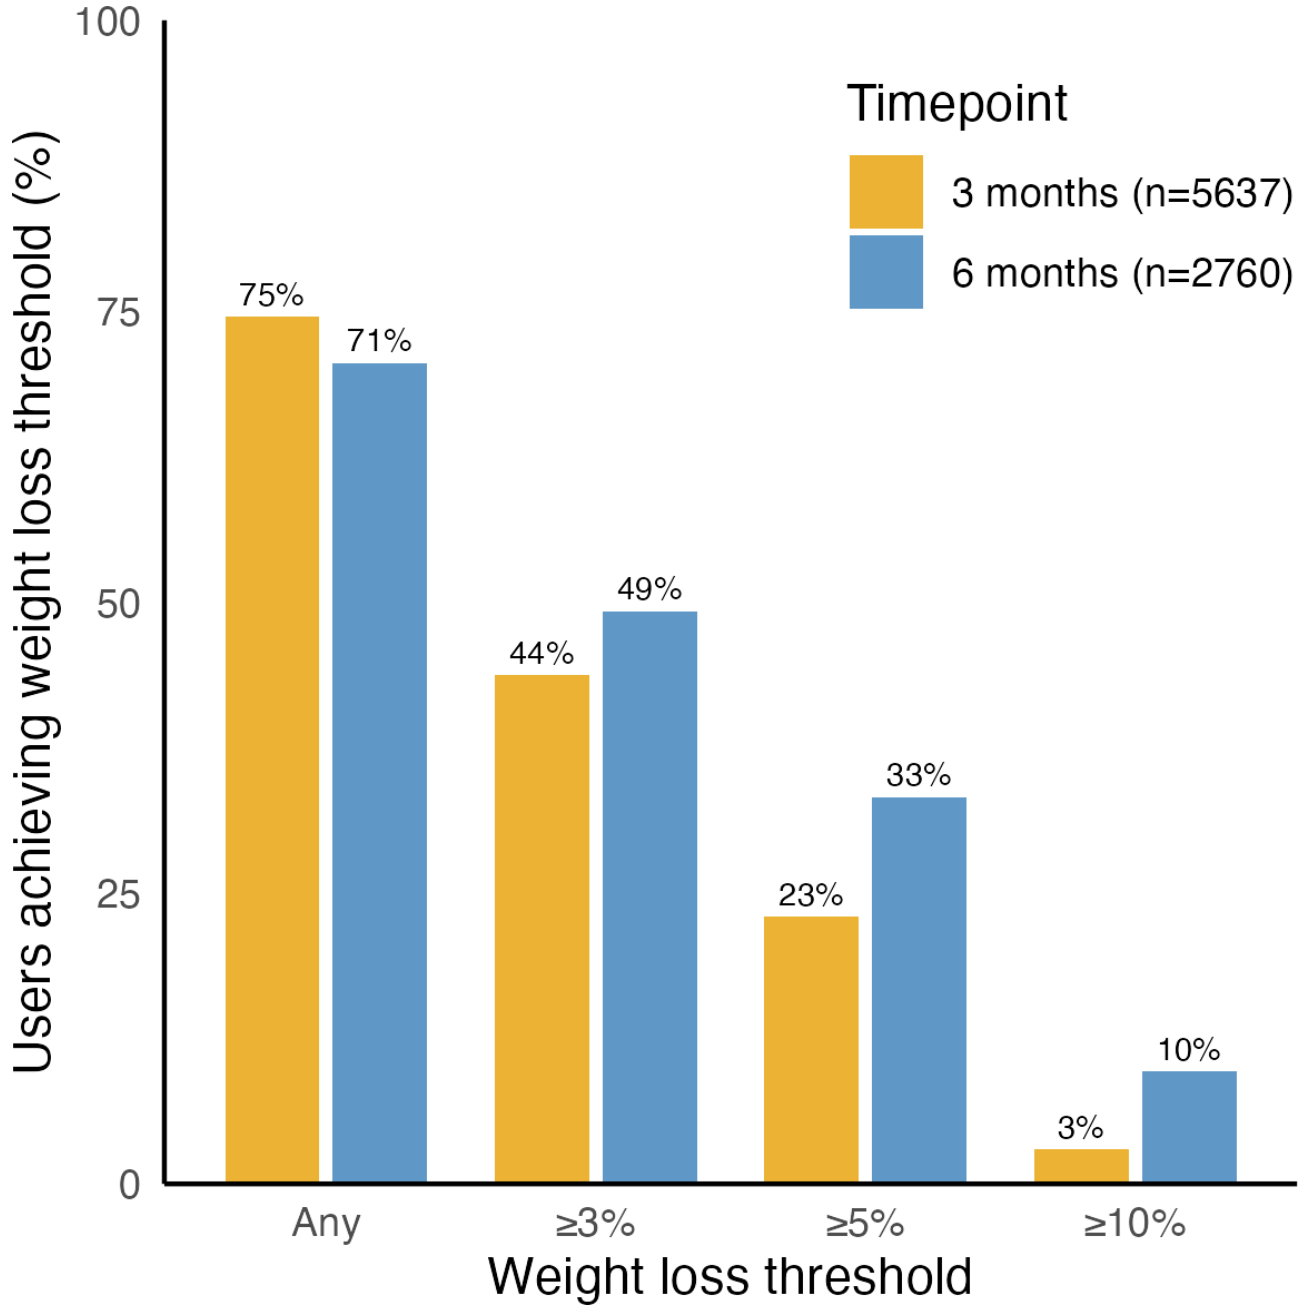
Weight Outcomes at 3 and 6 Months

Three months after joining Nutrium Care, active users lost 2.0 kg on average (2.4% of their body weight; 95% CI 1.9 - 2.0 kg; Figure 3). By 6 months, average weight loss increased to 2.3 kg (2.8%; 95% CI 2.2 - 2.4 kg). Weight loss was slightly more pronounced among male users and among users aged 50 or older, although this sample of users in this age group was small (n=547, 5.3%), and varied substantially by baseline BMI at both 3 and 6 months. At 6 months, users with overweight lost 1.7 kg on average (2.2%; 95% CI 1.6 - 1.8 kg), whereas users with obesity averaged 3.2 kg of weight loss (3.5%; 95% CI 3.1 - 3.4 kg) and users with morbid obesity averaged 4.2 kg (4%; 95% CI 3.5 - 4.9 kg). In the unrestricted sample, mean weight loss was 2.2 kg (2.6%; 95% CI 2.2 - 2.3 kg) at 3 months and 2.4 kg (2.9%; 95% CI 2.4 - 2.5 kg) at 6 months (Figure S1 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 3. Absolute weight loss at 3 and 6 months among active users (*P*<.001 for all estimates). A total of 22,043 weight measurements beyond baseline were recorded in the 0-3 month period and 18,641 in the 3-6 month period, contributed by 7941 and 8727 users, respectively.



Weight Loss Thresholds

At 3 months, weight was available within 30 days of the time point for 54.8% (5637/10,288) of active users. Among these, most (4200/5637, 74.5%) had lower weight compared with baseline (Figure 4). Nearly half of these active users (2464/5637, 43.7%) achieved at least 3% weight loss, nearly one quarter (1293/5637, 23%) achieved at least 5%, and a smaller proportion (166/5637, 2.9%) at least 10% weight loss at this time point. All users in the action phase cohort recorded a weight at or beyond 3 months, so users excluded at this time point had recorded a weight outside the 30-day window rather than having stopped weighing in.

XSL•FO
RenderX

Figure 4. Threshold weight outcomes at 3 and 6 months among active users. Users without a weight measurement within 30 days of the time point were excluded.

At 6 months, weight was available within 30 days of the time point for 26.8% (2760/10,288) of active users. Among these, a similar proportion of active users (1947/2760, 70.5%) weighed below their baseline weight, almost half (1358/2760, 49.2%) achieved at least 3% weight loss, one third (917/2760, 33.2%) achieved at least 5%, and one in 10 (266/2760, 10%) achieved at least 10% weight loss. Because 52% (5343/10,288) of active users accrued 6 months of follow-up, these proportions are restricted to active users who continued recording weights and are likely to be optimistic. Assuming instead that every active user without a weight near the time point did not reach the threshold gives lower bounds of 18.9% (1947/10,288) for any weight loss, 13.2% (1358/10,288) for 3% weight loss, 8.9% (917/10,288) for 5% weight loss, and 2.6% (266/10,288) for 10% weight loss. In the unrestricted sample, 48.5% (1377/2840) of users lost at least 3% of baseline weight at 6 months, 33% (929/2840) lost at least 5% and 9.4% (268/2840) lost at least 10% (Figure S2 in Multimedia Appendix 1). A sensitivity analysis that carried the last observed weight measurement forward among active users gave intermediate estimates between the primary estimates and lower-bound estimates presented here (Figure S3 in Multimedia Appendix 1).

Weight Outcomes by Engagement

Active users who met the engagement criteria had greater weight loss at 3 months compared with matched users who did not meet these criteria (Table 2). Among the engagement metrics considered, the largest differences were observed for users with more dietitian appointments. Users with at least 1 appointment every 2 months (bimonthly appointments) experienced 0.8 kg (95% CI 0.7 - 1.0) greater weight loss at 3 months compared with matched users without bimonthly appointments.

XSL•FO
RenderX

Table . Difference in weight loss at 3 months by engagement metric (N=10,288).

Engagement metric	Participants, n (%)	Weight loss difference (kg; 95% CI)[a]
Bimonthly appointment	7392 (71.9)	0.8 (0.7 - 1.0)
≥10 days of active use per month	2344 (22.8)	0.7 (0.6 - 0.9)
Weekly food logging	3126 (30.4)	0.4 (0.3 - 0.6)
Weekly water intake logging	2207 (21.5)	0.4 (0.2 - 0.5)
Weekly exercise logging	2799 (27.2)	0.3 (0.2 - 0.5)

[a]All estimates, $P<.001$.

Users with at least 10 DAU per month experienced 0.7 kg (95% CI 0.6 - 0.9) more weight loss. Logging behaviors showed less pronounced associations with weight loss at 3 months. Weekly food diary loggers experienced 0.4 kg (95% CI 0.3 - 0.6) additional weight loss, weekly water intake loggers experienced 0.4 kg (95% CI 0.2 - 0.5), and weekly physical exercise loggers experienced 0.3 kg (95% CI 0.2 - 0.5) additional weight loss compared with matched users who logged less frequently. Differences in weight loss by engagement metric were moderately larger in the cohort before the action phase restriction, with similar ordering across metrics (Table S1 in Multimedia Appendix 1).

Discussion

This study evaluated real-world longitudinal data among more than 10,000 users with overweight and obesity enrolled in the Nutrium Care program who progressed to the action phase, reflecting active commitment to achieving their weight goals. Active users lost, on average, 2.0 kg and 2.3 kg after 3 and 6 months, respectively. Among active users with a weight recorded near the 3-month time point, 74.5% (4200/5637) weighed less than at baseline, 43.7% (2464/5637) lost at least 3% of their baseline weight, 22.9% (1293/5637) lost at least 5% of their baseline weight, and 2.9% (166/5637) lost at least 10% of their baseline weight. Greater program engagement was associated with more weight loss across the included engagement metrics, with bimonthly dietitian appointments showing the strongest association with improved weight loss outcomes.

The findings reported in this study are consistent with the growing evidence supporting digital nutrition platforms [35]. The weight loss observed is comparable to outcomes reported for digital interventions and is consistent with losses reported in meta-analyses of smartphone-based apps [36]. Among active users with a weight recorded near the 3-month time point, 23% (1293/5637) reached at least 5% weight loss. The 5% threshold is the benchmark most commonly used to define clinically significant weight loss [37]. Some evidence indicates benefits for cardiovascular risk factors at more modest losses [38], although this is not the established standard. While current guidelines indicate that individuals with obesity will see the biggest health benefits when weight loss exceeds 10% of body weight, most experts agree that these amounts are more likely to result from surgical or pharmaceutical interventions rather than lifestyle changes [39-41].

Behavior change and lifestyle modification have been identified as integral components of successful weight management, including external support from health care providers such as dietitians [42]. Incorporation of techniques that encourage self-regulation, such as tracking hunger levels, mood, and other common cues associated with eating habits, can support increased awareness of an individual's environmental triggers that either facilitate or derail weight loss attempts [43]. However, simple tracking activities such as recording weight have been shown to be effective, particularly when paired with goal setting within a digital platform [44,45]. In this context, the engagement metrics assessed in the present study may reflect not only platform use but also behaviors associated with sustained participation in weight management.

The association between engagement and weight loss further contextualizes these results within the broader literature [46,47]. Active users attending bimonthly dietitian appointments lost 0.8 kg more than matched users without this level of contact, suggesting a relationship between professional interaction and weight loss [48,49]. These findings are consistent with evidence suggesting that digital interventions that include a component of actual human contact are more effective than fully automated programs [35] and that nutrition coaching, including medical nutrition therapy, delivered via telehealth can be as effective as traditional clinical nutrition care [11,48]. Within the TTM framework, behavioral processes of change such as helping relationships and reinforcement management are most prominent during the action phase, so forms of professional support that provide reinforcement may be particularly relevant for users working to sustain new routines [29]. Dietitian contact showed a stronger association with weight loss than self-directed platform engagement, although the design cannot establish why. However, in the absence of established benchmarks, the thresholds applied to engagement metrics were exploratory, so the estimated differences between more and less engaged users should be limited to hypothesis-generating interpretation. Further, statistical significance does not indicate clinical importance. The differences observed here, ranging from 0.3 kg to 0.8 kg at 3 months, may not be clinically meaningful for individual users.

The findings from this study should be interpreted considering its limitations. First, we relied on secondary observational data with no control group or comparison with other digital nutrition platforms. Therefore, we cannot establish causality in the weight loss results documented here, nor can we directly compare with the effectiveness of other weight loss solutions. Second, both criteria defining the action phase cohort depend on behavior

XSL•FO
RenderX

after baseline. Users met the action phase definition only by attending a second dietitian appointment within 6 months, and follow-up was measured from a user's first to last weight measurement, excluding those who stopped generating data before 3 months. Together, these criteria excluded 48.6% (11,192/23,024) of eligible users, compared with 6.7% (1544/23,024) excluded for joining too late to accrue 3 months of data. The cohort therefore represents users who remained active, and estimates should not be extrapolated to all enrolled users or to employer-sponsored digital nutrition programs more broadly. The action phase criterion is also conceptually adjacent to our strongest engagement exposure, since both are defined by continued dietitian attendance, so the engagement comparison is made within a group already selected on a related behavior. Estimates in the cohort without the action phase restriction were not smaller than our primary estimates, which offers no indication that the restriction inflated our findings, although that cohort includes many users whose values at 3 and 6 months are extrapolated from the fitted model rather than observed, so it cannot serve as a reliable counterfactual. Third, weight measurements were not recorded on a fixed schedule, so the threshold analyses depend on data availability near each time point. At 3 months, this reflects measurement timing rather than absent data, since all users recorded a weight at or beyond 3 months and those excluded had weighed in outside the 30-day window. At 6 months, approximately half the cohort had no recorded weight at or beyond that point. Users who stall or regain weight are more likely to stop recording weights, so the 6-month proportions based on measured weights alone are likely to overstate achievement of each threshold. We therefore report the lower bound of these proportions. Fourth, we were restricted in the length of follow-up. We addressed this by examining 2 time points, 3 and 6 months. However, further evidence on long-term weight loss maintenance, including after discontinuation of platform use, is needed. Fifth, this study was limited to weight loss as an outcome and does not include data on user experiences during the care they received and its impact on well-being. Sixth, the engagement analysis could not control for all possible confounders and potential reverse causality. For example, we did not have data on comorbidities experienced by users. Further, users experiencing difficulty with weight loss may be more engaged with the program, potentially biasing our estimate toward the null. Finally, we relied on data entered both by dietitians and self-reported by users, which may be subject to measurement error and reporting bias.

Our findings support the use of digital nutrition platforms as a meaningful tool to aid in weight management among users motivated and in the action phase of behavior change. Given the reality that primary care providers have limited time to incorporate behavioral change techniques during routine appointments, encouraging users with overweight or obesity to engage with a dietitian via a digital platform will increase access to the services and support needed. Having virtual access to a dietitian increases equity in care and reduces the logistical burden users experience associated with transportation and scheduling challenges that often occur with in-person appointments. Indeed, nutrition interventions using telehealth modalities are more cost-effective overall, with digital (mobile health) rated as the most cost-effective [50]. As employers (and health insurance companies) expand health benefits to include nutrition services from a dietitian, offering a digital nutrition platform provides a scalable yet evidence-based solution that can ultimately drive down medical costs as employees achieve weight management goals.

Nutrium Care's observational findings provide motivation for pragmatic randomized evaluations to more directly test causal effects and durability of outcomes beyond 12 months. This need is increasingly recognized within the digital nutrition field, where planned randomized trials have begun to examine longer-term effectiveness and maintenance of digital programs [51]. Further work is also needed to characterize platform use patterns associated with optimal outcomes, for example, by identifying combinations of engagement behaviors that predict clinically meaningful weight loss and maintenance. Finally, given the scale of obesity-related costs, formal economic evaluation is an important next step. Modeling should consider (1) health care use offsets, (2) productivity impacts, (3) program delivery costs (including clinician time), and (4) subgroup targeting where marginal benefit is highest (eg, higher baseline BMI categories).

Abstract

Background: Individuals with cardiometabolic disease typically average 10 to 14 hours of daily sedentary time, which increases the risk of cardiovascular disease.

Objective: This study aimed to evaluate the feasibility, acceptability, and preliminary efficacy of a “Sit Less” program in reducing sedentary behavior in people with cardiometabolic disease.

Methods: Participants with cardiovascular disease or type 2 diabetes underwent separate randomization into the Sit Less intervention or the control group. Sit Less included 1 in-person counseling session, a Fitbit, a smart water bottle, and tailored weekly text messages for 12 weeks. Control group participants received the American Heart Association’s “Answers by Heart” booklet. Sedentary behavior was measured using the activPAL for 7 days at baseline and postintervention. The secondary outcomes included physical activity, cardiometabolic biomarkers, continuous glucose monitoring metrics, and psychological factors. Generalized linear models estimated adjusted between-group differences, controlling for baseline values, cohort, cohort×group interaction, and leisure-time exercise.

Results: Of the 37 randomized participants, 35 (95%) completed the study (Sit Less: n=17, 48.6%; and control: n=18, 51.4%). Of the 35 participants who completed the study, 62% (n=21) were men, the median age was 67 (54-72) years, and their baseline sedentary time was approximately 10.4 hours per day. Sit Less participants demonstrated high adherence, including a text response rate of 81% and a median Fitbit wear time of 15 hours per day on 6.8 days per week, and 15 (88%) of 17 participants reported satisfaction with the program. Compared with the control group, Sit Less participants showed greater reductions in total sedentary time (adjusted mean difference −17.3 min/d, 95% CI −63 to 28; *P*=.45) and prolonged sedentary time of >30 minutes (−39.5 min/d, 95% CI −100 to 21; *P*=.20) and >60 minutes (−49.9 min/d, 95% CI −102 to 2; *P*=.06) and increases in sit-to-stand transitions (4.2 per day, 95% CI −2 to 10; *P*=.13), although none were statistically significant. Hemoglobin A_{1c} was lower in the Sit Less group than in the control group (adjusted mean difference −0.4%, 95% CI −0.8 to −0.1; *P*=.04). Continuous glucose monitoring outcomes, including mean glucose (−6.0 mg/dL, 95% CI −14.9 to 2.8; *P*=.18) and time in range (2.1%, 95% CI −4.8 to 9.1; *P*=.54), were not statistically significant but demonstrated similar directional changes. Other cardiometabolic biomarkers, physical

XSL•FO
RenderX

activity, and psychological outcomes were not significantly different, except for lower self-efficacy for moderate physical activity in the Sit Less group (−0.6, 95% CI −1.1 to −0.2; *P*=.003).

Conclusions: The Sit Less intervention was feasible and acceptable and showed possible improvements in sedentary behavior and glycemic outcomes. Although this pilot study had a small sample size and limited statistical power, with multiple outcomes examined and wide CIs observed, these findings support evaluation in larger, adequately powered trials.

Introduction

Background

Sedentary behavior is a strong modifiable risk factor for cardiometabolic disease [1,2]. It involves a lack of leg muscle contractions and restricted blood flow behind the knee when sitting, which causes reduced insulin sensitivity, vascular dysfunction, activation of low-grade inflammatory responses, and an imbalance in energy expenditure [3]. As a result, greater total sedentary time is related to increased cardiometabolic risk [2], including decreased high-density lipoprotein levels and increased triglycerides, fasting glucose [4], BMI, and waist circumference [5]. Prolonged sedentary time is also associated with a 12% higher risk of incidental cardiovascular disease (CVD) independent of physical activity levels [1]. Emerging evidence suggests that physical activity attenuates cardiometabolic risk but does not eliminate the increased risk associated with high sedentary time [1,6]. Despite the important role of sedentary behavior in CVD and metabolic disease, patients with cardiometabolic diseases, including patients with coronary artery disease or diabetes, spend 70% to 90% of their waking time in sedentary behavior [7-9] and 50% of their total sedentary time is prolonged (>30 min per bout) [7]. The reason for this prolonged sedentary time among these individuals may relate to fear of moderate-to-vigorous levels of physical activity due to their heart condition among those with CVD or the perceived development of hypoglycemia among those with diabetes [10,11]. Targeting sedentary behavior, which occupies most of the waking time of patients with cardiometabolic disease, could be a promising target behavior for secondary prevention in this population.

Frequent standing or walking can reduce total sedentary time and disrupt prolonged sitting, changing physiological pathways and improving cardiometabolic outcomes [12-14]. Others have shown that reducing sedentary time with frequent breaks is safe in other chronic health conditions and applicable to patients with cardiometabolic diseases [15-17]. Mobile technologies, including activity trackers (ie, Fitbit) and smart water bottles, offer a low-cost and sustainable approach to reducing sedentary behavior. The use of wearable technologies may be a promising strategy to reduce total sedentary time and disrupt prolonged sitting patterns through features such as self-monitoring and prompts. In addition, the use of a smart water bottle can naturally break sedentary time by encouraging increased water intake, resulting in more frequent trips to the kitchen and restroom. To date, no wearable technology–based sedentary behavior reduction programs focusing on sedentary breaks for patients with cardiometabolic diseases are available.

Study Objectives

This study aimed to assess the feasibility and acceptability of a multitechnology-based sedentary behavior reduction intervention (Sit Less program) in patients with cardiometabolic disease (CVD) or type 2 diabetes (T2D) and evaluate its preliminary efficacy in changes in sedentary behavior measured by total sedentary time, prolonged sedentary time (sedentary bouts >30 min and 60 min), and number of sit-to-stand transitions.

We hypothesized that participants in the Sit Less program would show greater reductions in total sedentary time and the number of prolonged sedentary bouts compared to those in the control group receiving usual care with an American Heart Association educational booklet. We also explored changes in secondary outcomes, including physical activity (eg, stepping time and standing time), cardiometabolic markers (eg, 24-h glycemic control, hemoglobin A_{1c} [HbA_{1c}], BMI, waist-to-hip ratio, blood pressure, insulin, high-sensitivity C-reactive protein [hs-CRP], and lipids), and psychological factors (eg, confidence in reducing sedentary behavior, confidence in increasing light levels of physical activity and moderate-to-vigorous levels of physical activity, and habit strength for sedentary behavior).

Methods

Study Design

Our study included 2 cohorts of participants with different cardiometabolic diseases (CVD or type 2 diabetes), each completing a randomized (1:1 ratio) controlled trial. The same protocol was implemented in each cohort, with randomization occurring separately. Both studies were approved by the Vanderbilt Institutional Review Board and registered on ClinicalTrials.gov (CVD cohort: NCT05534256, August 24, 2022; T2D cohort: NCT05691452, January 5, 2023). A detailed description of the study protocol has been published elsewhere [18]. The study was conducted in accordance with the CONSORT (Consolidated Standards of Reporting Trials) guidelines (Checklist 1).

XSL•FO
RenderX

Participants

Participants were eligible for inclusion in the trial if they were aged ≥18 years and had at least one of the following conditions: history of heart attack, coronary or carotid artery disease, ischemic heart disease, coronary stent placement, coronary artery bypass surgery, or T2D; self-reported sitting for ≥8 hours per day; ability to stand and walk; and owned a smartphone. Exclusion criteria included current use of an activity tracker, current participation in exercise or cardiac rehabilitation programs, non–English-speaking, unstable health conditions (eg, heart failure and uncontrolled arrhythmia) or kidney disease that limited daily water intake, any other conditions contradictory to standing or walking due to physical or cognitive limitations, or current pregnancy.

This pilot study was designed to assess the feasibility and acceptability of the Sit Less program rather than to conduct a fully powered hypothesis test. According to Viechtbauer et al [19], to detect a feasibility issue that has a 10% likelihood of occurrence, a sample size of 30 participants is required to identify the feasibility issue with a 95% CI.

Ethical Considerations

This study was approved by the Institutional Review Board of Vanderbilt University Medical Center (IRB: 220416 and 221566) and conducted in accordance with the Declaration of Helsinki. All participants provided written informed consent and were informed of their right to withdraw at any time. Data were deidentified to ensure confidentiality. All participants received a possible total of US $150—US $25 for completion of the baseline visit, US $25 for completion of the randomization visit, US $50 for completion of the postintervention visit, and US $50 for device return.

Recruitment

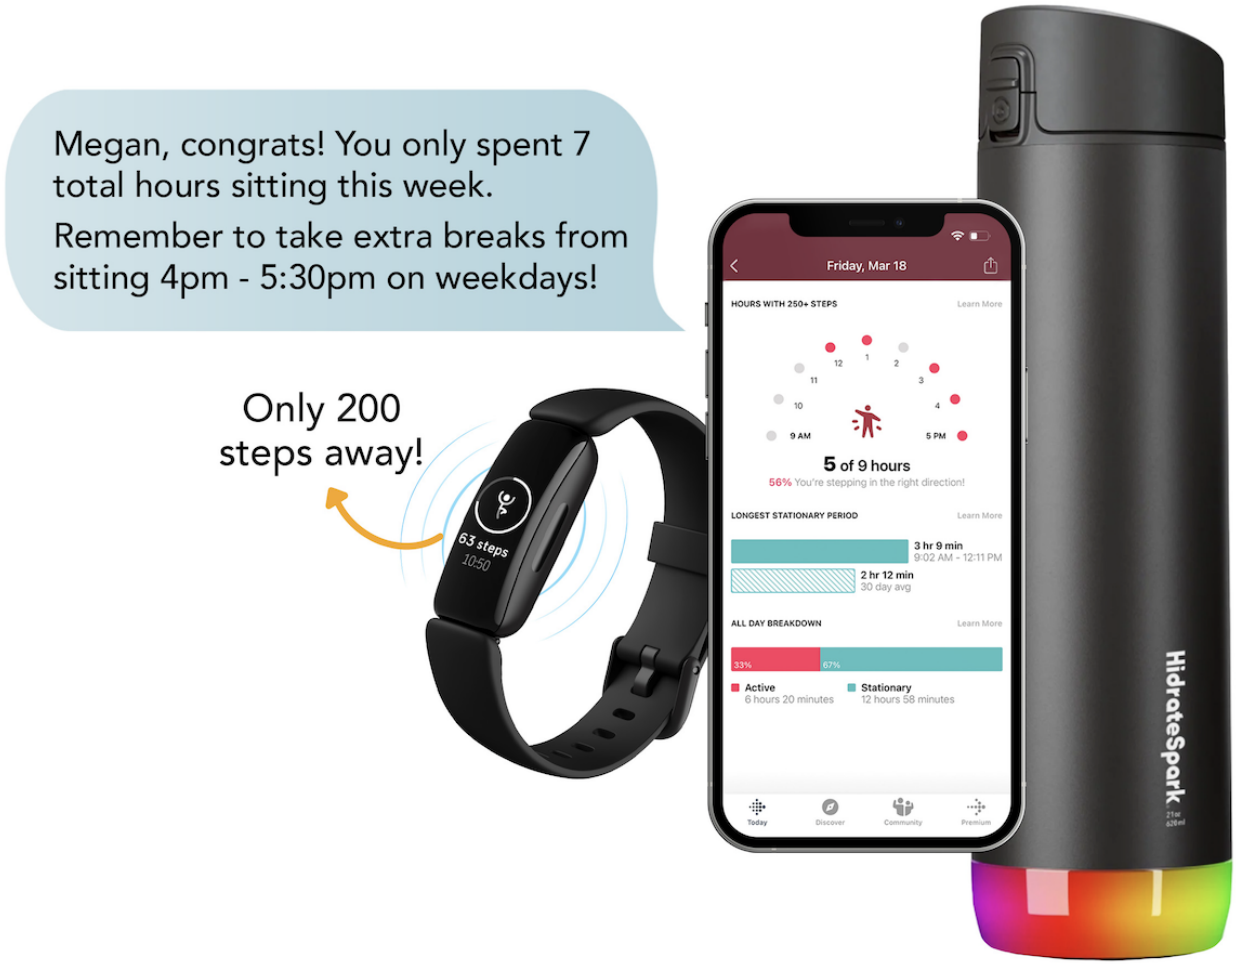
Participants were recruited from September 2022 to September 2023 through Vanderbilt University Medical Center outpatient clinics, the Vanderbilt University Medical Center employee distribution list, and ResearchMatch.org. Clinic patients received an opt-out letter or a message through the My Health at Vanderbilt app after electronic health record screening, followed by staff contact. Additionally, participants recruited via the Vanderbilt University Medical Center employee distribution list or ResearchMatch.org reached out to the study team after being notified by email about the study. Recruitment focused on participants residing near Nashville, Tennessee, due to blood sample collection.

Study Visit Schedule

The study included 3 visits: baseline, randomization, and postintervention. At baseline, eligible participants provided written informed consent, completed surveys, and underwent cardiometabolic assessments, including anthropometrics, blood pressure, and dried blood spot collection. Participants then wore the activPAL3 (PAL Technologies) devices on the thigh and a continuous glucose monitoring (CGM) device (FreeStyle Libre Pro; Abbott) for 7 days, 24 hours per day, and completed a daily sleep diary and a device wear log during this period. After 7 days, participants returned the CGM and activPAL3 devices in person and were randomized into either the Sit Less program or the control group (randomization visit). Following the 12-week intervention or control period, participants completed the same assessments and wore both devices again for 7 days (postintervention visit). Devices were returned by mail, and all participants received their pre- and postintervention data after study completion.

Randomization

Randomization occurred within each disease group. A 1:1 randomization list was created by a statistician and uploaded into the REDCap randomization module. Participants were informed of their group assignment immediately during their randomization visit. Participants and the interventionist were not blinded to the allocation due to the nature of the intervention program. However, outcome assessors and data analysts were blinded to the allocation.



Sit Less Intervention

Overview

The 12-week Sit Less program was developed based on a Habit Formation framework [20] to target sedentary behavior. The Sit Less program included (1) one in-person instructional and goal-setting session at the randomization visit, (2) the use of a wearable device (Fitbit), (3) a smart water bottle (HidrateSpark), and (4) 3 weekly tailored text messages for behavior reinforcement and weekly goal monitoring. Figure 1 describes the Sit Less program. The overall goals of the Sit Less program were (1) to reduce daily sedentary time by 120 minutes, and (2) to achieve a sedentary break (standing or walking) for 5 minutes every 30 minutes by the end of the intervention period. Participants were asked to gradually reduce their sedentary time by at least 10 minutes, up to a maximum of 30 minutes, per week [21]. Detailed information regarding the intervention is described elsewhere [18].

XSL•FO
RenderX

Figure 1. Overview of a multiple technology–based sedentary behavior reduction intervention ("Sit Less" program).

Instructional or Goal-Setting Session

The principal investigator reviewed the activPAL data with Sit Less participants to identify targetable prolonged sedentary bouts. Using a modified Top Ten Tips (TTT) booklet—adapted from Habit Formation Theory—the principal investigator guided participants in developing habits to take frequent sedentary breaks. The original TTT booklet, which included stretching and muscle-strengthening activities [22], was revised to 8 tips focused specifically on reducing sedentary behavior [23]. Sit Less participants completed weekly worksheets to set goals and plan actions to reduce sedentary time based on the selected tips.

Fitbit

Fitbits (Inspire model) were used to support participants as they self-monitor sedentary hours (ie, "total stationary hours" and "longest stationary period") and to provide real-time sedentary break prompts (ie, "Move alert"). The goal was to help participants become aware of their habitual sedentary behavior [24]. The Fitbit "Move alert" alerts participants after 60 minutes of sitting, prompting a 2 - to 3-minute walk (≈250 steps) to reset the alert. Participants were advised to wear the Fitbit during waking hours, optionally at night, and to synchronize weekly. Participants who failed to synchronize or wear the Fitbit for 2 days received a reminder text; continued noncompliance for another 2 days prompted a call from research staff to troubleshoot issues [18].

HidrateSpark Smart Water Bottle

The smart water bottle (HidrateSpark Smart Water Bottle) was used to motivate participants to break their prolonged sitting and stand up and move by frequently visiting the restroom and refilling the bottle. The water bottle used flashing lights and phone notifications to remind participants to drink water if they did not meet personalized hydration targets based on their body weight, age, sex, and activity levels.

Weekly Text Messages

Participants received 3 algorithm-derived, Fitbit-based tailored messages: Thursday (midweek sedentary behavior summary), Sunday (encouragement for achieving the weekly goal), and Monday. The Monday message included feedback on prior week goals (based on Fitbit), a sedentary behavior summary, 1 TTT tip, and a prompt to set new goals for sitting time and the duration and frequency of sitting breaks. These messages supported habit formation and weekly planning to reduce sitting time and increase sitting breaks. The detailed algorithm and contents are described elsewhere [18].

XSL•FO
RenderX

Control Group

The control group received standard care and the American Heart Association's "Answers by Heart" booklet [25]. This booklet guides tracking and managing body weight, blood pressure, and cholesterol levels. The booklet also notes general advice on healthy cooking and physical activity [25]. The control group did not receive a Fitbit, a smart water bottle, or tailored text messages.

Study Measures

Feasibility

Feasibility was evaluated by assessing recruitment or enrollment rates, dropout rates (percentage of participants who withdrew consent among enrolled participants), and adherence to the Sit Less program, defined as (1) ≥75% of participants using the Fitbit for ≥5 valid days per week for 75% of the study duration and (2) engagement with ≥80% of goal setting texts [26].

Acceptability

Acceptability of the Sit Less program was measured through satisfaction surveys by combining items from 2 different questionnaires [27,28]. The Lyons et al [27] questionnaire assessed overall program satisfaction, ease of use, and continued intention for each component and was adapted to evaluate Sit Less technological tools (Fitbit, app, and smart water bottle). The Burner et al [28] questionnaire focused on the text messaging aspect, examining content relevance, motivational degree, frequency, and timing of messages. Responses were rated on a 5-point Likert scale, with 75% agreement indicating acceptability.

Primary Outcome: Sedentary Behavior

Using the activPAL3 devices, we measured sedentary behavior as total daily sitting time, prolonged sitting time (time spent in sedentary bouts ≥30 minutes and time spent in sedentary bouts ≥60 minutes), and the number of sit-to-stand transitions for 7 days at baseline and at postintervention. The activPAL3, worn on the thigh, accurately detects sitting and standing postures and has been validated against direct observation [29]. ActivPAL3 data were used for analysis if the participant wore the device for more than 10 hours on a given day, at least 3 days [30]. Data for analysis were extracted from the device using PAL analysis (activPAL, version 8.11) with the validated CREA algorithm, which closely matches diary data in classifying wake time activities [31].

Secondary Outcomes

Physical Activity

Daily time spent standing and walking (stepping) was measured using the activPAL3 and processed through the CREA algorithm.

Cardiometabolic Markers

Cardiometabolic biomarkers included glycemic outcomes and additional cardiometabolic measures. Glycemic outcomes comprised HbA_{1c} and CGM metrics. Fasting finger-prick blood samples were collected onto dried blood spot cards (ZRT Laboratory) for HbA_{1c} analysis. CGM (Abbott FreeStyle Libre Pro) was conducted over 7 days to assess 24-hour average glucose, glucose management indicator, glycemic variability, and time in range (70 - 180 mg/dL) [32].

Additional cardiometabolic measures included BMI, waist and hip circumferences, waist-to-hip ratio, blood pressure, insulin, hs-CRP, and lipids. Anthropometric and blood pressure measurements were obtained using standardized procedures, and dried blood spot samples were analyzed for insulin, lipids, and hs-CRP [33,34]. Dried blood spot testing has shown a strong correlation with conventional serum tests, making it a reliable and convenient tool for screening for cardiometabolic risk factors [33,34].

Psychological Factors

We measured participant confidence in reducing sedentary behavior using the 12 items from the Self-Efficacy Questionnaire for Physical Activity and Sedentary Behavior (previously reported Cronbach α=0.79 and 0.85) [35]. The items assess the level of confidence for specific sitting behaviors and sedentary breaks. Habit strength for sedentary behavior was assessed using the validated Self-Report Habit Index measure (previously reported Cronbach α=0.91, 0.82, and 0.83) [36]. This 7-item index was adapted to assess the degree to which sedentary breaks (standing or walking) became habitual [36]. Depressive symptoms were measured using the Patient Health Questionnaire-9 (PHQ-9) [37].

Demographic and Clinical Characteristics

Demographics, socioeconomic characteristics, medical history, current medication, tobacco use, and alcohol intake were collected via self-report. Participants were asked about their level of activity associated with their current occupation, and responses ranged from "mostly sedentary" (eg, desk-based job) to "very active and physical" (eg, manual labor). Using the 16-item Rapid Eating and Activity Assessment for Participants Short Version, we determined participants' dietary habits [38].

Statistical Analysis

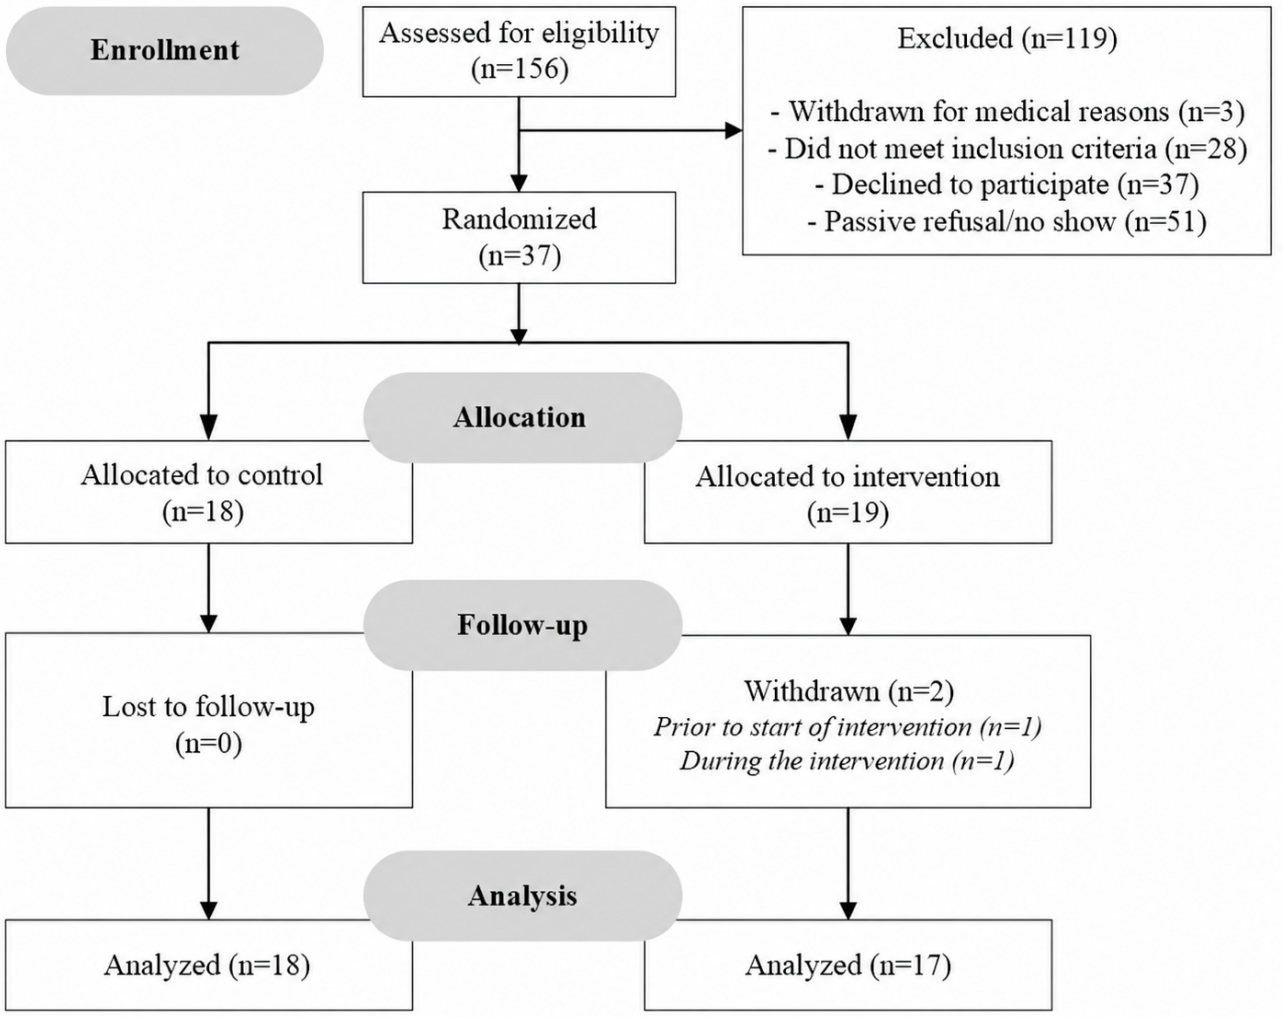
Statistical analyses were conducted using SPSS Statistics 29 (IBM Corp) and STATA 18 (StataCorp). We summarized nominal and ordinal variables via frequency distributions. Continuous variables were summarized using means and SDs when normally distributed, such as the primary outcome of sedentary behavior and psychological factors, including self-efficacy for physical activity and sedentary behavior and habit strength for sedentary behavior. Medians with IQRs were also used when distributions were skewed or contained extreme outliers. This applied to continuous demographic and clinical characteristics, as well as secondary outcome variables, including physical activity, cardiometabolic and glucose monitoring biomarkers, and PHQ-9 scores. Baseline group differences were assessed using chi-square tests of independence (nominal and ordinal) and Mann-Whitney (continuous) tests.

We evaluated the intervention effects in the following steps. First, we calculated the change in each outcome variable from baseline to postintervention for each participant. Within-group changes were generated using median (for skewed variables) and mean (for normally distributed variables), with bootstrapped 95% CIs. Second, we conducted between-group analyses using

XSL•FO
RenderX

generalized linear models with bias-corrected robust (Huber sandwich estimator, STATA) SEs to evaluate the effects of the intervention on primary and secondary outcomes. Each model included the corresponding baseline value of the outcome, cohort (CVD vs T2D), and the interaction between study group and cohort. Baseline outcome values were included to account for baseline variability, while the cohort and the cohort×group interaction term were included to account for known differences in cardiometabolic responses between the 2 clinical cohorts and to assess whether intervention effects differed by cohort. Leisure-time exercise was additionally included because it was the only baseline variable that differed significantly between groups and was considered clinically relevant to the outcomes. To maintain model parsimony and reduce the risk of overfitting, no additional covariates were included beyond those with clear clinical or methodological justification.

For each model, multicollinearity among the independent variables was assessed first. There was no multicollinearity problem among the variables for all models. We then conducted each model using the Gaussian distribution with the identity link function and evaluated the residuals for indications of extreme influence, lack of normality, and/or heteroscedasticity. When assumptions were violated, models were reestimated using a Gamma distribution with a log link, and the residuals were reevaluated. We also conducted the same analyses using transformed variables and the Gaussian distribution, with similar findings resulting from the models using the Gamma, log link function, enabling us to generate estimated mean differences on the original variable scale of measurement. A few biomarker variables had extreme outliers. Those variables could not be addressed through transformation or alternative model specifications. Given the small sample size, extreme values were winsorized by replacing them with the next highest observed value. Model assumptions were reevaluated following this adjustment. Final generalized linear models with appropriate distributions and link functions were used, and robust SEs were applied to estimate adjusted mean differences with 95% CIs. These estimates were used to evaluate the effect of the study group and to provide measures of effect size. All analyses were conducted using an intention-to-treat approach without data imputation.



Results

Participants

Of 156 participants who were contacted and assessed for eligibility, 128 (80%) met inclusion criteria, and of those, 37 (30%) completed all baseline assessments and were randomized (Figure 2). Of the 37 randomized participants, 19 (51%) were randomly assigned to the Sit Less group, and 18 (49%) were assigned to the control group. One (5%) participant from the Sit Less group completed baseline assessments but withdrew before the start of the intervention due to privacy concerns about the Fitbit displaying text messages and incoming calls. Another Sit Less group participant withdrew during the intervention due to a Fitbit data recording error. This participant used a walker, and because of the lack of wrist movement while walking with the walker, the Fitbit did not capture any steps or movement. Therefore, 35 (95%) of 37 participants completed the study and were included in the analysis (Sit Less: n=17; and control: n=18).

Figure 2. The CONSORT (Consolidated Standards of Reporting Trials) flow diagram for the Sit Less study with type 2 diabetes and cardiovascular disease cohort.

Baseline Demographics and Clinical Characteristics

The median age of the final sample was 67 (IQR 54 - 72) years. With the exception of leisure time exercise at baseline, no significant differences between groups were found in the demographic or clinical characteristics (Table 1). At baseline, 7 (39%) of 18 participants in the control group and 14 (82%) of 17 participants in the Sit Less group reported leisure-time exercise (*P*=.009).

Both the Sit Less and control groups wore the activPAL continuously (24 h/d), with minimal nonwear time (median 0 min/d, IQR 0 - 0). Participants provided a median of 7 valid wear days at both preintervention (IQR 7 - 8) and postintervention (IQR 6 - 7). On average, the participants spent a median of 624 minutes sitting (IQR 521 - 686), 182 minutes standing (IQR 108 - 230), 72 minutes stepping (IQR 45 - 86), 32 minutes in secondary lying positions (IQR 0 - 83), and 490 minutes sleeping (IQR 450 - 523). No significant between-group differences were found in nonwear time and baseline activities except for stepping time.

[b]REAP-S: Rapid Eating and Activity Assessment for Participants Short Version.

[c]CVD: cardiovascular disease.

Feasibility

As noted earlier, among the 37 participants enrolled, 35 (95%) completed all study activities. The Sit Less group had a dropout rate of 2 (11%) of 19; the reason for the dropout was privacy concerns about the Fitbit displaying text messages and incoming calls and Fitbit's data recording errors. Adherence to the Sit Less program was high according to our adherence definition (Figure 3). Fifteen (88%) of 17 participants wore the Fitbit for more than 75% of the intervention period. On average, participants wore their Fitbit for 76 of 84 days. Weekly, the Sit Less participants had a median of 6.8 valid wear days per week—where a valid day indicated wearing the Fitbit for more than 10 hours. Daily median Fitbit wear time was 928 minutes per day (IQR 902 - 944). Adherence to Fitbit wear peaked at weeks 5 and 7, with 96% wearing the device, and was maintained throughout the study period, except for week 12, when adherence dropped to 76%.

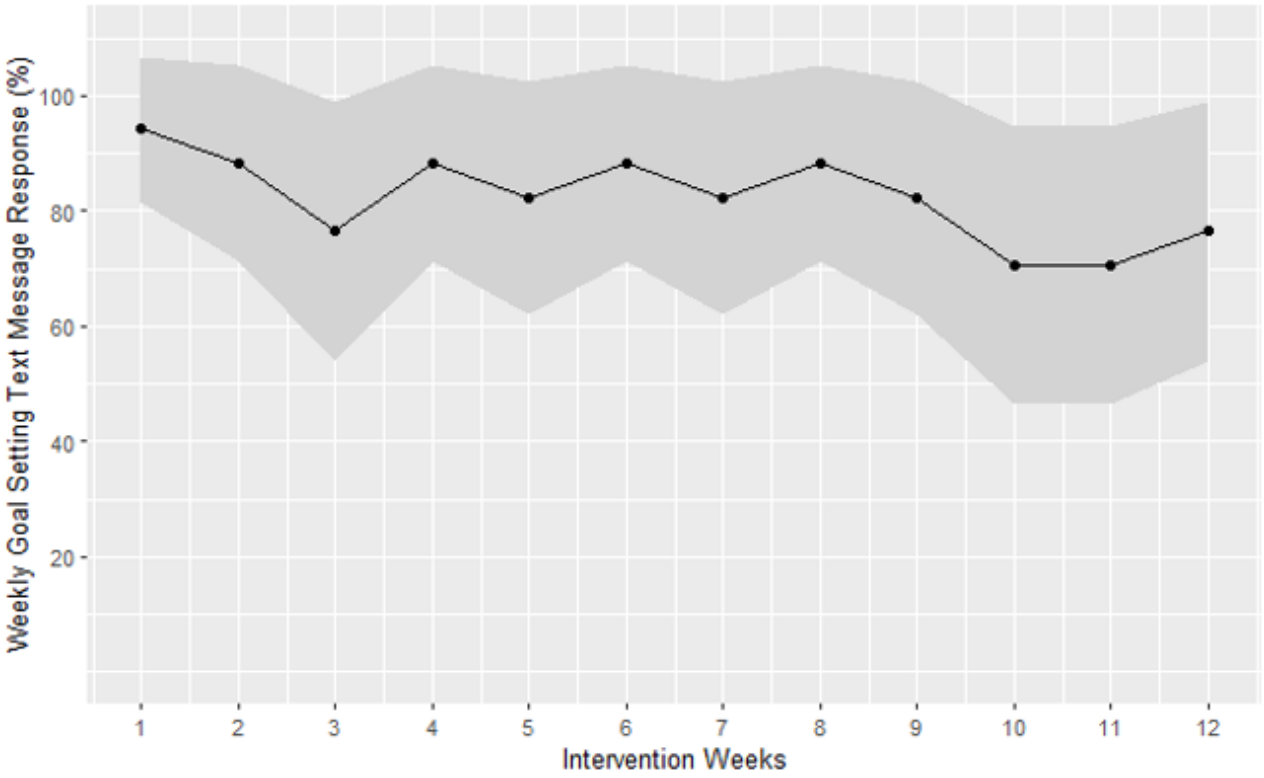

Figure 3. Weekly average adherence to wearing a Fitbit over 12 weeks. The gray area indicates the 95% CI.

For text message responses, participants were diligent in setting weekly goals and replying to us (Figure 4). The average rate of text message response over 12 weeks was 81%. Until week 9, participants consistently responded to goal-setting messages, with adherence rates ranging from 91% to 83%. However, in the last 3 weeks of the program, response rates decreased, ranging between 58% and 66%.

XSL•FO
RenderX

Figure 4. Weekly average adherence to responding to goal-setting text messages over 12 weeks. The gray area indicates the 95% CI.

Acceptability

A total of 17 Sit Less participants completed the satisfaction survey. Fifteen (88%) of 17 participants indicated that they would recommend the program to family and friends. Fifteen (88%) of 17 participants indicated that the program increased awareness of their sedentary behavior. Sixteen (94%) of 17 participants liked wearing the Fitbit monitor; 13 (77%) of 17 participants would continue checking sitting hours on Fitbit, and 11 (65%) of 17 participants indicated that the "Move Alert" from Fitbit was useful. The majority (11/17, 65%) of participants also indicated that they found the smart water bottle convenient to use. Fifteen (88%) of 17 Sit Less participants either agreed (47%) or remained neutral (41%) about whether they would like to receive text messages for a longer period. The majority (13/17, 77%) of participants either agreed or were neutral that the tips and advice felt specific to them, and they were motivated by the text messages. Most participants (16/17, 94%) indicated that the number of text messages was "just right."

Primary Outcome: Sedentary Behavior

Group differences in sedentary behavior at baseline and postintervention are presented in Table 2. Overall, the Sit Less intervention showed consistent directional improvements compared with the control group, although between-group differences were not statistically significant. For total sitting time, the control group increased from 588.3 (SD 100.2) to 593.6 (SD 83.4) minutes per day, whereas the Sit Less group decreased from 643.6 (SD 113.0) to 605.0 (SD 111.1) minutes per day. After adjustment for baseline values, cohort, cohort×group interaction, and leisure-time exercise, the Sit Less group showed a nonsignificant reduction of 17.3 minutes per day in total sitting time compared with the control group at postintervention (95% CI −63 to 28; *P*=.45).

XSL•FO
RenderX

Table . Changes in sedentary behavior outcomes from baseline to postintervention by study group (N=35; control: n=18; Sit Less: n=17; all baseline between-group differences were *P*>.05).

Outcomes	Baseline, mean (SD)	Postintervention, mean (SD)	Mean change (95% CI)	Estimated adjusted mean difference (95% CI)[a]	*P* value[b]
Sitting time (min/d)				−17.3 (−63 to 28)	.45
Control	588.3 (100.2)	593.6 (83.4)	5.3 (−38 to 50)		
Sit Less	643.6 (113.0)	605.0 (111.1)	−38.6 (−71 to 4)		
Sitting and secondary lying time (min/d)				−21.7 (−76 to 32)	.43
Control	660.2 (112.0)	669.4 (83.5)	9.2 (−47 to 70)		
Sit Less	679.4 (129.4)	642.0 (113.5)	−37.4 (−80 to 11)		
Time spent sitting bouts >30 min (min/d)				−39.5 (−100 to 21)	.20
Control	345.0 (144.0)	355.6 (106.4)	10.7 (−41 to 65)		
Sit Less	355.5 (135.7)	304.8 (140.5)	−50.7 (−115 to 8)		
Time spent sitting bouts >60 min (min/d)				−49.9 (−102 to 2)	.06
Control	203.1 (144.8)	205.0 (116.6)	1.9 (−47 to 44)		
Sit Less	194.4 (113.0)	142.4 (112.8)	−52.0 (−111 to 4)		
Sit-to-stand transitions (n per day)				4.2 (−2 to 10)	.13
Control	36.2 (13.7)	36.8 (12.0)	0.6 (−2 to 3)		
Sit Less	43.7 (9.9)	46.6 (8.9)	2.9 (−3 to 9)		

[a]Test of the difference between adjusted marginal means using a generalized linear model with a Gaussian distribution and identity link, with robust SEs (χ^2 statistic, df=1).

[b]Adjusted for study cohort, cohort×group interaction, baseline value, and leisure-time exercise; estimates generated using robust SEs.

Time spent in sedentary bouts of >30 minutes increased in the control group and decreased in the Sit Less group (Table 2), with a nonsignificant adjusted between-group difference of −39.5 minutes per day (95% CI −100 to 21; *P*=.20). For sedentary bouts of >60 minutes, the control group showed minimal change (1.9 min/d; 95% CI −47 to 44), whereas the Sit Less group decreased by 52.0 minutes per day (95% CI −111 to 4), with an adjusted difference of −49.9 minutes per day (95% CI −102 to 2; *P*=.06).

Sit-to-stand transitions were unchanged in the control group (36.2, SD 13.7 vs 36.8, SD 12.0) but increased in the Sit Less group (43.7, SD 9.9 vs 46.6, SD 8.9), with a nonsignificant adjusted mean difference of 4.2 transitions per day (95% CI −2 to 10; *P*=.13).

Secondary Outcome: Physical Activity

Group differences in physical activity at baseline and postintervention are presented in Table 3. Although not statistically significant, participants in the Sit Less group increased both standing and stepping time by approximately 10 minutes more than those in the control group, despite variability in change scores. For standing time, the control group decreased from 170.5 (IQR 99 - 255) to 158.1 (IQR 115 - 256) minutes per day, whereas the Sit Less group increased from 182.9 (IQR 144 - 228) to 193.4 (IQR 144 - 239). The adjusted between-group difference was 9.7 minutes per day (95% CI −52 to 71; *P*=.76), but it was not significant.

For stepping time, baseline values differed between groups (control: median 49.7 min/d, IQR 37 - 75; Sit Less: median 80.8 min/d, IQR 52 - 108; *P*=.01). Following the intervention, the control group and the Sit Less group both increased stepping time, but there was no statistically significant between-group difference following the intervention (adjusted mean difference 9.6 min/d, 95% CI −15 to 34; *P*=.44).

Step counts also increased in both groups; however, there was no statistically significant between-group difference following the intervention (adjusted mean difference 711.4 steps per day, 95% CI −983 to 2406; *P*=.41).

Table . Changes in physical activity outcomes from baseline to postintervention by study group (N=35; control: n=18; Sit Less: n=17)[a].

Outcomes	Baseline, median (IQR)	Postintervention, median (IQR)	Median change (95% CI)	Estimated adjusted mean difference[b] (95% CI)	*P* value[c]
Standing time (min/d)				9.7 (−52 to 71)	.76
Control	170.5. (99 - 255)	158.1 (115 - 256)	26.1 (−39 to 59)		
Sit Less	182.9 (144 - 228)	193.4 (144 - 239)	−0.5 (−30 to 44)		
Stepping time (min/d)				9.6 (−15 to 34)	.44
Control	49.7 (37-75)[d]	58.8 (45 - 80)	11.7 (−1 to 19)		
Sit Less	80.8 (52 - 108)	89.5 (53 - 107)	−0.8 (−11 to 22)		
Step counts (steps per day)				711.4 (−983 to 2406)	.41
Control	3682 (2680 - 5248)	4085 (3518 - 6274)	991 (−145 to 1340)		
Sit Less	5759 (4254 - 8337)	6299 (4216 - 8594)	36 (−447 to 1427)		

[a]Due to moderate skewness, median (IQR) and median change used to describe the observed distributions.

[b]Adjusted for the main effect of study cohort, the interaction of study cohort with study group, exercise during leisure time prior to study, and baseline values; estimated mean differences generated using robust SEs.

[c]Test of the difference between adjusted marginal means using a generalized linear model with a Gaussian distribution and identity link, with robust standard errors (χ^2 statistic, df=1).

[d]Baseline between-group difference, Mann-Whitney *U* test, *P*<.05. All other baseline between-group differences were *P*>.05.

Secondary Outcomes: Cardiometabolic Markers

Glycemic outcomes at baseline and postintervention are summarized in Table 4. HbA_{1c} levels were significantly lower in the Sit Less group compared with the control group at postintervention (adjusted mean difference −0.4%, 95% CI −0.8 to −0.1; *P*=.04), with a decrease observed in the Sit Less group (median change −0.4%, 95% CI −0.6 to −0.2) and minimal change in the control group (median change 0.1%, 95% CI −0.1 to 0.5). Although not statistically significant, CGM outcomes were directionally consistent with HbA_{1c}. Adjusted mean differences indicated lower glucose management index (−0.1%, 95% CI −0.4 to 0.1; *P*=.16) and average glucose level (−6.0 mg/dL, 95% CI −14.9 to 2.8; *P*=.18) in the Sit Less group compared with the control group at postintervention (Table 4). Participants wore the CGM device for a median of 9 days in both groups, with no between-group differences. Sensitivity analyses excluding extreme outliers were conducted for HbA_{1c} (n=1 control), CGM-based glucose management index (n=2 controls), and average glucose level (same 2 controls as GMI). While the estimated mean differences and *P* values changed slightly, interpretations of the results remained the same. Those summaries and findings are provided in Multimedia Appendix 1.

[e]Within-group change statistically significant based on bootstrapped 95% CI.

[f]Test of the difference between adjusted marginal means using a generalized linear model with a Gamma distribution and log link function, with robust SEs (chi-square statistic, df=1). Two extreme outliers in the control group, one at baseline and another at postintervention were winsorized prior to analysis.

[g]Test of the difference between adjusted marginal means using a generalized linear model with a Gaussian distribution and identity link, with robust SEs (chi-square statistic, df=1).

No statistically significant between-group differences were observed for other cardiometabolic outcomes, including weight, BMI, waist circumference, insulin, or blood pressure. Total cholesterol and low-density lipoprotein decreased and high-density lipoprotein increased, whereas triglycerides increased; however, none of these adjusted between-group differences were statistically significant (Multimedia Appendix 2).

Secondary Outcomes: Psychological Outcomes

Psychological outcomes at baseline and postintervention are summarized in Table 5. No adjusted between-group differences were observed for sedentary behavior habit strength (adjusted mean difference 0.0; 95% CI −0.7 to 0.8; *P*=.89). Self-efficacy for increasing physical activity increased in the control group but decreased in the Sit Less group, with a significant between-group difference observed for moderate activity (adjusted mean difference −0.6, 95% CI −1.1 to −0.2; *P*=.003;

XSL•FO
RenderX

Table 5). For depressive symptoms (PHQ-9), the adjusted between-group difference at postintervention was not statistically significant.

Table . Changes in psychological outcomes from baseline to postintervention by study group (N=35)[a].

Outcomes	Baseline, mean (SD)	Postintervention, mean (SD)	Mean change (95% CI)	Estimated adjusted mean difference[b] (95% CI)	*P* value[c]
Sedentary behavior habit strength (minimum=1 and maximum=7)				0.0 (−0.7 to 0.8)	.89
Control	6.0 (0.7)	5.8 (0.9)	−0.2 (−0.6 to 0.3)		
Sit Less	5.9 (1.1)	5.8 (1.0)	−0.1 (−0.7 to 0.4)		
Self-efficacy in reducing sitting (minimum=1 and maximum=5)				−0.4 (−0.9 to 0.2)	.15
Control	3.6 (0.9)	3.3 (0.9)	−0.3 (−0.8 to 0.2)		
Sit Less	3.5 (0.6)	3.1 (1.0)	−0.4 (−0.8 to 0.1)

[a]Control: n=18; Sit Less: n=17; all baseline between-group differences were *P*>.05.

[b]Adjusted for the main effect of study cohort, the interaction of study cohort with study group, exercise during leisure time prior to study, and baseline values; estimated mean differences generated using with robust SEs.

[c]Test of the difference between adjusted marginal means using a generalized linear model with a Gaussian distribution and identity link, with robust SEs (chi-square statistic, df=1).

[d]Patient Health Questionnaire-9 (PHQ-9) scores are reported as median (IQR) at baseline, postintervention, and for median change due to a skewed distribution. All other psychological values are presented as mean (SD) unless otherwise specified.

Discussion

Principal Findings

Frequent, short breaks (walking 5 min for every hour sitting) are practical, low-burden alternatives to exercise, proven to improve glucose and insulin levels [7,39]. However, intervention studies on sedentary breaks in T2D or CVD are limited and mostly short-term laboratory studies [7,39]. This is the first study integrating Fitbit devices and smart water bottle technologies and algorithm-driven text messages to encourage frequent sedentary breaks. Focusing on sedentary breaks addresses barriers associated with traditional exercise programs—such as fear of hypoglycemia, cardiac discomfort, and time constraints [1,6,11]—while concurrently reducing overall sedentary time and increasing standing and walking duration. The intervention demonstrated high feasibility, acceptability, and adherence within the patient with cardiometabolic diseases groups over a 12-week period, characterized by high engagement with text messaging and consistent use of Fitbits. Participants in the Sit Less group also reported that wearable technology and smart water bottles were instrumental in breaking up their prolonged sitting. Notably, these positive outcomes were observed in a participant group

XSL•FO
RenderX

with a median age of 67 years, indicating the potential of our multitechnology-based Sit Less program to reduce sedentary time and foster more active lifestyles among older adults with cardiometabolic conditions.

In this randomized controlled pilot trial, we were underpowered to detect intervention effects on outcomes, and CIs are wide; however, we still detected some directional changes in outcomes of interest in the Sit Less group relative to the control group. The Sit Less program was associated with reductions in total daily sedentary time compared with the control group, although between-group differences were not statistically significant. Over 12 weeks, the control group increased sitting time by 5.3 minutes per day, whereas the Sit Less group reduced sitting time by 38.6 minutes per day, corresponding to an adjusted difference of −17.3 minutes per day. Considering that reducing and replacing 30 minutes of sedentary time yields significant cardiometabolic benefits and reduces the risk of developing CVD and mortality [21], the observed reductions in the Sit Less group may have clinical relevance for individuals with diabetes and/or CVD.

Consistent patterns were observed for prolonged sedentary behavior, with decreases in time spent in bouts longer than 30 and 60 minutes in the Sit Less group compared with the control group. Prolonged, uninterrupted sitting is more strongly associated with adverse cardiometabolic outcomes than interrupted sitting [40,41]. A recent meta-analysis, while accounting for total sedentary time and moderate-to-vigorous physical activity time, revealed that even a single break per hour can modestly improve BMI, waist circumference, inflammation, and blood pressure [12,13]. Experimental studies confirm that sedentary breaks can improve glucose levels by 2% to 17% and fasting insulin levels by 15% [12,14]. In line with this, Sit Less participants had more sedentary breaks, shorter prolonged sitting, and lower HbA_{1c} (via dried blood spot) than controls postintervention. Our findings suggest that the intervention was feasible for targeting prolonged sedentary time and provide preliminary suggestions for further investigation in adequately powered trials. However, given the pilot nature of the study, small sample size, and multiple outcomes examined, the HbA_{1c} finding should be interpreted cautiously. Future studies powered to detect intervention effects and mechanisms of effects are needed.

With regard to physical activity outcomes, the Sit Less group spent 10 minutes more on stepping activities and standing compared to the control group postintervention, after adjustments. This level of change may have been insufficient to improve some cardiometabolic outcomes, including blood pressure and anthropometric measures. Considering that replacing sedentary time with higher-intensity physical activity leads to more substantial improvements in cardiometabolic markers, future interventions should encourage not only standing but also engaging in higher-intensity stepping for greater cardiometabolic benefits.

Despite these improvements in objective outcomes, psychological outcomes (eg, self-efficacy for reducing sedentary behavior and habit strength) did not change. Moreover, self-efficacy for increasing moderate physical activity was significantly higher in the control group compared to the Sit Less group at postintervention after adjustment. One possible explanation is that participants in the Sit Less group may have become more aware of the challenges of replacing sedentary behavior with moderate levels of physical activity, a phenomenon known as response shift, which is commonly observed in self-reported outcomes in behavioral interventions [42]. However, it is also possible that the measures used were not sufficiently sensitive to detect short-term changes in psychological constructs such as habit formation or that the pilot sample size was underpowered to detect modest psychological effects. Future research could incorporate approaches such as postintervention pretests, in which participants retrospectively assess their baseline perceptions, to better capture these changes. Future research could use a postintervention pretest in which participants report after the intervention what they would have reported at pretest, given what they have learned through the intervention.

Limitations

The goals of this pilot study were to assess the acceptability of the intervention and the feasibility of the study design. The small sample size aligns with these goals but limits our ability to make conclusions about the efficacy of the Sit Less intervention. The study was not powered to formally test hypotheses regarding intervention efficacy, and CIs were wide. Those findings should therefore be interpreted as a preliminary suggestion for testing the Sit Less intervention in a future fully powered trial. To maintain model parsimony and reduce the risk of overfitting, no additional exploratory covariates were included in the final models beyond those considered clinically or methodologically essential. Accordingly, the significant finding for HbA_{1c} should be interpreted with caution in light of the limited sample size and potential model instability.

In addition, several features of this study limit our generalizability. For instance, participants were recruited from a single hospital in Nashville, USA, and were predominantly White and highly educated. Although feasibility and acceptability were high in this sample, challenges such as varying comfort with technology and device usability may be more pronounced in other populations.

Moreover, baseline HbA_{1c} levels (median, approximately 5.0% - 5.5%) were within the nondiabetic or well-controlled range for many participants, and no participants had baseline HbA_{1c} levels >7.0%, further limiting generalizability. In addition, given the very small sample size within each cohort, the study is not designed to estimate differential treatment effects between CVD and T2D.

Finally, we are unable to determine the mechanisms driving change in objective outcomes. For instance, we did not collect objective data on smart water bottle use (eg, refill frequency), limiting our ability to assess its independent contribution to behavioral changes. Future larger studies, including those using multiple intervention conditions or fractional factorial designs that vary components, could examine how different components impact outcomes to understand mechanisms of change and seek

XSL•FO
RenderX

to evaluate Sit Less in more diverse and clinically complex populations.

Clinical Implications

Breaking up prolonged sitting should be a priority in the clinical management of patients with cardiometabolic diseases, as even short, frequent activity breaks can improve glycemic control and reduce sedentary time. The Sit Less program achieved these outcomes by integrating simple standing and walking breaks into daily routines, effectively overcoming common exercise barriers such as fear of hypoglycemia, cardiac discomfort, and time constraints. Its multitechnology was well received by older adults, reinforcing its suitability for patients with cardiometabolic diseases. In addition, the dropout of 1 participant due to inaccurate Fitbit data associated with walker use highlights a limitation of wrist-worn activity monitors in this population. Such devices may not accurately capture activity in individuals who rely on assistive devices, as arm movement is restricted. This should be considered in future studies and implementation efforts involving older or mobility-impaired cardiometabolic populations, where alternative monitoring approaches such as hip monitoring may be more appropriate.

Conclusions

In conclusion, the Sit Less intervention effectively integrated multiple technologies to reduce sedentary behavior in patients with cardiometabolic diseases. By targeting prolonged sedentary time, the program has shown a trend to decrease in total sitting time, increase in sedentary breaks, and possible improvements in glycemic outcomes. Our approach, which minimizes typical exercise barriers and promotes short active breaks, has demonstrated high feasibility and acceptance, suggesting its promise for future large-scale interventions. While further research is necessary to confirm these findings and assess their impact on a range of cardiometabolic markers, the initial results advocate for health care strategies that promote sedentary breaks to manage cardiometabolic disease.

Funding

This study was funded by the Moore Foundation and NIH/NIDDK (NIHDK020593). The funder played no role in study design, data collection, analysis and interpretation of data, or the writing of this manuscript. Dr. Park is supported, in part, by New Faculty Startup Fund from Seoul National University the under Award Number 810-20240026. This research was conducted while Dr. Chorong Park was affiliated with Vanderbilt University School of Nursing.

Abstract

Background: AI-powered digital mental health interventions (DMHIs) are a promising approach to address barriers to traditional mental health care. However, real-world evidence of their immediate and sustained benefits remains limited.

Objective: The purpose of this real-world, retrospective study is to explore patterns of perceived mood and stress change associated with the use of Yuna, an AI-powered DMHI. We aimed to (1) describe user demographics and session characteristics, (2) quantify the magnitude of mood and stress change within sessions and over time with continued Yuna use, and (3) identify session-level factors associated with changes in mood and stress.

Methods: Adult Yuna users (aged ≥18 y) who initiated at least one session with the Yuna app were included in this study. Users self-reported mood and stress on Visual Analog Scales (VASs; range 0 - 1) before and after sessions. Linear mixed effects models were used to explore the immediate, within-session improvements in mood and stress, and the sustained, between-session changes in symptoms of mood and stress. Linear mixed effects models were also used to examine session-level predictors of within-session improvements, including baseline symptom severity, session duration, total number of unique therapeutic approaches used, safety guardrail activation, and gender.

Results: A total of 5549 real-world users were included (2901/5549, 52.3% female; mean sessions 3.44, SD 9.83). Users demonstrated significant, immediate within-session improvements in both mood (d=0.55) and stress (d=0.56), with sensitivity analyses yielding consistent results. Between-session analyses revealed gradual improvements in baseline mood (d=−0.009) and stress (d=−0.011). Baseline symptom severity was the strongest predictor of immediate, within-session change (mood: β=.118, SE 0.003; P<.001; stress: β=.131, SE 0.004; P<.001), followed by session duration (mood: β=.027, SE 0.003; P=.003; stress: β=.029, SE 0.003; P<.001). A greater number of unique therapeutic approaches used was associated with smaller improvements in both outcomes (mood: β=−0.007, SE 0.003; P=.043; stress: β=-0.011, SE 0.003; P=.002).

Conclusions: Use of Yuna, an AI-powered DMHI, was associated with perceived within-session improvements in mood and stress, with preliminary evidence of gradual improvements in mood and stress across repeated sessions. However, the absence of a control group and potential selection bias preclude causal conclusions. These findings offer promising, real-world evidence for AI-powered DMHIs as accessible, on-demand support tools. Prospective, controlled designs are needed to establish causal effects and evaluate the sustainability of observed improvements.

KEYWORDS

mental health; digital mental health intervention; real-world evidence; conversational AI; mental health app

Introduction

Low mood (ie, persistent sadness or reduced emotional well-being) and chronic stress represent a major and growing public health challenge worldwide. Depression, a common form of persistent low mood, affects hundreds of millions of individuals globally [1], and emotional stress has steadily worsened across countries and employment groups over the past decade [2]. Together, mood and stress-related concerns represent a major source of disability worldwide, underscoring their substantial individual and societal burden [3]. These concerns are particularly salient in the workplace, where elevated stress, low mood, and emotional exhaustion are linked to diminished productivity, increased absenteeism, and impaired well-being [4-6]. As employers increasingly recognize the

XSL•FO
RenderX

impact of both mood and stress on workforce functioning, there is a growing demand for scalable, effective approaches to support employee mental health.

Despite heightened attention, access to timely and effective mental health care remains limited for many working adults. Traditional treatments such as psychotherapy and pharmacological care are often constrained by cost, provider shortages, scheduling barriers, and stigma [7,8]. Employee Assistance Programs (EAPs) are commonly offered as an initial workplace resource, yet usage remains persistently low, in part due to limited awareness, perceived stigma, and short-term or reactive models of care [9,10]. As a result, many employees who experience significant stress or mood symptoms do not receive sustained support through existing workplace systems, highlighting the need for interventions that are both accessible and engaging.

In response to barriers in traditional workplace mental health care, digital mental health interventions (DMHIs) have been increasingly adopted by employers as scalable tools to support employee well-being. These programs typically offer app-based cognitive behavioral strategies, mindfulness content, and stress-management resources [11]. While workplace DMHIs can produce modest improvements in mental health outcomes, real-world effectiveness is often limited by low engagement and high dropout [12-14]. Systematic reviews suggest that DMHIs achieve stronger outcomes and higher adherence when programs include guidance or reminders, raising concerns about the long-term sufficiency of purely self-guided formats and highlighting the potential value of more interactive support beyond self-help tools alone [13,15]. At the same time, stigma, privacy concerns, resource constraints, and scheduling barriers continue to limit uptake of human-delivered services in workplace settings [16-18]. Together, these limitations highlight the need for workplace mental health tools that provide timely, personalized support without requiring traditional appointments.

AI-powered DMHIs represent an emerging approach that may help address these challenges by offering conversational, adaptive support that bridges the gap between unguided self-help apps and traditional human care [19,20]. Conversational AI systems can provide real-time emotional check-ins, coping guidance, and reflective coaching in a format that may feel more engaging and responsive than static digital content, while also reducing barriers related to stigma, scheduling, and discomfort with human interaction [21,22]. One example is Yuna, an AI-powered DMHI, which provides employees with 24/7 access to an AI mental health coach through personalized, on-demand conversations. Yuna has been used by thousands of individuals through workplace partnerships, illustrating its potential as a scalable model for delivering evidence-based support. Despite rapid growth in the availability and adoption of AI-driven mental health solutions, empirical evidence remains limited regarding how these platforms are used in real-world workplace populations and whether employees experience meaningful improvements in mood and stress over repeated engagement.

The purpose of this real-world, retrospective study is to explore the association between use of Yuna, an AI-powered DMHI, and perceived mood and stress change. We aimed to (1) describe user demographics and session characteristics, (2) quantify the magnitude of mood and stress change within sessions and over time with continued Yuna use, and (3) identify session-level factors associated with changes in mood and stress. These findings provide real-world evidence on conversational AI mental health support in workplace settings and help inform the development of scalable AI-powered DMHIs for employees.

Methods

Study Design and Participants

This retrospective study analyzed secondary data from Yuna, an AI-powered DMHI. The dataset included self-reported mood and stress and app usage metrics from real-world Yuna users, collected as part of routine product evaluation activities in the Yuna platform. Users were included if they: (1) were adults (aged 18+ y), (2) were located in a country where Yuna is available, and (3) initiated at least one session with the Yuna platform. Eligible participants were identified through a retrospective cohort sampling approach from backend app usage records, spanning from December 29, 2024, to January 12, 2026 (ie, the date the data was extracted). As this study is a retrospective study, no direct recruitment took place. A formal power analysis was not conducted, as the retrospective nature of this study precluded prospective sample size determination. Instead, the analytic sample reflected the full population of eligible users available within the observation window. This sample size was sufficient to support accurate and stable estimation of multilevel model parameters [23]. This study was conducted and reported in accordance with the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines for observational cohort studies (Checklist 1).

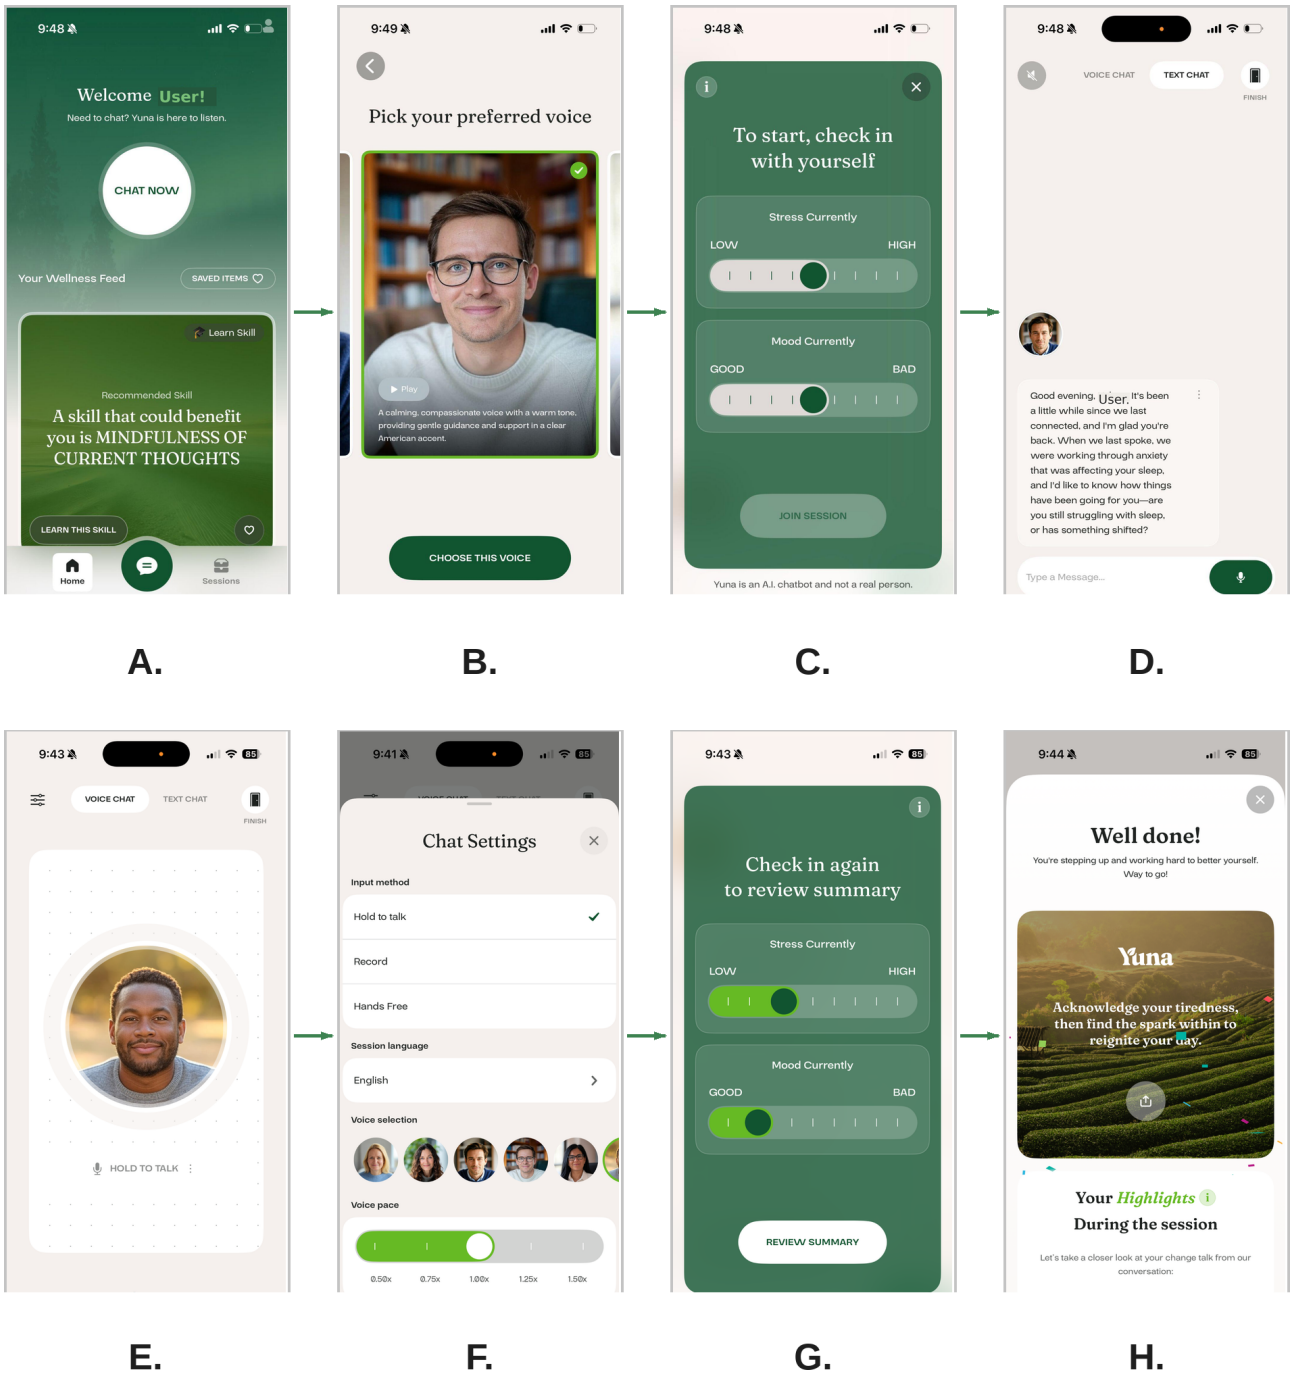
Ethical Considerations

The study protocol was reviewed and approved by the Solutions Institutional Review Board (IRB; study ID: 1001) under international expedited review procedures (ie, the study was not deemed exempt) and was conducted in accordance with US human subjects research regulations. The study involved a retrospective analysis of preexisting, deidentified data, with no direct interaction or intervention with users. Investigators did not have access to identifiable private information, and informed consent was waived by the IRB due to minimal risk. User data were collected during routine app use, and users agreed to the platform's terms and privacy policy, which permit the use of deidentified and/or aggregated data for service improvement and research purposes. The study used data from a global user population, processed in accordance with the platform's privacy policy. Participants were not compensated in any way for using the app or completing in-app questions or surveys. All data were deidentified prior to analysis.

App Description and Measures: Yuna App

Yuna is a commercially available mental health and wellness platform offered through workplace partnerships. Yuna's primary feature is a clinician-informed and evidence-based AI-powered mental health coach that provides users with unlimited, 24/7 support to improve well-being. Yuna

XSL•FO
RenderX



incorporates personalization features, such as selecting their preferred voice for the AI mental health coach, to foster a comfortable and individualized interaction. Additional features of Yuna include a library of wellness content, guided tools, and self-help resources. Together, Yuna is an emerging, scalable solution that offers more immediate and accessible support than traditional therapy services.

Yuna's AI mental health coach draws upon evidence-backed therapeutic frameworks, such as dialectical behavior therapy (DBT), cognitive behavioral therapy (CBT), and acceptance and commitment therapy (ACT). During conversations, the system dynamically applies techniques from these frameworks based on the user's expressed needs. These techniques are implemented as "therapeutic approaches," defined as discrete intervention strategies (eg, mindfulness exercises, emotion regulation skills, and cognitive reframing). Yuna leverages over 20 such therapeutic approaches, which are informed by clinician-developed prompts. Therapeutic approach selection follows a dual-layer logic. A central controller model analyzes user input, conversational context, and emotional tone to determine which approach is most appropriate for the user's presenting needs. Once activated, intraapproach logic guides the delivery of the specific approach sequence to ensure protocol fidelity. All therapeutic approach prompts and clinical protocols were developed by a licensed clinician, and the system undergoes iterative refinement through ongoing clinician review.

High-priority safety therapeutic approaches, including suicide risk-specific strategies and safety guardrails, continuously monitor conversations for high-risk content. Upon activation, standard coaching is suspended and users are provided with crisis deescalation support and emergency resources (eg, 988). To mitigate potential bias in AI-generated responses, Yuna's clinical team periodically audits deidentified session transcripts to identify and address inconsistencies in approach behavior, inappropriate responses, or gaps in protocol adherence. System performance is additionally monitored through automated quality metrics and a human-in-the-loop review process. Figure 1 depicts a standard Yuna user flow.

Study Measures

Overview

When a user first signs up for Yuna, they are able to provide their age and gender within their account profile. Gender was assessed with the item "What's your gender?" with response options of Male, Female, or Other. User country is derived from backend data.

Mood and Stress Levels

In the Yuna app, users are prompted to self-report their current mood and stress levels on a Visual Analog Scale (VAS) immediately before and after a session, defined as a discrete interaction with the AI mental health coach that begins when a user initiates a conversation and ends when the user selects "finish" in the conversation. For stress, users move a slider along a continuum from "Low" to "High," whereas mood is rated by sliding along a scale from "Good" to "Bad." The slider-based scale is continuous and does not display numerical values to users. Responses are recorded on a 0 - 1 continuous scale to the hundredth decimal place, with 10 tick marks serving as visual anchors to facilitate user responding. This measurement approach allows users to indicate their subjective experiences without being restricted to specific numerical values. Mood and

XSL•FO
RenderX

stress ratings before sessions were required, while postsession ratings were optional. This prepost assessment approach is consistent with measurement strategies used in other DMHIs [24].

Single-item VASs minimize user burden and support repeated, in-the-moment assessments within a real-world digital intervention context, and have been used widely in digital health research [25]. However, the measures examined in this study have not been psychometrically validated. These metrics are intended to capture subjective, perceived changes in mood and stress rather than capture clinically validated outcomes.

App Engagement

Engagement with the Yuna app was described by users' time with Yuna, total sessions, and session length. Time with Yuna was defined as the total number of days from a user's first initiated Yuna session to the last recorded Yuna session, representing the user's total period of possible exposure to the app, whether or not they were actively engaged daily or monthly. Sessions per user were defined as the total number of sessions each user had completed at the time of data extraction. Session length was defined as the average total minutes each session lasted.

Statistical Analyses

User demographics and session characteristics were characterized using descriptives, including mean and SD for continuous variables and total count and percentages for categorical variables. Mood and stress scores were scored continuously on a scale from 0 to 1, with higher values representing worse mood or higher stress. Data availability differed by research aim, resulting in separate analytic samples and models for within-session and between-session analyses. Within-session analyses required sessions with complete pre- and postsession ratings of mood and stress. Between-session analyses required users with repeated sessions with presession ratings of mood and stress. Because of this, sample sizes vary across models and are reported with each analysis. This approach aligns with best practices in observational, real-world studies, where complete data across all sessions cannot be assumed [26,27]. To characterize missingness and potential selection effects, missingness was quantified for key variables, and engagement was described using median and IQR for sessions per user. Users included in within-session analyses (ie, users with ≥1 session complete with pre-postsession data) were compared to excluded users. Sessions with complete postsession data were compared to sessions without postsession data. To formally evaluate missingness, a logistic regression model was conducted to predict postsession rating completion from presession mood, stress, gender, repeat-user status, and session number.

To examine within-session improvements in mood and stress, we fit separate linear mixed-effects models (LMMs) predicting mood improvement and stress improvement with a random intercept for the user to account for within-user correlation across repeated sessions. The outcome for the within-session models was a prepost change score computed within each session (ie, presession rating minus postsession rating). From this coding, positive values indicated improvement in mood or stress, whereas negative values reflect worsening mood or stress. To evaluate the robustness of within-session findings, two sensitivity analyses were conducted using the same LMM specifications as the primary model. One sensitivity model restricted the analytic sample to each user's first completed session to assess whether results were driven by repeat users. The second sensitivity model restricted the analytic sample to users with at least two sessions to evaluate whether findings were driven by one-time or minimally engaged users. To examine between-session improvements in mood and stress, separate LMMs were fit to model presession mood and presession stress over time among users with more than one session. To test whether users began subsequent sessions with improved mood or reduced stress, the outcome was baseline ratings at the start of each session. The fixed effect was the session number, defined as the within-user order of sessions, and the random intercept was the user. In these models, negative coefficients for the session number indicated an improvement, meaning that baseline mood or stress was improved at later sessions relative to earlier sessions. Effect sizes for within-session and between-session changes were calculated as standardized mean differences.

To identify session-level factors that were associated with within-session improvements in mood and stress, we fit fully adjusted LMMs with fixed effects for presession mood or stress, session length, safety guardrail activation, total number of unique therapeutic approaches used (ie, count of distinct therapeutic approaches deployed), and gender, and a random intercept for user to account for correlation across repeated sessions within individuals. Continuous predictors were standardized (z-scored) before modeling to facilitate comparability of coefficient sizes. To contextualize findings related to therapeutic approach use, we conducted an exploratory analysis of the three most frequently used therapeutic approaches: the default module (ie, a general supportive agent that guides the conversation and transitions to specialized agents when deeper support is needed), cognitive defusion (ie, an ACT-based technique that helps users disengage from distressing thoughts), and interpersonal effectiveness (eg, a DBT-based approach focused on assertive communication and boundary setting). Session-level indicators were created for each of these approaches and were included as fixed effects in LMMs predicting whether session improvements in mood and stress.

All models were estimated using restricted maximum likelihood (REML) and were adjusted for gender. *P* values were obtained using Satterthwaite approximation. Given the large number of sessions and users available across all analytic samples, the study was considered adequately powered to detect associations of the magnitude observed. All analyses were conducted in R Version 2024.12.0+4.67 (R Core Team) [28].

Bias Mitigation

Fit Minded, Inc, uses a standardized bias mitigation protocol across all industry-partnered research, applied prospectively and independent of study outcomes. For this study, the following safeguards were implemented. First, an independent academic researcher (CS), external to the commercial relationship with

XSL•FO
RenderX

Yuna, conducted a manuscript-level review encompassing the analysis plan, statistical approach, reported results, and interpretation. This review did not include direct access to the raw dataset or independent reexecution of the statistical models. CS received no financial compensation from Fit Minded, Inc. or Yuna in connection with this study. Second, missingness due to optional pre- and postsession mood and stress ratings was addressed by restricting each analytic model to sessions with complete data for the relevant outcomes and predictors, and additional sensitivity analyses were used to explore how different subsamples may be driving the estimated within-session changes in mood and stress.

Results

User Demographics and Session Characteristics

The full data set included 5549 Yuna users (Table 1). Users were predominantly female and primarily located in the United States, with additional representation from more than 100 countries. Users completed 3.44 sessions on average, though this distribution was highly right-skewed (median 1, IQR 1 - 2). The mean span between first and last session (ie, time with Yuna) was 29.6 days (median 0 d, IQR 0 - 15.9). Approximately 62% (3450/5549) of users completed only one session. Yuna users with ≥2 sessions presented with slightly lower baseline mood and stress scores, on average, compared to single-session users (Multimedia Appendix 1).

Postsession mood and stress ratings were missing for 75.3% (11,985/15,916) of sessions, and more engaged users completed more sessions than users who did not complete postsession ratings (mean 6.66, SD 15.87 vs mean 1.85, SD 3.51, respectively). Full missingness data and comparisons between users and sessions with and without complete data are reported in Multimedia Appendix 1.

Postsession stress, mean (SD)	0.45 (0.24)

[a]Users from 107 additional countries were collapsed into “Other.” Higher mood and stress values indicate worse mood or higher stress. Lower values indicate better mood or lower stress.

Within-Session Improvement of Mood and Stress

LMMs were used to assess the within-session change of mood and stress across participants, adjusted for gender. Yuna users demonstrated statistically significant within-session level improvements in both reported mood (d=0.55) and stress (d=0.56; both $P<.001$). Male users presented with a smaller magnitude of improvements compared to female users, though improvements were positive across groups (Table 2 and Figure 2).

To evaluate the robustness of the within-session findings, two sensitivity analyses were conducted. The first restricted the analytic sample to each user’s first completed session to assess whether primary results were driven by repeat users. The second restricted the samples to users with at least two sessions to assess whether findings were driven by one-time users. Results were consistent with the primary findings, indicating that primary within-session estimates were not driven by the subset of highly engaged users (Multimedia Appendix 1).

Table . Mixed-effects models of within-session improvement in mood and stress (n=3931 sessions; n=1570 users)[a].

	Mood				Stress			
	Estimate	SE	95% CI	*P* value	Estimate	SE	95% CI	*P* value
Fixed effects								
Intercept	0.100	0.006	0.09 to 0.11	<.001	0.100	0.007	0.09 to 0.11	<.001
Gender (male)	–0.040	0.009	–0.06 to –0.02	<.001	–0.030	0.010	–0.05 to –0.01	.006
Random effects								
User (intercept), SD	0.110	—[b]	—	—	0.140	—	—	—
Residual, SD	0.180	—	—	—	0.180	—	—	—

[a]Outcomes represented by within-session level improvement. Positive coefficients indicate improvement in mood or stress. Both models were adjusted for gender. Model diagnostics indicated no singular fits and low multicollinearity. Residual diagnostics suggested some nonnormality and heteroscedasticity, which is common in large observational datasets. For the mood model, adjusted intraclass correlation coefficient (ICC)=0.296, marginal R^2=0.009, and conditional R^2=0.302. For the stress model, adjusted ICC=0.357, marginal R^2=0.004, and conditional R^2=0.359, indicates not applicable.

[b]Not applicable.

Figure 2. Within-session changes in mood and stress. Mood and stress were assessed using a single-item visual analog scale ranging from 0 to 1, with higher values indicating lower mood and higher stress. Values represent mean prepost session ratings of mood and stress.

Between-Session Changes in Mood and Stress

LMMs were used to explore the changes in mood and stress over time. Baseline mood (β=−.00020, SE 0.00008; *P*=.011) and baseline stress (β=−.00029, SE 0.00008; *P*<.001) demonstrated statistically significant decreases across sessions (Table 3 and Figure 3), reflecting gradual improvements in mood (*d*=−0.009) and stress (*d*=−0.011). Gender was a significant predictor of baseline mood, with male users reporting lower presession mood compared to female users (β=−.030, SE 0.008; *P*<.001).

In Figure 3, baseline mood and stress were assessed using a single-item VAS ranging from 0 to 1, with higher values indicating lower mood and higher stress. Predicted baseline mood and stress ratings were estimated from LMMs. Shaded regions represent 95% CIs. The y-axis is truncated to improve the interpretability of between-session trajectories. The full scale ranges from 0 to 1. Truncation does not alter the statistical findings. The small magnitude of observed changes is acknowledged in the discussion.

Residual, SD	0.180	—	—	—	0.190	—	—	—

[a]Baseline mood and stress refer to presession ratings. Session number represents the order of sessions within each user. Negative coefficients indicate lower baseline distress at later sessions. Both models were adjusted for gender. Model diagnostics indicated no singular fits and low multicollinearity. Residual diagnostics suggested some nonnormality and heteroscedasticity. For the mood model, adjusted intraclass correlation coefficient (ICC)=0.378, marginal R^2=0.004, and conditional R^2=0.381. For the stress model, adjusted ICC=0.420, marginal R^2=0.003, and conditional R^2=0.422.

[b]Not applicable.

Figure 3. Baseline mood and stress across repeat sessions.

Session-Level Predictors of Mood and Stress

LMMs were fit to identify session-level factors that were associated with within-session improvements in mood and stress (Table 4). Higher baseline mood (β=.118, SE 0.003) and baseline stress (β=.131, SE 0.004) at the beginning of the session were significantly associated with greater within-session improvement for both outcomes. Longer sessions were significantly associated with greater improvements in mood (β=.027, SE 0.003) and stress (β=.029, SE 0.003), though the magnitude of these coefficients was smaller than the magnitude of baseline stress.

A greater number of unique therapeutic approaches used was associated with smaller within-session improvements in mood (β=−.007, SE 0.003; *P*=.043) and stress (β=−.011, SE 0.003; *P*=.002). Safety guardrail activation showed no significant

XSL•FO
RenderX

association with mood or stress improvements. Gender was not significantly associated with within-session improvement after controlling for other session-level factors.

To contextualize findings that a greater number of unique therapeutic approaches were associated with smaller within-session improvements, an exploratory analysis examined outcomes for sessions that included the three most frequently used therapeutic approaches: the default module (17909/42742, 41.9% of sessions), cognitive defusion (3826/42742, 9.0%), and interpersonal effectiveness (3288/42742, 7.7%). In adjusted mixed-effects models including indicators for these approaches, sessions that included the default module were associated with greater improvements in mood (β=.144, SE 0.040; *P*<.001). Cognitive defusion (β=.003, SE 0.007; *P*=.726) and interpersonal effectiveness (β=.008, SE 0.008; *P*=.310) did not reveal significant associations with mood. No therapeutic approach was significantly associated with stress improvements. (Multimedia Appendix 1).

Discussion

Principal Findings

The purpose of this real-world, retrospective study is to explore the association between use of Yuna, an AI-powered DMHI, and changes in perceived mood and stress. We aimed to: (1) describe Yuna user demographics and session characteristics, (2) quantify the magnitude of mood and stress change within sessions and over time with continued Yuna use, and (3) identify session-level factors associated with changes in mood and stress. Yuna users were predominantly from the United States (3386/5549, 61.0%) and female (2901/5549, 52.3%). On average, Yuna users spent approximately 30 days with Yuna, with an average of three total sessions. Yuna users showed statistically significant within-session improvements in both mood and stress. Within-session improvements were observed across gender groups, but male users demonstrated slightly smaller improvements compared to female users. Users also demonstrated gradual, between-session improvements associated with Yuna use, entering subsequent sessions with higher baseline mood and lower baseline stress compared to previous sessions. Baseline symptom severity of mood or stress and session duration were associated with greater within-session improvements in mood and stress, whereas the usage of more unique therapeutic approaches (ie, a greater number of distinct therapeutic approach types) was associated with smaller improvements. Safety guardrail activation did not negatively impact improvements in stress or mood, suggesting that safety mechanisms can operate without compromising perceived benefits.

XSL•FO
RenderX

Despite over half of users being from the United States (3386/5549, 61.0%), Yuna demonstrates notable international reach, with users spanning over 110 countries and six continents. This finding highlights the potential of AI-powered DMHIs (like Yuna) to expand access in low- and middle-income countries, where over 75% of individuals do not receive mental health treatment due to limited infrastructure [29]. On average, users engaged with the Yuna platform (ie, time with Yuna) for approximately 30 days, with an average of 3 sessions completed, but demonstrated considerable heterogeneity in their engagement (d with Yuna: mean 29.55, SD 65.15; total number of sessions: mean 3.44, SD 9.83). This suggests that Yuna may be suited to diverse user needs and engagement patterns. Unlike traditional interventions with fixed durations, Yuna's flexible format aligns with stepped care frameworks that emphasize as-needed support with the capability to modify intensity based on needs and preferences [30,31]. Future research is needed to explore how user engagement and reported outcomes may vary across diverse demographic profiles, especially given some of these tools have international reach [32].

Yuna was associated with within-session mood and stress improvements. Users demonstrated significant improvements in mood and stress following a single, 20-minute session (on average). Within-session effect sizes (d=0.55 for mood; d=0.56 for stress) are comparable in magnitude to those documented for single-session interventions delivered in controlled therapeutic environments (g=0.56 for anxiety; g=0.32 overall [33,34]). However, this comparison is illustrative of scale only and does not imply methodological equivalence. Effect sizes from unvalidated, single-item VAS scales cannot be directly compared to standardized mean differences from controlled trials using validated, normed instruments, where regression to the mean, demand characteristics, and selection bias are controlled. Specifically, widely used measures such as the Patient Health Questionnaire-9 and Generalized Anxiety Disorder-7 carry established psychometric properties and clinically defined thresholds for meaningful change that the single-item VAS measures used here do not. The observed within-session improvements demonstrate that Yuna may be associated with immediate benefits through brief, self-initiated conversations with an AI mental health coach, positioning AI-powered DMHIs as a promising option for mood and stress management. A couple of Yuna's features may explain the observed within-session changes. First, Yuna is an accessible, on-demand platform that connects users with support at moments of high distress and when a sense of support may be most salient [35,36]. Additionally, the judgment-free, user-directed nature of AI-powered DMHIs may influence deeper engagement with the platform's content. Although male users demonstrated smaller within-session changes compared to female users, they still presented with meaningful improvements. Future research should explore how stigma and gender norms may influence user engagement and outcomes in AI-powered DMHIs. Importantly, whether the within-session improvements observed here reflect transient distress relief or more durable benefit remains an open question. Users may have self-initiated sessions at moments of heightened distress, and the observed improvements may partly reflect natural mood fluctuation following peak distress rather than a lasting change. Future research incorporating follow-up assessments and validated outcome measures would help clarify whether session-level changes translate into meaningful improvements in real-world functioning such as productivity, sleep, or interpersonal relationships.

In addition to immediate symptom relief, AI-powered DMHIs like Yuna may also be associated with sustained, between-session benefits. Users who returned for more than one session showed gradual reductions in baseline stress and mood (ie, lower scores indicating better functioning) across subsequent sessions. However, this finding must be interpreted with considerable caution. The between-session sample represents 33% (1838/5549) of the full analytic sample, and the majority of users completed only a single session and are absent from this analysis. Users who returned are, by definition, a self-selected group most likely to have responded positively to initial use. The observed improvement trend is precisely what survivorship bias would produce, independent of any therapeutic mechanism. These gradual improvements may reflect, but do not confirm, Yuna's application of therapeutic approaches across sessions. Unlike many AI-generated mental health chatbots that focus on supportive listening or psychoeducation, Yuna leverages therapeutic approaches that are designed to teach evidence-backed skills (eg, cognitive reframing and emotion regulation) and transferable strategies to real-world contexts [37]. If these mechanisms are operative, AI-powered DMHIs may build on previous recommendations and reinforce skills over time, enabling a scaffolded learning experience for users, an approach consistent with prior work indicating that progressive skill-building and reinforcement can enhance skill acquisition [38,39]. However, these interpretations are speculative and are not directly supported by the current data, especially considering the VAS measures used are not validated, so the clinical significance of the observed reductions cannot be confirmed. Lastly, though the between-session coefficients reached significance, their magnitude was small, and the practical significance of these reductions remains uncertain. Future research should incorporate validated outcome measures into routine practice to expand upon these findings and allow for more robust comparisons with traditional intervention modalities.

Several session-level factors were associated with within-session improvements in mood and stress. Baseline symptom severity was the strongest predictor of within-session change: users who entered a session with high baseline stress or lower baseline mood showed significantly greater within-session improvements in both outcomes, suggesting that the association between Yuna use and symptom change is more pronounced when users are experiencing higher levels of distress. This finding aligns with common patterns observed across both traditional interventions and DMHIs [40,41]. However, it is important to acknowledge that baseline symptom severity as the strongest predictor of improvement is also consistent with regression to the mean (eg, [42]). Users may be more likely to initiate sessions during periods of heightened distress, and the observed within-session improvements may partly reflect natural fluctuation in mood and stress rather than a therapeutic response. This alternative

XSL•FO
RenderX

explanation cannot be ruled out in the absence of an appropriate control condition.

Longer session durations were positively associated with improvements in both mood and stress, consistent with prior work indicating that increased engagement time in AI-powered DMHIs can support symptom improvement [14]. The number of unique therapeutic approaches activated (ie, clinically-informed strategies and intervention techniques) negatively predicted within-session improvements. In alignment with prior work on intervention complexity, this finding suggests that leveraging a smaller set of focused therapeutic approaches may be more effective in improving baseline mood than integrating numerous therapeutic approaches that may reduce the clarity or impact of individual approaches [43]. Future research should explore and validate how AI-powered DMHIs, such as Yuna, combine, sequence, and select therapeutic approaches during sessions, and how these selections can influence symptom improvement.

Safety guardrail activation was not significantly associated with within-session improvements in mood or stress. This finding suggests that the activation of safety protocols does not detract from the perceived benefits of a session, addressing concerns in the literature about the potential trade-offs between safety mechanisms and engagement with AI-powered DMHIs [44,45]. Well-designed safety guardrails, such as those implemented by Yuna, may not be associated with diminished symptom improvement and may co-occur with stress reduction when discussing a sensitive topic. An important next step will be to qualitatively examine users' experiences of safety, trust, and disclosure in AI-powered DMHIs to understand how safety guardrail design may influence engagement and symptom improvement.

Strengths and Limitations

This study has multiple strengths. First, the findings were a combination of self-reported mood and stress measures and app usage metrics from real-world users of Yuna, a commercially available AI-powered DMHI. This approach captures naturalistic user experiences in real-world settings, offering critical insights into outcomes associated with AI-powered DMHI use beyond the controlled conditions of standard efficacy trials [46]. Second, analyses at both the single session and across session levels offered a comprehensive view of the immediate and sustained changes observed across Yuna use. These strengths support the value of real-world evidence for understanding the clinical impact of AI-powered DMHIs, like Yuna, and how these tools function across users and needs.

The study is not without limitations. First, this study does not include a control group, precluding the ability to make causal inferences about the impact of Yuna on mood and stress. Second, demographic data were incomplete, with only 5.4% (298/5549) of users reporting their age range and no collection of other critical variables that may influence response to AI-powered DMHIs, such as education level, socioeconomic status, race, or clinical history. In addition, although gender was assessed directly, the response options offered (Male, Female, and Other) did not follow current best practices for inclusive gender measurement, such as including specific nonbinary or transgender categories or using a two-step gender assessment; this may limit both the precision of gender-based analyses and comparability with studies using more inclusive measures. Though common to retrospective, real-world studies [47], the lack of complete demographic data has direct implications across three domains: (1) without demographic data, we cannot assess whether the analytic sample is representative of the broader population of working adults who might use AI-powered DMHIs; (2) this limits the generalizability of findings to specific age groups, cultural contexts, or clinical populations; and (3) systematic differences between users who provided demographic information and those who did not may introduce bias into observed associations; for example, users who complete profile fields may differ in motivation, digital literacy, or baseline symptom severity. Third, this study included a self-selected sample of Yuna users. Those who are voluntarily engaging in AI-powered DMHIs such as Yuna may differ systematically from the broader population due to differences in motivation or symptom severity. In addition, due to the voluntary nature of app use, data from nonusers for Yuna were not available, and direct comparison between Yuna users and nonusers could not be conducted. As a result, findings should be interpreted with caution and may not generalize to broader populations. Future research should include a prospective study with a larger, more representative sample to understand how effectiveness may vary across demographic groups and profiles, as previous work has reported differences in engagement patterns, therapeutic alliance, and trust with AI-powered DMHIs and AI mental health coaches (like Yuna [32,48]). Fourth, missing data represent a key limitation. Users included in the within-session analyses were more engaged, on average, than those excluded. This means that findings may not generalize to one-time users. While sensitivity analyses among subsamples with different engagement patterns yielded similar results, selection bias may still have influenced the findings. Fifth, the present study relied on a single-item VAS rather than validated outcome measures to assess mood and stress. Although this may influence the reliability and validity of the reported outcomes, it is important to note that these single-item measures are typically used in industry because they enable rapid, low-burden assessments and are more suited for repeated designs [49-51]. Because these single-item scales have not been psychometrically validated, and their reliability and validity for measuring mood and stress have not been formally established, it is not possible to determine whether the observed changes correspond to clinically meaningful improvements. For context, validated instruments such as the Patient Health Questionnaire-9 (PHQ-9) and Generalized Anxiety Disorder-7 Scale (GAD-7) use established thresholds for minimal clinically important differences (eg, a 5-point change on the PHQ-9). The single-item scales used in this study do not permit such comparisons, and findings should be interpreted as reflecting subjective, within-person perceived changes in mood and stress rather than clinically defined symptom change. Future research should integrate repeated validated outcome measures to more accurately capture perceptions of and changes in mood and stress. Future research would benefit from controlled designs to establish causal effects between AI-powered DMHIs relative to standard care. Lastly, the external review conducted by CS constituted a

XSL•FO
RenderX

manuscript-level evaluation rather than an independent data audit; the absence of independent verification of the raw data and statistical models is a limitation of the current bias mitigation protocol, and future industry-partnered research should seek to establish more structurally independent oversight at the level of data access and analysis.

Conclusion

This study found that use of Yuna, an AI-powered DMHI, was associated with both immediate, within-session improvements and gradual, sustained changes in self-reported stress and mood across repeated sessions. Baseline symptom severity was the strongest predictor of within-session improvement, with users entering sessions with higher stress or lower mood presenting with the greatest observed changes, though regression to the mean cannot be ruled out as a contributing explanation. Session duration and the total number of unique therapeutic approaches implemented during the session were also associated with within-session improvements. Safety guardrail activations were not associated with diminished perceived session benefits, suggesting that safety mechanisms can operate without compromising user experience. These findings offer preliminary, real-world evidence that AI-powered DMHIs may represent an accessible and scalable option for mood and stress support. Future research should prioritize prospective, controlled designs to establish causal effects, incorporate validated outcome measures, and explore design features that maximize positive outcomes and user safety.

Acknowledgments

Generative AI tools were used in a limited capacity during the preparation of this manuscript, including to review and confirm editorial changes and language revisions. Generative AI was not used to generate, draft, or substantively write any portion of the manuscript. All content was written and approved by the authors, who take full responsibility for the integrity and accuracy of the content presented.

Funding

This study was not externally funded. Retrospective, de-identified data were provided by Yuna as part of an ongoing scientific partnership with Fit Minded, Inc. Fit Minded, Inc. received compensation for services rendered as the embedded scientific team for Yuna, independent of the conduct or outcomes of this research.

Data Availability

The dataset used for this retrospective analysis is not publicly available given Yuna's privacy policy for patient data. However, aggregated and anonymized data may be shared with interested parties upon reasonable request.

Authors' Contributions

All authors contributed substantially to the manuscript. KLM and CJ: Conceptualization, Methodology, Formal Analysis, Writing – Original Draft, Writing – Review & Editing, Final Approval. CS: Methodology, Writing – Review & Editing, Final Approval. JLH: Conceptualization, Methodology, Supervision, Writing – Original Draft, Writing – Review & Editing, Final Approval.

Conflicts of Interest

Fit Minded, Inc, served as the embedded scientific team for Yuna and received compensation for those services. JH is the Founder and CEO of Fit Minded, Inc, and KM and CJ are employees of Fit Minded, Inc. CS is an independent academic researcher affiliated with Arizona State University who received no financial compensation from Fit Minded, Inc, or Yuna in connection with this study. No author's employment status or compensation is contingent upon the direction or outcome of the findings.

Abstract

Background: Behavior change support systems aim to shape, modify, or strengthen attitudes or behaviors without using coercion or deception. One of the main software features of persuasive system design is self-monitoring, which provides the means for users to continuously track their own performance or status, thereby facilitating goal attainment.

Objective: The aim of this study is to examine whether self-input of weight (self-monitoring frequency) and its interaction with time influence weight loss in adults using a mobile health behavior change support system (mHBCSS). We hypothesized that higher self-monitoring frequency would be associated with greater weight loss, with effects varying across the intervention period.

Methods: This secondary analysis used data from the intervention group of a randomized, open, waitlist-controlled trial in adults with obesity (BMI 30 - 40 kg/m²). Participants used the mHBCSS for 12 months, and analyses included only participants who maintained self-monitoring for at least 6 months (N=75). Weight changes were analyzed across 9 time periods. Quantile regression (QR) was applied to examine effects on the 25th, 50th (median), and 75th percentiles of weight loss. The models included self-monitoring frequency, time periods, and their interaction. A sensitivity analysis using a multiple imputation procedure was performed to assess the robustness of the QR.

Results: The time period variable was significant at the 25th weight loss percentile (QR coefficient: −1.164, 95% CI −1.453 to −0.756) and at the 50th weight loss percentile (QR coefficient: −0.603, 95% CI −0.733 to −0.493). The interaction variable was significant at the 50th (QR coefficient: −0.018, 95% CI −0.047 to −0.003) and 75th (QR coefficient: −0.036, 95% CI −0.051 to −0.027) weight loss percentiles. Self-monitoring frequency alone was not statistically significant.

Conclusions: The study demonstrates that the effect of self-monitoring on weight loss is time-dependent. While a higher frequency of self-monitoring is associated with greater weight loss early in the intervention, its influence decreases as time progresses. These findings emphasize the importance of sustained engagement with self-monitoring rather than focusing solely on frequency, suggesting that interventions should incorporate strategies to maintain consistent self-monitoring use throughout the behavior change process.

Introduction

Self-monitoring in Digital Health

Persuasive systems have been widely used to motivate users and enhance user experiences, especially in the field of health and well-being [1]. Nevertheless, for these interventions to be practically effective, they must lead to significant modifications in behavior, resulting in better health outcomes. The concept of behavior change support systems (BCSSs) was developed to fulfill this objective. A BCSS is defined as a sociotechnical information system that aims to shape, modify, or strengthen attitudes, behaviors, or compliance without coercion or deception [2].

The implementation of BCSS is approached through the persuasive systems design (PSD) model. This model establishes the postulates (psychological and software design principles) that underlie the design of persuasive systems and emphasizes the importance of considering the context of use, the user, the

XSL•FO
RenderX

technology context, and the specific features implemented in persuasive systems. Within the 4 main categories, primary task support specifically refers to design aspects meant to assist users in performing their primary objective [3].

Self-monitoring, a feature of this category, enables individuals to continuously track their own performance or status, facilitating their goal attainment [3]. It may also happen unknowingly through the system, for example, through wearable sensors [4]. To elaborate, self-monitoring is to a great extent a dynamic self-management skill that involves observing and recording one's own behavior. It is a multicomponent procedure that involves identifying a specific behavior that needs improvement, being aware of when the behavior occurs, documenting how often and how long it happens, comparing it to a standard, and then creating a plan to change it [5]. Examples of usage include self-recognition of symptoms (such as difficulty breathing in asthma), manual recording of blood pressure, and the use of self-maintained electronic databases to monitor blood glucose levels in the management of diabetes [6].

According to the literature, the self-monitoring feature is the most widely used strategy in interventions aimed at promoting health and wellness [7-9]. For instance, a meta-analysis comprising 19 studies with a total of 2800 participants showed that interventions using self-monitoring as a behavior change strategy have the potential to decrease sedentary behavior in adults [10].

Self-monitoring is also widely used in cognitive behavioral therapy (CBT)–based interventions, where it supports the assessment, change, and maintenance of behavioral patterns. Prior qualitative evidence from mobile smoking cessation interventions indicates that CBT-based app designs are favorably perceived in terms of features, design, information quality, and engagement and are associated with changes in users' perceptions and ways of thinking about the target behavior [11], thereby highlighting the relevance of such mechanisms beyond any single application domain. One idea within CBT's mechanisms posits that mere cognitive awareness of one's actions might induce modifications. Another interpretation suggests that the act of monitoring itself triggers reactivity, with individuals internally generating reinforcement or punishment. Yet another view sees monitoring as functioning like prompts or cues that influence behavior. Those explanations show that both cognitive and behavioral processes contribute to the effectiveness of self-monitoring techniques [12]. Recently, a systematic review and meta-analysis of randomized controlled trials (RCTs) evaluating mobile health (mHealth) app self-management interventions for blood pressure management found that self-monitoring was among the most commonly used behavior change techniques. These interventions led to significant reductions in both systolic and diastolic blood pressure compared to usual care, emphasizing the central role of self-monitoring across mHealth applications [13]. In the context of weight change, digital interventions have also made extensive use of self-monitoring alongside established behavior change theories. Most programs combined behavior change techniques and PSD principles, particularly self-monitoring, feedback, goal setting, and tailoring, to guide behavior [14]. Taken together, these findings highlight self-monitoring not only as a frequently applied technique but also as a core functionality embedded across digital health interventions.

Importantly, while self-monitoring is one of the most ubiquitous features in digital BCSS, it is often treated as a generic component rather than being examined as a central mechanism of change whose usage patterns and temporal dynamics may critically shape intervention effectiveness. As a result, the theoretical and empirical understanding of how self-monitoring exerts its effects in real-world digital interventions remains limited.

Another important aspect of this function is the interaction between the frequency of self-monitoring usage and time. A study that investigated how the usage patterns of mHealth app functions affect user retention found that the consistent use of the self-monitoring function helped slow the decline in app usage over time. This suggests that self-monitoring has a beneficial long-term influence on user engagement [15].

Building on this evidence, a large-scale digital weight loss study demonstrated that higher weight self-monitoring frequency was significantly associated with greater weight loss over 6 months. Clinically meaningful weight loss (≥5%) was linked to at least 3 weight SMOs per week, and analysis of outcome-based subgroups further confirmed that individuals with ≥10% weight loss engaged in weight self-monitoring more frequently than those with smaller or no weight changes. These findings reinforce the importance of self-monitoring frequency for weight management while also suggesting that different patterns of usage may correspond to different levels of success [16].

Despite substantial evidence supporting the benefits of self-monitoring for health behavior change, existing research has primarily treated self-monitoring as a static behavior change technique, offering limited insight into how its intensity and temporal dynamics function as mechanisms of change. In particular, it remains unclear whether self-monitoring frequency alone, or its interaction with time, differentially shapes outcomes such as weight loss in digitally delivered BCSSs. For example, prior research has shown that greater consistency of self-monitoring across weight, food, and exercise behaviors predicts weight loss, although adherence to self-monitoring tends to decline over time [17]. This suggests that both how often and how consistently individuals engage in self-monitoring may be critical to understanding its effectiveness.

Therefore, the objective of this study was to examine whether self-monitoring frequency and its interaction with time affect weight loss in adults using an mHBCSS. By focusing on self-monitoring as a core persuasive mechanism and modeling its temporal dynamics, this study aims to advance a more fine-grained understanding of how persuasive system features operate over time, thereby contributing to both BCSS theory and the design of more effective digital weight management interventions. We hypothesized that higher self-monitoring frequency would be associated with greater weight loss and that this association might vary over the course of the intervention, reflecting the dynamic nature of behavior change processes.

Theoretical Background

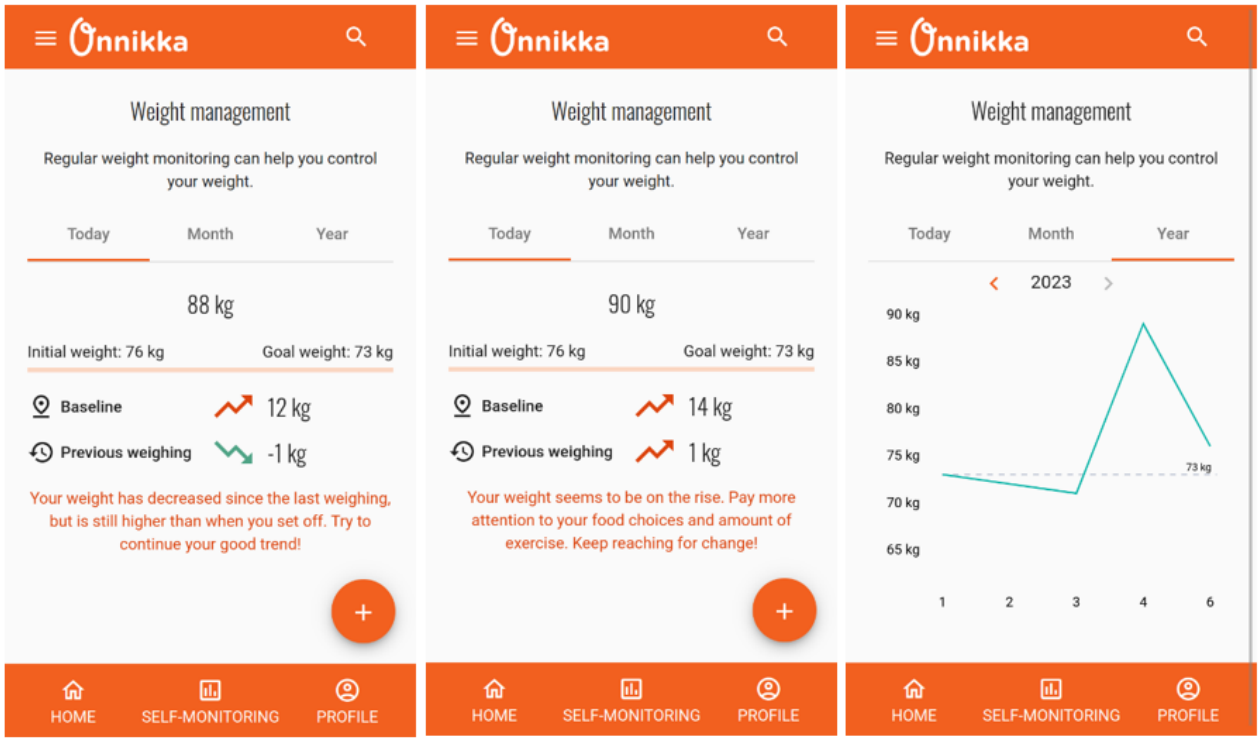
Analyzing the persuasion context, choosing persuasive design principles, specifying software requirements, and then implementing the software are among the key processes that Oinas-Kukkonen and Harjumaa [3] suggested for creating persuasive systems for behavioral modification. By considering these processes, the aim is to place greater emphasis on improving the entire user experience and increasing user involvement over the long term [2].

The PSD model comprises 4 feature categories: primary task support, dialog support, social support, and credibility support [3]. This study focuses on primary task support (supporting weight tracking and progress monitoring) and dialog support (reminders and suggestions that encourage sustained self-monitoring). Credibility support was present in the app (verifiable expert content and links to external sources), but its analysis is beyond the scope of this paper.

The PSD framework is guided by postulates emphasizing that persuasive systems are value-laden rather than neutral, that persuasion often unfolds incrementally, that both direct and indirect routes of influence are important, and that persuasive systems should be open, unobtrusive, useful, and easy to use [3]. Grounding this study in PSD allows self-monitoring to be examined not as an isolated feature but as part of a broader persuasive system, highlighting the roles of context, temporal dynamics, and sustained engagement in supporting weight loss.

Methods

Sample and Mobile Health Behavior Change Support System



This study is a secondary data analysis of a randomized, open, waitlist-controlled, 2-arm trial. The trial's design was approved by the Ethics Committee of the Northern Ostrobothnia Hospital District and the Finnish Medicines Agency, which classified the mobile health behavior change support system (mHBCSS) as an investigational medical device. The trial investigated whether an mHBCSS could help participants lose weight. It started in October 2020, and the clinical phase ended in September 2022. Participants were randomly assigned to one of two groups: (1) the intervention group (n=100), who received immediate access to the mHBCSS, and (2) the waitlist control group (n=100), who did not receive the intervention during the initial 6 months of the study period. In total, 200 adults (18 - 65 years) with a BMI of 30 to 40 kg/m² were eligible to participate in the study. The primary outcome of the main trial was weight loss from baseline to the 6-month visit. Detailed information, including inclusion and exclusion criteria, was published previously [18,19]. Our study sample comprises the intervention group, with a subsample of "self-monitoring users," that is, individuals who continued self-monitoring their weight from 6 months until the 12-month period, when access to the application was discontinued (n/N=75/100). Two participants were excluded because pregnancy and cortisone use could have influenced weight changes, introducing potential bias.

The app named "Onnikka," (Onnikka Health Ltd) translated as "bus" in Finnish, provided self-monitoring features, enabling participants to monitor their own progress as shown in Figure 1. These functionalities included weight monitoring, food and exercise diaries, and a mood log where users could register their feelings and motivation during the behavior change process. After recording their weight in the application, participants also received an automated, system–generated comment about their weight loss progress (Figure 1). The gradual process of behavior change was metaphorized as a bus journey with symbolic "stops" where new content (expert-created material, videos, external links along with open-ended, multiple-choice, and slider-based interactive tasks) was delivered, aimed at guiding participants on the weight loss journey. The theoretical content was developed based on the PSD principles and the BCSS framework to support weight management among adults with obesity.

The mobile intervention applied the 3 PSD categories: primary task support (self-monitoring–related tools), dialog support (praise for progress, suggestions, and reminders for tasks), and credibility support (expertise regarding the content, verifiability by providing links to external evidence–based resources, and transparency in the privacy policy). Each Monday morning, participants received a reminder to weigh themselves. This approach aligns with the PSD principle of unobtrusiveness, providing scheduled prompts at consistent times to encourage predictability, minimize required interactions, and reduce perceived intrusiveness.

Quantile Regression

After assessing the normality of the data using the Shapiro-Wilk test in R 4.4.0 software (R Foundation for Statistical Computing) [20], we used a nonparametric approach, quantile regression (QR) [21], to examine the influence of self-monitoring frequency on weight loss. QR allows the modeling of different quantiles of the conditional distribution of the response variable, providing a more detailed view of the effects of the explanatory variables at different points in the weight loss distribution [22]. Modeling multiple quantiles enables a more comprehensive understanding of the influence of predictors on the response distribution [23]. The rationale for using this method is that it offers greater versatility than other regression techniques in identifying associations at different points of the dependent-variable distribution [24]. Moreover, quantiles, such as the median (p=50%, where p denotes the quantile being estimated), are robust to outliers due to their emphasis on the proportion of data within a specific range, rather than on distance [25]. The QR parameter estimates the change in a specified quantile of the response variable produced by a 1-unit change in the predictor variable.

QR models were fitted to the 0.25, 0.50 (median), and 0.75 quantiles using the rq function of the quantreg package in R [26]. The model included an interaction term between self-monitoring frequency at each time period (TP) and the TPs themselves, aiming to capture how the effect of self-monitoring on weight change varied over time. Multicollinearity was detected using the variance inflation factor, with all values exceeding 5 [27] (Multimedia Appendix 1).

Variables

Dependent Variable

The dependent variable was the average weight loss percentage (self-reported data). This variable represents the average percentage change in weight relative to the initial weight recorded by the user for each TP (1 - 41 d, 42 - 83 d, 84 - 125 d, 126 - 167 d, 168 - 209 d, 210 - 251 d, 252 - 293 d, 294 - 335 d, and 336 - 377 d). Negative values indicate weight loss, while positive values indicate weight gain.

It was divided into 9 TPs in this analysis to balance temporal resolution and interpretability. Given that users were required to weigh themselves weekly, the intervention was organized into 6-week windows, with the exception of the first period (40 d) to ensure symmetry. This structure allowed each interval to include sufficient observations for stable QR estimates while capturing meaningful variation over time.

Independent Variables

The independent variables consisted of the self-monitoring frequency at each time point, the 9 TPs, and the interaction between self-monitoring and the TP (TP interaction).

Sensitivity Analysis

To assess the robustness of the results to missing data, a sensitivity analysis was performed using multiple imputation [28,29]. Missing data were imputed using the multiple imputation method implemented in the mice package in R, which generates multiple imputed datasets to reflect the uncertainty associated with imputation [30]. Finally, the QR was applied to each imputed dataset separately.

Ethical Considerations

The study was approved by the Ethics Committee of the Northern Ostrobothnia Hospital District (approval: 138/2020) and the Finnish Medicines Agency, with the mHBCSS classified as an investigational medical device. The trial was registered at ClinicalTrials.gov (identifier: NCT04558801). During the conduct of the trial, the participants received oral and written information about the trial, and written informed consent was obtained.

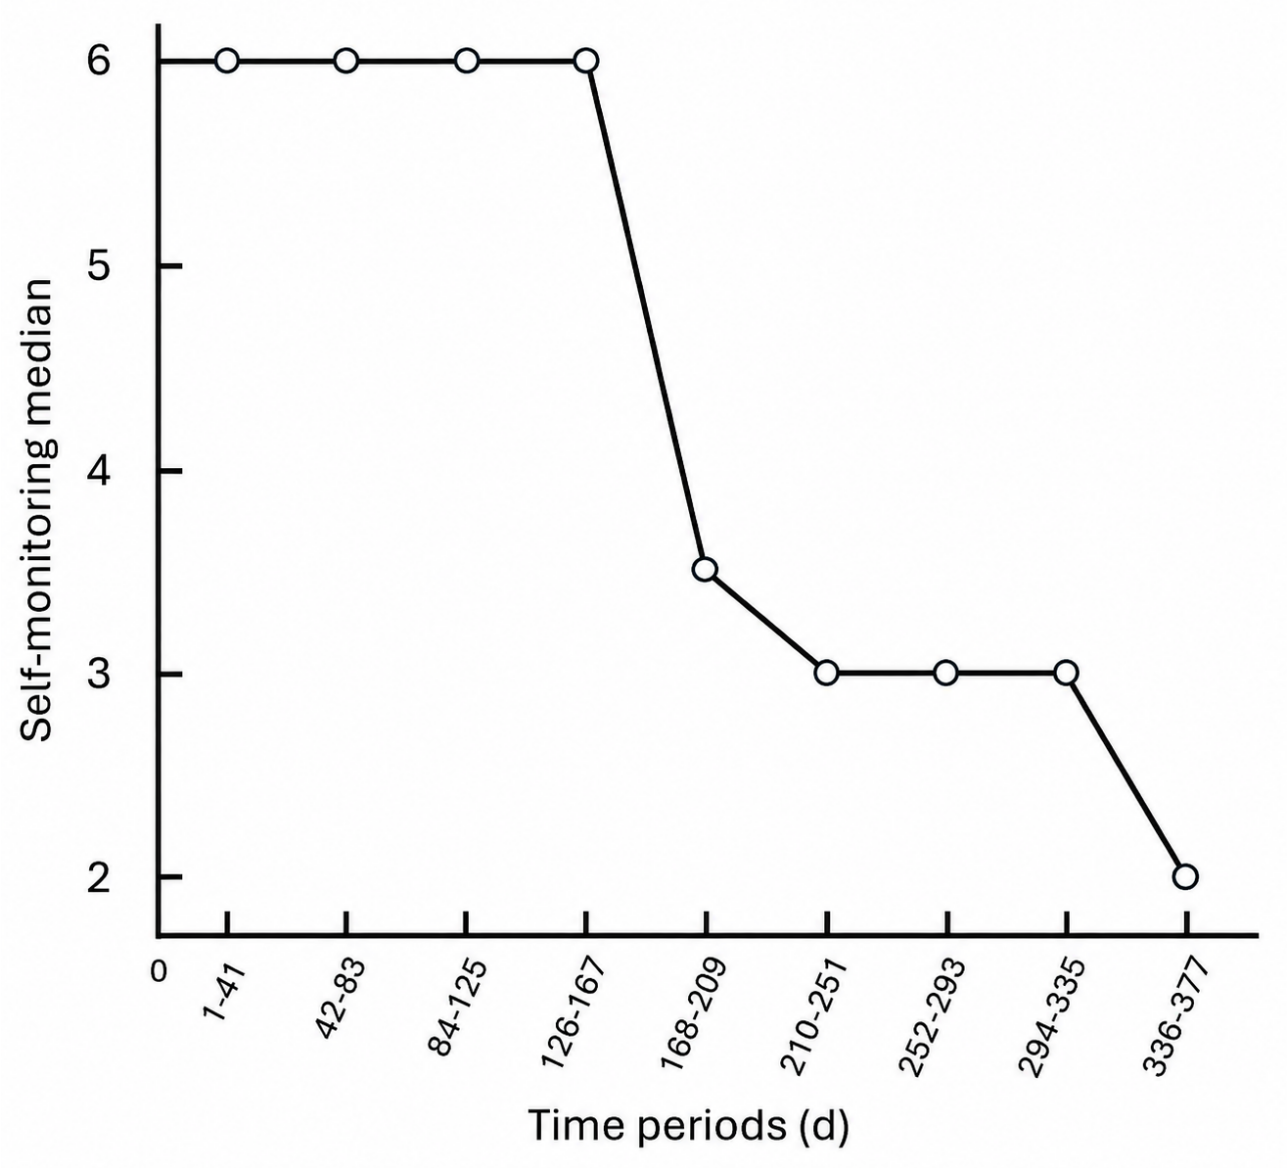
Results

Sample Characteristics

In the analyzed dataset, a total of 75 participants were included, consisting of 11 males (14.7%) and 64 females (85.3%). The mean age of the participants was 48.4 (SD 9.90) years, with a median age of 49 years (IQR 41-58). Participants exhibited a mean total self-monitoring frequency of 34.6 (SD 22.4), with a median of 30 (IQR 24-40), representing the cumulative number of self-weighing inputs over the full 12-month study period. Table 1 summarizes descriptive statistics for the participants. The individuals' detailed demographic information for the participants is shown in Multimedia Appendix 2.

Table . Descriptive statistics of self-monitoring frequency and weight by age group[a].

Age range (y)	Frequency, n (%)	Mean self-monitoring frequency (SD)	Median self-monitoring frequency (IQR)	Mean weight change (SD), (%)	Median weight change (IQR), (%)	Mean weight at baseline (SD), (kg)	Median weight at baseline (IQR), (kg)
24 - 39	14 (18.7)	26.3 (9.77)	28.5 (19.8-32.2)	−2.77 (2.77)	−3.03 (−4.95 −0.91)	97.2 (13.8)	92.6 (85.20-109.20)
40 - 49	24 (32)	36.1 (28.7)	29 (24.8-40)	−3.13 (5.03)	−1.55 (−4.44 −0.14)	96.2 (12.8)	97.7 (86-102.45)
50 - 59	27 (36)	39.7 (21.9)	37 (27-48)	−3.88 (3.83)	−2.72 (−5.77 −1.14)	94 (13)	91 (87.60-99.10)
60 - 65	10 (13.3)	28.6 (10.7)	26 (19.2-38.8)	−2.27 (2.91)	−1.57 (−4.04 −0.39)	97.4 (13.8)	93.9 (86.10-103.10)



[a]Weight change is expressed as percentage change over the full 12-month study period, with negative values indicating weight loss. Self-monitoring frequency refers to the total number of self-weighing inputs over the 12-month period.

The mean weight change relative to baseline across all 9 TPs was −3.24%, which was lower than the median decrease of 2.22%, suggesting a left-skewed distribution. Moreover, the 25th percentile of weight change was −5.11%, meaning that 25% of participants lost 5.11% of their weight or more. The median weight change was −2.22%, indicating that 50% of participants lost at least 2.22% of their weight.

Figure 2 shows that during the first 4 TPs (1 - 41 d, 42 - 83 d, 84 - 125 d, and 126 - 167 d), the median self-monitoring frequency remained consistent at 6 times. In contrast, the median began to decrease in the fifth TP, reaching 3.5 times and stabilizing at 3 times during TPs 6 (210 - 251 d) through 8 (294 - 335 d). By TP 9 (336 - 377 d), the median dropped further to 2 times.

XSL•FO
RenderX

Figure 2. The median number of self-monitored frequency for the 9 time periods.

Percentile Analysis

In this study, the 25th, 50th, and 75th percentiles refer to participants experiencing low, median, and high percentage weight loss, respectively, across the study period.

Results of the percentile analysis in Table 2 show that for the 25th percentile (participants with relatively low percentage weight loss), the coefficient for TP was −1.164 (95% CI −1.453 to −0.756), with statistical significance. This indicates that, across TPs, participants in this group lost more weight in earlier periods, and the rate of weight loss decreased over subsequent periods.

XSL•FO
RenderX

Table . Quantile regression coefficients and 95% CIs for weight loss by percentile[a].

Variables	Quantile regression coefficients (95% CI)		
	25th percentile	50th percentile	75th percentile
Intercept	0.53 (−1.24 to 1.64)	−0.16 (−0.78 to 0.93)	−0.10 (−0.45 to 0.42)
SMO frequency	−0.20 (−0.37 to 0.08)	0.01 (−0.17 to 0.08)	0.05 (−0.03 to 0.10)
TP[b]	−1.16 (−1.45 to −0.76)[c]	−0.60 (−0.73 to −0.49)[c]	−0.12 (−0.28 to 0.02)
TP interaction	0.02 (−0.09 to 0.05)	−0.02 (−0.05 to −0.00)[c]	−0.04 (−0.05 to −0.03)[c]

[a]Values are rounded to decimal places.

[b]TP: time period.

[c]Significant coefficients at the 95% CI. The 25th, 50th, and 75th percentiles refer to participants with relatively low, median, and high percentage weight loss, respectively, across all TPs.

In the 50th percentile (participants with median percentage weight loss), self-monitoring frequency alone was not significantly associated with weight change. However, both the TP variable (QR coefficient: −0.603, 95% CI −0.733to −0.493) and the interaction between self-monitoring frequency and TPs (QR coefficient: −0.018, 95% CI −0.047 to −0.003) were statistically significant. This suggests that weight loss per TP tends to be smaller in later periods at the median, and the influence of self-monitoring frequency on weight loss decreases as time progresses.

Finally, for the 75th percentile (participants with high percentage weight loss), only the interaction (QR coefficient: −0.036, 95% CI −0.051 to −0.027) was significant, suggesting that the effect of self-monitoring frequency on weight loss also diminishes over time for this group.

Overall, the influence of self-monitoring frequency on weight loss diminishes over time, with this effect being more pronounced at higher percentiles of weight loss.

The 3 intercepts (the expected initial weight loss when both the TP and self-monitoring frequency are zero) were not statistically significant.

Multiple Imputation Procedure

To account for missing data, a multiple imputation procedure was applied, generating 5 imputed datasets. QR was performed on each imputed dataset, and the results were consistent across all imputations. Detailed results are presented in Tables 1 to 3 of Multimedia Appendix 3.

The effect of time was significant and negative, indicating that weight loss was greater in the earlier periods and declined over subsequent periods. The interaction between self-monitoring frequency and time was significant in most models, showing that the effect of self-monitoring frequency on weight loss changes over time. In contrast, self-monitoring frequency alone was not significant, highlighting that its impact can only be understood in combination with time.

Discussion

Principal Findings

The main finding of this study is that self-monitoring does not exert a stable effect on weight loss over time; rather, its influence is time-dependent. Specifically, the interaction between self-monitoring frequency and time was significant at the median (50th percentile) and higher (75th percentile) levels of weight loss. More frequent self-monitoring was associated with greater weight loss in the early stages of the intervention, but this effect diminished over time. Self-monitoring frequency alone did not have a significant independent effect, indicating that its impact depends on when it occurs during the behavior change process.

These results suggest that *when* and *how consistently* individuals engage in self-monitoring may matter more than how frequently they do so at a single point in time. The added value of frequent self-monitoring appears to be concentrated in the early phases of the intervention, whereas sustained engagement over time may be more relevant for maintaining weight loss, particularly among individuals achieving higher levels of success.

In contrast to prior work that has primarily examined self-monitoring as a static behavior change technique [8-10] or focused on its overall frequency [16], this study extends existing research by demonstrating that the effectiveness of self-monitoring is time-dependent and varies across different outcome levels of weight loss. By applying QR, we show that self-monitoring operates differently for individuals achieving median versus higher levels of weight loss, thereby offering a more nuanced, distribution-sensitive understanding of its role in digital weight management interventions.

The results of this study also add to the findings of Karppinen et al [31]. Based on their qualitative results, self-monitoring was perceived by users as a beneficial persuasive feature among those who achieved 5% weight loss. The interaction with time reflects and explains how self-monitoring integrates into an ongoing process of adaptation, learning, and sustained behavior change, emphasizing that its power lies in commitment rather than immediacy. This idea is supported by previous research on BCSS [32], which highlighted the importance of encouraging consistency by helping users commit to specific goals over time. Systems that reinforce user commitments are more successful in driving behavior change. That research also identified a key challenge: many individuals struggle to follow through on health-improvement goals due to a lack of self-control or willpower. Consequently, people often choose simpler solutions that fail to produce significant, long-term results because they lack strong commitments. Finally, Oduor and Oinas-Kukkonen

XSL•FO
RenderX

[32] also found that primary task support, a main category of self-monitoring features, had the greatest impact on perceived competence and users' intentions to continue, suggesting that systems encouraging goal commitment are more likely to drive lasting behavior change.

In this study, the frequency of self-monitoring alone was not significant. This is consistent with the findings of a secondary data analysis of an RCT in which individuals who used a smartphone-based system for behavioral weight loss did not experience increased weight loss despite engaging in more self-monitoring [33]. Similar findings in a prospective study showed that self-monitoring of blood glucose levels had no influence on glycemic management in individuals newly diagnosed with type 2 diabetes [34]. This evidence emphasizes our findings, indicating the importance of analyzing the interaction with time to understand the impact of self-monitoring.

Since the diminishing effect is significant at the 50th and 75th weight loss percentiles, these insights are particularly relevant for individuals in the median-to-upper ranges of weight loss. For individuals in this stage, sustained engagement with self-monitoring may demand additional support or motivational, personalized strategies. A previous study has shown that users who proactively set up a reminder have significantly higher long-term adherence to an mHealth app to improve nutrition literacy and support healthy dietary behaviors. Moreover, the relevance of the social role feature was further demonstrated by the fact that users who selected a female conversational agent had a higher likelihood of being long-term adherents [35]. A recent systematic literature review supports this evidence by showing that the most persuasive patient engagement features of mHealth apps come from dialog support (praise, rewards, reminders, suggestions, and social role) [36]. In this way, PSD features within dialog support, such as reminders, suggestions, and social role, could be effective strategies to sustain the user's engagement. In this study, participants received 26 weekly reminders to weigh themselves during the active intervention period (the first 6 months). This structured approach ensured consistent self-monitoring during the initial phase of the study. However, after the 6-month period, these reminders ceased, potentially contributing to a decline in self-monitoring. The lack of continuous reminders may have affected participants' adherence to routine self-weighing, leading to a decline in their capacity to maintain consistent self-monitoring behavior over time.

Moreover, self-expansion, explained as increasing positive self-content by engaging in novel and rewarding activities [37], is associated with better behavioral weight loss outcomes, including a greater likelihood of achieving a clinically significant (5%) weight loss through an internet-based behavioral weight loss intervention [38]. Self-expanding activities and/or experiences, such as learning new things about weight loss, behavioral challenges, and social interaction, might have offered alternatives to food rewards [38]. Those interpretations could lead us to infer that adding the persuasive feature "reward," which also belongs to dialog support, could be another good strategy to be combined with self-monitoring. There is a neurophysiological basis behind this claim, since food triggers the release of dopamine in the brain, generating feelings of pleasure and reinforcement [39].

In this same direction, the reward feature was shown to be linked to the emotional state of happiness in a large-scale empirical study (n=660) aimed at investigating if and how people respond emotionally to persuasive features. Reward was the only feature that was not connected with any negative feelings (eg, anger, disgust, fear, and sadness) [40]. This is particularly relevant because people with obesity or who are overweight often turn to food as a source of reward, which can perpetuate a cycle of addiction [39]. Introducing digital rewards (eg, reward features), therefore, could represent an alternative form of stimulation, helping to replace the search for pleasure through food and facilitating the adoption of new healthy behaviors.

In practice, our study suggests that when self-monitoring is decreasing over time, it should be interpreted as a signal that the intervention needs to be strengthened or adjusted. While self-monitoring remains a valuable feature in itself, additional supportive strategies are needed to maintain or enhance its long-term effectiveness. Interventions might need to evolve to sustain engagement and impact, perhaps by introducing new elements such as social support features. Karppinen et al [31] found that the need for these features increased over the duration of an earlier web version of this same intervention. Additionally, the absence of social support was linked to lower self-monitoring, according to a qualitative study that examined the experiences and emotions related to self-monitoring in eating behaviors among participants who had completed an 18-month behavior weight reduction study [41].

Furthermore, prior research revealed that self-monitoring encourages healthy habits by inspiring reflective thinking about an individual's behavior. As individuals tend to strive to surpass their previous main task-related records, this tendency also leads to internal competition between their previous and current attitudes [7]. However, reflection alone may not be sufficient; combining self-monitoring with other software features (such as dialog and primary task support) may help transform the need for reflection into actionable insights [42], thereby supporting long-term behavior change.

Another aspect of reducing or stopping users' self-monitoring should be considered. Based on the results of an international survey involving users of self-monitoring technologies, Ajana [43] found that, although this feature increases motivation and encourages a healthier lifestyle, its quantitative aspects can sometimes lead to excessive behavior, which can increase pressure on the user, resulting in feelings of inadequacy, for example. Self-monitoring could also lead to health disorders (eg, in users with anorexic tendencies) and depression [7]. Other aspects on the negative side of self-monitoring are the tediousness and lack of enjoyment of the activity, reinforcing that it should be implemented alongside other strategies [7]. In the mHBCSS under investigation here, users received a brief comment about their weight loss progress after recording their weight, potentially reducing the likelihood that these last 2 factors would cause a decrease in self-monitoring. However, to overcome potential adverse effects of self-monitoring, the designers probably should adopt a comprehensive approach to

XSL•FO
RenderX

promoting health and well-being, rather than monitoring just one marker of health behavior [7].

Finally, our results extend PSD theory by highlighting the temporal dimension of engagement: although self-monitoring is most impactful in the early stages, its influence diminishes over time, suggesting that persuasive systems should be designed not only to encourage initial adoption but also to sustain long-term engagement. This suggests that while PSD principles such as reminders (dialog support) can initially sustain engagement, additional strategies may be required to maintain long-term adherence. Together, these findings refine the application of PSD by emphasizing that its principles need to be considered in a temporal context. Specifically, persuasive features may be most effective in the early phases of behavior change, whereas later phases may require adaptive or complementary strategies.

Limitations and Future Research

This study has several limitations. First, the sample size (N=75) was relatively small, which limits statistical power and may increase the risk of type II errors. Second, the majority of the sample was female (64/75, 85.3%), and the study was conducted in a single cultural and geographic context (Finland), which may limit the applicability of the results to other populations or settings.

Third, while QR allowed us to examine effects across different percentiles of weight loss, the findings are specific to the quantiles analyzed (25th, 50th, and 75th) and cannot be directly generalized to the entire population. Fourth, self-monitoring frequency was measured as the total number of self-weighing entries recorded, but this metric does not capture qualitative aspects of engagement, such as adherence to recommended behaviors, motivation, or the accuracy of self-reported data. Finally, the study design was observational, limiting causal inference between self-monitoring and weight loss outcomes.

Building on the time-dependent effects observed in this study, future longitudinal research could examine how different trajectories of self-monitoring engagement relate to distinct weight loss trajectories and how adaptive intervention strategies might sustain engagement in later phases. Given the observational design of this study, experimental or adaptive trial designs (eg, just-in-time adaptive interventions) would be valuable to establish causal relationships between self-monitoring patterns and outcomes. It might also be valuable to explore the mental and emotional impact of self-monitoring and adapt this strategy, avoiding possible negative effects and improving adherence. Additionally, the effects of age, gender, and other characteristics should be studied to personalize the interventions. Finally, future studies could examine how the framing of system-generated feedback, such as positive versus negative comments, affects motivation, consistency, and commitment to self-monitoring, providing insights to further optimize digital behavior change interventions.

Conclusions

In this research, self-monitoring, a core functionality of the presented mHBCSS, was studied over time to understand its impact on weight loss. While self-monitoring frequency alone did not show a statistically significant independent effect, the interaction between self-monitoring frequency and time was significant at the 50th and 75th weight loss percentiles. This suggests that the potential influence of self-monitoring on weight loss may vary across the intervention period, with a stronger association observed in earlier phases that diminishes over time. These findings highlight the importance of considering the timing of behavioral engagement, suggesting that sustained self-monitoring may be more valuable for long-term effectiveness than intensity alone. Future interventions may benefit from designing strategies that encourage consistent engagement with self-monitoring tools throughout the behavior change process to maximize weight loss outcomes.

Acknowledgments

The authors thank the research staff of the 2 research units as well as the study participants for their dedication and contributions to this study.

Funding

This study has received funding from the Research Council of Finland under decision 351670, with the theme “Persuasive digital health interventions: Software features as key predictors for successful prevention and treatment of overweight, obesity, metabolic syndrome and cardiovascular diseases.” It has also received funding from the Business Finland under decision 6704/31/2019. The trial was also supported by the Novo Nordisk Foundation (NNF21OC0072621), the Suorsa Healthcare Foundation, and the Finnish Foundation for Cardiovascular Research.

Data Availability

The data that supports the findings of this study may be available on reasonable request from the corresponding author. Personal data is not publicly available due to privacy and ethical restrictions.

Abstract

Background: Sustaining self-management is critical for optimizing clinical outcomes in individuals with type 2 diabetes mellitus (T2DM). Although digital health interventions (DHIs) have shown benefits for glycemic control and self-care, much of this evidence has focused on efficacy, and the behavioral mechanisms through which DHIs produce sustained effects remain insufficiently understood. Clarifying these mechanisms could inform the development of theory-driven interventions.

Objective: This study examined the longitudinal behavioral pathways through which Artificial Intelligence-based Health Education Accurately Linking System, a WeChat (Tencent)–based digital health program, influences T2DM self-management, using the Extended Multi-Theory Model (MTM) of health behavior change.

Methods: An explanatory sequential mixed methods prospective longitudinal cohort study was conducted among adults with T2DM (aged ≥18 y and proficient in WeChat use), recruited from 45 primary health care institutions in Beijing, China, between July 2023 and July 2024. Self-management behavior was assessed as the primary outcome using the Summary of Diabetes Self-Care Activities, and psychosocial determinants using the Extended MTM Scale and the Diabetes-related Skills Scale. Exploratory and confirmatory factor analyses assessed the construct validity of the Extended MTM Scale. Structural equation modeling examined longitudinal pathways among Artificial Intelligence-based Health Education Accurately Linking System users across baseline and 3, 6, and 12 months. For the qualitative phase, a purposive subsample was selected through maximum variation sampling based on baseline glycated hemoglobin; interviews were analyzed thematically until thematic saturation, and integrated with quantitative findings using a joint display.

Results: Of the 406 enrolled participants, 391 completed baseline assessments. The Extended MTM Scale demonstrated a 6-factor, 22-item structure with excellent internal consistency (Cronbach α=0.928) and satisfactory construct validity. The structural equation modeling showed satisfactory fit (CFI=0.984, RMSEA=0.036). Changes in the social environment (β=0.23, 95% CI 0.07 - 0.38; *P*=.003) and physical environment (β=0.25, 95% CI 0.10 - 0.40; *P*=.001) at baseline, and diabetes-related skills at month 6 (β=0.16, 95% CI 0.03 - 0.29; *P*=.01), were directly associated with self-management behavior at month 12, whereas behavioral confidence and emotional transformation showed no significant direct effects. Social environment changes were indirectly associated with behavioral confidence through participatory dialogue at month 3 (β=0.20, 95% CI 0.04 - 0.36; *P*=.01; β=0.66, 95% CI 0.57 - 0.74; *P*<.001). Thematic analysis of 17 interviews identified 3 domains: environmental context, cognitive processes, and attitudes and skills. Environmental factors converged across both data strands, while qualitative data expanded on the cognitive and attitudinal processes underlying sustained self-management.

XSL•FO
RenderX

Conclusions: This study is among the first to apply the Extended MTM framework to DHI-supported T2DM self-management, with environmental factors emerging as key drivers alongside selected cognitive, attitudinal, and skills-related processes. Complementing efficacy-focused research, it illuminates the psychosocial pathways underlying sustained self-management and refines the Extended MTM in digital health contexts. These insights can inform the design of theory-driven DHIs in primary care.

Introduction

Background

The prevalence of type 2 diabetes mellitus (T2DM) continues to rise and has emerged as a major global public health challenge [1]. This chronic condition not only imposes a substantial burden on individual health, marked by increased risk of disability, reduced quality of life, and shortened life expectancy [2], but also results in significant medical and socioeconomic costs [3]. According to the International Diabetes Federation, China has the highest number of people with diabetes and diabetes-related deaths worldwide, and the age of onset is trending younger [4].

As a lifelong condition, effective management of T2DM largely depends on patients' self-management capabilities [5], which encompass dietary regulation, regular physical activity, medication adherence, blood glucose monitoring, foot care, and routine eye examinations. However, awareness, treatment, and glycemic control rates in China remain suboptimal [6], highlighting a substantial gap in diabetes self-management practices. Therefore, the implementation of professionalized, standardized, and evidence-based self-management strategies is critically important for individuals living with T2DM.

In recent years, digital health interventions (DHIs) have shown great promise in supporting diabetes self-management [7,8]. By leveraging smartphones and other mobile devices, DHIs can overcome the time and space limitations of traditional community-based care, promote behavioral changes, and enhance the accessibility and equity of health services. To this end, our research team developed the Artificial Intelligence-based Health Education Accurately Linking System (AI-HEALS), implemented on the WeChat (Tencent) platform under the name Peking Diabetes Butler. This mobile application integrates knowledge graphs and natural language processing technologies and comprises an AI chatbot, tailored health education delivery, and blood glucose monitoring reminders [9]. It aims to provide patients with personalized and continuous support for diabetes self-management.

Theoretical Framework

Various theoretical models have been used in diabetes self-management interventions, including the Health Belief Model, Social Cognitive Theory, Self-Efficacy Theory, and social support frameworks [10]. These models emphasize strengthening individuals' cognitive, psychological, and social resources to address barriers to behavior change. However, most conventional models primarily focus on behavior initiation and provide more limited insight into the processes that support long-term maintenance. The Multi-Theory Model (MTM) of health behavior change has emerged as an integrative framework that draws on key elements from several traditional theories. MTM is particularly relevant to diabetes self-management, which involves multiple sustained behaviors such as dietary regulation, physical activity, blood glucose monitoring, and medication adherence. The model conceptualizes behavior change in 2 phases: behavioral initiation, including participatory dialogue, behavioral confidence, and changes in the physical environment, and behavioral sustenance, including emotional transformation, practice for change, and changes in the social environment [11,12].

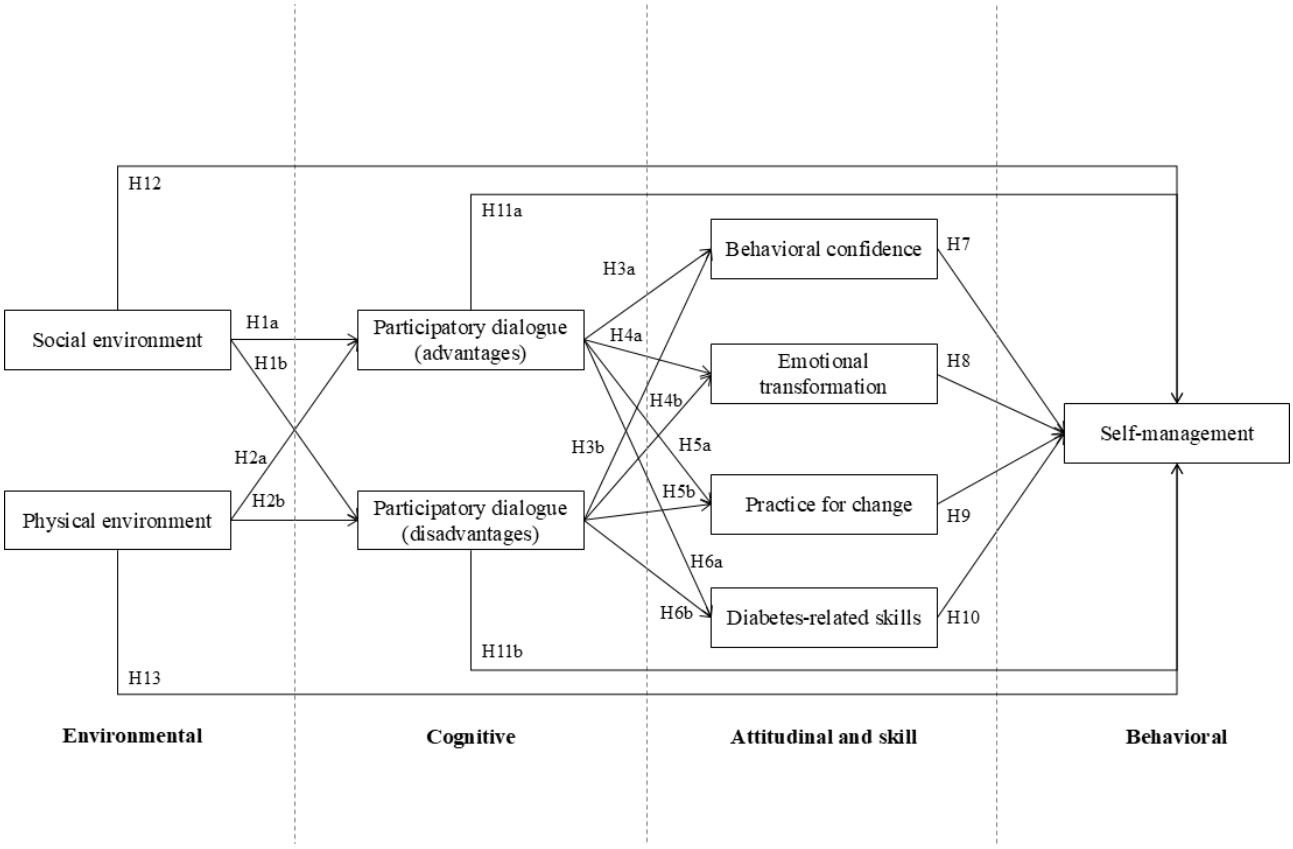
To date, MTM has been applied in interventions targeting smoking cessation [13], dietary behavior [14], and physical activity [15], with evidence of benefit for quality of life and disease-related psychological outcomes [16,17]. However, most applications have been conducted in offline settings, and empirical evidence supporting MTM in DHIs remains limited. In addition, previous studies suggest that the explanatory performance of MTM varies across behavioral contexts and populations [11], indicating a need to examine its applicability in specific settings. In diabetes self-management, sustained behavior depends not only on motivation and environmental support but also on patients' ability to carry out routine self-care tasks, such as blood glucose monitoring, dietary adjustment, and medication management [18]. Therefore, the present study used MTM as the core theoretical framework and incorporated diabetes-related skills as an additional construct to better capture the practical demands of diabetes self-management in a digital intervention context.

Study Objective

Therefore, this mixed methods study aimed to examine the behavioral mechanisms through which AI-HEALS influences diabetes self-management using an Extended MTM framework and to integrate quantitative and qualitative evidence regarding these mechanisms.

XSL•FO
RenderX

Methods



Study Design

This study was a mixed methods prospective longitudinal cohort substudy within the AI-HEALS program (Chinese Clinical Trial Registry: ChiCTR2300068952; registered March 2023), examining the behavioral mechanisms underlying diabetes self-management. An explanatory sequential mixed methods design was used, in which data were collected prospectively. Reporting followed the Good Reporting of A Mixed Methods Study guideline [19]. The completed checklist is provided in Checklist 1.

The quantitative phase comprised 2 components. First, the psychometric properties and construct validity of the Extended MTM Scale were assessed using baseline data through exploratory and confirmatory factor analyses. Second, to examine the hypothesized behavioral pathways, AI-HEALS users were followed over 12 months, with self-report assessments at 4 time points (baseline and 3, 6, and 12 months), and structural equation modeling was applied to these repeated measures. In the subsequent qualitative phase, a purposive subsample of the AI-HEALS users was interviewed to interpret and contextualize the quantitative findings.

The Extended MTM framework was organized into 4 domains—environmental, cognitive, attitudinal and skills, and behavioral—reflecting the hypothesized progression from contextual conditions to proximal individual-level processes and, ultimately, to self-management behavior. Figure 1 presents the hypothesized model, comprising 13 hypothesized pathways (H1–H13) linking environmental factors to cognitive processes, cognitive processes to attitudinal and skill-related constructs, and all preceding domains to self-management behavior. This framework guided both the quantitative path analysis and the qualitative inquiry.

Figure 1. Hypothesized model of the extended Multi-Theory Model of health behavior change for diabetes self-management behavior. The hypothesized model comprises 13 pathways (H1–H13) linking environmental, cognitive, attitudinal and skill, and behavioral domains among adults with type 2 diabetes mellitus. H1–H2 represent pathways from environmental factors to participatory dialogue; H3–H6 represent pathways from participatory dialogue to attitudinal and skill-related constructs; H7–H10 represent pathways from attitudinal and skill-related constructs to self-management behavior; H11–H13 represent hypothesized direct pathways from environmental and cognitive constructs to self-management behavior.

Intervention

Participants received standard diabetes primary care supplemented by AI-HEALS, a personalized DHI delivered via WeChat. AI-HEALS comprised an interactive AI chatbot, tailored health education delivery, and individualized blood glucose monitoring reminders. During the first 3 months, participants received at least one tailored self-management message per day and were provided with an operational guide in the first week. After the initial 3 months, the program shifted from proactive daily message delivery to a maintenance phase in which participants retained access to the chatbot, educational resources, and reminder functions.

Setting and Participants

A total of 406 adults with T2DM were enrolled from 45 primary health care institutions in Daxing and Shunyi districts of Beijing. Eligibility criteria included age≥18 years, diagnosis of T2DM,

XSL•FO
RenderX

residency in Beijing with less than one month of annual travel outside the city, smartphone ownership and proficiency in WeChat use, no use of psychiatric medications, and the ability to independently complete questionnaires.

Baseline data from participants with complete assessments were randomly split into 2 subsets: one for item selection via exploratory factor analysis (EFA), and the other for scale validation via confirmatory factor analysis (CFA). Longitudinal structural equation modeling (SEM) was conducted among participants who used AI-HEALS, examined across baseline, 3, 6, and 12 months.

For the interviews, participants were purposively sampled from among AI-HEALS users who had completed the quantitative assessments. A maximum variation sampling strategy based on glycated hemoglobin (HbA_{1c}) levels measured at baseline was applied to capture diverse diabetes management profiles. Recruitment continued until data sufficiency was achieved across the range of sampling variation.

Quantitative Data Collection

Quantitative data were collected using coded questionnaires between July 2023 and July 2024. At baseline, all eligible participants completed the Extended MTM scale for construct validity assessment. Factor analyses were conducted to assess the construct validity of the Extended MTM Scale. Participants who used AI-HEALS completed follow-up assessments at 3, 6, and 12 months.

Qualitative Data Collection

Qualitative data were collected through one-on-one telephone interviews conducted by the author at the 6-month follow-up (January 8 and February 20, 2024). After obtaining verbal informed consent, interviews were conducted privately with only the interviewer and participant present. Interviews continued until thematic saturation was reached, defined as the point at which no new themes or codes emerged from successive interviews. A semistructured interview guide was used to explore participants' experiences with AI-HEALS, covering usage behaviors, perceived usefulness and accessibility, perceived impact on self-management (including diet, physical activity, blood glucose monitoring, and medication adherence), and suggestions for improvement. The full interview guide is provided in Multimedia Appendix 1.

Ethical Considerations

The study was approved by the Peking University Biomedical Ethics Committee (IRB00001052-22058). Informed consent was obtained from all participants prior to participation in any component of the study. Written consent was obtained before the completion of the quantitative surveys, and verbal consent was obtained prior to the telephone interviews. Prior to analysis, all data were deidentified by replacing personal identifiers with coded study identifiers, with the linkage key stored separately; no images or materials in the manuscript or supplementary files contain information that could identify individual participants. Participants who completed all follow-up assessments in the quantitative phase received a gift valued at approximately 40 Chinese Yuan (CNY; approximately US $5 - 6 [1]), and those who participated in the qualitative interviews received a gift valued at approximately 100 CNY (approximately US $13 - 14) upon completion.

Measurements

Baseline data included sociodemographic and behavioral variables (eg, sex, age, education, marital and employment status, household income, smoking, and alcohol consumption). The following validated self-report instruments were administered: (1) Chinese Version of the Extended MTM Scale (Developed specifically for this study based on the MTM [12]), this 5-point Likert scale (1=strongly disagree, 5=strongly agree) assesses cognitive and behavioral constructs associated with diabetes self-management. Scale development and psychometric evaluation, including reliability and validity testing, are described in the Results section. (2) Diabetes-related Skills Scale: This 12-item scale evaluates patients' competencies in dietary planning, physical activity adjustment, blood glucose monitoring, and hypoglycemia prevention [20]. Responses are scored on a 5-point scale, with higher scores indicating better skills. In the current study, the scale showed excellent internal consistency (Cronbach α=0.912). (3) Summary of Diabetes Self-Care Activities: This 10-item instrument assesses the frequency of diabetes self-management behaviors over the past week, across 5 domains: general diet, specific diet, exercise, blood glucose testing, and foot care [21]. Responses range from 0 to 7 days, with total scores from 0 to 77; higher scores reflect better self-care. Internal consistency in this sample was acceptable (Cronbach α=0.736).

Statistical Analyses

To validate the Extended MTM scale, baseline data from participants with complete assessments were randomly split into 2 subsets for item screening and confirmatory evaluation. Item selection was based on EFA, item-total correlations, and internal consistency (Cronbach α). Construct validity was further assessed using CFA.

Sample size for the path analysis was determined based on empirically derived SEM criteria, including a ratio of approximately 10 - 20 observations per estimated parameter and a minimum sample size of 150 - 200 [22,23]. The Extended MTM model included 9 - 12 free parameters in the structural component; therefore, a minimum sample size of approximately 180 was required. Path analysis using maximum likelihood estimation was conducted on longitudinal data from AI-HEALS users to estimate direct and indirect effects among MTM constructs, diabetes-related skills, and self-management behavior. Little Missing Completely at Random (MCAR) test was used to examine the missing data mechanism, and missing data were handled using full information maximum likelihood estimation. Pearson correlation coefficients were calculated to examine associations between variables. Model fit was evaluated using standard indices, including the comparative fit index (CFI), Tucker–Lewis index (TLI), and root mean square error of approximation (RMSEA), with acceptable thresholds defined as CFI and TLI>0.90 and RMSEA<0.08. Statistical significance was set at P<.05. All analyses were performed using IBM SPSS Statistics 27.0 (IBM Corp), IBM SPSS Amos 23.0 (IBM Corp), and Mplus 8.3 (Muthén & Muthén).

XSL•FO
RenderX

Qualitative data were analyzed using thematic analysis following the approach described by Braun and Clarke [24], adopting a primarily inductive coding strategy within a framework-informed analytic approach. Audio recordings were transcribed verbatim within 24 hours of each interview, with nonverbal cues (eg, tone, pauses, laughter) noted to preserve contextual meaning. Where local dialect terms were encountered, clarification was sought from native speakers to ensure accurate interpretation. A large language model (Doubao, version 7.3.0) was used solely for minor grammatical refinement of transcripts without altering meaning. Two researchers (YJ and BK) independently verified all transcripts against the recordings for accuracy. Transcripts were imported into NVivo 12.0 (QSR International) for analysis. Researchers first familiarized themselves with the data through repeated reading. Initial codes were generated inductively and recorded in a coding log to ensure auditability and traceability of analytic decisions. The coding log was iteratively consolidated into subthemes and higher-order themes through constant comparison within and across cases, with regular team discussions held to resolve discrepancies and reach consensus. The Extended MTM domains were used as an interpretive lens to organize emergent themes and facilitate integration with quantitative findings.

Integration of quantitative and qualitative findings was conducted using a joint display approach, mapping MTM constructs to qualitative themes to examine areas of confirmation and expansion [25,26].

Results

Participant Characteristics

Of 406 enrolled participants, 15 were lost to follow-up over 12 months (attrition rate 3.7%), resulting in 391 participants with complete baseline data. These baseline data were randomly split for item selection via exploratory factor analysis (EFA; n=202) and scale validation via confirmatory factor analysis (CFA; n=189). The longitudinal structural equation model was subsequently conducted among the 202 AI-HEALS users across baseline and 3, 6, and 12 months. The mean age was 56.6 (SD 11.2) years, 207/391 (53%) participants were female (Table 1), and the mean HbA_{1c} was 7.29% (SD 1.61%).

[a]Characteristics pertain to participants with type 2 diabetes mellitus (T2DM) who used Artificial Intelligence-based Health Education Accurately Linking System (AI-HEALS), recruited from community health centers and outpatient clinics in Beijing, China.

[b]HbA_{1c}: glycated hemoglobin.

[c]OAD: oral antidiabetic drug.

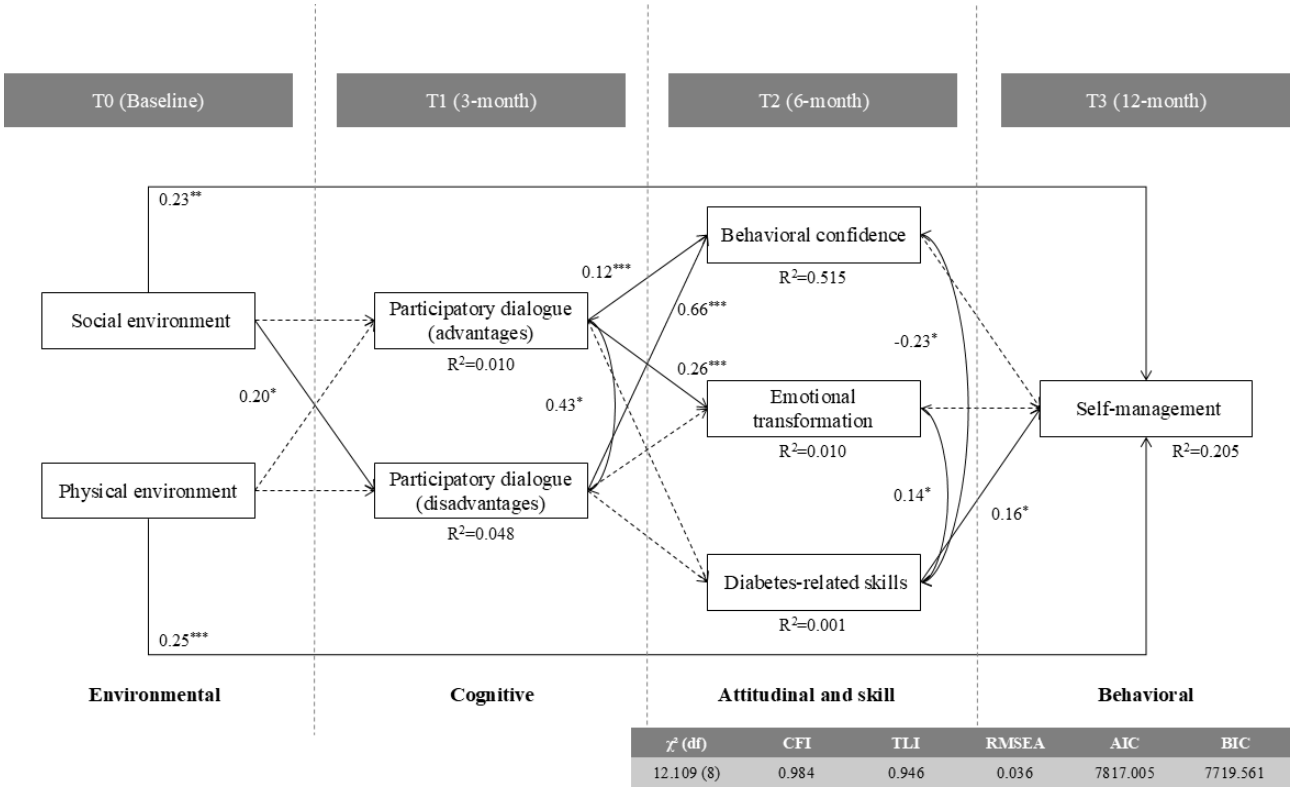
[d]CNY=Chinese Yuan.

[e]Monthly income ≤3000 Chinese Yuan (CNY) (approximately ≤ US $400); 3000 - 9000 CNY (approximately US $400 - 1200); ≥9000 CNY (approximately ≥ US $1200)

For the qualitative phase, thematic saturation was achieved after 17 interviews, with no new themes emerging in the final interviews. Among them, 10 of 17 (58.8%) were women and 7 of 17 (41.2%) were men. Ten of 17 (58.8%) were aged <60 years and 7 of 17 (41.2%) were aged ≥60 years. HbA1c was <7% in 8 of 17 (47.1%) and ≥7% in 9 of 17 (52.9%). Monthly income ranged from ¥3000-¥9000 (approximately US $400 - 1,200) for 10 of 17 (58.8%) participants, and 10 of 17 (58.8%) had completed high school or vocational education. Interview duration ranged from 12 - 45 minutes.

Scale Development and Validation of the Extended MTM Scale

Baseline data were randomly split for item selection via EFA and scale validation via CFA. All items demonstrated satisfactory psychometric properties, with coefficient of variation values exceeding 0.3 and item-total correlation coefficients above 0.4. EFA with varimax rotation was conducted based on the original 7-dimension MTM framework. As practice for change and emotional transformation loaded onto the same factor, expert consultation and theoretical review were undertaken, resulting in the exclusion of practice for change due to conceptual overlap with emotional transformation. The final 6-factor structure encompassed changes in the physical environment, participatory dialogue (advantages and disadvantages), behavioral confidence, emotional transformation, and changes in the social environment, with a cumulative variance explained of 86.34%, well above the recommended 50% threshold. The retained 22-item scale demonstrated excellent internal consistency (Cronbach α=0.928; greatest lower bound =0.967). CFA confirmed satisfactory structural validity (CFI=0.979, RMSEA=0.052; Multimedia Appendix 2). It should be noted that the exclusion of practice for change limited the availability of direct quantitative evidence for this dimension.



Quantitative Findings

Descriptive statistics and correlations among Extended MTM constructs, diabetes-related skills, and self-management behaviors are summarized in Multimedia Appendix 2. The Extended MTM framework includes 4 levels: environmental (changes in the physical and social environment), cognitive (participatory dialogue advantages and disadvantages), attitudinal and skill (behavioral confidence, emotional transformation, diabetes-related skills), and behavioral (self-management). At baseline, the mean scores for changes in the physical and social environment were 9.64 (SD 3.57) and 12.35 (SD 3.03), respectively. At month 6, emotional transformation averaged 12.27 (SD 2.91), diabetes-related skills 37.66 (SD 10.03), and behavioral confidence 12.75 (SD 2.64). Self-management behaviors at month 12 had a mean score of 49.70 (SD 17.16). Emotional transformation showed strong correlation with diabetes-related skills (r=0.744; P=.008) and moderate correlation with behavioral confidence (r=0.474; P=.005). Behavioral confidence was also positively correlated with diabetes-related skills (r=0.471; P=.004).

Among the 202 AI-HEALS users included in the SEM, complete data were available for 173 (85.6%) at month 12. Little MCAR test indicated that the data were missing completely at random (χ^2_{272}=270.54; P=.51); missing data were therefore handled using full information maximum likelihood estimation. As shown in Figure 2, changes in the social environment (β=0.23, 95% CI 0.07 - 0.38; P=.003) and physical environment (β=0.25, 95% CI 0.10 - 0.40; P=.001) at baseline, and diabetes-related skills at month 6 (β=0.16, 95% CI 0.03 - 0.29; P=.01) were directly associated with self-management behaviors at month 12, supporting H12, H13, and H10. In contrast, behavioral confidence and emotional transformation showed no significant direct effects on self-management behaviors, leaving H7 and H8 unsupported. Changes in the social environment at baseline were significantly associated with participatory dialogue (disadvantages) at Month 3 (β=0.20, 95% CI 0.04 - 0.36; P=.01; H1b), and participatory dialogue (disadvantages) was in turn significantly associated with behavioral confidence at month 6 (β=0.66, 95% CI 0.57 - 0.74; P<.001; H3b). As participatory dialogue (disadvantages) was reverse-coded, these positive coefficients reflect negative underlying effects. Participatory dialogue (advantages) at month 3 was additionally associated with behavioral confidence (β=0.12, 95% CI 0.02 - 0.23; P=.02; H3a) and emotional transformation (β=0.26, 95% CI 0.11 - 0.40; P=.001; H4a) at month 6. All remaining hypothesized pathways were non-significant (Multimedia Appendix 2).

XSL•FO
RenderX

Figure 2. Longitudinal structural equation model of diabetes self-management behavior based on the extended Multi-Theory Model (MTM) of health behavior change. The model was estimated among adults with type 2 diabetes mellitus who used AI-HEALS (n=202), recruited from community health centers and outpatient clinics in Beijing, China, across 4 time points: baseline (T0), month 3 (T1), month 6 (T2), and month 12 (T3). Standardized path coefficients (β) are shown. Solid lines indicate significant paths; dashed lines indicate non-significant paths. R^2 values represent explained variance. *P<.05, **P<.01, ***P<.001. AIC: Akaike information criterion; AI-HEALS: Artificial Intelligence-based Health Education Accurately Linking System; BIC: Bayesian information criterion CFI: comparative fit index; MTM: Multi-Theory Model; RMSEA: root mean square error of approximation; TLI: Tucker–Lewis index;

χ^2 (df)	CFI	TLI	RMSEA	AIC	BIC
12.109 (8)	0.984	0.946	0.036	7817.005	7719.561

The model demonstrated satisfactory fit (χ^2_8=12.109, CFI=0.984, TLI=0.946, RMSEA=0.036), supporting the hypothesized structure of the Extended MTM framework.

Qualitative Findings

Based on the Extended MTM, qualitative findings were organized into 3 hierarchical domains: environmental, cognitive, and attitudinal and skills, encompassing 7 themes and 18 subthemes (Multimedia Appendix 1). Below is a concise summary of each domain.

Environmental Domain

Changes in both physical and social environments influenced participants' engagement in diabetes self-management. At the level of the physical environment, accessibility and usability of digital tools were key determinants of engagement. Participants were more likely to apply health information when content was perceived as relevant, clear, and easy to use. For example, one participant described using dietary information to guide daily decisions:

> *If I want to eat something, I'll check whether it's suitable for people with diabetes. If the sugar content is high, I won't buy it.* [T-BJ-360, female, 62 years]

However, limitations in information reliability and clarity were also reported. Some participants expressed uncertainty about the trustworthiness of certain content, which could reduce confidence in using the platform. As one participant noted,

> *Some medication info seems unreliable.* [T-BJ-033, male, 58 years]

This suggests that inconsistencies or lack of transparency in information presentation may hinder sustained engagement.

At the level of the social environment, family involvement and broader social support played a reinforcing role. Emotional and practical support from family members enhanced motivation and facilitated adherence to self-management behaviors. For instance, one participant stated,

> *My daughter and son both really care about this.* [T-BJ-194, female, 72 years]

Participants also highlighted the importance of wider societal support for health promotion:

> *I truly hope the government can promote health knowledge among young people.* [T-BJ-194, female, 72 years]

Cognitive Domain

Interactions with the digital platform, together with input from health care providers and social networks, supported participants' understanding and decision-making processes. Participants described how exposure to structured information helped them reassess prior beliefs and make more informed choices. For example, one participant noted,

XSL•FO
RenderX

> *I've read a lot of the content. I used to think certain foods were low in sugar or sugar-free, but now I know they're not.* [T-BJ-182, female, 51 years]

This reflects a process of cognitive correction and improved health literacy.

In addition, the combination of digital information and offline guidance appeared to enhance perceived usefulness and credibility. As one participant stated,

> *This content, combined with the community doctor's talks, fully meets my needs.* [T-BJ-173, female, 67 years]

Another participant emphasized the practical value of the platform:

> *I've learned so many things through this. I'm sure it will help me solve a lot of problems going forward.* [T-BJ-035, male, 61 years]

Attitudinal and Skills Domain

This domain encompassed behavioral confidence, emotional transformation, practice for change, and diabetes-related skills. Behavioral confidence emerged as a central factor influencing proactive engagement. Participants who perceived themselves as capable of managing their condition were more likely to adopt and maintain behavioral changes. For example, one participant stated,

> *If you want to live long and live well, you must have confidence.* [T-BJ-194, female, 72 years]

Trust in the platform also contributed to this confidence, as reflected in the following statement:

> *The materials you provided feel really trustworthy…* [T-BJ-407, male, 49 years]

Emotional transformation was another important process, whereby participants shifted from anxiety or passive coping to more proactive self-management. Structured information and repeated engagement appeared to support this transition. As one participant noted,

> *There's no use being anxious. Since I've got the disease, I might as well manage it properly...* [T-BJ-182, female, 51]

Participants also described practice for change through reminders, self-monitoring, and the gradual incorporation of self-management behaviors into daily routines. For instance, one participant reported,

> *Just last night, I forgot to check, and the Peking Diabetes Butler reminded me.* [T-BJ-184, male, 56 years]

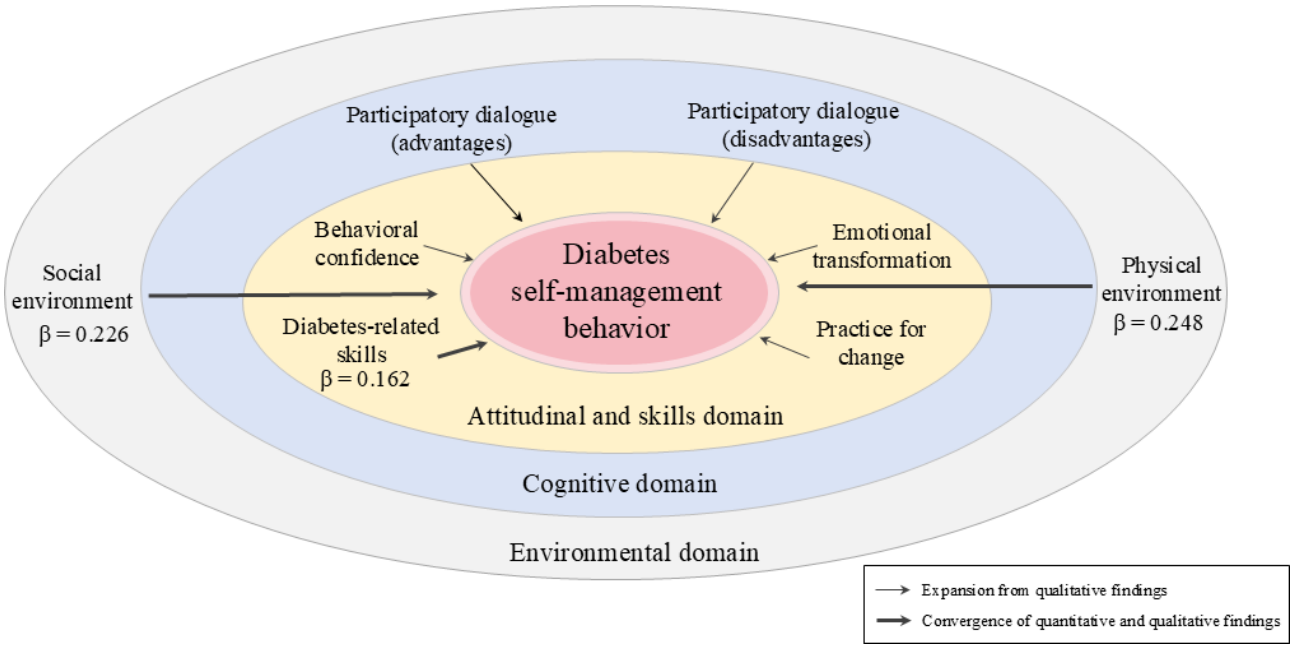
In parallel, participants described improvements in diabetes-related skills, particularly in blood glucose monitoring, diet, medication use, and physical activity. As one participant explained,

> *My workouts are regular now... I used to exercise blindly, but now I know what I'm doing.* [T-BJ-182, female, 51 years]

Nonetheless, some participants identified limitations in content presentation, particularly regarding clarity and format. For example, one participant suggested,

> *Some of the exercise illustrations aren't clear enough. Videos would be much better...* [T-BJ-182, female, 51 years]

This indicates that insufficiently intuitive or engaging content may reduce usability and limit the effectiveness of skill acquisition.



Building on the subtheme analysis, we assessed whether overarching themes differed by participants' HbA_{1c} levels. No clear differences in the overarching themes were observed across interview participants with different HbA_{1c} levels, although some variation in emphasis was noted in individual accounts.

Integration of Quantitative and Qualitative Findings

As illustrated in Figure 3 and Multimedia Appendix 3, integration of quantitative and qualitative data revealed both convergent and complementary patterns across the Extended MTM domains.

XSL•FO
RenderX

Figure 3. Integrated model of quantitative and qualitative findings on diabetes self-management behavior based on the extended Multi-Theory Model of health behavior change. Based on an explanatory sequential mixed methods study among adults with type 2 diabetes mellitus who used Artificial Intelligence-based Health Education Accurately Linking System, recruited in Beijing, China (n=202). Thin arrows indicate pathways derived from qualitative findings, whereas thick arrows indicate pathways supported by both quantitative and qualitative evidence. Standardized path coefficients (β) are shown for direct associations with diabetes self-management behavior identified in the quantitative model.

Environmental factors showed the strongest convergence. SEM confirmed direct associations of physical and social environment changes with self-management behavior at month 12 (β=0.25, 95% CI 0.10-0.40 and β=0.23, 95% CI 0.07-0.38), and qualitative accounts described how access to digital tools, self-management resources, and family and community support facilitated behavioral engagement. Diabetes-related skills similarly showed convergence, with a direct quantitative effect (β=0.16, 95% CI 0.03-0.29) corroborated by participants' descriptions of applying glucose monitoring, dietary, and medication management skills in daily practice.

Qualitative findings expanded on constructs showing limited direct effects in the SEM. Behavioral confidence and emotional transformation were not significant direct predictors of self-management behavior, yet participants described both as present and influential in their self-management experience. Practice for change, which was excluded from the quantitative model during scale revision, was nonetheless frequently referenced by participants as part of their behavioral routines.

Participatory dialogue showed complementary patterns across both strands. Quantitative pathways linked social environment changes to behavioral confidence and emotional transformation via participatory dialogue at month 3 and month 6. Qualitative accounts described interactions with the platform, health care providers, and peers as sources of knowledge, motivation, and decision-making support.

Discussion

Principal Findings

This study used an explanatory sequential mixed methods design. The integrated findings provided partial confirmation and substantial expansion of the Extended MTM framework in the context of DHIs for diabetes self-management. SEM confirmed that physical and social environmental factors and diabetes-related skills had direct positive effects on self-management behavior, with environmental factors showing particularly prominent influence. Qualitative findings expanded these results by elucidating how participatory dialogue, behavioral confidence, emotional transformation, and practice for change operated alongside environmental support to facilitate sustained behavior change. Together, these findings underscore the prominent role of environmental factors, complemented by cognitive, attitudinal, and skills-related processes, in shaping effective self-management. This study represents the first application of the MTM framework to diabetes self-management and extends it based on the behavioral characteristics of this context.

Results from the SEM showed that changes in the physical and social environment had direct positive associations with diabetes self-management behaviors [27,28]. Environmental constructs showed clearer direct associations than the psychological constructs included in the model, whose pathways were not statistically significant. This pattern may be interpreted from a socioecological perspective, which views self-management behavior as embedded within broader physical and social environments rather than determined solely by individual-level psychological processes [29]. In this model, physical and social environmental changes were therefore positioned as antecedent contextual conditions for self-management, whereas psychological and skills-related constructs were modeled as downstream individual-level processes that develop within, and partly in response to, these conditions. In AI-HEALS, accessible information, reminders, and ongoing support may have strengthened the environmental conditions under which self-management occurs, which may help explain the

XSL•FO
RenderX

prominence of environmental constructs in the final model. This suggests that DHIs may not act solely by strengthening internal determinants such as confidence or emotion-related processes, but may also increase the salience of contextual determinants, consistent with evidence that context-aware digital behavior change interventions dynamically tailor support based on real-world factors [30]. From an intervention perspective, strengthening supportive environmental conditions may therefore be an important entry point for promoting sustained behavioral engagement [31].

Diabetes-related skills were also found to have a direct positive influence on self-management behaviors, aligning with previous studies [32]. Diabetes self-management education should integrate behavior change techniques, such as goal setting and self-monitoring, with skills training to enhance patients' practical capabilities [33]. Evidence suggests that skill internalization interventions can support behavioral persistence [34]; patients who acquire blood glucose monitoring skills early demonstrate significantly better self-management awareness than those without systematic training [35]. Neuroscientific studies suggest that skilled individuals show reduced activation in decision-related brain regions like the prefrontal cortex [36]. Skill internalization may shorten the neural pathway between cognitive appraisal and behavioral execution, thereby improving the efficiency and automatization of behavioral performance [37]. These findings suggest that practical skill acquisition may represent a more proximal determinant of behavioral outcomes than attitudinal processes alone, with implications for the design of DHIs that prioritize applied skills training alongside informational content.

This study found that changes in the social environment indirectly enhanced behavioral confidence through participatory dialogue (disadvantages), while participatory dialogue (advantages) directly improved behavioral confidence and emotional transformation. These findings align with previous research. In T2DM management, participatory strategies such as interactive education and motivational interviewing have been shown to strengthen behavioral confidence and emotional resonance, thereby improving patients' motivation for self-management [38,39]. Encouraging a focus on positive emotions, such as hope and achievement, can reduce fear and helplessness and promote behavioral engagement [40]. Experience sharing and emotional support in online communities may further enhance self-efficacy as an extension of social support [41]. However, neither behavioral confidence nor emotional transformation demonstrated a significant direct effect on self-management behavior in the SEM, suggesting that their influence may operate indirectly through skills development and routine consolidation rather than directly driving behavioral outcomes. Prior meta-analyses have indicated that knowledge-based interventions exert limited behavioral impact in the absence of accompanying skills training [42], which may partly account for this pattern. This interpretation was further supported by qualitative accounts, in which participants described confidence and emotional regulation as enabling conditions for sustained engagement rather than immediate behavioral triggers.

Qualitative findings further suggest that improvements in diabetes self-management are shaped by the interplay between environmental accessibility, cognitive support, and the development of attitudes and practical skills. At the environmental level, the accessibility and usability of the AI-HEALS platform appear to provide a foundation for behavioral engagement, facilitating access to structured health information and ongoing support. In addition to these system-level features, participants frequently described the importance of family involvement and professional guidance in sustaining behavioral continuity, indicating that broader social support contexts may complement DHIs in reducing barriers to long-term engagement. These observations are consistent with prior evidence indicating that supportive environments can facilitate sustained self-management in patients with T2DM [31,43]. From a cognitive perspective, interaction with the platform appeared to support processes of understanding, appraisal, and decision-making. The delivery of timely and structured information, together with interactive feedback, may help reduce informational asymmetry and enhance users' confidence in interpreting and applying health guidance. Rather than functioning as a standalone driver, this cognitive support seems to operate in conjunction with external reinforcement from health care providers and personal networks. The use of interactive digital platforms and conversational technologies has been shown to enhance user trust and engagement in health communication [44,45]. At the level of attitudes and skills, behavioral confidence and emotional adjustment emerged as closely linked processes that support sustained self-management. Participants described how increased confidence enabled them to translate concerns related to glycemic control into actionable strategies, while repeated engagement with the platform facilitated the gradual internalization of self-management skills. Over time, this process contributed to the establishment of routine practices across key domains, including glucose monitoring, dietary regulation, physical activity, and medication adherence, reflecting a transition towards more autonomous self-regulation. This interpretation is supported by prior research highlighting the role of emotional regulation and self-efficacy in sustaining behavioral change [46,47]; as well as behavior change techniques embedded in DHIs [48]. Notably, practice for change—though excluded from the quantitative model due to scale revision—was consistently described by participants as a mechanism linking knowledge acquisition to behavioral maintenance, suggesting its continued theoretical relevance within the Extended MTM framework. The absence of quantitative evidence for this dimension reflects a methodological limitation of the scale revision process rather than a theoretical dismissal of its role. Future studies should consider retaining or separately operationalizing practice for change to enable fuller quantitative testing of the Extended MTM framework.

Building on these observations, variation in participants' accounts suggested that behavioral processes are shaped by the relative prominence of barriers and self-regulatory capacity. Participants with comparatively higher HbA_{1c} at month 6 more often emphasized constraints related to symptom burden and practical barriers, whereas those with lower HbA_{1c} levels tended

XSL•FO
RenderX

to highlight established routines and greater behavioral confidence [49]. These differences illustrate how behavioral priorities and self-regulatory strategies vary across individuals, highlighting the dynamic nature of diabetes self-management processes. In this context, DHIs may benefit from adapting to these differing needs, particularly by strengthening external support and providing more tailored guidance for individuals facing greater behavioral constraints [50,51]. These observations also highlight areas for further optimization of the AI-HEALS system, as qualitative findings indicated concerns regarding the reliability of certain medication information and the clarity of visual content, alongside limited adaptability to individual needs, particularly among older adults and those with lower digital literacy. Addressing these issues may enhance system effectiveness through improved interface design, incorporation of multimodal content such as video-based guidance, and greater adaptability to diverse user needs, while closer integration with broader care systems and real-world support structures, including community-based platforms [52,53], may further support sustained engagement in diabetes self-management.

Grounded in the Extended MTM, this study demonstrates that AI-HEALS supports diabetes self-management through a pathway of environmental facilitation, cognitive reinforcement, and attitudinal and skill consolidation. Across both data strands, environmental factors emerged as the most consistently supported drivers of behavior change, while cognitive and attitudinal processes showed complementary roles that were more fully captured through qualitative inquiry. The convergence of findings across these domains supports the applicability of the Extended MTM as an explanatory framework for DHI-supported behavior change in chronic disease management.

Limitations

There are several limitations that should be recognized. First, participants were recruited from community health centers in Beijing, which may limit the generalizability of findings to other geographic, cultural, or health care contexts. Second, the sample may have been subject to selection bias, as less cooperative or less digitally proficient patients may have been systematically excluded. Third, reliance on self-reported outcome measures may introduce recall bias, potentially affecting the accuracy of self-management behavior assessments. Fourth, although the longitudinal design and SEM allowed examination of temporal pathways, SEM identifies associations consistent with hypothesized causal structures but cannot establish causality definitively. Fifth, the findings are based on AI-HEALS, a single program delivered via WeChat, and may not generalize to other digital health programs with different technological platforms, user interfaces, or engagement strategies. Sixth, the exclusion of the practice for change dimension during scale revision precluded its quantitative examination, limiting the completeness of the Extended MTM framework testing.

Conclusions

This study is among the first to apply the Extended MTM framework to diabetes self-management, demonstrating that environmental factors, alongside selected cognitive, attitudinal, and skills-related processes, play an important role in sustaining behavior change among AI-HEALS users. While environmental factors and diabetes-related skills showed direct associations with self-management behavior, behavioral confidence and emotional transformation appeared to operate indirectly, illuminating psychosocial mechanisms that efficacy-focused evaluations alone cannot capture. These findings contribute to the theoretical refinement of the Extended MTM in digital health contexts and suggest that prioritizing environmental support and skill-building in the design of digital health programs may help sustain patient engagement and self-management in primary care settings.

Acknowledgments

We thank the trial steering experts, participating patients, and all staff involved in the development, implementation, and maintenance of AI-HEALS for their support of this study. The authors declare the use of generative AI in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to generative AI (GenAI) tools under full human supervision: proofreading and editing. The GenAI tool used was Doubao (version 7.3.0). Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. The GenAI tool Doubao (version 7.3.0) was used to assist with language refinement of qualitative interview transcripts during data processing. The AI was applied solely to improve clarity and readability and did not generate, modify, or analyze study data. All AI-assisted outputs were reviewed and verified by the research team against the original audio recordings to ensure accuracy. No AI was used for data analysis, interpretation, or independent decision-making.

Funding

This study was supported by Capital's Funds for Health Improvement and Research (grants 2022-1G-4252 and 2026-2R-4403). The funder had no role in the design of the study; collection, analysis, and interpretation of data; writing of the manuscript; or the decision to submit the manuscript for publication.

Data Availability

The data sets generated and analyzed during this study are not publicly available because participants were assured that the raw data would remain confidential. Deidentified data may be made available from the corresponding author on reasonable request, subject to institutional review and data governance requirements.

Feasibility, Usability, and Preliminary Effectiveness of an mHealth App to Promote Screening Behaviors Among High-Risk Populations for Breast Cancer: Randomized Controlled Pilot Study

Abstract

Background: Breast cancer is a major public health challenge worldwide. Women at high risk for breast cancer are more likely to develop the disease; yet, screening participation remains. Mobile health interventions may improve breast health awareness and screening behaviors, but evidence in high-risk populations for breast cancer remains limited.

Objective: This study aimed to evaluate the feasibility, usability, and preliminary signals of potential effectiveness of the "Ruaikang" mobile health app, designed to support breast health awareness and engagement with early screening among high-risk populations for breast cancer.

Methods: In this pilot randomized controlled trial, eligible high-risk populations for breast cancer were randomly assigned (1:1) to a 4-week intervention using the "Ruaikang" app or a control group receiving standard breast cancer screening guidelines. Feasibility was assessed via recruitment and completion rates. Usability was measured using the System Usability Scale. Use data were collected through the app's back-end system. Preliminary effectiveness was assessed through changes in willingness to participate in breast cancer screening, screening knowledge, health beliefs, and self-efficacy at both the fourth (T1) and eighth (T2) weeks. Semistructured interviews were conducted with a purposive subsample of intervention participants to explore user experience and suggestions for improvement.

Results: Of 62 eligible women approached, 50 enrolled (recruitment rate 80.6%) and were randomized to intervention (n=25) and control (n=25) groups. In total, 19 participants in the intervention group completed the study (completion rate 76%), reflecting good feasibility. The mean usability score was 88.82 (SD 10.29), indicating high usability. Back-end use data showed that participants actively engaged during the intervention period. At T1, the intervention group showed preliminary signals of improvement in willingness to participate in breast cancer screening, screening knowledge, health beliefs, and self-efficacy, although these changes were less pronounced at T2. Qualitative interviews with 8 participants identified 2 core themes: "perceived value and acceptability of the app" and "system limitations and user-centered improvement needs." Participants highlighted that the app was easy to use and content-rich and provided actionable feedback for optimizing interactive features, navigation, and content depth.

Conclusions: The "Ruaikang" mobile health app demonstrated good feasibility and usability and provided preliminary signals of potential effectiveness in improving willingness to participate in breast cancer screening, screening knowledge, health beliefs, and self-efficacy among high-risk populations for breast cancer. Participants' feedback indicates that the app aligns with users' core needs and supports engagement with breast health information. Future work should refine the app based on user feedback and conduct larger-scale, longer-term randomized controlled trials to confirm and further validate the preliminary effectiveness observed.

Introduction

Breast cancer presents a significant public health challenge for women globally. According to the International Agency for Research on Cancer [1], there were approximately 2.3 million new breast cancer cases and 670,000 deaths worldwide in 2022, making it the leading cause of cancer death among women after lung cancer. In China, approximately 350,000 new cases and 75,000 deaths were estimated in 2022, ranking it as the second leading cause of cancer-related mortality among Chinese women [2]. Cancer screening is an effective strategy for the early detection of breast cancer [3]. It involves the application of effective, simple, and economical breast examination to identify asymptomatic individuals at an early stage. As the most effective approach to enhancing early diagnosis rates, survival, and quality of life for patients, breast cancer screening is particularly vital for high-risk populations for breast cancer [4]. High-risk populations for breast cancer refer to women who carry established risk factors, such as a family history of breast cancer, relevant gene mutations, a history of benign breast disease, unhealthy lifestyle habits, smoking, and alcohol abuse [5]. Studies show that such individuals face a significantly elevated risk of developing breast cancer, which can be up to 10 times that of the general population [6].

Since the beginning of the 21st century, European Union countries such as the United Kingdom, Ireland, and Italy have actively promoted breast cancer screening programs, recommending that eligible women be screened every 2 to 3 years [7]. In 2009, the Chinese government launched a free "two cancers" (cervical cancer and breast cancer) screening program for eligible women and incorporated breast cancer screening into the national public health service in 2019 to encourage broader participation [8]. Despite these clear policy measures, participation in breast cancer screening remains low, particularly among high-risk populations for breast cancer. A study by Kırca et al [9] among first-degree relatives of patients with breast cancer in the largest hospital in southwestern Turkey revealed that fewer than 20% of participants had undergone screening. Similarly, a survey by Zhang et al [10] of 15,550 high-risk populations for breast cancer in Beijing showed that less than 50% were willing to participate in screening. Further findings from Zhao et al [11] highlighted low screening participation among first-degree relatives of patients with breast cancer, with only 6.7% of respondents performing breast self-examination once a month and 22.8% undergoing breast ultrasound or mammography once a year. According to the National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines [12], individuals identified as being at high risk for breast cancer include those with a lifetime risk of 20% or greater based on validated risk assessment models, a history of chest radiation therapy or breast cancer, the presence of high-risk breast lesions, or a family history suggestive of hereditary breast cancer. For this population, NCCN recommends earlier and more intensive screening, including annual mammography and breast magnetic resonance imaging, as well as clinical breast examinations every 6 to 12 months. The Chinese breast cancer screening guidelines [3] provide definitions and recommendations for high-risk populations for breast cancer that align closely with those of the NCCN. Therefore, it is imperative to develop and implement targeted interventions for high-risk populations for breast cancer to improve breast cancer screening participation, thereby alleviating the public health burden.

Previous studies suggested that factors such as breast cancer awareness, health beliefs, social support, and self-efficacy play significant roles in influencing women's screening behaviors [9]. Researchers have developed various interventions, such as health education, peer support, patient navigation services, and decision assistance tools, to improve participation in breast cancer screening, and these studies have shown a positive promotion effect on screening participation [13-16]. Despite the demonstrated benefits of existing interventions, their implementation often depends on face-to-face delivery or printed materials, which require substantial personnel, time, and financial resources, thereby limiting scalability, flexibility, and long-term sustainability [17,18]. These challenges are particularly pronounced for women with demanding schedules, limited mobility, or those living in geographically dispersed areas, who may face difficulties in accessing such support [19]. In addition, most interventions focus on a single behavioral determinant, whereas women's breast cancer screening behaviors are influenced by multiple interacting psychosocial factors [20]. Consequently, there is a need to develop more comprehensive, multicomponent intervention strategies that leverage digital platforms to improve accessibility, deliver timely support, and promote sustained participation in breast cancer screening.

With the global popularization of the internet, mobile health has become an integral component of contemporary health care [21]. As a key medium of mobile health, mobile health apps have been widely applied in multiple fields, including health monitoring, disease prevention, and chronic disease management [22-24]. To date, a considerable number of studies have been devoted to developing mobile health apps to promote breast cancer screening. For instance, Yusuf et al [25] developed a health education app tailored for women in northeastern Malaysia. By integrating content on breast anatomy, breast cancer knowledge, support group information, screening reminders, and culturally adapted educational materials, the app successfully enhanced screening confidence and willingness among the target population. Similarly, Roh et al [26] developed an app to encourage breast cancer screening among Native American people. This app offers breast cancer education, information on screening clinics, and regular text-message reminders and has shown promising results in real-world applications. However, existing apps primarily target the general population of healthy women, with limited attention to those high-risk populations for breast cancer. Compared to the general population, high-risk populations for breast cancer require more comprehensive breast health knowledge and more proactive health behaviors.

The research team developed a mobile health app named "Ruaikang" to provide breast cancer screening support resources for high-risk populations for breast cancer, enhance their breast health awareness, and promote participation in early screening. This pilot randomized controlled study aimed to evaluate the

XSL•FO
RenderX

feasibility and usability of the "Ruaikang" mobile health app among high-risk populations for breast cancer and to explore its potential impact on promoting breast cancer screening behaviors.

Methods

Study Design

This pilot randomized controlled study was conducted from January to October 2025. The trial was registered in the Chinese Clinical Trial Registry (registration: ChiCTR2500108593) and reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) extension for pilot and feasibility trials (Checklist 1) [27].

Participants and Setting

Participants were from a grade A tertiary hospital in eastern China. Convenience sampling was adopted to recruit the high-risk populations for breast cancer who visited the hospital during the study period. The inclusion criteria for the participants were as follows: (1) meeting the definition of high-risk populations for breast cancer per Chinese women's breast cancer screening guidelines [3], including those with breast cancer susceptibility gene, family history of breast cancer (parents, children, and siblings), personal history of breast cancer, history of chest radiotherapy, and diagnosed with lobular carcinoma in situ, atypical ductal hyperplasia, or atypical lobular hyperplasia before 40 years; (2) women; (3) age ≥18 years; (4) possession of an Android smartphone and proficiency in its operation; and (5) those who voluntarily participated in this study and signed an informed consent form. The exclusion criteria were as follows: (1) physician-diagnosed confusion or cognitive impairment and (2) previous history of mental illness.

Sample Size

In pilot studies, a minimum of 12 participants per group has been recommended to provide reasonable estimates of key parameters, such as the mean and variance, for planning future definitive trials [28]. In accordance with this guideline, the quantitative component of this study established a minimum sample size of 12 participants in each group. To account for a potential dropout rate of 20%, the final sample size was adjusted to at least 15 participants per group. For the qualitative component, participants were purposively sampled from the intervention group based on age, educational level, and app use patterns to ensure diverse and information-rich perspectives. The sample size was guided by the concept of information power [29], and data collection continued until sufficient information power was achieved to adequately address the study objectives.

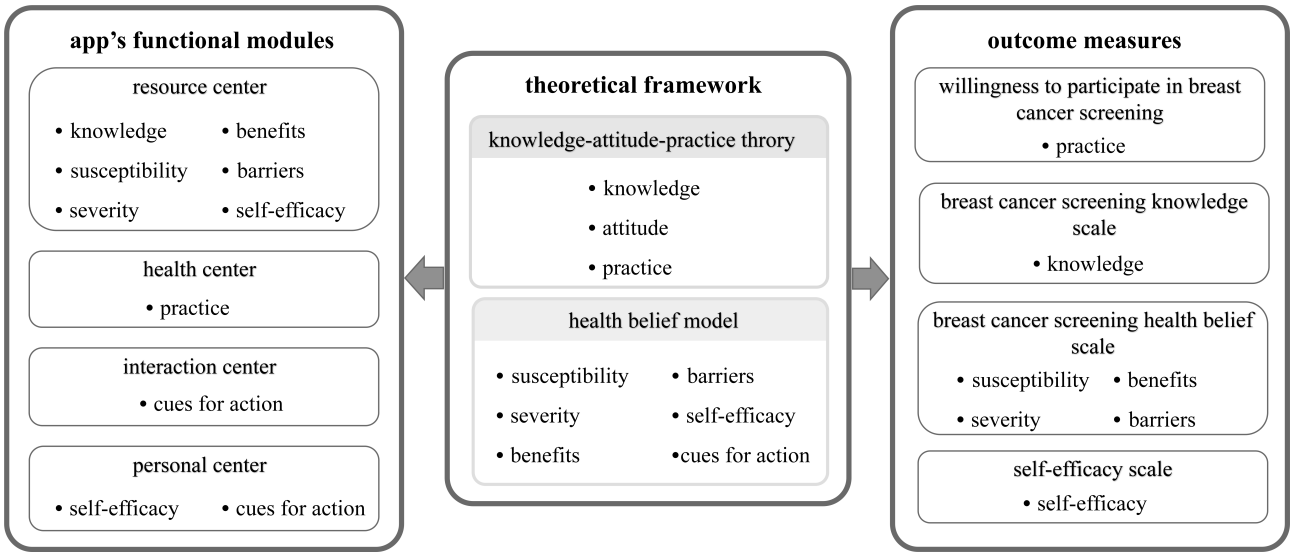
Procedures

The research team comprised 3 research assistants, 1 breast cancer care specialist, and 1 software engineer. The research assistants were primarily responsible for participant recruitment, intervention implementation, and data collection. The breast cancer care specialist provided clinical expertise and addressed participants' medical questions. The software engineer was responsible for app maintenance and ensuring stable technical operation.

Research assistants screened potential participants in hospital wards and outpatient departments against the inclusion criteria. Eligible individuals received an explanation of the study's background, purpose, and procedures. After providing informed consent, participants completed the baseline (T0) questionnaire and were randomly assigned to either the intervention group or the control group. The intervention group received a 4-week intervention via a mobile health app named "Ruaikang," while the control group received the printed "Breast Cancer Screening Guidelines" manual [3]. Participants in the intervention group installed and registered the "Ruaikang" with the research assistants' guidance. The assistants helped them log in, complete their personal profiles, and demonstrate the functionality of each module. Follow-up assessments were conducted with all participants at the fourth (T1) and eighth (T2) weeks. At T1, participants in the intervention group were also invited to participate in a semistructured interview about user experience and improvement suggestions for the app.

Randomization and Blinding

A computer-generated random sequence was created by an independent statistician, who was not involved in participant recruitment or intervention delivery. Eligible participants were allocated in a 1:1 ratio to the intervention or control group. To ensure allocation concealment, the statistician prepared sequentially numbered, opaque, sealed envelopes, which were stored and managed by a research coordinator independent of participant enrollment and outcome assessment. Envelopes were opened sequentially only after participant enrollment and baseline data collection. Participants could not be blinded due to the nature of the intervention. Outcome assessors and research staff involved in follow-up and data collection remained blinded, and group assignment was not disclosed to assessors during follow-up to minimize detection bias.



Intervention

The "Ruaikang" mobile health app was developed based on the knowledge-attitude-practice theory [30] and the health belief model (HBM) [31]. The knowledge-attitude-practice model outlines 3 stages for behavioral change: knowledge acquisition, attitude formation, and practice adoption. Knowledge enables attitude shifts, which drive behavioral change for health goals. HBM explains health behaviors through 6 belief dimensions: perceived susceptibility, perceived severity, perceived benefits, perceived barriers, self-efficacy, and cues for action. In this study, "knowledge" refers to understanding of breast cancer pathology and early screening protocols. "Attitude" refers to the cultivation of positive beliefs and attitudes toward early screening participation among high-risk populations for breast cancer, with conceptual alignment to core HBM dimensions. "Practice" refers to adoption of regular breast cancer screening behaviors by high-risk populations for breast cancer, informed by acquired knowledge and reinforced attitudes. This theoretical framework informed both the design of the app's functional modules and the selection of outcome measures, as illustrated in Figure 1. The app comprises 2 core systems: the user side and the back-end management system. The user side is designed to deliver breast health education, early screening guidance, health behavior promotion, and psychosocial support for

XSL•FO
RenderX

high-risk populations for breast cancer, including 4 core functional modules: the resource center, health center, interaction center, and personal center. The back-end management system is designed to oversee and control the overall operation of the app. The detailed information on the app's development process, user side features, and back-end management functions is shown in Multimedia Appendix 1.

Figure 1. Conceptual framework.

Outcome Measures

The Feasibility and Usability of the App

The feasibility and usability of the app are as follows:

- Feasibility: The feasibility of the app was assessed using 2 key indicators: recruitment rate and completion rate. The recruitment rate was defined as the percentage of volunteers who participated in the study among all individuals who met the eligibility criteria. The completion rate referred to the percentage of participants who finished the entire intervention out of all those who agreed to participate. Based on previous studies [32], the feasibility threshold was set as follows: recruitment rate ≥80% and completion rate ≥75%.
- Usability: The usability of the app was assessed using the System Usability Scale [33]. The scale comprises 10 items; responses were scored on a 5-point Likert scale, and each item yielded a value between 0 and 4. The sum of all item scores is multiplied by 2.5 to produce a total score ranging from 0 to 100. If the total score is ≥70 [34], the usability of the app is considered to meet the standard. The Cronbach α value of the scale was 0.84, and in this study, it was 0.87.
- Use: Researchers collected users' use duration, the number of resource page visits, comments posted, and health consultations through the app's back-end management system.

The Preliminary Effectiveness of the App

Primary Outcome

Willingness to participate in breast cancer screening was assessed using items embedded within the general information questionnaire.

Secondary Outcomes

Breast Cancer Screening Knowledge

The Breast Cancer Screening Knowledge Scale [35] was used to assess participants' knowledge of breast cancer and screening. This instrument was developed based on the Chinese breast cancer screening guidelines and authoritative educational materials and has been publicly used in China [36,37]. This questionnaire comprises 17 items assessing knowledge across 3 domains: high-risk factors for breast cancer, clinical manifestations, and early screening methods. All items are presented as true or false statements. Each correct response earns 1 point, with no points awarded for incorrect answers. The total score ranges from 0 to 17 points, with higher scores indicating a higher level of knowledge about breast cancer and screening. The Cronbach α value of the scale was 0.72 [35], and the Cronbach α in this study was 0.82.

Breast Cancer Screening Health Belief

The Breast Cancer Screening Health Belief Scale [38], which was developed based on the HBM framework, was used to assess women's beliefs and attitudes toward breast cancer screening. The scale consists of 12 items, each scored on a 5-point Likert scale (ranging from 1 to 5). The scale comprised 4 dimensions: perceived susceptibility, perceived severity, perceived benefits, and perceived barriers. Total scores for each dimension ranged from 2 to 10 for perceived susceptibility, 3 to 15 for both perceived severity and perceived benefits, and 4 to 20 for perceived barriers. Higher scores indicated stronger health beliefs regarding breast cancer screening. The scale has been publicly used [39]. The Cronbach α value of the scale was 0.89 [38], and in this study, it was 0.70.

Self-Efficacy

The General Self-Efficacy Scale [40] was used to assess women's confidence in their ability to complete breast cancer

XSL•FO
RenderX

screening when faced with various challenges. The General Self-Efficacy Scale has been applied in patients with cancer and has demonstrated good reliability and validity [41]. The scale was translated and culturally adapted into Chinese by Wang [42]. It consists of 10 items, and responses to the questions were scored on a 4-point Likert scale. The total score ranges from 10 to 40 points, with higher scores indicating higher levels of self-efficacy. The Cronbach α value of the scale was 0.87, and in this study, it was 0.95.

User Experience and Improvement Suggestions for the App

The interview guide was developed based on the unified theory of acceptance and use of technology framework [43], prior usability and user experience studies of mobile health apps [44], and the specific objectives of this study. It was further refined through discussion among the research team and consultation with oncology and mobile health experts to ensure that the questions were clear, relevant, and aligned with the study goals. The interview guide included the following questions: What is your overall experience with the app? What benefits did you gain from using the app? Which aspects of the app do you believe need improvement? Would you recommend the app to others? Why?

Data Collection

After receiving standardized training, the research team members conducted data collection following unified instructions. Participants in both groups completed questionnaires at T0, T1, and T2, with each questionnaire taking approximately 10 - 15 minutes to complete. Data at T0 were collected through face-to-face paper questionnaires, while data at T1 and T2 were collected via telephone, electronic questionnaires, or face-to-face administration. After retrieving the questionnaires, researchers promptly checked the completeness and validity of the responses and conducted supplementary investigations when necessary. All collected data were anonymized, securely stored, and used solely for the purposes of this study. The research process strictly adhered to ethical principles, ensuring participants' voluntariness, confidentiality, and data security, while minimizing potential risks.

Feedback regarding the experience and improvement suggestions for the app were collected from participants in the intervention group through face-to-face or telephone interviews. The interviews were conducted by 2 researchers (LZ and MX) with 3 years of clinical experience in oncology and training in qualitative research. The data collection process was as follows: (1) the purpose and significance of the interview were explained to participants who had completed the intervention, written informed consent was obtained, and permission to record the interview was granted; and (2) the researchers conducted one-to-one, semistructured interviews while audio-recording each session. Each interview lasted approximately 20 - 30 minutes.

Data Analysis

Quantitative data were analyzed using SPSS software (version 27; IBM Corp). Descriptive statistics were used to summarize participants' sociodemographic characteristics, as well as the feasibility, usability, and use of the app, and the outcome variables of effectiveness at different time points. Continuous variables were presented as mean and SD, while categorical variables were presented as frequency and percentage. Differences in baseline characteristics between groups were examined using 2-tailed independent-samples *t* tests and chi-square statistics. In accordance with the intention-to-treat principle, generalized estimating equations (GEE) were used to compare changes in outcome variables between the control and intervention groups across time points. In the GEE analysis, missing data were handled using multiple imputation, and a sensitivity analysis was conducted to assess the robustness of results by comparing outcomes before and after handling missing data. The level of statistical significance was set at $P<.05$.

Qualitative data analysis was initiated following the first interview. Upon completion of each session, the interviewing researchers reviewed the audio recordings, performed verbatim transcription, and imported the transcripts into NVivo (version 12.0; QSR International) within 24 hours. Analysis was conducted following a coding-reliability thematic analysis approach to ensure transparency, objectivity, and reproducibility of the findings [45]. The research team repeatedly read all transcripts to become thoroughly familiar with the data and held meetings to discuss preliminary impressions, establishing a shared understanding to guide systematic coding. Based on the research questions, a structured initial codebook was developed, with each code assigned a clear name, operational definition, and inclusion or exclusion criteria. Two researchers (LZ and MX) independently applied this codebook to a randomly selected subset of transcripts for pilot coding. Intercoder reliability was assessed using both percentage agreement and Cohen κ (initial agreement=85%; κ=0.78). Discrepancies were discussed and resolved by referring to the original transcripts, and the codebook was revised and finalized for use in coding the full dataset. The finalized codebook was then applied independently to the remaining transcripts. Any novel or marginal data encountered during coding were documented for periodic review but did not modify the established coding framework. Once coding was complete, all coded data were exported, and the researchers examined the codes in relation to their frequency, patterns of co-occurring codes, and coverage within the dataset to identify potential themes. Each theme was then reviewed against the original transcripts to ensure that it accurately represented the data and was supported by sufficient evidence. Final themes were refined and clearly defined, with descriptive labels that accurately reflected the content of the data while avoiding overinterpretation. These descriptive themes directly addressed the research questions and provided reliable evidence. Data collection was concluded once the researchers determined that sufficient information power had been achieved. Additionally, both researchers selected representative quotations from the dataset and translated them into English. In cases of ambiguity during translation, the team consulted professional translation experts to ensure semantic accuracy and preserve the original intent of the participants' statements.

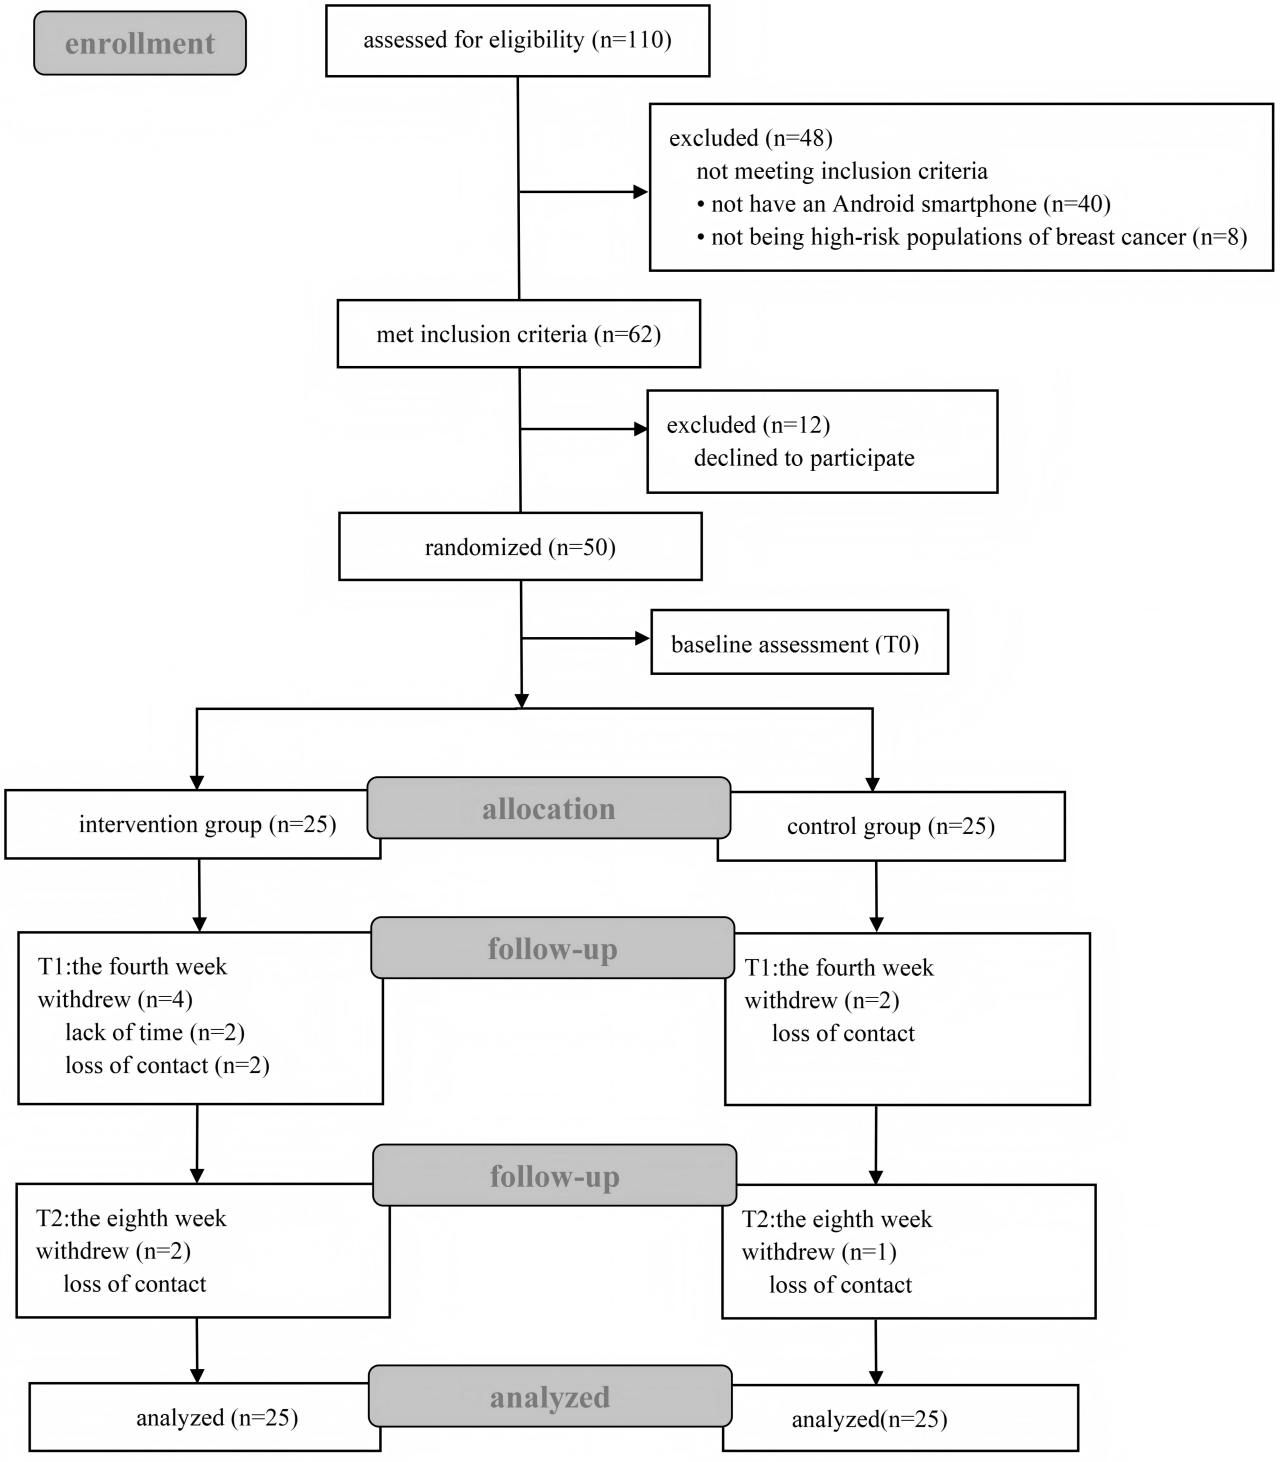
Ethical Considerations

This study received approval from the ethics committee of Xuzhou Mining Group General Hospital (approval 2025082501). All procedures performed were in accordance with the ethical principles of the Declaration of Helsinki. Written informed consent was obtained from all participants before randomization. Prior to the study, the research objectives and procedures were thoroughly explained to participants, and all inquiries were addressed. Participants were assured of the strict confidentiality of their personal information and were informed of their right to withdraw unconditionally at any time. As compensation for their time and contribution, each participant received a gift worth US $7.35 upon completion of data collection.



Results

Recruitment and Characteristics of the Participants

A total of 110 women were assessed for eligibility, with 62 meeting the inclusion criteria and 48 excluded due to not having an Android smartphone (n=40) or not being high-risk populations for breast cancer (n=8). Among the eligible participants, 12 declined to participate, resulting in 50 participants who were successfully enrolled and randomly assigned to either the intervention or control group. During follow-up, 6 participants in the intervention group withdrew due to lack of time or loss of contact, while 3 participants in the control group withdrew due to loss of contact. The recruitment flow and reasons for dropout are detailed in Figure 2. Baseline characteristics of participants in both groups are shown in Table 1, with no significant differences across measures, indicating comparability between groups.

Feasibility and Usability of the App

The feasibility of the app was illustrated by the CONSORT flowchart (Figure 2). The recruitment rate was 80.6% (50/62), and the completion rate was 76% (19/25).

The average total score on the System Usability Scale was 88.82 (SD 10.29), and the score of each item is shown in Table 2. Among the odd-numbered items on the scale, the highest score was for the item “I think that I would like to use this system frequently” (mean 3.89, SD 0.32), indicating the strongest agreement among participants with this statement. Among the even-numbered items, the lowest score was for the item “I think that I would need the support of a technical person to be able to use this system” (mean 3.05, SD 1.03), reflecting the highest level of disagreement among participants.

Table . The average score of the System Usability Scale (n=19).

Items	Mean (SD)
I thought that I would like to use this system frequently	3.89 (0.32)
I found the system unnecessarily complex	3.58 (0.61)
I thought the system was easy to use	3.74 (0.45)
I thought that I would need the support of a technical person to be able to use this system	3.05 (1.03)
I found the various functions in this system were well integrated	3.74 (0.45)
I thought there was too much inconsistency in this system	3.42 (0.51)
I would imagine that most people would learn to use this system very quickly	3.68 (0.58)
I found the system very cumbersome to use	3.47 (0.51)
I felt very confident using the system	3.74 (0.45)
I needed to learn a lot of things before I could get going with this system	3.21 (0.86)

During the intervention period, the app use of participants in the intervention group is shown in Table 3. The average app use duration was 2.03(SD 0.77) hours, the average number of resource page visits was 30.42 (SD 10.93), the average number of comments posted was 1.05 (SD 1.27), and the average number of health consultations was 0.89 (SD 0.99).

Preliminary Signals of Effectiveness

As shown in Table 4, the proportion of participants willing to participate in breast cancer screening increased from T0 to T1 in both groups, with a more pronounced increase in the intervention group. However, this proportion declined in the intervention group from T1 to T2. As shown in Table 5, GEE analysis indicated that at T1, participants in the intervention group tended to report higher willingness compared to those in the control group (odds ratio 4.889, 95% CI 1.343-17.801), while by T2, this difference was less pronounced (odds ratio 2.667, 95% CI 0.717-9.912).

[a]OR: odds ratio.

[b]T1: the fourth week.

[c]T2: the eighth week.

[d]β: regression coefficient.

Breast cancer screening knowledge scores increased from T0 to T1 in both groups, with a greater improvement observed in the intervention group. Although the intervention group's scores declined from T1 to T2, they remained above the baseline (Table 4). As shown in Table 5, GEE analysis indicated that knowledge scores in the intervention group tended to be higher than those in the control group at T1 (β=7.557, 95% CI 6.031-9.083) and T2 (β=5.813, 95% CI 4.055-7.570).

The intervention group showed increases from T0 to T1 in scores for perceived susceptibility, severity, and benefits. Although a slight decline occurred by T2, scores remained above baseline. Conversely, perceived barriers decreased at T1 before a slight rebound at T2. Throughout the study, scores in the control group showed minimal fluctuation (Table 4). Analysis of GEE indicated that changes in health belief scores across all dimensions tended to be greater in the intervention group compared with the control group (Table 5).

Regarding self-efficacy, scores in the intervention group increased from T0 to T1. Although a slight decline was observed at T2, they remained above baseline. Changes in the intervention group tended to be greater than those in the control group, which showed smaller fluctuations (Table 4). According to GEE analysis (Table 5), the improvement in self-efficacy in the intervention group was consistently greater than in the control group at both T1 (β=11.224, 95% CI 8.952-13.496) and T2 (β=8.206, 95% CI 5.598-10.813). Given the pilot and formative nature of this study, these findings should be interpreted as exploratory trends rather than conclusive evidence of effectiveness.

To evaluate the robustness of the findings to missing data, a sensitivity analysis was conducted by comparing the GEE results from the multiple imputed dataset with those obtained from the original dataset. Overall, the direction of the intervention effects was largely consistent across analyses, indicating that the findings were stable regardless of the method used to handle missing data. The detailed results of the sensitivity analysis are presented in Multimedia Appendix 2.

User Experience and Improvement Suggestions for the App

Overview

In total, 8 participants were interviewed. The participants ranged in age from 35 to 57 years (mean 45.38 years, SD 6.99), used the app for a total of 1 to 4 hours (mean 2.25 hours, SD 1.04), and interview duration ranged from 21 to 27 minutes (mean 23.75 minutes, SD 2.43). Detailed demographic and use characteristics are presented in Multimedia Appendix 3. Analysis of the interview transcripts initially generated 20 codes. Based on recurring patterns and relationships among the coded data, these codes were grouped into 4 subthemes, which were subsequently refined into 2 core themes: "perceived value and acceptability of the app" and "system limitations and user-centered improvement needs." The details are shown in Multimedia Appendix 4.

Theme 1: Perceived Value and Acceptability of the App

Participants provided positive feedback on the "Ruaikang" mobile health app, with its strengths and value summarized into 2 subthemes: hybrid approach to promote effectiveness and long-term or sustained use and significant health promotion effectiveness.

Hybrid Approach to Promote Effectiveness and Long-Term or Sustained Use

Participants reported that the app's content was professionally rigorous, clearly illustrated, and highly practical. Its information architecture was logically structured to cover the entire spectrum of breast health management, including disease awareness, prevention strategies, and daily self-management. They also reported that the app was simple and easy to use. The combination of high-quality content and user-friendly design enhanced participants' engagement with the app and fostered a strong willingness to continue using it. Furthermore, participants expressed a willingness to actively recommend the app to others, citing its professional content, practical utility, and ongoing updates. They viewed it as a valuable tool for educating friends and family about breast health and reducing anxiety, which further reinforced its potential for sustained use and wider dissemination.

> *The application provides comprehensive content, from disease awareness and prevention strategies to daily self-management strategies, eliminating the need to consult disparate online sources. This integrated approach offers considerable convenience. The detailed self-examination video facilitates effective self-screening at home, promoting earlier detection of potential issues. Furthermore, the user experience is very comfortable, with no unnecessary clutter, making all features readily accessible.* [S4]

> *People are paying more attention to self-care these days, and knowing about breast health is important for protection. The application provides professional, readily accessible information. I plan to use it often if it stays updated ... It is comprehensive and practical, useful for helping my mother and friends gain knowledge and reduce anxiety. I'll definitely recommend it.* [S2]

XSL•FO
RenderX

Significant Health Promotion Effectiveness

By providing professional content and practical features, the app contributed significantly to participants' breast health knowledge and awareness, while also supporting the development of healthier lifestyle habits.

> *The application taught me the warning signs for breast cancer and how to prevent it. It clearly explained the screening process, including when and how to get checked, which was so valuable. Thanks to the self-examination guide, I now check myself every week. It makes me feel much more secure.* [S5]

> *Now I make more mindful, healthier choices, like buying more of the recommended vegetables when shopping for groceries, controlling my dinner portions, and sticking to my daily health tracking. It's all helping me build solid habits.* [S8]

Theme 2: System Limitations and User-Centered Improvement Needs

Participants identified limitations in the "Ruaikang" mobile health app pertaining to its functionality, content, and user interaction and proposed constructive optimizations. This theme can be summarized into 2 subthemes: lack of active engagement and interactions and functional and content-related limitations.

Lack of Active Engagement and Interactions

Participants identified several issues related to active engagement and interaction within the app. They proposed adding an AI-powered question-and-answer system or chatbot to facilitate timely communication and support. Participants also recommended incorporating a check-in incentive mechanism to enhance user engagement. In addition, they highlighted the absence of a platform for user-to-user communication and suggested creating a community forum to facilitate discussion and experience sharing.

> *I would like to see AI-powered features added, such as an instant Q&A system or a chatbot ... Additionally, incorporating incentives into the Health Center, for example, rewarding users with a free consultation upon completing a health plan, would further boost engagement and support self-management.* [S3]

> *The interactive center lacks a section for users to discuss issues, and users cannot view others' shared experiences or respond to questions. I hope to see an interactive space where people can talk about problems they encounter and learn how others have solved them.* [S6]

Functional and Content-Related Limitations

Participants highlighted several limitations related to the app's interface and content. They noted ambiguous section boundaries, difficulty locating desired information, a lack of direct access to frequently used content, and highly repetitive visual elements, which reduced usability and visual comfort. Participants recommended optimizing page layouts, improving content organization, providing quicker access to commonly used information, and enhancing design diversity to improve the user experience. Regarding content presentation, participants reported that locating key information within videos was time-consuming and suggested providing concise summaries, such as text descriptions, slide decks, or flowcharts, to facilitate information retrieval and comprehension. Participants also perceived limitations in the existing content, particularly within the health center, and expressed a need for more detailed explanations of specialized topics, such as breast cancer staging, symptoms, and policy-related information. In addition, they emphasized the importance of regularly updating content to ensure that information remains current and relevant.

> *The dietary recommendations are buried within a broad category and lack a direct access point. Creating a more visible shortcut for such frequently used content would save significant time ... It would be helpful to summarize the key points from the video into a separate format, like a flowchart or a slide deck, to distill the core content for quick comprehension.* [S5]

> *Regarding breast cancer staging, I hope to see clearer explanations for each stage's definition, symptoms, and management approaches. The current symptom illustrations are only in cartoon form, I recommend adding realistic image options to make the content more comprehensive and meet diverse needs.* [S4.]

Discussion

Principal Findings

"Ruaikang" as a pioneering mobile health app designed specifically to promote early screening behaviors among high-risk populations for breast cancer demonstrated good feasibility and usability in this study. Preliminary findings suggested trends toward improvements in participants' willingness to participate in breast cancer screening, screening knowledge, health beliefs, and self-efficacy, although these results should be interpreted cautiously, given the exploratory, formative nature of the pilot study. Qualitative analysis further suggested that participants perceived its strengths in content expertise, user-friendly operation, practical functionality, and health promotion impact. However, it also identified areas for improvement in functional optimization, user interaction, and content presentation, which can inform subsequent refinement and development.

In this study, the recruitment rate reached 80.6% (50/62), and the completion rate was 76% (19/25), exceeding the feasibility thresholds for mobile health apps (recruitment rate ≥80% and completion rate ≥75%) [32], indicating that "Ruaikang" demonstrates strong feasibility among high-risk populations for breast cancer. High engagement levels not only confirm that the app's core functions effectively align with the health needs of the target group [46] but also reflect the potential of mobile health tools in early breast cancer prevention [47]. Moreover, qualitative findings corroborate these results, as participants reported the app's content to be practical and its features relevant to their needs. When conducting large-scale randomized controlled trials in the future, participation and completion rates can be further enhanced through optimizing recruitment

XSL•FO
RenderX

strategies [32], establishing strategies to support sustained engagement [48], and others.

The usability score of "Ruaikang" was 88.82 (SD 10.29), which is similar to the score (83.20) reported for the mobile health app developed by Rezaee et al [49], indicating that "Ruaikang" demonstrates good usability. Participants reported that the app was easy to operate, intuitive, and usable without professional guidance. These findings were further supported by use data and qualitative feedback, which together indicated active engagement and ease of navigation, reflecting strong learnability and user-friendliness. Several factors may explain this high level of usability. First, "Ruaikang" was specifically developed for high-risk populations for breast cancer, allowing the content to closely align with their unique needs, concerns, and risk perceptions. Prior studies have emphasized that tailoring health information to a defined target group is a key determinant of usability and engagement, as users are more likely to interact with information they perceive as personally relevant [50]. Second, the structured and comprehensive design of the app integrates educational content, self-management guidance, and practical tools in a logical and accessible manner, reducing the need to seek information from multiple sources and thereby enhancing convenience. Systematic reviews of mobile health usability note that clear organization and efficient information flow are central to perceived usability, as they reduce cognitive load and support efficient task completion [51]. Finally, the inclusion of multimedia resources, such as videos and images, improves clarity and engagement, providing a more interactive and motivating learning experience than text-based apps. Empirical studies suggest that multimedia elements can enhance understanding and make complex health information easier to process, which in turn supports sustained interaction with mobile health tools [52]. These features likely contributed to participants' strong engagement and willingness to use the app frequently, suggesting that tailored content, structured design, and interactive elements can significantly enhance the usability of mobile health interventions targeting high-risk populations for breast cancer. Nevertheless, the relatively high feasibility and usability observed in this study may be partly attributable to the recruitment of participants from a single tertiary hospital, all of whom owned and regularly used smartphones. Such participants likely possessed higher digital literacy and greater familiarity with mobile technologies, which facilitated their engagement with the app and led to more positive evaluations [53].

This study provides preliminary signals of improvement in willingness to participate in breast cancer screening, screening knowledge, health beliefs, and self-efficacy among high-risk populations for breast cancer, as supported by both quantitative and qualitative findings. These results are consistent with a systematic review of Salman et al [47], which evaluated mobile health apps in cancer screening and reported potential effects on screening participation and health outcomes. Importantly, several key outcome scores declined at the follow-up (T2) assessment, suggesting that the initial gains were not fully sustained. This pattern is consistent with prior research on mobile health interventions, which has shown that benefits often peak immediately after the intervention and may diminish over time without ongoing support, highlighting the potential importance of sustained engagement for maintaining behavior change [54]. In addition, the relatively wide CIs further limit the precision of these estimates and should be considered when interpreting the observed trends. Qualitative insights suggest that the decline in engagement and outcome scores at T2 may be interpreted as reflecting participants' need for more interactive and dynamically updated content, as well as motivational elements. These findings may highlight the need for strategies that extend beyond short-term initiation to promote continued engagement and behavior reinforcement. Future iterations of the app could incorporate more interactive and updated content, gamification mechanisms, personalized reminders, and theory-driven features to strengthen long-term engagement and maintenance of screening-related behaviors. Importantly, the primary outcome of this study was willingness to participate in screening, which reflects behavioral intention rather than actual screening uptake. However, these findings should be interpreted as hypothesis-generating rather than confirmatory, given the pilot nature of the trial. Future studies with larger samples and longer follow-up periods using fully powered randomized controlled trial designs are warranted to confirm these findings.

In addition to recognizing the app's strengths, participants also identified several areas for improvement, including functional and interaction features, interface and content presentation, and the depth and frequency of content updates. These comments do not negate that the app meets the core needs of high-risk populations for breast cancer and instead reflect users' expectations for greater convenience, enhanced interactivity, and content relevance in real-world use. The low frequency of interactive feature use may be related to inconspicuous entry points, delayed feedback, and limited opportunities for peer interaction. Consistent with research on mobile health interventions, users prefer features that facilitate active engagement and meaningful interaction, which are critical for sustained use [44]. Navigation and content presentation issues suggest a misalignment between the app's linear, chapter-based knowledge structure and the fragmented, problem-focused use patterns of high-risk populations for breast cancer. Research on user-centered design for breast cancer-related apps has highlighted that clear navigation tools and well-organized content are key factors influencing usability and engagement [55]. Feedback regarding content depth and update frequency further indicates that users expect information to be directly relevant to their health status and screening decisions, as well as updated promptly to reflect the latest evidence and guidelines. Overall, these improvement suggestions emphasize the importance of usability, interactivity, and content relevance for high-risk populations for breast cancer, pointing to future optimization strategies such as enhancing interactive features, reorganizing information architecture for rapid access, and increasing content update frequency, thereby strengthening user engagement and the overall value of the app.

Limitations

This study has several limitations. First, the small sample size from one hospital inherent in this pilot study limits the ability to draw definitive conclusions, and the preliminary effectiveness

XSL•FO
RenderX

findings should therefore be interpreted as hypothesis-generating rather than confirmatory. Second, the enrolled high-risk populations for breast cancer in this study did not encompass individuals with genetic susceptibility or a history of chest radiotherapy. Subsequent studies should incorporate these groups to improve the generalizability of the results. Third, willingness to participate in screening was selected as the primary outcome, which represents behavioral intention rather than actual screening uptake. Future multicenter randomized controlled trials with longer follow-up periods are warranted to further evaluate the preliminary findings and to determine whether improvements in screening willingness translate into actual screening participation. Finally, the app was developed only for Android devices, which may limit the generalizability of feasibility and usability findings to iPhone users.

Implications and Future Work

This pilot study demonstrates that the "Ruaikang" mobile health app exhibits good feasibility and usability among high-risk populations for breast cancer, providing preliminary signals of potential effectiveness in supporting health-related beliefs. The app is well-aligned with users' core needs and may contribute to improvements in screening intention, although these effects should be interpreted cautiously, given the exploratory nature of the study. "Ruaikang" could serve as a key bridge connecting health care resources with high-risk populations for breast cancer. Through continuous refinement of health intervention strategies, it may facilitate broader adoption of early screening practices, alleviate the public health burden of breast cancer among Chinese women, and enhance their sense of health empowerment and overall well-being.

In future work, the research team will systematically refine the app's core features, user interaction, content depth, and presentation based on feedback collected during the pilot phase. A larger-scale, multicenter randomized controlled trial with an expanded sample covering diverse geographic regions will be conducted to further validate these preliminary findings. In addition, a long-term follow-up mechanism will be established to monitor the sustainability of screening behaviors and changes in early detection rates, thereby generating longitudinal evidence to support the app's continued development and broader implementation.

Conclusions

This study demonstrated that the "Ruaikang" mobile health app is feasible and usable and provides preliminary signals of potential effectiveness for high-risk populations for breast cancer. The app may contribute to enhancing awareness and supporting willingness to participate in breast cancer screening among this population. Future research will optimize the app based on participant feedback and conduct studies with larger samples and longer follow-up periods to further examine the sustainability and potential impact on screening behaviors among high-risk populations for breast cancer.

Acknowledgments

The authors appreciate all women who agreed to participate in the study. The authors confirm that no generative AI or AI-assisted tools were used in any part of the manuscript's writing, analysis, or figure preparation.

Funding

This study was supported by the National Science and Technology Innovation 2030, Noncommunicable Chronic Diseases-National Science and Technology Major Project (grants 2024ZD0524300 and 2024ZD0524305), and the National Natural Science Foundation of China (grant 72204209).

Abstract

Background: Heart failure (HF) is a major health care challenge in the United States, with approximately 900,000 older adults hospitalized annually. Gaps in self-management, including unrecognized worsening symptoms and failure to adhere to dietary sodium restriction, can reduce quality of life and precipitate hospital admissions. Existing mobile health approaches to HF self-management have produced mixed results, highlighting the need for innovative strategies to improve postdischarge outcomes in at-risk patients.

Objective: The ManageHF trial aimed to evaluate the effectiveness of 2 just-in-time adaptive interventions delivered via a mobile app to enhance HF self-management. The interventions focused on symptom recognition and lower dietary sodium restriction, with the goal of reducing readmissions and improving health-related quality of life (HRQOL) over a 12-week period.

Methods: The trial was a 2×2 factorial, double-blind, randomized controlled study conducted across several US institutions. Participants recently hospitalized for acute HF were randomized into 4 groups: both interventions, either intervention alone, or an active control. The primary outcome was a composite measure assessing time to all-cause death, time to first HF readmission, and HRQOL changes, using the Minnesota Living with HF Questionnaire.

Results: Recruitment was hindered by the COVID-19 pandemic, leading to the early discontinuation of the trial. Of the 62 participants enrolled, 43 completed the study. Participants were diverse, with a mean age of 55 (SD 14.4) years, 32% (20/62) were female, and 55% (34/62) identified as Black or African American. Most had HF with reduced ejection fraction. However, due to the early termination and small sample size, the ability to detect statistically significant differences was limited.

Conclusions: The ManageHF trial highlighted the potential of mobile health technology to support HF management, particularly in enhancing HRQOL. Future studies using more effective recruitment and retention strategies are crucial for establishing the efficacy of these interventions with greater certainty.

Introduction

Heart failure (HF) is the leading hospital discharge diagnosis among older adults in the United States, affecting 1.2 million patients in 2021 [1]. Roughly 20% of these patients are readmitted within 30 days, and half are readmitted within 6 months [2-8]. HF readmissions represent significant and potentially avoidable costs, with hospitalizations accounting for nearly 70% of annual HF costs [4]. Approximately one-third of patients who survive an HF hospitalization die within a year [9]. Many US hospitals have established quality improvement teams focused on 4 key domains: enhancing patient education, increasing the use of evidence-based therapies, ensuring timely postdischarge follow-up, and improving communication between inpatient and outpatient care providers [10,11]. However, despite these initiatives, results have been mixed, with recent improvements in readmission rates possibly attributable to changes in risk coding rather than actual outcomes [12,13]. Both crude and risk-adjusted 30-day mortality rates for HF have increased, indicating a need for new approaches to improve postdischarge outcomes [14,15].

Challenges with HF self-management, including failure to recognize clinical worsening and nonadherence to dietary sodium restrictions [2-6], are primary drivers of readmissions. Studies suggested that better dietary adherence, early help-seeking, and adequate medical support could prevent 23% to 31% of readmissions [3], reducing the 30-day readmission rate from approximately 20% to roughly 13.8% to 15.4%.

Self-monitoring has been shown to improve health-related quality of life (HRQOL) in patients with HF [16,17]. In a prospective single-center study, a web application designed to promote self-regulation was tested over 12 weeks, yielding positive outcomes for chronic HF symptoms [18]. Participants, predominantly older adults with New York Heart Association class II or III symptoms, used the application daily. Improvements were observed in the New York Heart Association classification and the Minnesota Living with HF Questionnaire (MLHFQ) scores, with notable numerical improvements in weight, exercise frequency, walking distance, jugular venous distension, and peripheral edema.

Dietary nonadherence, particularly excess dietary sodium intake, is a frequent precursor to HF decompensation and hospitalization [2-6]. Chronic neurohormonal activation and reduced renal perfusion in patients with HF promote sodium and fluid retention. Historically, guidelines have advocated a dietary sodium restriction of 2000 to 3000 mg/d [19,20], and current HF guidelines recommend avoiding “excessive” sodium intake [21]. In the Study of Dietary Intervention under 100 mmol in HF trial, aggressive sodium restriction did not reduce clinical outcomes. Still, it was associated with improved HRQOL [22] in stable outpatients with HF. The baseline sodium intake in the Study of Dietary Intervention under 100 mmol in HF was approximately 30% less than in US patients hospitalized for HF [23], who could derive more significant benefits from low-sodium dietary interventions [24].

The ManageHF trial aimed to evaluate the effectiveness of 2 just-in-time adaptive interventions (JITAIs) within a mobile app. These interventions targeted the two leading causes of hospital readmissions: (1) failure to recognize clinical worsening and (2) dietary nonadherence to lower-sodium food options. The study assessed the impact of JITAIs directed at HF symptoms and diet on mortality, hospital readmissions, and HRQOL over 12 weeks, hypothesizing that each intervention would yield reductions in mortality and readmissions, as well as improvements in HRQOL, as measured by the MLHFQ.

Methods

General Design

ManageHF was a 2 × 2 factorial, double-blind, randomized, controlled, multicenter clinical trial to determine the efficacy of JITAIs using a mobile app that focused on self-management and dietary support, either together or separately, compared with a control. Participants and study personnel were blinded to participant group assignment throughout the study. These interventions build upon previous work done by the research team [18,25,26]. The University of Michigan was the lead site, along with investigators at Henry Ford Health System, Virginia Commonwealth University, University of North Carolina, Washington University, University of Alabama at Birmingham, and Emory University. Eligible participants were randomized in a 1:1:1:1 manner to 4 conditions and stratified by site, gender, and HF type (HF with reduced ejection fraction vs HF with preserved ejection fraction). The four conditions were (1) diet and clinical worsening interventions (both), (2) diet intervention only, (3) clinical worsening intervention only, and (4) active control (neither intervention). All enrolled participants were asked to self-monitor with the mobile app, which included a daily survey, a blood pressure cuff, a scale, and a wearable activity monitor (3 devices provided to participants by Withings). The study protocol was updated throughout the study to reflect changes in the study workflow and updates to participant eligibility criteria. A full description of all protocol changes can be found in Multimedia Appendix 1. Advarra acted as the single institutional review board and approved this study. The trial was registered at ClinicalTrials.gov (NCT04755816; March 19, 2021) and was funded by the National Institute on Aging (R01AG062582).

Study Participants

To participate in the study, individuals had to provide informed consent and meet the following criteria: be aged 18 years or older, hospitalized or recently hospitalized (within 14 d) for acute or acute-on-chronic decompensated HF, and fulfill specific heart function requirements, either left ventricular ejection fraction less than or equal to 40% or left ventricular ejection fraction greater than 40% with elevated B-type natriuretic peptide or N-terminal pro-B-type natriuretic peptide levels adjusted for BMI. Additional criteria included having a personal physician for follow-up, a compatible smartphone for the ManageHF app, a valid email address, being fluent in English, and providing signed informed consent. Participants were excluded if there was a contraindication to recommending a sodium-restricted diet; planned intervention for primary valvular heart disease during the study period; cardiac resynchronization therapy; on dialysis; previous cardiac transplantation or

XSL•FO
RenderX

implantation of a ventricular assistance device or implantation expected within 3 months after randomization; cardiac or noncardiac illness with expected survival less than 3 months based on clinical judgment; listed status 1, 2, or 3 for a heart transplant; discharged to a setting other than their home; requirement for chronic inotropic therapy; inability to use Withings devices (weight scale, blood pressure monitor, and watch) due to equipment limitations or contraindications; or were currently pregnant or intended to become pregnant during the study period.

Potential participants were identified from current HF admissions at the enrollment site. The study teams were responsible for identifying eligible participants using inclusion and exclusion criteria. A potential participant was approached by a study team member to obtain consent before enrollment. Once enrolled, participants completed baseline questionnaires and surveys, created accounts with both Withings and ManageHF, and downloaded the ManageHF app.

Intervention

The University of Michigan developed a mobile app named ManageHF, which was studied in this clinical trial. The app featured 2 novel JITAIs activated based on randomization. The mobile app aimed to facilitate self-management and behavioral change by providing participants with real-time, contextual feedback and support. This approach aimed to leverage adaptive technologies and personalized interventions to improve participants' health outcomes and dietary habits.

The clinical worsening intervention focused on enhancing self-monitoring and self-management skills [27]. It used a health status indicator that adapted to users' reported symptoms and provided feedback. The health status indicator was presented in a speedometer-like graphic that ranges from green (good health) to red (poor health) based on the answers to daily app questionnaires. Participants received 2 push notifications per day if they were in the yellow zone (fair health) and 3 per day if they were in the red zone, until they returned to the green zone. These notifications are linked to in-app educational resources to promote self-management behaviors. Personalization involved a baseline survey adapted from the Self-Care in HF Index [28] that gauged the user's confidence and past behaviors in managing symptoms. These data helped tailor the messages for each user, using their name, emojis, and appropriate times of day to engage them effectively.

The dietary sodium intervention was designed to help users make lower-sodium choices by sending contextual messages linked to tailored in-app content [26]. The intervention notified the user when they were in a grocery store or restaurant. The Universal Product Code (UPC) in grocery stores helps to view tailored dietary information from the store, helping them identify and select lower-sodium options. Personalization was based on a confidence survey and a sodium intake screener, which asked users to identify their high-sodium foods and lower-sodium alternatives. Push notifications were purposely framed to align with the user's confidence and dietary habits.

Both JITAIs relied on NumberEight, an internet-based service that uses various sensors to predict the user's location. The NumberEight algorithm ran on the device, and data from these sensors were anonymized to ensure participant privacy and stored securely when the app was active. The study staff did not have access to participants' location data.

Outcomes

The primary outcome was a hierarchical composite of time to all-cause death, time to first HF readmission, and change from baseline to week 12 in the MLHFQ using the win ratio [29]. Death from any cause occurring during the study period was reported by each site. HF readmission was defined as admission to an inpatient unit or a stay in the emergency department following discharge after the index hospitalization, resulting in at least a 12-hour stay [30]. Only admissions associated with events that occur on an emergency or unplanned basis were considered potential end points and adjudicated. An HF readmission must have clinical manifestation of new dyspnea, orthopnea, paroxysmal nocturnal dyspnea, edema, pulmonary basilar rales or crackles, jugular venous distension, renal hypoperfusion with no other apparent cause, or radiological evidence of acute HF, and additional increased treatment with either intravenous HF medications (diuretics, inotropes, and vasodilators) or mechanical or surgical intervention directed explicitly at the treatment of HF. Only readmissions during the study period were assessed.

The MLHFQ tool comprises 21 questions that assess patients' perceptions of the effects of HF on their daily lives [31]. The questions produce a total score ranging from 0 to 105, with higher scores indicating poorer HRQOL. The MLHFQ was collected at baseline, 6 weeks, and 12 weeks. A score change of 5 or more was considered a clinically significant difference for the hierarchical composite end point.

Nutritional questionnaires were used to assess the participants' nutritional status and sodium intake. The Food Frequency Questionnaire (FFQ), collected at baseline, 6 weeks, and 12 weeks, was used to measure sodium intake. The 110-item Block FFQ (NutritionQuest, LLC) was electronically self-administered to record commonly consumed foods and estimate nutrient and energy intake.

Statistical Approach

The primary outcome was a composite of death, HF readmission, and change in quality of life using the win ratio method, which incorporates a hierarchy of clinical prioritization on event occurrence. The win ratio was chosen to prioritize outcomes in a patient-focused fashion using a composite end point. Following the Finkelstein and Schoenfeld unmatched pairs win ratio method [32], each participant receiving the intervention was compared to each who did not receive the intervention, resulting in pairwise comparisons [29,33]. Within each pairing, the participant with the longest survival time is counted as the "winner" of that pairing. The win ratio is the number of winners divided by the number of losers associated with the intervention. Ties were excluded. The estimate of the win ratio and its 95% CI were calculated using bootstrap methods. The test for intervention effect is a nonparametric rank sum test. A win ratio of 1 indicates that both comparison groups have equivalent outcomes in terms of events and quality of life. In contrast, a

XSL•FO
RenderX

win ratio greater than 1 indicates that the intervention group has a favorable profile compared to the control group, while a ratio less than 1 indicates an unfavorable profile. Using the intention-to-treat approach, the primary outcome was compared between each intervention and control. Based on standard 2 × 2 factorial designs, the clinical worsening intervention included those randomized to both the interventions and the clinical worsening-only conditions. The dietary sodium intervention included those randomized to both interventions and the dietary sodium–only conditions. The control for each intervention was the 2 remaining groups of the 4 randomized conditions.

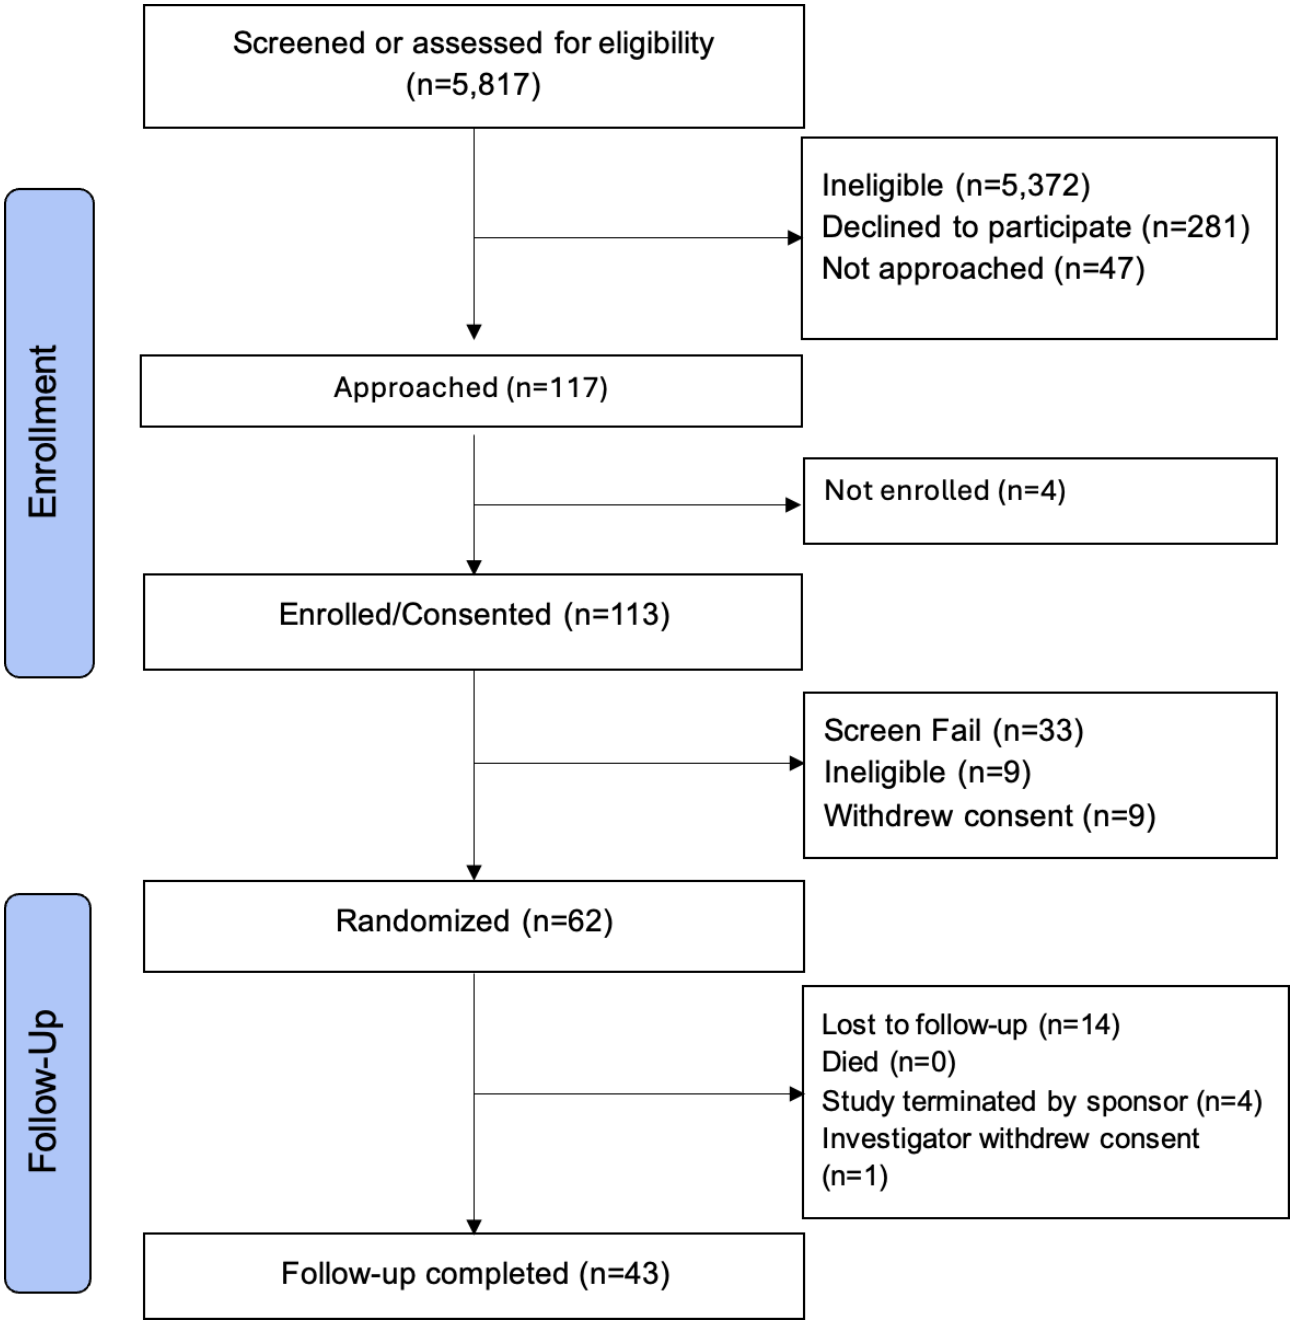
The win ratio for the hierarchical end-point was estimated from our pilot study, where the win ratio was 1.33 in favor of the intervention group [27], meaning that people who received the intervention would be 33% more likely to experience favorable outcomes compared to the group not given the intervention. Assuming 10% dropout, 500 randomized participants (250 per main intervention arm) would provide 80% power to show a win ratio of 1.30 (56.6% winners in the intervention group excluding ties), assuming a 2-sided 5% type I error rate [29,32,33]. After accounting for dropout, 225 participants per arm would produce 50,400 (225 × 224) permutations of paired comparisons. The same reasoning was used to determine the power and sample size necessary to analyze the dietary sodium intervention. We did not design the study for sufficient power to detect an interaction effect of both interventions relative to the control.

For secondary end-points, each intervention versus control was examined in terms of individual components of the composite outcome using survival methods for time-to-event outcomes and linear mixed-effects models or piecewise linear regression for longitudinal continuous outcomes (eg, MLHFQ). Days alive and out of hospital (DAOH) were analyzed using Poisson regression. SAS (Statistical Analysis System; version 9.4; SAS Institute Inc) was used for all statistical analyses. Data are also presented in mean and SD for continuous variables normally distributed and median and IQR for those not normally distributed. Categorical variables are presented as a percentage of the total in that group. For completeness, outcome variables are presented across all 4 randomized conditions.

Ethical Considerations

Advarra acted as the single institutional review board and approved this study (Pro00046349). Participants signed an informed consent document before participation in the clinical trial. After the study was completed, the data were deidentified for analysis and eventual release into a repository. Participants were compensated with US $200 for their time spent completing study-related tasks, and all participants were allowed to keep the devices provided during enrollment in the study. The reporting of the trial follows the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) guidelines (Checklist 1).

Results



Overview

The clinical trial was funded in April 2020, and enrollment began in June 2021. In February 2023, the Data and Safety Monitoring Board recommended discontinuing the clinical trial due to concerns regarding recruitment and retention. A total of 62 participants were randomized, but 43 completed follow-up. As requested by the funding agency, the National Institute on Aging, 19 participants were contacted in February 2023 to discontinue their participation in the study. This paper reports the trial's results up until that point. Figure 1 shows the CONSORT (Consolidated Standards of Reporting Trials) diagram for this trial.

The mean age of participants was 55 (SD 14.4) years. Among the 62 participants, 32% (n=20) were female and 55% (n=34) identified as Black or African American. Most participants (n=48, 77%) were diagnosed with HF with reduced ejection fraction, and 40% (n=25) expressed class III symptoms. They had an average time from HF diagnosis of 2.9 (SD 4.56) years. Upon enrollment, 73% (n=45) were taking an aldosterone antagonist, and 48% (n=30) were taking an SGLT2 inhibitor. Table 1 demonstrates the baseline demographics overall and for each study group.

[k]FFQ: Food Frequency Questionnaire.

Participant Engagement

Regardless of subgroup, all participants were asked to engage with the ManageHF app survey and use remote device monitoring on a daily basis for the 84-day study. Of the 62 participants enrolled in the clinical trial, 66.1% (41/62) completed at least one app survey. Among the 41 participants who completed at least 1 survey, the median was 22 (IQR 2-47) days. The wearable device was used by 78.5% (47/62) of participants. The median number of days using the device was 74 (IQR 39-84). Blood pressure was measured by 78.5% (47/62) of participants. Participants measured blood pressure on a median of 35 (IQR 15-51) days.

Clinical Worsening Intervention

The hierarchical analysis of the overall primary end point showed a numerically larger number of wins in the clinical worsening intervention compared to the control group (346/960, 36% vs 200/960, 20.8%; win ratio 1.73, 95% CI 0.81 - 4.44; *P*=.18). Both individual outcomes of time to HF readmission and change in MLHFQ demonstrated a larger number of wins in the clinical worsening intervention compared to the control group (HF readmissions: 201/960, 20.9% vs 109/960, 11.4%; MLHFQ: 145/960, 15.1% vs 91/960, 9.5%). Table 2 summarizes the hierarchical analysis of the primary end point in participants randomized to the clinical worsening intervention versus control. There were no deaths in the clinical trial. HF readmission was 13.3% (4/30) in the clinical worsening intervention and 21.8% (7/32) in the control group (hazard ratio 0.56, 95% CI 0.16-1.90; *P*=.35). From baseline to 12 weeks, the MLHFQ improved by a mean of 42 (SD 28) points in the clinical worsening intervention and by a mean of 29 (SD 28) points in the control group (*P*=.21). The mean number of DAOH was 83 (SD 22.45) in the clinical worsening group and 84 (SD 22.65) in the control group (*P*=.7).

Out of the 30 participants in the clinical worsening intervention group, 16 received 1066 push notifications during the study period, classified as yellow or red. Throughout the study, these participants received a median of 24 (IQR 6-70) push notifications.

Table . Hierarchical end point and win ratio for both interventions[ab].

Outcome	Clinical worsening intervention wins, n (%)	Clinical worsening control wins, n (%)	Ties, n (%)	Dietary sodium intervention wins, n (%)	Dietary sodium control wins, n (%)	Ties, n (%)
Time to all-cause death	0 (0)	0 (0)	—[c]	0 (0)	0 (0)	—
Time to heart failure readmission	201 (20.9)	109 (11.4)	—	136 (14.9)	156 (17.1)	—
Change in MLHFQ[d] from baseline to 12 week	145 (15.1)	91 (9.5)	—	147 (16.1)	61 (6.7)	—
Overall (across 3 outcomes)	346 (36)	200 (20.8)	414 (43.1)	283 (31)	217 (23.8)	412 (45.2)

[a]Clinical worsening intervention versus control: win ratio 1.73 (95% CI 0.81–4.44); *P*=.18.

[b]Dietary sodium intervention vs control: win ratio 1.30 (95% CI 0.57–3.26); *P*=.53.

[c]—: not applicable.

[d]MLHFQ: Minnesota Living with Heart Failure Questionnaire.

Dietary Sodium Intervention

The hierarchical analysis of the primary end point, as shown in Table 2, demonstrated a numerically larger number of wins in the dietary sodium intervention compared with the control group (283/912, 31% vs 217/912, 23.8%; win ratio 1.30, 95% CI 0.57 - 3.26; *P*=.53). The change in MLHFQ showed a larger number of wins in the dietary sodium intervention compared to the control group (147/912, 16.1% vs 61/912, 6.7%). From baseline to 12 weeks, the MLHFQ improved by 39 (SD 34) points in the dietary sodium intervention and by 24 (SD 25) points in the control group (*P*=.17). In contrast, the dietary sodium intervention group had a numerically smaller number of wins than the control group in terms of the outcome time to HF readmission (136/912, 14.9% vs 156/912, 17.1%). HF readmission was 18.4% (7/38) in the dietary sodium intervention and 16.7% (4/24) in the control group (hazard ratio 1.10, 95% CI 0.32-3.74; *P*=.88). By FFQ at 12 weeks, sodium intake was 2359 (SD 2770) mg in the intervention and 2142 (SD 1671) mg in the control group (n=32; *P*=.23). By sodium screener at 12 weeks, sodium intake was 2122 (SD 1280) mg in the intervention and 2390 (SD 796) mg in the control group (n=30; *P*=.89). The mean number of DAOH was 86 (SD 18.49) in the dietary sodium intervention and 82 (SD 21.96) in the control group (*P*=.16).

Of the 38 participants in the dietary intervention group, 23 received 786 notifications at grocery stores or restaurants. Throughout the study, these participants received a median of 10 (IQR 2-41) push notifications.

Both Interventions

Across all 4 conditions, 18 participants were randomized to both interventions, 12 to the clinical worsening intervention only, 20 to the dietary sodium intervention only, and 12 to neither intervention. HF readmission was 11.1% (2/18) for those randomized to both interventions, 16.7% (2/12) in the clinical worsening only group, 25% (5/20) in the dietary sodium only group, and 16.7% (2/12) for those in neither intervention. The change in MLHFQ showed a 47 (SD 28) point improvement for those in both interventions, a 31 (SD 29) for those in the clinical worsening only group, a 34 (SD 38) point improvement in the dietary sodium only group, and a 19 (SD 22) point improvement for those assigned to neither intervention. There were no statistically significant differences between these 4 conditions.

Discussion

This study was a novel trial of 2 JITAIs delivered via a mobile app, using push notifications and in-app content, at 2 critical time points in HF self-care: when a patient feels worse and when dietary sodium support is needed when entering grocery stores and restaurants. Although the primary end-point showed a trend in both intervention groups relative to control, it did not reach statistical significance and was substantially underpowered due to early stopping. The early discontinuation of the trial resulted in a smaller-than-planned sample size (62 participants, of whom only 43 completed follow-up). This limited the statistical power to detect significant differences between the intervention and control groups. The reduced number of participants limits the generalizability of the findings and is an important limitation of this study. This trial demonstrates innovative methods that, unfortunately, were implemented during a global pandemic that significantly hindered clinical research.

Several mobile app–based interventions for HF [34-36] and sodium intake [37-39] have been studied. While several of these studies implement self-monitoring to drive self-management in HF, none provide a JITAI using several factors to personalize the intervention for success. The ManageHF app provides self-care push notifications and in-app educational content when patients are experiencing worsening symptoms. The self-care push notifications were personalized to the self-care methods the participant had found effective in the past. A bank of over 50 push notifications paired with detailed in-app educational content was used for this intervention. Push notifications and in-app content did include information about guideline-directed medical therapy, medication adherence, and loop diuretic efficacy. The ManageHF app did not directly provide

XSL•FO
RenderX

information about adding or titrating guideline-directed medical therapy. The lack of medication optimization is one of the most critical interventions in HF to reduce hospitalizations, and digital health interventions in this area are essential [40].

In a recent systematic review of mobile health interventions aimed at reducing sodium intake, only 6 were randomized controlled clinical trials [38]. Of those trials, only 2 were mobile app interventions published in English. One of those apps is SaltSwitch, which originates from New Zealand [37]. SaltSwitch was designed to help users locate food products with low sodium levels at grocery stores. However, the SaltSwitch app does not personalize recommendations based on the user's specific requirements for high-sodium foods. Additionally, it lacks features such as push notifications to remind users to scan items and does not provide contextual food information for restaurants. SaltSwitch has not been studied in HF to date. Two quasi-experimental dietary intervention studies were conducted in patients with HF, and neither involved mobile apps. One was a game-based interactive tool for self-management [41], and another was an SMS text messaging intervention [42]. Neither study assessed clinical outcomes.

The National Institute on Aging funded this trial in April 2020, 1 month after the United States declared a nationwide public health emergency, and the same month, more than 1 million cases of COVID-19 were confirmed worldwide. Multiple funding agencies issued statements to researchers regarding collaboration during this challenging period to facilitate research [43,44]. Due to the COVID-19 pandemic, significant challenges arose in all research areas [45]. Many of our sites saw unprecedented issues with access to their health care facilities, and resources for research were impacted. All study sites experienced research closures, which were site-specific, meaning that at any given time, only some of our research sites were recruiting participants. There were also participant-level challenges in recruiting patients with HF. During the COVID-19 pandemic, HF hospitalizations declined significantly [45-47], resulting in [46-48] a smaller patient pool to recruit from and a lower-than-expected HF readmission rate for our clinical trial. Potential participants may have been less likely to enroll due to societal or individual pandemic-related circumstances. Additionally, participants who did enroll were less likely to visit restaurants and grocery stores during the pandemic, which is a limitation of this trial.

Demographic diversity is a crucial discussion point in clinical trials [49], particularly in those discontinued by the Data and Safety Monitoring Board due to low recruitment. Black participants represented 55% (34/62) of the enrolled population in this study, compared to less than 10% in other recent randomized trials enrolling patients with HF [50-53]. Recruiting and enrolling diverse patients in clinical trials is vital, but it requires additional staff resources and time. We have shown that enrolling diverse participants from a federally qualified health center required 1.4 times the full-time equivalent staff compared to a less diverse university hospital setting [54]. This is even more important in mobile health–related clinical trials, where interventions can exacerbate inequities [55].

An important aspect of this clinical trial is the inclusion of an active control. All participants received a blood pressure cuff, a scale, and a wearable activity monitor and were asked to self-monitor using the mobile app, which included a daily survey. This was done to fulfill the third aim of the research grant, which was to determine if passive preclinical measurements from these devices could predict symptoms of worsening HF. Using an active control can reduce the chance of detecting a statistically significant outcome. An active control can also add rigor to the trial because it biases the results toward showing no difference between the groups. This should be accounted for in the clinical trial statistical power assessment and is a limitation of this study.

Despite pandemic-related recruitment challenges, the ManageHF study successfully engaged a diverse cohort of high-risk patients with HF in self-management activities. Future studies using more effective recruitment and retention strategies are crucial for establishing the efficacy of these interventions with greater certainty.

Abstract

Background: There is an urgent and critical need to support the mental health of health care providers, given high rates of stress and burnout. Although the issues are complex, digital access to information and support can help address the needs, as technology can facilitate on-demand links to private, customized resources, including peer support. Beyond Silence (McMaster University) is an evidence-informed mobile health platform co-designed with health care workers and grounded in prior evidence that mental health literacy and peer support can reduce stigma and facilitate earlier help-seeking.

Objective: This study aimed to (1) explore how health care workers across diverse health care settings use the app and (2) identify opportunities and barriers to implementation.

Methods: A multiple-case study framework, informed by the Consolidated Framework for Implementation Research (CFIR), was applied to capture 4 months of implementation across a purposive sample of 7 diverse Canadian health care organizations. Implementation within each organization was led by designated organizational champions who leveraged existing communication channels and standardized promotional materials to invite employees to voluntarily download and use the app. Implementation outcomes were assessed using app analytics (downloads and feature use) and semistructured baseline and follow-up interviews with organizational champions to explore contextual influences on uptake.

Results: Approximately 1066 employees downloaded the app over the 4-month period, ranging from <2% to >45% of employees across the 7 organizations. Interviews with 28 organizational champions noted that there was good leadership support for the technology, aligning with their mission to address employee mental health. Barriers to use, however, included workplace culture surrounding mental health and help-seeking, lack of awareness about when and how to use the app, and infrastructure-related challenges, such as limited time and a lack of private spaces to download and use the technology.

Conclusions: Effective implementation is a precondition for positive outcomes; therefore, strategies are needed to optimize technology implementation. Recommendations include evaluating organizational readiness, building mental health literacy, creating a multimodal communication and implementation plan, addressing technology requirements, and embedding the technology into organizational policies and practices. This study highlights key challenges in the implementation of the Beyond Silence peer support platform for health care workers, including slow adoption linked to mental health stigma, competing demands, and limited frontline engagement. Addressing these barriers will require innovative, trust-building strategies to support meaningful uptake and sustained use.

Trial Registration: ClinicalTrials.gov NCT05514093; https://clinicaltrials.gov/study/NCT05514093

implementation science; mental health; technology; workplace; mhealth; mobile health

Introduction

The mental health of health care providers demands immediate and sustained support. Health care workers experience elevated rates of stress and burnout, which have been exacerbated by the COVID-19 pandemic [1]. Sustained psychological burden and high workloads have led to a high rate of workforce attrition, leading to a human resource crisis that may take years to resolve [2]. Issues facing health care workers are complex and can range from high workloads to exposure to workplace violence and/or potentially traumatic situations [1]. For example, many clinicians feel isolated and unsupported by their workplace [3,4].

XSL•FO
RenderX

A growing body of literature underlines the value of peer support for health care workers in mitigating the impact of stress and posttraumatic stress disorders (PTSD) [5,6]. Peers understand the unique context of health care work and can therefore be a trusted source of support. Access to peer support, however, can be challenging in some workplace contexts, particularly if there is a negative workplace culture or resource and time pressures that make it difficult to reach out. E–mental health interventions are gaining recognition as a strategy to enable mental health support across different contexts, including the workplace [7]. Mobile technology can provide accessible, on-demand information and links to support and has the potential to reach a wide range of users, including those in underresourced settings [7,8]. Access to peer support via mobile technology can also be a cost-effective first-line approach and conduit for professional support within a stepped model of care [9].

Evidence for the effectiveness of mobile health (mHealth) apps has been noted through systematic reviews and meta-analyses, including evidence for reducing symptoms related to common mental health disorders such as anxiety and depression both in the general population and clinical populations [8,10]. In addition to studies in the general population, there are a growing number of studies examining the impact of digital mental health interventions in workplace settings [11]. One systematic review and meta-analysis of mHealth apps implemented in workplace settings found mixed evidence for improving mental health symptoms with poor sustainability of the effects over time [12]. An umbrella review was published in 2025 of 14 systematic literature reviews of the effectiveness of digital mental health interventions in the workplace (9 systematic reviews and 5 meta-analyses) [13]. The review noted growing evidence of the small to moderate impact of digital tools on reducing depression, anxiety, and perceived stress.

Although these studies highlight the potential of mHealth apps, outcomes remain variable across and within studies, and gaps persist in our understanding of implementation over time and across contexts [13]. A review of eHealth interventions for health care professionals, for example, highlighted inconsistencies in outcomes and limited implementation data [14]. Implementation science frameworks such as the Nonadoption, Abandonment, Scale-up, Spread, and Sustainability (NASSS) model of health and care technology highlight the challenges associated with consistent and sustained engagement with mHealth technology, grounded in an appreciation of the various complexities of implementation [15]. The Consolidated Framework for Implementation Research (CFIR) also notes the importance of understanding different domains of implementation, considering how the context and process of implementation shape adoption [16]. There remains a need not only to assess the impact of technologies but also to understand the factors influencing uptake and implementation, and how these evolve over time. It is not enough to understand whether an app is designed well; it is important to systematically explore how it is adopted in a real-world context [7,8,12]. This study aimed to (1) examine the adoption of Beyond Silence (McMaster University), an mHealth peer support platform designed by and for health care employees across 7 diverse Canadian health care organizations, and (2) identify and describe perceived organizational facilitators and barriers to its implementation both within and across these settings.

Methods

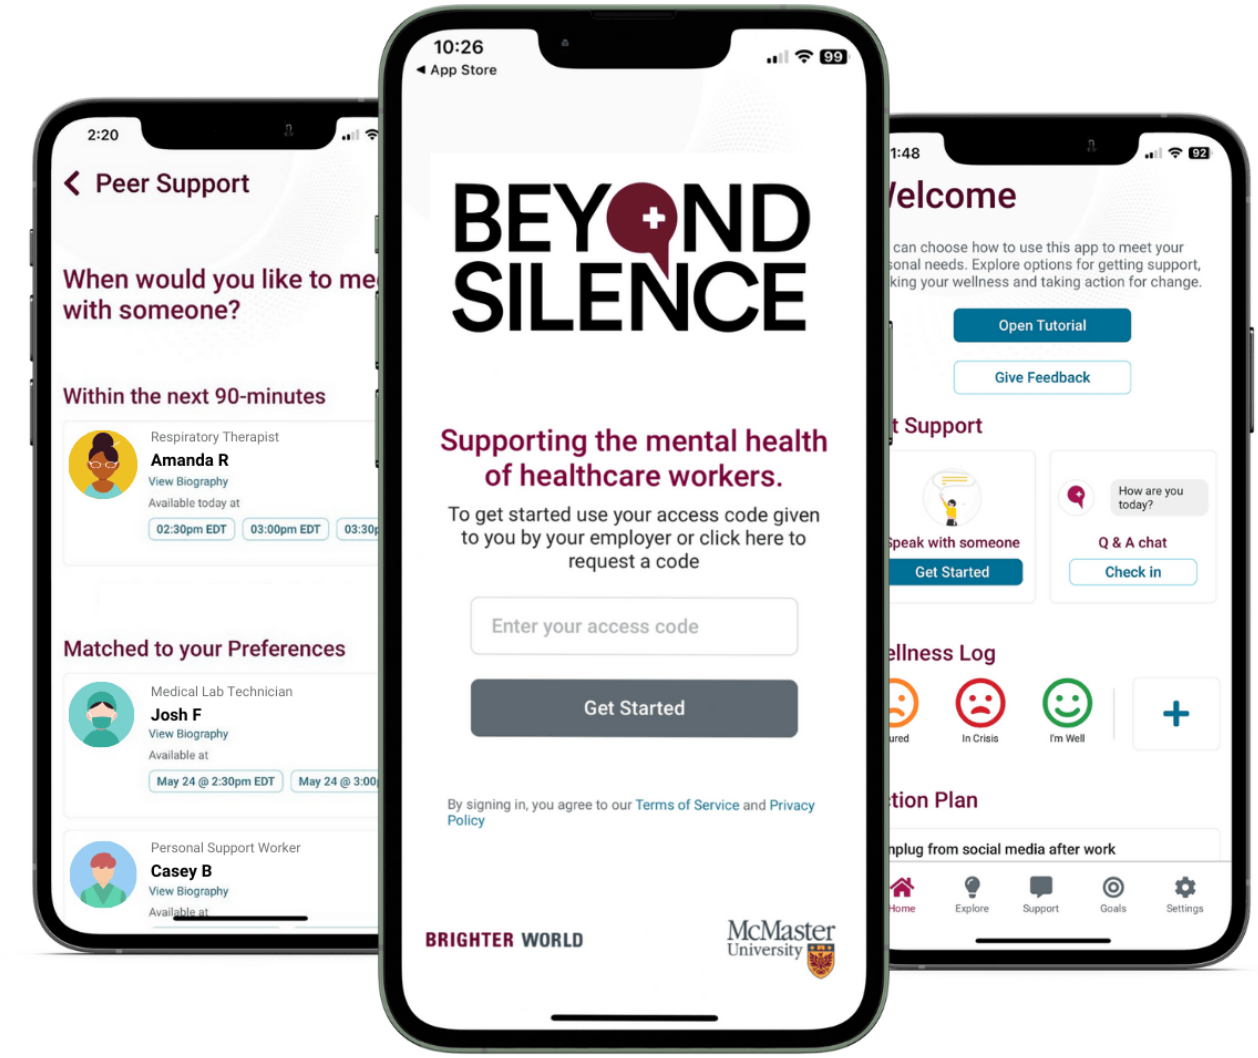
Study Design

A mixed methods implementation case study design [17] was adopted to explore implementation and uptake of the Beyond Silence platform across 7 health care organizations. A case study approach provides an effective way to study contemporary phenomena within a real-life context, particularly when it is difficult to separate the case from the context and can lead to new explanations that consider the complexities of place and time [18]. Exploring multiple case study sites enabled cross-case comparison across different workplace contexts. A multistage mixed methods framework was adopted, starting with qualitative interviews to explore the perceptions of organizational champions regarding the context for app implementation [19]. This was followed by the collection of quantitative app usage data. Finally, follow-up interviews were conducted with the organizational champions, during which they were asked about the individual and contextual forces that shaped trends in app usage within the workplace context [20]. Data collection and analysis were informed by CFIR, one of the most commonly used frameworks to assess contextual factors affecting real-world implementation [21].

Ethical Considerations

Ethics approval was obtained through the Hamilton Integrated Research Ethics Board (HiREB number 14740), and all participants provided written consent to participate. In order to maintain privacy and confidentiality, the names of participating organizations and organizational champions are disguised. All app usage data are reported in aggregate; app users were anonymous. Organizational champions received a CAD $100 (US $70.95 as of July 24, 2026) gift card honorarium for participating in each champion interview. Peer supporters in each organization were not paid for their role; however, external peer support providers were provided a stipend of $55 per 3-hour shift. Peer support providers who participated in the focus group discussions were invited to enter a draw for one of 2 CAD $50 (US $36.50) gift cards of their choice.

An advisory team provided input throughout the project, including 4 academic leaders in workplace mental health, mHealth technology, and trauma-informed care, and 6 knowledge user partners representing national associations of nurses, personal support workers (PSWs), social workers, and long-term care workers, a national mental health service provider, and a provincial health and safety association. The team met 3 - 4 times a year to provide input at key stages in the project and to facilitate communication within their extensive networks.



Intervention

Beyond Silence (see Figure 1) is a digital platform (including a mobile app for frontline health care workers and an organizational portal for peer supporters and organizational champions) designed to provide accessible, anonymous, and peer-led mental health support to Canadian health care workers.

XSL•FO
RenderX

It builds on a decade of successful research collaborations with health care stakeholders to identify and address their unique mental health and support needs [19,20]. Development was informed by findings from a randomized controlled trial of an in-person workplace mental health training program with over 200 health care workers [21]. The in-person training was effective but resource-intensive and not accessible to all workers; therefore, an mHealth platform was explored as an alternative approach.

Figure 1. Screenshots of the Beyond Silence mobile app for frontline workers.

Development of the Beyond Silence platform (2017 - 2019) was supported by a Canadian Institute of Health Research (CIHR) development grant, and informed by the Knowledge-to-Action Framework, a structured approach for knowledge creation and a 7-phase cycle that moves knowledge into practice [22]. In addition, best practice principles of mHealth design were considered, including engagement (customization and interactivity), functionality (ease of use), aesthetics, information quality, and data security [23]. Additional funding (2022 - 2024) from the Public Health Agency of Canada (PHAC) allowed for additional app enhancements. Core functionalities of the app for frontline workers include (1) access to evidence-informed information customized for health care workers (articles, infographics, video, and audio clips) on a range of topics from mindfulness to moral injury; (2) links to self-management tools, including a wellness toolbox, wellness check-ins, and goal-setting feature; and (3) private, secure links via text or phone to a range of health care providers trained to offer peer support. App users can browse the biographies of the available peer supporters within and outside their organization, choose how they want to connect (phone or text), click on who they want to connect, and the time at which they want to connect (either within the next 90 minutes or at a scheduled time that their preferred peer is available). A notification is then sent to the identified peer regarding the anonymous request for support and a secure, private connection is made through the app for the health care worker seeking support.

In addition to the app for frontline health care workers, the platform includes an interconnected web-based portal for trained peer support providers to respond to requests for support. The online portal provides space for peer supporters to upload their pictures and short biographies (visible to the app users), as well as sign up for 3-hour shifts, respond to peer support requests (by text or phone), record digital notes on their encounters, access resources to support their work (eg, crisis protocols and contact details for relevant resources), and connect with a clinical supervisor and/or other peer supporters. Although the

XSL•FO
RenderX

peer support providers were visible to frontline app users, the person accessing support was anonymous (digital ID number). A total of 156 health care professionals were trained to offer peer support in the app over the course of the study, including 88 from participating organizations and 68 central peer supporters who were external to the participating organizations and accessible to all. Details of the peer support training are reported in a separate paper [24].

The Beyond Silence platform also included an administrative portal where organizational champions could upload local resources, manage their internal peer support provider list, send notifications, and track overall patterns of app use. It is important to note that the app was available through app stores, but an organizational code was required to download the app, since the app is customized for each organization (including local resources and peer support access). As noted above, there was an onboarding process for the participating organizations and peer supporters, which included training on risk management and data security protocols.

Organization Recruitment

Health care organizations were recruited through established networks of the project advisory team. Interested organizations were asked to complete an application form to assist in screening for diversity across size, geographic location, workplace setting, and type of health care service. To be eligible to participate, organizations required: (1) a project agreement letter signed by organizational leaders, (2) at least one organizational champion designated to liaise with the research team, and (3) at least 2 - 3 internal staff members who agreed to be trained peer support providers (numbers varied based on size and resources available within the organization).

The goal was to recruit 6 - 8 organizations to explore how implementation varied across workplace contexts. Purposive sampling was conducted to ensure diversity in size (small/medium/large), geographical location, setting (rural/remote and urban), type of service (long-term care, acute care, tertiary care, and primary care), and at least 1 organization where employees spoke French (since the app is available in both French and English). A total of 22 organizations expressed interest in the study; however, 14 of these organizations did not have the capacity to participate. For organizations that declined to participate, the primary reason for declining was documented (typically due to limited resources to support the app implementation and evaluation).

Implementation setting and scope A champion-led, organization-embedded implementation strategy was used to introduce Beyond Silence within each participating organization. Champions were individuals representing participating organizations who approached us to be involved in the study. They were responsible for liaising with the research team, communicating about the app to employees, and acting as the contact point for any questions or concerns among staff. Each site designated one or more organizational champions to serve as local implementation leads and primary points of contact.

Champions represented a range of organizational roles, including senior leaders, health and safety coordinators, and frontline clinicians, including 20 women and 6 men in both clinical (n=13) and nonclinical (n=13) positions. As noted in Table 1, there were typically 1 - 3 champions in each organization who agreed to communicate with employees about the app and to be interviewed about their insights at the outset and conclusion of the project. One large multisite organization had 11 champions volunteer to participate in the study.

6. Large urban hospital	12,463	November 2023-March 2024	12	19
7. National health service	5000	February 2024-June 2024	4	36
Total (all organizations)	32,753	November 2022-June 2024	27	88

[a]PSW: personal support worker.

The target population for implementation was determined by each organization based on local capacity and readiness. Most included all employees, but 3 organizations chose a specific subgroup (Organization 1–nurses, Organization 2A–laboratory technicians, and Organization 4–PSWs). Recruitment relied on existing organizational communication channels and included distribution of standardized promotional materials (posters, email scripts, brochures, and branded materials) containing information about the app, a QR code for download, and a unique organizational access code. Employees were invited to voluntarily download and use the app for the implementation period.

Implementation included organizational onboarding, app deployment to frontline staff, and integration of trained peer support providers accessible through the platform. Uptake, engagement, and variability were tracked across organizational contexts over a 4-month period. Guided by an implementation framework (CFIR), contextual factors, resource requirements, and implementation processes were examined to inform scalability and sustainability.

Data Collection and Outcomes

Data collection focused on prespecified implementation outcomes and used a mixed methods approach combining app usage analytics and qualitative interviews with organizational champions. Evaluation focused on reach, adoption, implementation, and patterns of use rather than effectiveness or health impact.

Quantitative implementation metrics were assessed using real-time, aggregate app analytics captured through the administrative portal. App users remained anonymous and were identified only through a unique user ID. Metrics were selected to characterize adoption and engagement and included the number and proportion of employees who downloaded the app, the number of times the app was opened, mean number of app opens per user, and frequency of use of key features, including content views, goals set, wellness check-ins, and peer support appointments booked. Additional descriptive data captured peer support outreach modality (text or call) and choice of peer supporter. App use data were examined monthly within each organization to describe trends over the 4-month implementation period and to support cross-case comparison; inferential analyses were not conducted.

An update to the app occurred during which onboarding questions were added, asking app users to respond to optional demographic questions regarding age, gender, years of professional experience, and health care role (clinical/nonclinical). Given the timing of this change, only 5 of the 7 organizations included this demographic data. As such, demographic data were not collected or reported for organizations 1, 2A, 2B, and 3.

The study is registered on ClinicalTrials.gov (NCT05514093) as an implementation and evaluation study of a mHealth intervention designed to support the mental health of health care workers in Canada. However, while multiple mental health outcome measures (including standardized pre-post surveys of depression, anxiety, PTSD, burnout, and help-seeking behavior) were included in the study protocol, survey response rates at follow-up were too low to permit meaningful quantitative analysis. As a result, the mental health survey data are not reported, and no conclusions can be drawn regarding changes in mental health outcomes based on these measures.

XSL•FO
RenderX

Qualitative Implementation Data

Qualitative data were collected to explore contextual factors influencing implementation. Interviews with the organizational champions included baseline interviews conducted prior to app implementation (n=19 interviews with 27 individuals) and follow-up interviews conducted at least 3 - 4 months following implementation (n=18 interviews with 26 individuals). Interviews were conducted virtually, audio-recorded, and transcribed verbatim, with durations of approximately 60 - 90 minutes. Some champions were interviewed individually, but others were interviewed in pairs or groups of 3. Interview guides with the champions were informed by the five dimensions of the CFIR, including questions exploring (1) perceptions of the intervention (characteristics of the app), (2) the outer setting (eg, societal context and policies), (3) the inner setting (eg, organizational culture and access to resources), (4) individuals (role of leaders, peer supporters, and characteristics of frontline workers), and (5) the implementation process [16]. Specific questions within each domain were developed using the CFIR interview guide tool. Since organizational champions were embedded within the organization, their insights enabled identification of critical factors that shaped uptake of the technology.

No predetermined numerical targets for adoption or engagement were specified. Given the exploratory nature of the implementation and the lack of established benchmarks for uptake of this type of workplace mental health and peer support app in comparable health care settings, the study aimed to descriptively characterize implementation outcomes and variability across organizations rather than assess performance against predefined thresholds.

Analysis

Descriptive data regarding app use included monthly reporting within each organization to examine trends in downloads and use of the different features. Cross-case comparisons were also conducted to review similarities and differences in usage patterns across organizations, but inferential statistics were not calculated.

Organizational champion interview data were transcribed and coded, with initial coding categories informed by the CFIR. Coding was an iterative process that began with reviewing transcripts, categorizing them by the 5 CFIR domains (deductively), and then inductively identifying the key issues within each domain. At least 2 team members coded each transcript, initially coding 2 - 3 transcripts independently, then meeting together to compare codes and refine the codebook to ensure consistency. A series of team meetings was held to discuss emerging analytic ideas and revise the codebook to capture key facilitators or barriers to implementation across organizational contexts. Strength and valence ratings of the key forces within each organization were conducted in order to facilitate cross-case comparison [24]. Identification of key forces represented comments across multiple organizations, with quotes selected to illustrate, considering representation across all participants. Dedoose (SocioCultural Research Consultants, LLC) software [25] was used to manage the qualitative interview data. The qualitative data were used to explain the app use trends and facilitate actionable insights to optimize implementation.

Strategies to ensure methodological rigor included triangulation of data sources (app use metrics and interviews with multiple champions over different time points in each organization). Triangulation strengthened in-depth understanding of the organizational context and implementation forces within and across organizations that shaped app use, leading to data saturation across categories and understanding of the contextual forces shaping objective patterns of app use. In order to ensure coding consistency, biweekly meetings were held with the research team to review the coding and to engage in peer debriefing. Meetings between coders were scheduled to calibrate approaches and refine definitions in the codebook until there was at least 85% coding consistency. Reflexive analysis was strengthened through analytic memos that were discussed in the peer debriefing meetings. CFIR was used as a sensitizing framework, but the iterative, inductive analysis process led to nuanced understanding of the key issues shared by participants. Member checking was conducted through sharing preliminary analyses with champions via draft organizational reports, then exploring their reflections on the analysis in follow-up interviews.

Results

Overview

The study findings are presented in three parts: (1) an overview of the participating organizations and app users, (2) descriptive metrics regarding patterns of app use, and (3) qualitative analysis of champion interview data regarding factors shaping app use (informed by the CFIR framework), considering the social and organizational context (outer and inner setting), response to the app innovation, influence of organizational stakeholders, and impact of the implementation strategies.

Participating Organizations

A total of 7 diverse health care organizations participated in the study, joining at different time points. As outlined in Table 1, 2 of the organizations were large (over 10,000 employees), and one was small (n=55 employees). Organization 2 was a large professional association that engaged in the study at different time points, initially with a subgroup of workers (2A/2B) and then later as the full organization (2C). Their participants were members of the association (paying membership dues), rather than employees, and the app was offered as a member benefit. Organizations 1 and 4 chose to focus on a subgroup of health care providers within the organization (nurses and PSWs, respectively), but other organizations provided access to all employees (clinical and nonclinical). Organizations 3, 6, and 7 were multisite facilities, and organizations 1 and 4 provided community care with no on-site services. The number of champions and peer supporters varied across sites. As such, there were various implementation contexts for implementation. The app for frontline workers was made available to a total of 32,753 health care workers across these organizations.

Demographic data were collected from app users in organizations 2C, 4, 5, 6, and 7 via onboarding demographic

XSL•FO
RenderX

questions that were added in June 2023. As noted in Table 2, app users in these organizations (n=840) included 77% (n=650) who identified as women, 21% (n=173) as men, and 2% (n=17) as nonbinary or chose not to disclose. Just over half of participants were between the ages of 30 and 49 (n=458, 55%) years. In terms of professional experience, 41% (n=348) had ≥16 years, followed by 15% (n=129) with 6 - 10 years. Most participants held clinical roles (n=505, 60%), while 24% (n=205) were nonclinical.

Table . Characteristics of app users (in organizations 2C, 4, 5, 6, and 7).

Characteristic	Participants
Age (years), n (%)	
18 - 29	103 (12)
30 - 39	217 (26)
40 - 49	241 (29)
50 - 59	204 (24)
60 - 69	47 (6)
Undisclosed	28 (3)
Gender, n (%)

6 - 10	219 (15)
11 - 15	114 (14)
≥16	348 (41)
Undisclosed	40 (5)
Role, n (%)	
Clinical	505 (60)
Nonclinical	205 (24)
Undisclosed	130 (16)

App Engagement Metrics

A total of 1066 employees downloaded the app across all organizations over the 4-month implementation trial. As noted in Table 3, the number and proportion of downloads within each organization ranged from <2% (n=108) in the largest organization to >45% (n=25) in the smallest organization. The mean download rate across organizations was approximately 11.6% (SD 15.2) of employees, but the overall downloads represented only 3% of the total number of eligible participants.

XSL•FO

7	266 (5)	704	2.65	140 (20)	39 (6)	95 (13)	21
Total	1066 (3.24)	3127	—[a]	779	201	492	94
Average, mean (SD)	11.6 (15.2)	—	3.22	111	29	70	10

[a]Not applicable.

User engagement, measured by app opens and feature use, also varied across organizations. As noted in Table 3, the app was opened 3127 times over the course of the study, ranging from a total of 85 opens (45% of employees) in the smallest organization (Organization 5) to 1324 opens (4% of employees) in the second largest organization (Organization 6). Each downloaded app was opened a mean of 3.22 times (range from 2.1 to 4.9).

Given the sample size, normal approximation methods were used to calculate 95% CIs for proportions. A total of 309 app users viewed at least one content item, representing 30% of users (95% CI 27.2% - 32.9%). When viewing the content, users could provide a rating from 1 to 3 stars. There were 105 user-submitted content ratings, with a mean rating of 2.58 (SD 0.68) out of 3, corresponding to 86% of the maximum possible score. The most frequently accessed content by app users was an article titled “6 Mindfulness Exercises,” which received more than twice as many views (n=92) as the next most accessed item (n=35).

Engagement with other app features included (1) wellness check-ins initiated by 25% of app users (95% CI 22.3% - 27.7%), representing between 10% and 22% of the app openings; (2) goal setting initiated by 13% of app users (95% CI 11.0% - 15.2%); and (3) peer support outreach was accessed 94 times (56 calls and 38 texts) by 40 unique app users, with a wide range from 0 (in the smallest organization) to 49 (in the largest organization). Appointments were booked with 38 different peer support providers.

Analysis of Forces Shaping App Engagement

Overview

Data from 19 baseline and 18 follow-up interviews with organizational champions (n=37 in total) informed the analysis of factors shaping patterns of app use. Informed by dimensions of the CFIR framework (outer/external context, inner/organizational context, the app innovation, the individuals’ role/characteristics, and the implementation process), we will highlight key facilitators and barriers to engagement noted by the organizational champions, followed by an in-depth analysis of implementation strategies within and across organizations. See Table 4 for a summary of the findings organized by the CFIR dimensions. Participant quotations to illustrate each issue are identified by their organizational affiliation.

XSL•FO
RenderX

Table . Summary of facilitators and barriers to app use.

CFIR dimension	Facilitator	Barrier
Outer context	• High mental health needs as a result of system/pandemic pressures	• High fatigue, burnout, and mistrust of new initiatives as a result of system/pandemic pressures
Inner context	• Alignment with organizational mission to support staff • Complements other wellness initiatives	• Stigma associated with the need for mental health support • Culture of skepticism/mistrust • Not able to use phones at work • Unstable internet • No time or private space to call
Innovation characteristics	• Easy to use, accessible, relevant content, choice re: when/how to access support, anonymous and private connection to support	• Time needed to download
Individual roles and characteristics	• Commitment from organization champions and leaders • Trained peer supporters (local and external)	• Health care worker reluctance to reach out for support • Limited digital literacy
Implementation process	• In-person connections • Leadership endorsement • Messaging from trusted organization champions • Ongoing, strategic communication	• Passive promotion (email and posters) not engaging • In-person events don't reach everyone (shift work and offsite) • Employer-endorsed approach can be met with suspicion • Lack of proactive follow-up • Lack of integration with other wellness initiatives

Opportunities and Facilitators to Uptake

One consistent finding was that the external context of health care has created the need for mental health support. Many champions talked about the unique challenges and pressures faced by frontline health care workers. Even though the work context ranged from acute hospitals to community rehabilitation, and from large urban centers to small rural settings, almost all champions described challenges related to workload that were exacerbated by the COVID-19 pandemic, and how this elevated the level of fatigue and staff burnout. As one champion explained, "right now, we're seeing levels of burnout and a bit of jadedness that's come from being in this grind of the pandemic for quite a long time" (Organization 2). Similarly, another champion noted, "Health care is still reeling [from] the effects of COVID…there are staffing pressures and fatigue," underlining the urgent need for support, explaining that "the building is burning as we're trying to build the new fire station" (Organization 6). As a result, organizations were acutely aware of the significant pressures on staff members and the urgent need to support their frontline workers.

Introducing a tool like the Beyond Silence platform also aligned with the inner context or mission of most participating organizations to support employee mental health. Organizational planning in all organizations included a key focus on employee mental health and included support from the organizational leadership team. Champions explained that the app for frontline workers complemented existing wellness strategies, noting that peer support and digital tools were complementary or even natural extensions of their ongoing psychological health and mental wellness efforts. As noted below, one champion explained that the app was a catalyst for innovation and expansion of their wellness services:

> *It came at a very good time because our psychological health and wellness initiatives were occurring. And actually, having the app helped us broaden the people involved in our peer support efforts…. it also gave us momentum to do some creative things* [Organization 3]

There were also many characteristics of the app that were valued. Participants valued the relevance of the content, with customization to the unique context of health care. It was noted that the app was "easy to use... helpful, interesting articles, appropriate… relevant" (Organization 1). One of the participants explained:

> *the fact that it's geared specifically for health care providers, I think was really important for us. Anytime we're looking at providing a new product or service to our members, making sure that… it's very specific to their role. And so that was really appealing* [Organization 2]

Participants talked about the value of the portability of the app since employees could carry their phones with them as a "one-stop shop" (Organization 7) for information and support that they can access at any time. In terms of features, some talked about how they preferred to access the online resources; others liked the wellness check as a quick and easy tool to track

XSL•FO
RenderX

change over time. It was noted that the opportunity to text, as opposed to phoning someone, was important.

> *I definitely can see why the chat function would probably be-- it's easy, accessible. People chat a lot now as opposed to picking up a phone. Like, we're not as much a phone culture as we used to be.* [Organization 6]

Another valued feature was the opportunity to access anonymous, private connections to information and peer support.

> *There's anonymity there. You can go and talk to someone, look at resources, set goals for yourself that nobody else is privy to. You can listen to what you want to help build your pocket of resilience* [Organization 7]

In addition, several participants talked about the value of being able to browse the biographies of the peer support providers and choose whom and when to reach out. Overall, the opportunity to choose when and how to use the app features was noted as a benefit.

The final key facilitator relates to the characteristics and roles of individuals in the organization (champions, leaders, and peer supporters). In particular, many of the organizational champions played an active role in reaching out to their colleagues to promote the app, adopting a range of contextually relevant communication approaches. Several champions also noted the important role of supportive leaders:

> *I think those types of [supportive] messages coming from leaders carry a lot of weight, you know, and especially around sensitive topics, such as mental health and self-care.* [Organization 1]

In addition to the leaders, access to a network of trained peer support providers both within and outside the organization was noted to play a key role in facilitating engagement. This was particularly relevant for employees who did not have access to other supports. One organizational champion explained that not everyone has access to employee assistance programs (EAPs) and not all of them feel safe going to EAP. "And some of our lowest-paid workers, because they're part-time and casual, don't have access to EAP. The very people who need it the most" (Organization 4). The app for frontline workers therefore provided an opportunity to link with a trusted peer who had an understanding of their unique situation, filling an important gap in workplace supports.

Challenges or Barriers to Engagement

Despite the recognized need for mental health support and the potential for the Beyond Silence platform to meet this need, we heard about a number of barriers to adoption of the technology, many of which were related to the inner organizational context. These included cultural factors, such as workplace attitudes toward mental health and help-seeking, and structural challenges, including availability of time and space to download and use the app.

The workplace culture was identified as a challenge in many organizations in terms of trust and openness to seeking support. In some cases, we heard that there was a culture of stoicism and an expectation to manage the stress of the work.

> *Based on some preliminary conversations that I've had with our nursing group is that they … are more inclined to, kind of assume sort of a stoicism, like, you know, "This is sort of part of the job, part of the role. … and it is the responsibility of those that are in this role to be able to deal with that.* [Organization 1]

As outlined, many health care workers internalize the belief that their role is to provide support rather than seek it. This self-perception can hinder both the recognition and acknowledgment of personal mental health needs. Participants described a tendency among staff to often "avoid or ignore symptoms" (Organization 2A) and may not recognize a situation when the app might be valuable. Persistent stigma surrounding mental health further compounded this challenge, serving as a barrier to reaching out.

In addition to stigma, participants talked about skepticism and lack of trust, which interfered with uptake of any initiative or reaching out to others. Some explained how trust has been broken in the aftermath of COVID-19, and/or how people are tired and don't see how things will change. One participant talked about the skepticism, with employees asking, "How is this gonna help me when the situation is not changing?" (Organization 6). They noted high levels of fatigue and questioned the value of any new initiative. Another participant talked about the overall persona of a subgroup of laboratory workers who "trust no one." They explained that

> *they're highly skeptical. It makes them awesome at what they do. It also makes them sometimes not the easiest to work with because we trust nobody. So sharing things might be too much vulnerability for them* [Organization 2]

It was recognized that some employees may be more receptive than others to technology, or any new initiative. One participant explained that some are "just against whatever new thing that was going to happen" (Organization 3), and another explained that,

> *there's people who love technology and people who don't. There's people who really bring their issues to the team, and then there's people who are extremely private and, you know, won't want to be engaged in this at all* [Organization 5]

Although some may be more receptive than others, overcoming the reluctance of frontline workers was noted to be a significant challenge both within and across organizations.

Another barrier noted by many participants was linked to the infrastructure of work. Some could not use their phones at work, had unstable internet connections, or did not have the time or private space to make a call. Given that many are short-staffed at work, they explained that there is no time even to download the app, let alone reach out for support. As one participant noted, "If it takes more than three clicks to install, then forget it. … They have so many other priorities" (Organization 5). There were many comments about the lack of time to access the app

XSL•FO
RenderX

during work hours, explaining that they think "I don't have time now, I'll do it later," but then later never comes (Organization 6).

Overall, analysis of the forces shaping app engagement revealed that despite perceiving the app as a valued tool that complements existing services and supports, there was a disconnect in terms of actual uptake. As one champion noted,

> *"They see it. They value it. They say they like it. They recognize they need it moving forward. However… when they're asked to opt into those types of services, uptake is almost always super low, lower than what we would expect given how much they say they value it, how much they say they like it"* [Organization 2]

This sentiment was echoed by another participant,

> *Some people said they weren't sure why they would use it. … [others said] 'Oh, this is great. This is a great idea.' But they weren't at the stage where they needed it yet. It was just at the curiosity stage* [Organization 6]

These comments underscore the challenges of engagement and suggest that transitioning from initial interest to adoption may take time. They also reflect a perceived lack of an immediate or urgent need to use the new technology.

Implementation Strategies to Promote Engagement

The implementation process was an important factor that shaped uptake of the technology. Implementation included communication about the app to facilitate awareness and inspire employee engagement. This process looked a little different in each organization given their established communication channels and resources. Common engagement methods included targeted email campaigns, in-person launch events, and dissemination of printed materials such as posters, wallet cards, and flyers, and distribution of promotional materials (pens and water bottles) to enhance visibility and encourage uptake.

In all organizations, champions were asked to send email messages to employees inviting them to participate in the research study, with a brief description of the project and features of the app, a poster that provided a QR code to learn more about and download the app, and a unique organizational code to open the app. In 4 of the 7 organizations, information was posted in monthly or bimonthly staff newsletters and/or on the staff wellness section of their intranet. In general, more passive strategies (eg, email and newsletters) were seen as more efficient but not as effective in promoting engagement. As one champion noted, "I don't think blasting emails works; our staff are always in transit" (Organization 4). Another champion talked about information overload, "[I] suspect people are just inundated with information hanging on the bulletin boards. So, it probably, unfortunately, got overlooked" (Organization 5).

In contrast, in-person launch events were reported to be much more effective. In six of the organizations, the materials were distributed at on-site launch events where staff could get assistance downloading the app (if needed) and ask questions about the project and the technology. The highest download rate (45%) was in a small organization where employees in a staff meeting were engaged in a structured engagement activity (20 - 30 minutes), to not only download the app, but to engage with different features. In 2 of the multisite hospitals, a brief visit was scheduled at multiple sites where staff were invited to meet the team and engage with the technology. Although it was noted that in-person promotion was effective, it can also be difficult to achieve, "the challenge... is trying to just find people... and get in front of them for, for five minutes in, in a face-to-face" (Organization 1). In some cases, staff worked shifts or across different sites, so it was difficult to find a time and place to reach everyone. Not everyone was able to engage in the on-site launches due to the demands of their work; therefore, the in-person sessions only reached a small fraction of employees, particularly in larger sites. In other cases, staff worked primarily offsite so it was not possible to do an on-site launch.

In addition to the format for information sharing, the people providing the messaging had an important impact on uptake of the technology. Champions in this study came from a range of departments and levels within their respective organizations, varying from frontline supervisors to senior directors to health and wellness leads. Implementation success was often tied to a champion's ability to leverage established networks and tailor outreach in ways that aligned with the organization's structure. Endorsement from leadership was noted to be important, "leadership involvement made all the difference; when supervisors talked about the app at team meetings, it sent a message that this was important" (Organization 6). While top-down endorsement was valuable, champions also reflected on the potential drawbacks of delivery through formal leadership structures, particularly if staff did not trust management. As one champion noted:

> *So, I think we were very well-intentioned to have our... delivery of this app come from management so that staff understood that it was valued and important. However, the double-edge of that is then perhaps the buy-in isn't as great if folks are struggling with anything to do with the agency. So, they may see it as, 'Here's yet another thing my employer is trying to do, and I'm already frustrated with them. Why would I engage?'* [Organization 5]

The same participant described the importance of trusted peers as an alternative to messaging from leaders.

> *It doesn't necessarily have to be the most extroverted person. It doesn't even have to be anybody in any kind of formal leadership position. It just has to be somebody whose staff are willing to look to and hear them when they speak. And I think that would create better buy-in.* [Organization 5]

The person delivering the information was therefore considered to be just as important as the nature of the message.

The other important lesson in implementation was the importance of ongoing, strategic communication to sustain interest and engagement over time. The organization with the lowest level of engagement sent an initial message but did not engage in proactive follow-up. Regular updates, transparent communication, and collaborative decision-making processes

XSL•FO
RenderX

were important. Sending "push notifications" through the app itself regarding new content, or reminders to reach out was noted to be a valuable feature of the app. It was noted that "every time we push something out, you get a little [spark] in behavior" (Organization 2). One of the most impactful strategies seemed to be personal follow-up. As one champion noted:

> *it's really me walking around and doing check-ins. And I think it's the champions keeping it front and center … us having it on our iPads and showing them [in peer support drop-in sessions]* [Organization 3]

Champions talked about natural time points when a reminder about the app was effective, explaining that a critical incident in the organization would be an ideal time to remind staff about the resources available to them.

Discussion

Principal Findings

The study findings point to an interesting paradox regarding adoption of the Beyond Silence platform. On the one hand, we heard many positive comments about the need to support frontline health care workers and how the app met many needs for a customized, confidential tool to increase access to relevant information and peer support. On the other hand, the overall app use was relatively low (download rate of <10% in 5 of 7 organizations; average of just over 3 opens per user), which was attributed to a range of barriers to engagement.

Theories about technology adoption can shed light on the findings related to app engagement. The technology acceptance model (TAM), for example, focuses on perceived usefulness and perceived ease of use, and how these impact intention to use the technology [23]. In our study, organizational champions noted that the app was easy to use and that it was very useful in enhancing their current employee support initiatives. These beliefs, however, did not necessarily translate to frontline workers. Ease of use for frontline workers was complicated by poor internet connections in some organizations or inability to use their phones at work, and by lack of time and private space to download and use the app. Furthermore, frontline health care providers may not see the usefulness of the app given that they often ignore their own support needs in their effort to help others, and by their skepticism, lack of energy, and time to invest in new initiatives. As such, they may be more reluctant to use a digital platform to access formal peer support given that it represents a departure from simple, informal interactions with peers and requires time and effort to learn something new.

The unified theory of acceptance and use of technology (UTAUT) is another model, which builds on the factors outlined in the TAM model to expand understanding of forces influencing adoption. In addition to the focus on effort expectancy (perceptions re: ease of use) and performance expectancy (the belief that using the app will increase personal productivity), this model sheds light on the important role of social influence (beliefs that key people expect them to use the app) and facilitating conditions (belief that the necessary organizational and technical infrastructure exists to support usage) on intention to use and actual use of technology [24]. In our study, there were differences between organizations regarding both social influence and facilitating conditions. In the smallest organization, which had the highest proportion of downloads (45% in Organization 5), the organizational champion had many personal connections with their colleagues (social influence), and they set aside time during a staff meeting for employees to learn about the app and try out the different features (facilitating conditions), thereby increasing initial employee engagement. In contrast, the large professional organization with the lowest proportion of downloads (2% in Organization 2) had limited personal connection with members since members worked in diverse organizations across the country. Furthermore, this organization did not have the infrastructure to actively invest in supporting app usage, using largely passive means of communication about the opportunity to participate (initial but no follow-up emails and occasional posts about the app in the electronic membership newsletter). These implementation conditions at an organizational level with limited contact and few active engagement opportunities clearly had an impact on employee engagement.

Finally, the framework outlining NASSS of health and care technology provides additional insights to consider given that the Beyond Silence platform represents a complex intervention that is implemented at an organizational level [14]. According to the NASSS framework, there are 6 main sources of complexity that need to be considered in understanding technology implementation and uptake, namely the condition, the technology, the value proposition, the adopter system (eg, staff and patients), organization implementation, and the wider (institutional and societal) context. In the case of the Beyond Silence platform, mental health "conditions" can be considered complex in that they are often insidious, unpredictable, and stigmatized, and therefore can be difficult to identify and manage. Health care workers may fail to perceive or acknowledge their own psychological distress and often avoid seeking support due to the stigma associated with mental health issues [21,26]. The technology itself was noted to be valuable, but it is available on an "as needed" basis with no requirement for initial or ongoing use. As noted in a systematic review of eHealth interventions with health care professionals, smartphone apps have the advantage of convenience, but they may be either too flexible or too subtle to prompt regular engagement [14]. Another area of complexity relates to the value proposition for frontline workers. Although there was general buy-in from leaders, the value was not necessarily evident for frontline workers given the time, energy, and trust required to adopt something new. Organization implementation was also complex given the challenges in connecting with workers who may work different shifts, across different sites, and have little time available to download or use new technology. Understanding and addressing these dimensions of complexity is critical to creating an effective implementation plan.

The insights provided by these technology implementation theories reveal that low adoption rates may not be a failure of the technology itself, but rather a failure of implementation. There is a growing body of literature on e-mental health interventions in the workplace, including several systematic reviews [27,28], and one umbrella review of 14 review articles

XSL•FO
RenderX

published between 2014 and 2023 [13]. The review studies explore a range of web-based and app-based tools, with many rooted in principles of cognitive behavioral therapy (CBT) and mindfulness, including studies that focus specifically on health care workers. Overall, there appears to be a positive impact of these tools on reducing mental distress and improving employee mental health, with a clear value proposition related to accessible, customizable tools that can expand the reach of workplace mental health initiatives [6,13,28]. These studies underscore the value of the technology itself in the context of the workplace.

A notable gap in the literature, however, is in examining implementation processes that shape uptake and impact. Studies of digital mental health interventions note variability in engagement across studies, with a paucity of consistent data to track adoption and engagement, making it difficult to conduct comparisons across different types of technology innovations and workplace contexts [29,30]. As such, this study contributes important data regarding implementation of an app-based peer support intervention, comparing implementation across a range of organizational contexts in the health care sector. The focus on an upstream mHealth intervention, rooted in self-management and peer support, is also unique, given that many studies focus on therapeutic apps (cognitive behavioral therapy and mindfulness).

Recommendations

Based on analysis of the key facilitators and barriers noted in this study, as well as principles of implementation science theory and practice noted above, there are several recommendations to consider in order to optimize future uptake of workplace mental health apps such as the Beyond Silence platform within the context of health care workplaces. The recommendations are also based on a review of several implementation checklists and guidelines regarding strategies to foster implementation [31], including the Expert Recommendations for Implementing Change (ERIC) [32] and the European Platform to Promote Wellbeing and Health in the workplace (EMPOWER) checklist, which specifically examines strategies to foster adoption of occupational e-mental health interventions [33].

Evaluate Organizational Readiness for Implementation

The concept of organizational readiness to change, as theorized by Weiner [34], involves a shared resolve among organizational members (health care workers in this case) to implement a change (adoption of the Beyond Silence platform), and a shared belief in their individual and collective capability to do so. As noted in the TAM and UTAUT models, shared beliefs about the value of the app and how easy it is to use are important prerequisites to acceptance and actual use [35,36]. Readiness can be different at an individual, group, program, or organizational level [34]. The findings of our study, for example, revealed that organizational leaders appeared to be more committed and confident in adopting the Beyond Silence technology when compared to frontline workers. The degree to which they were committed to building a psychologically safe work environment beyond technology implementation; however, was not evaluated. Leadership commitment is consistently noted to be an important determinant of implementation success; trusted frontline managers can be influential, underscoring the importance of relational trust in driving intervention uptake [37]. Less is known, however, about the commitment of frontline workers. Even some programs within multisite organizations in our study were more engaged than others. Taking time to note dimensions of readiness and as well as potential sources of resistance is important in developing an implementation plan. Establishing the infrastructure to support implementation (eg, champions for change, clear, and sustained communication strategies) as well as opportunities to build collective commitment are critical to success.

Address Mental Health Literacy and Stigma

Beyond Silence is a platform for accessing information and support, but if people don't recognize when and how to reach out, and/or have concerns about the stigma associated with seeking help, they may not see the need and be reluctant to use the technology. It is therefore important to build awareness such as education on burnout, moral injury, and signs of anxiety or depression, as well as access to self-screening tools (like the ones available in the app). Personal stories about seeking help from respected colleagues can be effective to reduce stigma and build a culture of proactive outreach [21,38], as is encouragement from managers and peers regarding the value of peer and professional support. We have started to develop "use case" examples for when and how to use the app, with strategies to emphasize access, noting that "help is just a click away." To address stigma, it is also important to emphasize the privacy and anonymity features of the app and the peer support outreach.

Generate a Communication and Implementation Plan That Includes Multimodal Strategies to Reach a Range of Employees

Identifying who might be credible, trusted champions for change, including both leaders and frontline influencers, is a critical step since a range of voices at different levels of the organization is needed to inspire change [33]. In terms of messaging, passive strategies such as email and posters are an efficient way to reach people but may be overlooked given the many competing demands for attention. The most effective strategies involved setting aside time and space to download the app, try out features, and ask questions. Time has been noted as an influential determinant of app use in the implementation literature and one that can compromise adoption and sustainability [39]. Addressing time barriers therefore requires selecting or tailoring strategies that reduce the time burden and align with existing workflows. Implementation efforts should therefore incorporate structured assessments of time availability early in the planning process and prioritize low-effort, high-impact adaptations that facilitate integration into routine practice. Consider introducing the app at key moments (eg, new staff orientation, morning huddles, or following difficult shifts). Since staff turnover can be high in some health care settings, introducing the app as part of new employee orientation can be an effective way to embed it into organizational communication strategies. There is considerable evidence that initial and ongoing communication is also needed to sustain engagement over time [33,39]. Consider how and when to promote during

XSL•FO
RenderX

the year (eg, mental health week or prior to the holiday season, which can be difficult and isolating for some employees). Without ongoing reinforcement and integration into regular workflows, engagement may decline over time [31].

Consider Technology Requirements, Including mHealth Access and Digital Literacy

Digital e-mental health interventions can be valuable tools to increase access to information and support, but varying levels of comfort with technology can impact adoption [33,39]. Champions in our study noted generational differences in digital literacy; therefore, it may be important to host hands-on/experiential practice sessions with employees to not only download the app but also to explore the different features. Virtual onboarding sessions, question and answer (Q&A) sessions, tutorials, frequently asked questions (FAQs; available in the app), and a contact for technology troubleshooting are important strategies to address questions that may arise over time [33]. It should be noted that some of the technology issues noted in our study were related more to the infrastructure of work, from unreliable internet to a lack of time or private space to access support. This may require organization-level interventions to build time and space for support.

Embed the App Platform Into Existing Organizational Policies and Practices

It takes time to introduce new ways of thinking about peer support and to build awareness, trust, and new habits regarding technology as a tool to access information and support [39]. There are many reports of the importance of social support in the context of health care [3,40], but this is often informal, and the idea of reaching out through an app may take time to build awareness and comfort with what peer support is and how it can help. Integrating the app platform into the workplace requires clear communication on how it fits within an overall model of care [33,41]. There is no “one size fits all” approach since every person is different in terms of their needs and preferences for accessing support; there may be generational differences in digital literacy and openness to accessing support, as well as different levels of need for peer support. The Beyond Silence platform was designed to promote early intervention and support but could also be another tool in the toolbox to support new employees, to facilitate connection with professional supports, or to facilitate reintegration following a workplace absence. There is currently no protocol for using the app; it is available on an “as needed” basis, but the platform is designed to easily add new content, depending upon what might be relevant to the organization. Co-developing a vision for the peer support technology within existing initiatives and working with intended users to co-create the work routines that the technology is intended to support are important strategies to optimize uptake [41]. Depending on the goal of the organization, it may not be realistic to expect all employees to use the app on a regular basis; in some cases, simply ensuring it is available when needed may be sufficient.

Study Strengths, Limitations, and Future Work

This study provides an early examination of mental health app implementation across a diverse range of health care organizations, informed by the CFIR framework and consideration of a range of technology adoption models. There are, however, several limitations, which constrain the strength and generalizability of the findings. A 4-month implementation period provided an opportunity to observe initial short-term patterns, but may not have been sufficient to assess longer-term integration into organizational culture. The follow-up period revealed the challenges associated with maintaining long-term engagement, highlighting the importance of iterative refinement and continued evaluation. Studies of EAP use, for example, report low annual usage rates but significantly higher uptake over a 5-year period, reflecting the time required for integration into organizational culture and workflows [42]. These findings underscore the importance of examining cumulative use over time, with at least a 6 - 18 month implementation period. Future research should explore extended longitudinal studies to assess delayed impacts and long-term behavioral changes. As such, the present findings should be interpreted as preliminary, and future studies should use longer observation periods to capture delayed adoption and sustained behavioral change.

The sample of 7 participating organizations also limits generalizability. Although they represented diversity in size, function, and location, all were situated within the Canadian health care system and represented a time when formal peer support and technology to support workplace health were relatively new and a time when the health care system was still recovering from the impact of the pandemic. International contexts may vary in terms of policy environments, workplace cultures, and the maturity of peer support infrastructures.

Data were only collected from organizational champions regarding why they thought that employees downloaded and engaged with (or did not engage with) the app. As nonadopters represented a significant proportion of eligible staff, their perspectives, barriers, and decision-making processes are unknown. This limits understanding of overall receptivity, organizational fit, and determinants of uptake. In addition, the absence of a comparison group restricts the ability to infer causal relationships between implementation strategies and observed outcomes.

The focus of the study was on implementation but did not track mental health or workplace outcomes of the intervention. Future research should incorporate outcome evaluation alongside implementation assessment, include comparison groups, extend follow-up periods, and gather data from both adopters and nonadopters to produce more conclusive evidence regarding effectiveness, reach, and generalizability. There is also a need to track the cost-effectiveness of this intervention approach to help employers to reflect on the value of this type of digital support intervention in their workplace context.

Conclusion

This study provides important insights regarding implementation of the Beyond Silence peer support platform for health care workers. The findings point to a relatively slow adoption of the technology, attributed in part to the stigma and silence surrounding mental health issues, to competing demands on attention and time, and challenges with initial and ongoing engagement of frontline workers. At the same time, the findings

XSL•FO
RenderX

also point to strong mission alignment for organizations that are looking for tools to support their frontline workers, and strong support for the opportunity to access high-quality customized information and resources for health care providers and to access tools to facilitate anonymous connections to trained peer supporters. We argue that understanding and addressing issues related to implementation is a necessary precondition to optimize impacts on mental health and workplace outcomes. Inspiring frontline workers to take the time and energy to access resources and peer support via the app requires reflection on potential barriers to change, and innovative approaches to build trust and inspire new ways of responding to mental health issues. Longitudinal research is needed since time is needed to study integration of the technology into workplace policies and practices.

Acknowledgments

We are grateful to trainees and research staff, including Sheila Addanki, Saleha Ansari, Maria Bargeman, Lindsay Crocco, Esther Chow, Vivian Lee, and Lisa Wolfe who played an instrumental role in supporting various stages of the app development, project implementation and evaluation. Thanks also to Henrietta Van Hulle who was an integral member of the advisory team and to the many health care leaders and champions who contributed their valuable time and insights.

Generative AI was not used in any portion of the manuscript writing.

Funding

The research was supported through funding from the Public Health Agency of Canada (PHAC) as part of their Addressing Posttraumatic Stress Disorder (PTSD) and Trauma in Those Most Affected by COVID – 19 initiative [Grant: 2122-HQ-000408]. The funder had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript.

Data Availability

Data specific to each organization and app user are considered confidential, so they are not available in a public repository. Requests for deidentified data files can be made directly to the corresponding author.

Authors' Contributions

SM led conceptualization of the study and funding acquisition, and was primarily responsible for the overall investigation, methodology, formal analysis, supervision of the study team, and writing the initial and revised drafts of the paper. MP was responsible for project administration and managing resources, and contributed to data curation, formal analysis, data visualization, and writing the initial draft, as well as review and editing. PS contributed to the conceptualization of the study, formal analysis of the study data, and to the review and editing of the final paper. ES contributed to computer software resources and support, and to writing, review, and editing.

Conflicts of Interest

The first author (SM) was the developer of the Beyond Silence technology, owned by McMaster University. A partnership with Stepped Care Solutions (a not-for-profit organization) was developed following completion of the research in 2024 in order to lead commercialization on a cost-recovery basis. The agreement included a clause for ongoing access for research, and the potential for a small royalty from commercialization that would be reinvested into research.

Abstract

Background: Digital health interventions show promise for promoting behavior change, but how they incorporate action planning strategies is underreported. This oversight limits understanding of how to implement behavior change techniques. iSIPsmarter is a digital health intervention aimed at reducing sugar-sweetened beverage (SSB) consumption among Appalachian adults.

Objective: This study aimed to examine the digital action planning process in the iSIPsmarter intervention, specifically by (1) assessing the frequency of action plan engagement, (2) evaluating participants' perceived difficulty implementing their action plans and examining progress toward achieving SSB reduction and weight goals, and (3) exploring the selection of barriers and strategies.

Methods: The digital action planning process is embedded within 5 of iSIPsmarter's 6 behavioral content modules (Cores) and paired with self-monitoring of SSB intake via SMS text messaging and weight via a cellular-enabled scale. Participants first self-select program goals for SSB intake (in ounces) and weight (loss or maintenance). Then, in Cores 2 - 6, they complete action plans using personalized tracking feedback, recommendations, and goal progress updates. Participants identify barriers and strategies using preprogrammed or write-in responses. Summary statistics described the aims.

Results: Participants (n=119) were predominately White (Caucasian), female, aged between 18 and 44 years, college-educated, and from rural counties. On average, participants completed 4.5 (SD 1.1) of 5 possible SSB action plans, with 80% (95/119) completing all 5. Across all Cores, perceived difficulty implementing action plans and achieving goals remained relatively stable, with an average of 48% rating the tasks as impossible or hard, 29% as neither hard nor easy, and 24% as easy or very easy. Nearly half achieved their self-selected weekly SSB goals, and one-third made progress toward them. At Core 6, 57% (54/95) of participants met their self-selected SSB program goal, while 46% (44/95) met the recommended SSB intake of less than 8 ounces per day. Of 119 participants, 53 (45%) modified their SSB barriers, and 63 (53%) selected new strategies during action planning. Top reported SSB barriers included (1) caffeine, (2) taste, and (3) habit. Among those with a program weight loss goal (n=94), the average weight loss was −1.3% (SD 2.6) at the 9-week follow-up, with 61% (57/94) achieving their goal. By 6 months, weight loss increased to −2.1% (SD 5.6), with 54% (49/90) achieving their goal. Of those completing weight action plans, 62% (69/112) modified their barriers. Top weight barriers included (1) sweets, (2) portion sizes, and (3) eating healthy foods.

Conclusions: Findings underscore the value of digital action planning as a central behavior change technique within a nutrition-focused digital intervention. High action plan completion and consistent strategy adaptation suggest that structured, digitally personalized goal setting and action planning processes can effectively support behavior change, particularly among underserved populations with limited access to preventative care.

Introduction

Background

Digital technologies, which include web programs, mobile apps, and SMS text messaging, are increasingly being used within behavior change interventions. Their widespread availability marks a promising shift in the field, offering improvements in accessibility and personalized support. This is especially important for hard-to-reach populations, such as those in rural or underserved areas, who often face barriers to traditional in-person interventions [1]. By leveraging digital platforms, these interventions can extend their reach and improve health outcomes in populations with limited access to preventive care [2].

Behavioral interventions often use behavior change techniques (BCTs), which provide structured strategies targeting specific behavioral mechanisms [3]. Michie and colleagues' [4] well-recognized taxonomy of 93 distinct BCTs offers a comprehensive set of evidence-based strategies to facilitate behavior change. While BCTs are often used in behavior change interventions, there is limited understanding of their application and impact within digital health interventions. Similarly, although action planning is a key BCT associated with improved outcomes in behavioral interventions [5,6], its use and impact within digital health interventions remain underexplored and underutilized.

Action planning involves creating a detailed and concrete plan for how and when a specific behavior will be performed, including details on the context, frequency, duration, and intensity of the behavior [4]. Among BCTs, action planning is particularly vital because it helps individuals translate behavior change intentions into actionable steps, effectively bridging the gap between motivation and sustained behavior change. Likewise, action planning functions as the central BCT that integrates self-monitoring, goal setting, and problem-solving by providing a structured technique for translating participants' goals into concrete plans through barrier identification and strategy selection [4,7]. Given its central role in facilitating the implementation of behavior change intentions, action planning has been consistently associated with improved outcomes across a range of health behaviors, making it a key focus for behavior change intervention design and evaluation [7,8].

A recent umbrella review of systematic reviews and meta-analyses identified the most effective BCTs at improving health outcomes among adults within digital health interventions targeting the prevention and management of noncommunicable disease. The review concluded that action planning, goal setting, feedback and monitoring, and personalization should be prioritized for inclusion in digital health interventions [9]. Yet, only 15% (13/85) of systematic reviews identified digital health intervention studies using action planning, and the included studies rarely provided sufficient detail on how action planning was implemented. This lack of use and limited reporting create a significant gap in understanding how to design and use action planning components effectively in digital health contexts. Addressing this gap in both implementation and reporting of digital action planning strategies is essential to improving the design of digital health interventions and ensuring that high-impact BCTs are used effectively to support behavior change and improve health outcomes.

Digital Health Interventions and Sugar-Sweetened Beverage Context in Rural Appalachia (United States)

As the digital divide—the gap between those with and with no reliable access to internet-connected technology [10]—continues to narrow, digital health interventions have become increasingly vital for rural communities like those in the Appalachian region of the United States [11,12]. Appalachia faces numerous barriers to accessing behavioral health interventions, including transportation challenges, limited infrastructure for health care, and socioeconomic constraints [13]. Compounding these issues are the high prevalence of sugar-sweetened beverage (SSB; eg, soda, sweet tea, sports and energy drinks, and fruit drinks) consumption and SSB-related health outcomes, including obesity and weight-related conditions [13,14]. In southwest Virginia, a part of Appalachia and the focus region of this study, SSB intake is more than double the national average and more than 4 times the recommended daily amount of 8 ounces or less per day [15,16]. Importantly, in recent years, strides have been made in bridging the digital divide as access to broadband and greater device ownership throughout Appalachia has increased [17,18]. Thus, given the relatively low cost and high scalability of digital health interventions, they offer promise in overcoming barriers to accessing behavioral interventions and improving nutrition-related health outcomes in the underserved Appalachian region. Although a recent review identified several digital behavioral interventions that incorporated action planning, none specifically targeted nutrition-related behaviors [9]. Notably, one promising feasibility study has begun to address this gap, highlighting the need for further research in this area [19].

iSIPsmarter, the program of focus of this paper, is a theory-based, digital behavioral health intervention designed to reduce SSB intake among Appalachian adults [20]. Using a randomized controlled trial (RCT), iSIPsmarter was shown to be effective in reducing SSB ounces and in improving weight compared with a static participant education comparison group [21]. Also, intervention engagement was high, and no significant relationship was found between engagement levels and outcomes. However, knowing that action planning is a vital self-regulatory BCT, providing detail and examining its role explicitly will help not only in better understanding the success of iSIPsmarter but also for others in creating digital health interventions [9].

Therefore, this study reports findings from a personalized digital action planning process, focused on SSB and weight, that is embedded within the iSIPsmarter digital behavioral health intervention. The study aims are to (1) assess the frequency of action plan engagement, (2) evaluate participants' perceived difficulty implementing their action plan and examine their progress toward achieving SSB reduction and weight goals, and (3) examine the selection of SSB- and weight-related barriers and strategies. This process evaluation corresponds to a prespecified secondary aim of the larger RCT focused on engagement with intervention components [20].

XSL•FO
RenderX

A recently published secondary analysis from the larger RCT examined the demand and implementation costs associated with iSIPsmarter's stepped care engagement approach to promoting participant engagement in the digital intervention [22]. In contrast, this manuscript focuses specifically on engagement with the intervention's action planning component. Findings are used to offer considerations for future integration of digital action planning components into behavioral interventions.

Methods

Study Design

Overview

This paper is an exploratory, longitudinal process evaluation of digital action planning embedded within the iSIPsmarter intervention. A 2-group RCT examined the efficacy of 2 internet-based programs aimed at decreasing SSB consumption [20]. Participants were randomized to receive one of two conditions: (1) iSIPsmarter (n=127), in which participants received 6 modules (ie, "Cores") with personalized action planning and behavioral tracking of SSB and weight via SMS and cellular-enabled scales, or (2) a patient education website (n=122), in which participants had access to a static education site with no action planning and optional tracking of SSB and weight via paper diaries. Participants were enrolled in this study from July 2021 to December 2022. This paper focuses on process data from iSIPsmarter participants. While most digital action planning occurred in the first 9 weeks, extending the analysis through the 6-month assessment allowed for exploration of longer-term weight-related goal achievement.

Participants

The larger 2-group RCT recruited participants from Southwest Virginia and surrounding Appalachian counties using community-engaged, multimodal recruitment strategies. Recruitment efforts were conducted in partnership with a wide range of community stakeholders, including federally qualified health centers, local health districts, hospitals, local government agencies, and higher education institutions [23]. Recruitment strategies included both passive methods (eg, print materials, emails to listservs, web page postings, and press releases) and active methods (eg, community presentations and outreach events). Interested individuals completed an online eligibility screener, and eligible participants were subsequently contacted by study staff to complete informed consent and baseline assessment procedures. To be eligible for the study, participants were required to (1) be English-speaking, (2) be aged at least 18 years or older, (3) reside in Southwest Virginia or surrounding Appalachian counties, (4) consume more than 200 calories of SSB per day as assessed by a validated beverage intake questionnaire [24], (5) not participate in another program focused on energy balance–related behaviors, and (6) be willing to access an internet-enabled computer or tablet at least 1 time per week and receive SMS text messaging–based reminders. Participants included in this analysis were those who were randomized to receive the iSIPsmarter intervention and who had completed at least 1 iSIPsmarter Action Plan (ie, 2 Cores) (119/127, 94%).

iSIPsmarter Intervention Overview

In brief, iSIPsmarter was adapted from the original evidence-based SIP*smart*ER SSB intervention, which was informed by several phases of formative research and included three 90-minute in-person small-group classes and interactive voice response calls for behavioral self-monitoring and action planning [25,26]. Furthermore, guided by the Model for Internet Interventions [27] and best practices in human-centered design [28], a robust human-centered design process was used to adapt iSIPsmarter's digital intervention structure, including the Cores, behavioral self-monitoring, and action planning [29]. The comprehensive 3-phase human-centered design process (contextual inquiry, prototype testing, and end user testing) spanned approximately 18 months. It involved a series of 13 semistructured, one-on-one interviews with 7 advisory team members from the targeted user group. Complete details of the intervention's development and content are described elsewhere [20,29].

iSIPsmarter is a self-guided digital health intervention delivered via a secure web-based platform. Participants log in to iSIPsmarter with their email address and password to access 6 behavioral content Cores. Each Core is metered out to the user, with a new Core unlocked 7 days after completion of the previous Core. Therefore, while it is possible for Cores to unlock on a weekly schedule, the Cores do not always correspond to calendar weeks as participants may take longer than 1 week to complete a Core. Core content includes various media formats of text, audio, video, interactions, animations, and vignettes focused on SSB-related topics and skill building. Core content highlights the connection between SSB and weight outcomes through personalized interactions and messaging, which helps participants recognize how SSB reduction supports weight management and overall health. The Cores also provide tailored calorie and added sugar recommendations aligned with each participant's weight-related goal. A complete list of each Core's learning objectives is described elsewhere [20]. The program integrates digital behavioral tracking through SMS prompts and a cellular-enabled scale to support daily self-monitoring of SSB intake and weight. A personalized dashboard allows participants to view and track their progress, while the digital action planning process—embedded within 5 of the 6 Cores (ie, Cores 2 through 6)—guides participants through goal setting and problem-solving or coping planning (ie, barrier identification and identification of strategies to overcome barriers) with personalized feedback.

Behavioral Self-Monitoring

Throughout the intervention, participants engage in daily behavioral self-monitoring of both SSB and weight through an integrated system. iSIPsmarter delivers daily prompts for participants to report their total SSB intake in ounces for the previous day, offering the flexibility to receive these reminders via SMS text messaging, email, or both. Two-way SMS text messaging queries allow participants to reply directly with their SSB intake, which is automatically uploaded to their online iSIPsmarter dashboard. Alternatively, participants can manually enter their intake by signing into the program online. In addition, the daily email prompt encourages participants to weigh

XSL•FO
RenderX

themselves using their cellular-enabled electronic BodyTrace scale and monitor their progress toward their weight goals. The BodyTrace scale automatically transmits weight data to the dashboard when a cellular connection is available, with the option for participants to manually log their weight online, if necessary.

Program Goals

Participants set a program goal in ounces for SSB in Core 2. Additionally, at the start of the intervention, participants select a weight-related reason for joining iSIPsmarter to either "lose weight" or "maintain weight."

Action Planning With Personalized Feedback

Throughout the program, participants can complete up to 5 personalized action plans. Action plans are embedded at the end of Cores 2 through 6. Thus, participants must complete an action plan in order to complete the Core. The iSIPsmarter action planning process was designed to provide automated, tailored behavioral support to participants to self-monitor and reduce their SSB intake and manage weight behaviors. During this structured process, participants set personal goals and identify barriers to making behavioral changes and strategies to overcome the barriers. Figure 1 provides a step-by-step overview of the action planning process.

As shown in Figure 1, the first step in the action planning process includes feedback on participants' SSB behaviors and weight through a summary of tracking completed during the previous 7 days (step 1). Participants then receive personalized feedback on SSB and weight data (step 2), including progress toward SSB and weight goals, total SSB and weight change, comparisons to SSB and weight recommendations, and total number of days tracked. Participants are required to have at least 3 days of data to receive personalized feedback. Those with less than 3 days of data are prompted to manually enter data for up to the previous 7 days. Next, participants are encouraged to reflect on factors influencing SSB behaviors (ie, select a top reason for their highest and lowest SSB days), before receiving personalized feedback on their SSB patterns (step 3). Then, participants are encouraged to set a weekly goal to decrease their SSB in ounces by 20% - 50% from their previous week's average (step 4); however, participants can choose a goal outside of the recommended range. This reduction target is repeated in subsequent action plans until the participant meets the recommendation of less than 8 ounces of SSB per day.

Participants' achievement of their weekly SSB goal is assessed using their average intake during the 7 days preceding each Core. A participant's goal is met if the average SSB ounces are less than or equal to the goal amount set in the prior Core. Some progress is achieved if the average SSB ounces are greater than the goal amount set in the prior Core but less than the average SSB ounces from the prior Core. No progress is achieved if the average SSB ounces are greater than the goal amount and greater than or equal to the average SSB ounces from the prior Core. If participants have less than 3 days of SSB diary data, they receive feedback that there are not enough data to determine progress toward their goal.

After setting their goals, participants are guided through a structured problem-solving process (step 5). They begin by selecting 2 SSB-specific barriers from a prepopulated list, followed by identifying 2 strategies per barrier to help overcome these challenges. To promote behavior change intentions, participants are prompted to complete the statement, "To help me reach my goal this week, I will..." and choose from a list of specific strategies mapped to each barrier.

The prepopulated barriers and strategies were intentionally designed to be specific and actionable, with many strategies incorporating key BCTs such as context cues and habit formation. The barrier and strategy lists were developed and tested through formative research to inform the original SIPsmartER intervention [26] and iterative end user testing to ensure that they were both culturally relevant and feasible for the intended population [29]. Barriers and strategies are prepopulated in drop-down menus to streamline decision-making and reduce participant burden, a critical consideration in internet-delivered interventions.

Participants also have the option to enter their own strategy if none of the listed options align with their needs, which prompts a free-text response field for personalized entry. In subsequent action plans, participants are shown their previously selected barriers and strategies and can choose to either maintain or revise them to reflect evolving challenges or preferences.

XSL•FO
RenderX

Figure 1. iSIPsmarter digital action planning process. SSB: sugar-sweetened beverage.

XSL•FO
RenderX

After participants select SSB-related barriers and strategies, they are offered the choice to select weight-related barriers and strategies or skip them if they want to focus exclusively on SSB. The weight action plan mirrors the SSB action planning process, in that participants identify 2 weight-related barriers and 2 corresponding strategies per barrier (step 6). Either skipping or selecting weight barriers and strategies concludes the action planning process for the Core. Thus, participants' final action plan includes up to 4 self-selected barriers and up to 8 strategies to work on for the upcoming week. Once complete, the action plan is locked and cannot be changed (step 7). Participants can access their completed action plans from their website dashboard, and they can be printed as a PDF document.

In subsequent Cores, participants are prompted to rate how easy or hard it was for them to stick to the action plan they set in the previous Core. Tailored feedback is provided based on their response. For example, participants who report that their action plan was impossible or hard to follow are encouraged to choose smaller weekly goals and to select different strategies to support their success.

Measures

Overview

Demographic data were self-reported at baseline via an online questionnaire. Participants' zip codes and the rural-urban continuum codes (RUCC) were used to determine rurality status. The codes range from 1 to 9, with higher values indicating more rural areas [30]. Process data for each participant, including action planning goals and goal achievement, perceived action planning difficulty, barrier and strategy selections, SMS text messaging–based and manual SSB tracking entries, and weight data transmitted through cellular-enabled scales or manually entered online, were automatically captured through the iSIPsmarter web-based administrative platform. Baseline and 6-month follow-up data were exported from the administrative platform for analysis.

SSB Action Planning

Participants' action planning data included self-selected personal reasons to change, summaries of SSB behavioral self-monitoring, a program SSB goal, and weekly SSB goals (all SSB summaries and goals were in ounces).

Participants' Perceived Difficulty Implementing Their Action Plan

Participants' perceived difficulty implementing their action plan was assessed at the start of Cores 3 - 6. Perceived difficulty was not assessed in Core 2 because participants did not complete an action plan in Core 1. The question, "How hard or easy was it to stick to your action plan this past week?" was rated on a 5-point Likert scale ranging from (0) "impossible" to (4) "very easy."

SSB Goal Achievement

Participants received feedback on their weekly goals, which included (1) goal achieved, (2) some progress toward the goal, (3) no progress toward the goal, and (4) not enough diary data to provide feedback.

SSB-Related Barriers

Data included participants' self-selected SSB barriers for each completed action plan. For each action plan, participants selected 2 barriers from a list of 14 SSB-related barriers. See the Results section for the complete list.

SSB-Related Strategies

Within each SSB barrier, participants selected 2 strategies. Strategies were mapped to barriers and ranged from a total of 4 - 9 per barrier, with a total of 80 possible strategies.

Weight Action Planning

Participant weight was measured via a cellular-enabled BodyTrace scale. Participants' weight action planning data included a program weight goal (ie, lose or maintain weight), which was set in Core 1.

Weight Goal Achievement

Participants' percent weight change was assessed from baseline to 9-week and baseline to 6-month follow-up assessments. The program weight loss goal was achieved if the participants lost at least 1 pound. The program weight maintenance goal was achieved if the participants' weight change was less than 1 pound [31].

Weight-Related Barriers

Participants selected 2 weight-related barriers from a list of 13. See the Results section for the complete list.

Weight-Related Strategies

Participants selected 2 weight-related strategies per barrier. Possible strategies to choose from for each barrier ranged from 8 to 13, with a total of 115 possible strategies.

Data Analysis

Data analysis was conducted using SPSS (version 29.0; IBM Corp). Descriptive statistics were used to calculate frequencies and percentages at each Core for action plan completion, perceived difficulty implementing action plans, and SSB and weight goal achievement. SSB and weight barrier and strategy frequencies were aggregated across all completed action plans.

Ethical Considerations

This study was approved by the University of Virginia Institutional Review Board (IRB-HSR 22130) and was also registered with the ClinicalTrials.gov registry: NCT05030753. All participants provided written informed consent prior to enrollment. Participants were allowed to withdraw from the study at any time during the research process. All data used in this analysis were deidentified to ensure participant privacy and confidentiality. Participants received compensation in the form of a cellular-enabled scale at baseline and gift cards (US $50) at the follow-up assessments.

Results

Sample and Demographics

Of the 127 enrolled iSIPsmarter participants, 119 (94%) participants completed at least 1 action plan and are included in this analysis. As shown in Table 1, most participants were

XSL•FO
RenderX

Caucasian, female, and from more rural counties (ie, RUCC 3=54, 45%; RUCC 4 - 9=52, 44%), with an average age of 42 (SD 11.9) years. Just over half were college educated and nearly half had household incomes less than US $55,000 per year. SSB intake at baseline averaged 43.2 (SD 23.6) fluid ounces. Notably, 27 (23%) of participants were overweight and 74 (62%) had obesity.

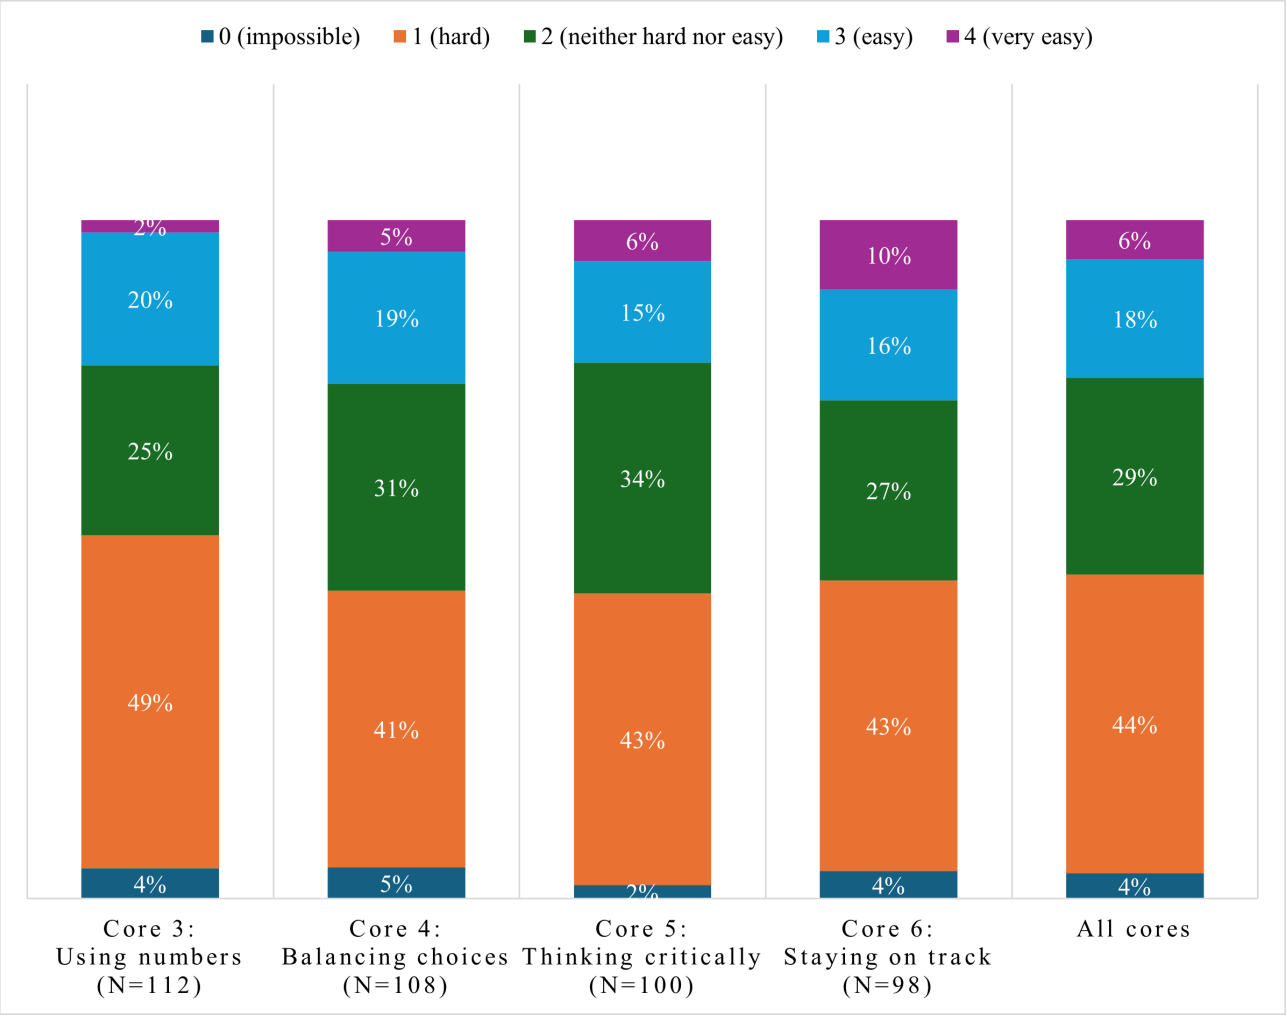
XSL•FO
RenderX



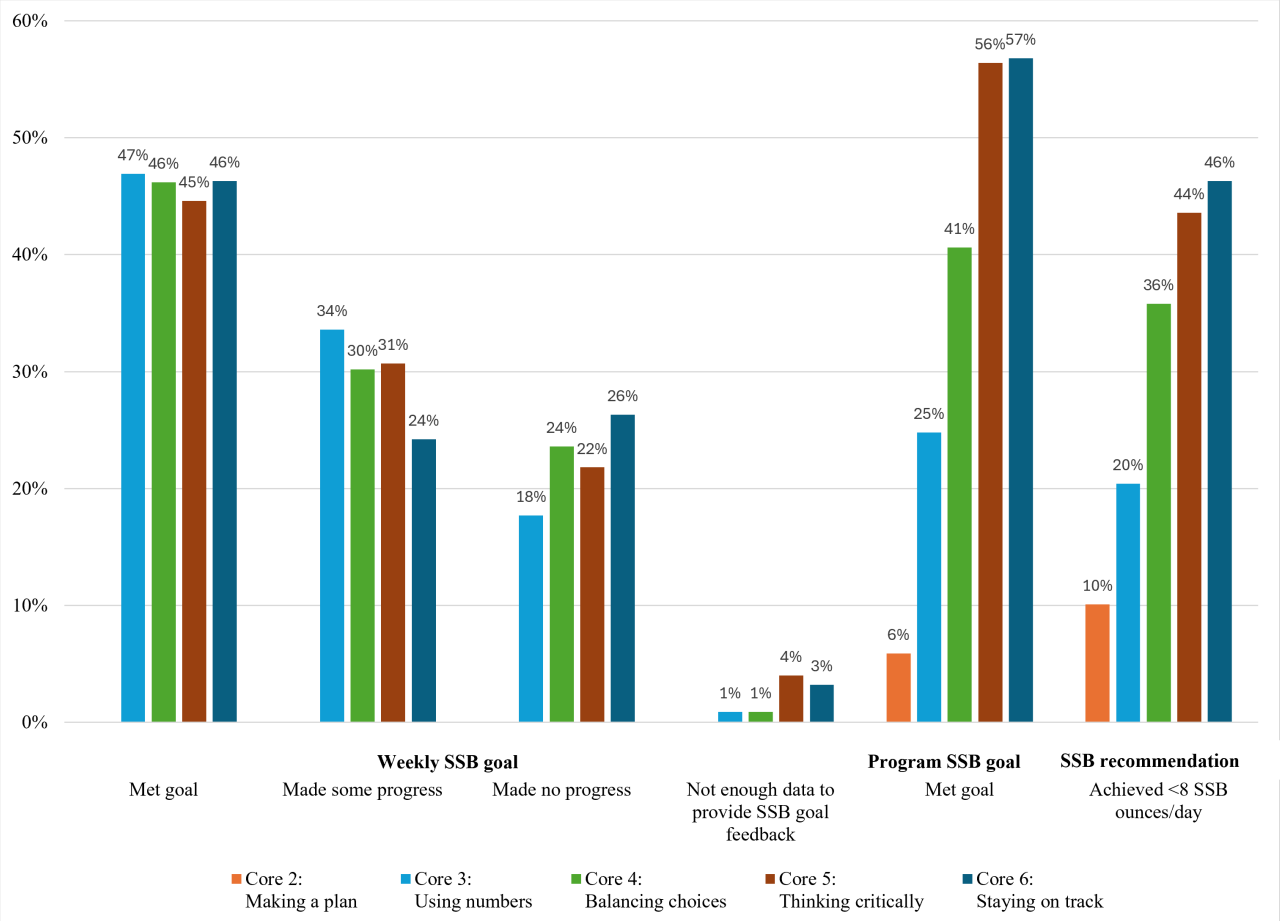
SSB Action Plan Engagement

Participants completed on average 4.5 (SD 1.1) out of 5 SSB action plans. Furthermore, of the 119 participants who completed at least 1 action plan (Core 2), 95 (80%) completed all 5 (Cores 2 - 6). Action plan completion declined slightly over time, with 113 (95%) participants completing Core 3, 106 (89%) completing Core 4, and 101 (85%) completing Core 5. This pattern mirrors the overall decline in Core completion across the intervention.

Participants' Perceived Difficulty Implementing Their Action Plan

As shown in Figure 2, across all Cores, participants' perceived difficulty implementing their action plan remained relatively stable. On average, 48% rated the tasks as impossible or hard, 29% as neither hard nor easy, and 24% as easy or very easy.

Figure 2. Participants' perceived difficulty implementing their action plan.



SSB Goal Achievement

Across each of the Cores, Figure 3 illustrates participants' progress toward three SSB goals: (1) their weekly goal, (2) their program goal, and (3) achievement of <8 ounces of SSB per day recommendation. Regarding weekly SSB goals, the percentage of participants meeting their goals remained relatively stable across the Cores, averaging about 45%. Also, about one-third of participants made some progress toward their weekly goals at each Core. Meanwhile, there was a steady increase in the proportion of participants who reduced their daily SSB intake to achieve the recommendation of <8 ounces per day. At the end of Core 6, 57% (54/95) of participants met their program goal and 46% (44/95) achieved the recommendation of <8 ounces of SSB per day.

XSL•FO
RenderX

Figure 3. Participants' progress in achieving SSB goals and recommendations. SSB: sugar-sweetened beverage.

SSB Barrier and Strategy Selection

As shown in Table 2, 45% (53/119) of participants selected different SSB barriers at least once during the action planning process, and 53% (63/119) of participants revised their chosen strategies at least once. On average, participants selected 2.8 (SD 1.1) unique barriers and 6.4 (SD 2.9) unique strategies. As shown in Table 3, the most common reported barriers to reducing SSB were (1) needing caffeine from SSB, (2) not wanting to give up the taste of SSB, (3) SSB being a habit, (4) not liking the taste of no-calorie sugar substitutes, and (5) needing energy from SSB. The top five reported strategies to reducing SSB were as follows: (1) reduce my caffeinated SSB slowly to avoid caffeine withdrawal, (2) replace sugary caffeinated drinks with nonsugary caffeinated drinks, (3) get more sleep to feel less tired and dependent on caffeinated SSB, (4) slowly reduce SSB to tame my sweet tooth, and (5) use the iSIPsmarter Diary to track SSB and learn my habit.

Table . Summary of SSB[a]-related and weight-related barriers and strategies.

	SSB-related barriers and strategies (n=119)	Weight-related barriers and strategies (n=112)
Participants who changed barriers, n (%)	53 (45)	69 (62)
Number of unique barriers selected, mean (SD) (possible range 2 - 10)	2.8 (1.1)	3.0 (1.0)
Participants who changed strategies, n (%)	63 (53)	82 (73)
Number of strategies selected, mean (SD) (possible range 4 - 20)	6.4 (2.9)	6.6 (2.7)

[a]SSB: sugar-sweetened beverage.

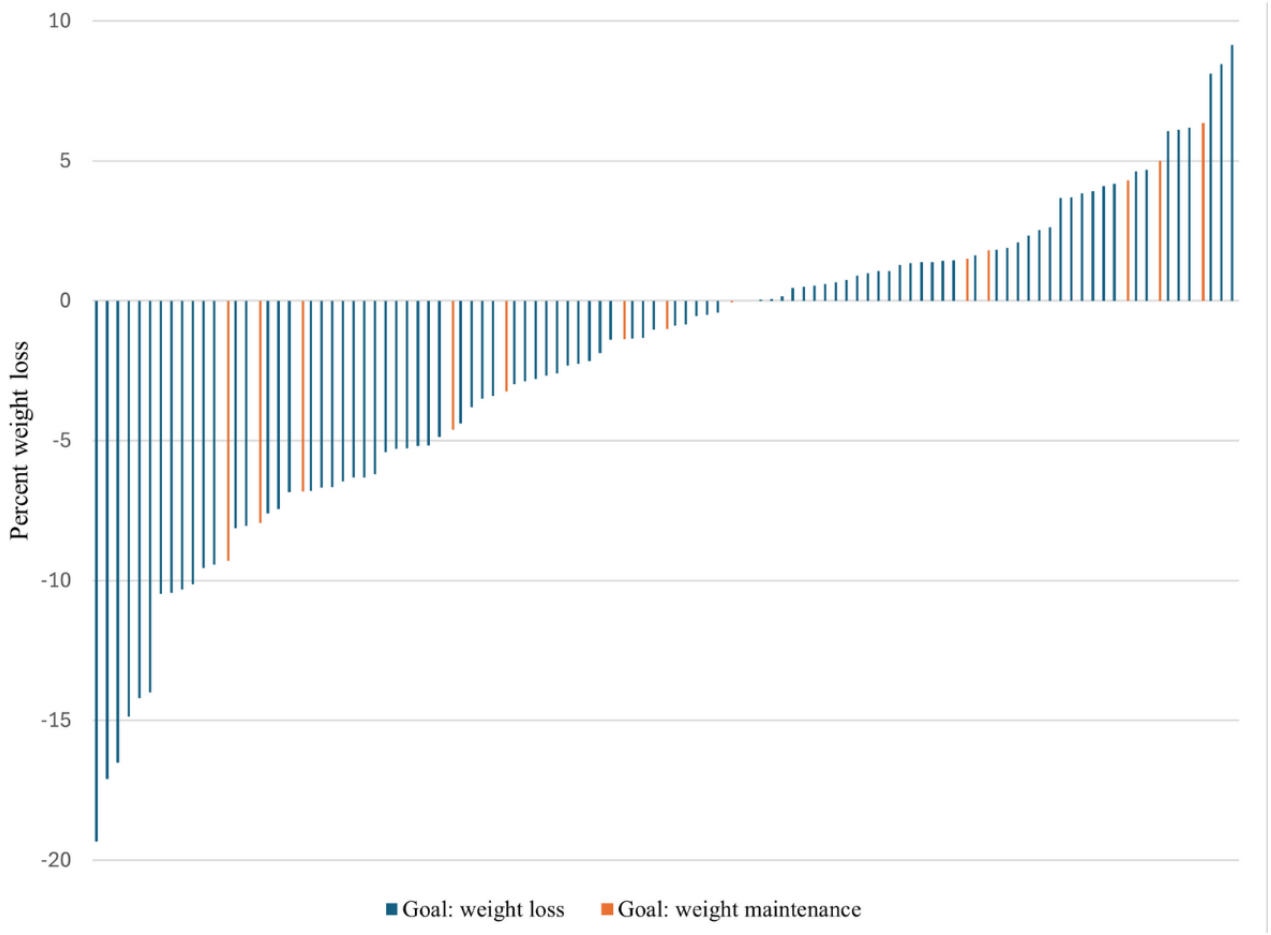
Weight Action Plan Engagement

Participants completed on average 3.3 (SD 1.5) weight action plans, with 94% (112/119) of participants completing at least 1 weight action plan. Engagement in weight action planning varied, as 6% (7/119) of participants skipped weight action planning, 7% (8/119) completed 1 weight action plan, 24% (29/119) completed 2 weight action plans, 7% (8/119) completed 3 weight action plans, 29% (34/119) completed 4 weight action plans, and 28% (33/119) completed all 5 weight action plans.



Weight Goal Achievement

At the beginning of the intervention, 86.6% (103/119) of participants set a weight goal to lose weight. Among these participants with follow-up weight data, the average weight loss was −1.3% (SD 2.6) at the 9-week follow-up, with 61% (57/94) achieving their goal. By 6 months, weight loss increased to −2.1% (SD 5.6), with 54% (49/90) achieving their goal (Figure 4).

The other participants (16/119, 13.4%) set a goal to maintain weight during the intervention. Among these participants with follow-up weight data, 7% (1/14) achieved their goal at the 9-week follow-up, and 8% (1/13) achieved their goal at the 6-month follow-up. At 6 months, the average weight change was −1.2% (SD 5), with most participants losing, rather than maintaining weight (Figure 4).

XSL•FO
RenderX

Figure 4. Participants' progress in achieving program weight goal at 6 months.

Weight Barrier and Strategy Selection

As illustrated in Table 2, 62% (69/112) of participants revised their weight barriers throughout their action planning process, and 73% (82/112) of participants updated their weight-related strategies. As shown in Table 4, the most common reported weight-related barriers were (1) enjoying sweets, (2) struggling with portion sizes, (3) being too busy or tired to eat healthy foods, (4) having difficulty staying motivated, and (5) snacking throughout the day. The top five reported weight-related strategies were as follows: (1) limit or stop buying sweets at the grocery or convenience store; (2) preportion my serving when I have sweets, and not eat straight from the package; (3) keep sweets out of sight or in a hard to reach area at home and at work; (4) replace sweet treats with fruit, such as berries, melon, or apples; and (5) ask myself if I really need a second helping and wait 20 minutes before deciding.

XSL•FO

Discussion

Overview

This is one of the first studies to thoroughly explore a digital action planning process and to conduct a comprehensive process evaluation of a nutrition-focused digital behavioral health intervention [3,9,26,32]. In contrast to existing digital interventions that mention action planning superficially or as a single feature, the iSIPsmarter intervention incorporates it as a multistep, iterative process aligned with behavioral theory and delivered through personalized, user-guided digital Cores. This level of integration and process evaluation contributes to the much-needed understanding of how key BCTs are operationalized in digital formats. Findings from our study contribute to the growing body of literature on digital behavioral health interventions, emphasizing the value of structured and personalized goal-setting and action planning strategies in supporting self-regulatory behaviors, such as SSB intake and weight management.

Principal Results

SSB Action Planning

Findings from this study highlight the usefulness of embedding a low-cost, scalable action planning process within a digital behavioral health intervention. The iSIPsmarter action planning component provided automated, tailored support to help participants monitor their SSB intake, set goals, identify barriers, and select personalized strategies. Engagement was high, with 80% (95/119) of participants completing all 5 action plans. iSIPsmarter's action planning process allowed the user to create new action plans or repeat previously made plans to reinforce them. High engagement across all 5 action plans aligns with recent research indicating that the number of action plans is positively associated with improved health behaviors, with the strongest associations observed when individuals create 5 plans [7]. Furthermore, high engagement with iSIPsmarter's action planning process underscores the program's usability and key design features, which were adapted and developed from our prior efficacious SSB intervention [26] and using best practices in human-centered design [28,29]. Findings from this study are especially meaningful, given its rural context, in which rural populations often encounter persistent barriers to accessing face-to-face behavioral health interventions. This suggests that well-designed, digitally delivered behavior change interventions can extend the reach of behavioral programs to underserved communities.

Participants' Perceived Difficulty Implementing Their Action Plan

Reducing SSB intake is a complex and difficult behavior to change. It is often embedded in daily routines and driven by habit, preference, and societal norms. Within this study, participants' perceived difficulty in implementing their weekly action plans reflected this challenge. Across much of the program (Cores 3 - 6), participants rated implementing their action plan "hard" most often, with only a small number of participants rating their plans "impossible" or "very easy." These difficulty ratings closely mirrored goal achievement patterns. Importantly, those who rated their plans as difficult continued to engage in the action planning process. This persistence speaks to the value participants placed on the intervention and its relevance to their goals. This suggests that well-designed digital behavior change interventions can sustain engagement and support progress, even when the target behavior is difficult. Future research should use data capturing participants' perceived difficulty to provide real-time tailoring, with added support for those consistently reporting difficulty sticking to their action plan.

SSB Goal Achievement

Our study findings illustrate an encouraging trend in participants' progress toward reducing SSB intake. While the proportion of participants meeting their personalized weekly

XSL•FO
RenderX

SSB goal was stable at about 46% across the action planning process, an additional 33% made some progress toward their weekly goals. Together, 79% of participants made progress each week, which reflects a high level of progress, especially given the complexities of changing SSB behaviors. Goal attainment rates align with other behavioral nutrition interventions, where about half of the participants meet their goals [33].

Furthermore, there was a notable, steady increase in those reducing their SSB intake to the recommended less than 8 ounces. By the final action plan, nearly half of the participants had met this recommendation. Although nationally representative data typically report SSB intake by frequency or total added sugars intake, available estimates suggest that on a given day, US adults consume approximately 145 calories from SSB [34], which is approximately one 12-ounce serving of soda. Thus, very few US adults meet the less than 8-ounce recommendation. The achievement of this recommendation among iSIPsmarter participants is especially encouraging, given that participants' average SSB intake at the start of the intervention was approximately 43 ounces per day, equivalent to more than 3½ cans of soda.

SSB-Related Barriers and Strategies

Over half of the participants maintained the same 2 SSB-related barriers throughout the action planning process, indicating consistency in perceived challenges. The most frequently cited barriers (ie, the need for caffeine, reluctance to give up the taste of SSBs, and the habitual nature of SSB consumption) are consistent with findings from prior SSB-related literature across diverse populations [35,36]. However, over half of the participants modified their strategies associated with these goals at least once during the action planning process. This adjustment in strategy selection may reflect participants' efforts to identify the most effective approaches for overcoming barriers, which are likely to change over time. This finding highlights the importance of flexibility in goal setting and troubleshooting barriers through repeated action planning. Moreover, research has shown that counterhabitual actions are important for intentions to be effective in breaking strong habits [7]. In the case of iSIPsmarter, strategies were tailored to barriers and were structured so that they could facilitate the deconstruction of ingrained SSB consumption barriers.

The most frequently selected SSB strategies–such as gradually reducing caffeine intake, substituting nonsugary caffeinated drinks, improving sleep to reduce SSB caffeine dependency, and using tracking tools such as the iSIPsmarter Diary—highlight the importance of providing users with multiple strategies to reduce SSB consumption. These strategies target both the physical drivers of SSB consumption, such as caffeine dependence and taste preferences, and behavioral factors, such as habit formation and building self-awareness through behavioral self-monitoring. These strategies have been shown to be key BCTs in behavioral health interventions focused on improving dietary behaviors [37].

While some research has emphasized the potential benefits of self-constructed plans, this approach can introduce participant burden, especially in digital settings without human-delivered support. To balance personalization with usability, iSIPsmarter offered an evidence-informed list of barriers and strategies developed through prior evidence-based research and rigorously tested using a user-centered design approach [26,29]. Furthermore, a free-text "use my own strategy" option was available but was used infrequently, suggesting that most participants preferred and were able to identify their strategies using the structured list. This design may reduce cognitive load while still allowing for personalization, particularly among populations with limited health literacy or digital experience. Developing and testing intervention components, such as barriers and strategies, from the end user's perspective is recognized as a critical element in the design and implementation of digital behavioral interventions [38].

Weight Action Planning

The varying levels of participant engagement with the weight action planning component provide insights into how optional aspects of an intervention may influence participation. While the majority (112/119, 94%) of the participants completed at least 1 weight action plan, fewer (33/119, 28%) completed all 5 weight action plans. Although 87% (103/119) of the participants identified weight loss as an initial goal, engagement with weight action planning diminished over time. Reasons for this decline in weight action planning are not entirely clear, yet it is plausible that some participants may have experienced weight-related information avoidance or negative emotions with weight self-monitoring and action planning [39,40]. Furthermore, the weight action planning patterns may suggest that participants were selective, possibly prioritizing the SSB-focused components of the intervention over the weight-specific ones. The ability to choose between SSB-related and weight-related barriers likely allowed for a more customized approach but may have also led participants to limit engagement with optional elements when those did not align as closely with their perceived barriers. This selective engagement reflects the need for flexibility in interventions, as well as for further examination of how weight self-monitoring can best be structured to support engagement over time. Given that 85% (101/119) of the enrolled iSIPsmarter participants were with overweight or obesity, compared with the estimated national prevalence of 74%, the need for future research efforts to promote engagement in weight action planning is especially critical in Appalachia and other regions facing similar weight disparities [41].

Weight Goal Achievement

Participants' weight-related goal achievement underscores iSIPsmarter's success in supporting weight loss goals. Over half of the participants who set a weight loss goal successfully met it, demonstrating the intervention's potential to support meaningful behavior change. By 6 months, the average percent weight loss was nearly double among those with a weight loss goal compared with those with a weight maintenance goal. Additional opportunities for future research are to explore the relationship between engagement with weight action planning components and the achievement of weight-related goals.

XSL•FO
RenderX

Weight-Related Barriers and Strategies

The high proportion of participants who changed their weight-related barriers and strategies illustrates a dynamic process of problem-solving and coping planning. In contrast to SSB-related barriers, participants appeared to face more variable challenges related to weight. The most common weight-related barriers—enjoying sweets, struggling with portion sizes, and being too busy or tired to eat healthy foods—reflect common and complex challenges in weight management [42,43]. The top barrier of sweets reveals participants' affinity for all sugar and should be considered for future SSB interventions incorporating nutrition-related content. Frequent updates to weight-related strategies suggest that participants engaged in action planning as an ongoing, iterative process rather than a one-time exercise. Notably, most participants selected new strategies at least once, indicating that repeated action planning may promote more flexible and personalized approaches to overcoming barriers. This pattern of strategy modification may reflect participants' efforts to fine-tune their weight-related behaviors through trial and error, adapting their approaches in response to evolving challenges and contexts, as well as instances where previous strategies were unsuccessful. The most reported strategies, such as limiting or stopping the purchase of sweets, preportioning servings, and replacing sweet treats with fruit, are practical and actionable steps that participants can take to modify their eating habits. The emphasis on portion control and environmental modifications (eg, keeping sweets out of sight) aligns with behavioral strategies to support sustainable weight management [44].

Comparisons With Prior Work

While prior research has established the importance of action planning as a BCT, detailed reporting on how action planning is operationalized and reported across digital interventions remains limited. Many studies reference action planning without describing how plans are structured, how frequently they are completed, or the extent to which plans are personalized and adapted over time [3,32,45]. This limits the ability to compare digital health interventions and understand which aspects of digital action planning best support behavior change.

A recent umbrella review underscores this gap in reporting. Although a small subset (ie, 41/388, 11%) of digital health intervention studies used action planning, descriptions of action plan completion varied widely, and details regarding the number of action plans created were often overlooked [9]. Among those who did report frequency, more than half relied on a single action plan throughout the intervention period, despite evidence that goal setting and action planning are most effective when implemented at multiple time points and reevaluated with personalized feedback [46].

Our study helps address these gaps by providing detailed process data on a multitimepoint, digitally delivered action planning process within a nutrition-focused intervention. Without this level of detail in the literature, it is difficult to replicate successful digital action planning strategies across health domains and populations. Moreover, although evidence supports the effectiveness of digital action planning across multiple health domains, there is a dearth of literature on digital action planning in nutrition-related behavioral interventions [9].

Limitations

Several limitations should be considered when interpreting study findings. First, generalizability may be limited by the study population and targeted rural Appalachian region. Second, reliance on self-reported SSB intake data may introduce recall bias, potentially affecting the accuracy of reported consumption levels. Third, due to the exploratory nature of this paper and the absence of hypothesis testing, only descriptive statistics were used, which may limit interpretations. Although there may be interesting questions regarding associations among the reported descriptive variables, this study was not designed or powered to test inferential relationships, and attempting to do so could introduce analytical error and interpretations. Fourth, while participants rated their perceived difficulty sticking to their action plans, they did not explicitly rate whether they executed their action plan. This is an important area of future research. Finally, while the study reports on engagement with action planning, it does not explore user perceptions or qualitative feedback on the digital action planning experience. Perceptions of participants' experience with the iSIPsmarter intervention, including barriers to adherence, usefulness, and perceived impact, are explored elsewhere [47]. These limitations should be considered in the context of the study's strengths, which include (1) leveraging a digital health intervention to gather rich, longitudinal data on participants' engagement with digital action planning, (2) using digital technologies to collect SSB and weight data for self-monitoring and personalized feedback, and (3) the inclusion of a comprehensive set of prepopulated barriers and strategies informed by prior research.

Future Research

Our study highlights several important areas for future research. First, future studies should capture adherence to selected action plan strategies, perhaps through ecological momentary assessment methods [48]. Ecological momentary assessment could provide valuable real-time insights into when and why action plans are or are not enacted and provide opportunities to support implementation intentions. Second, future research should examine the optimal number of action plans, barriers, and strategies, as well as the impact of prepopulated versus open-ended (write-in) options on participant engagement and behavior change. These studies could help determine the best balance between minimizing participant burden and maximizing intervention effectiveness. Third, researchers should investigate the long-term effects of digital action planning on maintaining behavior changes beyond the intervention period. Fourth, future research should evaluate the scalability and adaptability of digital action planning strategies in diverse populations, including those with varying socioeconomic, cultural, and geographic contexts. Such efforts will be critical for optimizing digital action planning strategies and maximizing their potential to support sustainable health behavior change across diverse settings. Additional considerations for digital action planning in behavioral health interventions are provided in Textbox 1.

XSL•FO
RenderX

Textbox 1. Considerations for digital action planning in behavioral health interventions.

Although action planning has been identified as a key behavior change technique, there are a limited number of studies using digital action planning in digital health interventions. Moreover, few studies report on key design features or key process data from action planning. As such, we offer four considerations for developing digital action plans for digital health interventions:

1. *Leverage formative data and human-centered design processes to inform the development of digital action planning components*: Integrating formative data (eg, qualitative interviews or focus groups with intended users) with human-centered design processes can support the development of structured, preprogrammed action planning components that are relevant, realistic, and accessible to the intended users. In digital interventions, this approach helps balance personalization with usability and scalability, reduces participant burden, and supports sustained engagement by ensuring that action planning processes are culturally relevant and responsive to user needs.
2. *Capture and transparently report process-level engagement data*: Descriptive data on action plan utilization offer valuable context for interpreting participant engagement with an intervention. Furthermore, reporting participants' perceived difficulty, goal progress, and strategy modification can help researchers understand how individuals interact with action planning components over time and support replication of successful digital action planning processes.
3. *Digital action planning strategies should be personalized and incorporate feedback on self-monitoring behaviors*: Personalized feedback on self-monitoring behaviors provides a tailored approach to supporting users in achieving and sustaining behavior change goals. This approach can enhance motivation and engagement and reduce barriers to making changes. Digital action plans that tailor feedback to the user provide personalized insights into strategy modifications needed to maintain or improve behaviors, ultimately leading to more successful and sustainable behavior change outcomes.
4. *Optimize data collection to align with the intervention's budget and constraints*: Digital action planning offers unique opportunities to not only collect and analyze individual-level process data but also structure interventions in novel ways, such as adaptive interventions and those with personalized, tailored feedback. Ultimately, the budget, scope, and technical capabilities will inform how digital action planning can be structured and how much data can be collected. Researchers and interventionists should consider the cost-benefit of developing action planning systems that can be replicated across multiple health behaviors and behavioral interventions.

Conclusions

This research provides a detailed process evaluation of digital action planning as a core BCT within a nutrition-focused digital behavioral health intervention. Specifically, the findings highlight the usefulness and strong participant engagement with a structured, digitally personalized goal setting and action planning process. Participants' high utilization of action plans, frequent strategy updates, and steady progress toward SSB and weight goals suggest that action planning was useful. This is especially relevant for underserved populations where access to preventive health care is limited. By embedding action planning alongside other self-regulatory BCTs—such as goal setting, self-monitoring, and personalized feedback—iSIPsmarter created a cohesive digital behavior change framework that allowed participants to adapt their SSB and weight-related strategies over time. These findings reinforce the importance of designing digital action planning components that are user-centered and responsive to individual needs and contexts.

As digital behavioral health interventions continue to expand, this study underscores the value of elevating action planning from a passive or single-use BCT to a central, iterative component that drives engagement and behavior change. Researchers and interventionists interested in digital action planning can use findings from this study and considerations for digital action planning to integrate effective action planning components into their digital behavioral health interventions. Although focused on a nutrition behavior, it may provide insights into digital action planning strategies that can be applied across various health domains and behaviors. Overall, this study contributes to the growing body of literature on digital action planning as a key BCT and highlights its potential for promoting health behavior change in underserved populations.

Acknowledgments

The authors thank the community partners who supported recruitment efforts for this study. The authors are also grateful to their colleagues at the University of Virginia's Community Cancer Control and Obesity Research Center for their assistance with participant management, and to the Center for Behavioral Health and Technology for their program development and technical support. Finally, the authors sincerely thank the participants whose time and involvement made this study possible. No generative artificial intelligence tools were used in the manuscript writing process.

Funding

This study was funded by the National Institutes of Health, National Institute on Minority Health and Health Disparities (R01MD015033). The National Institutes of Health was not involved in the design of this study or writing of this manuscript.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Background: E-cigarette use among adolescents presents challenges distinct from traditional smoking issues. The perception that e-cigarettes are less harmful and their distinctive appeal as a means of sensation seeking among adolescents suggest that traditional smoking prevention programs may not guarantee effectiveness in preventing e-cigarette use. Therefore, there is an urgent need for educational interventions to prevent adolescents from using e-cigarettes.

Objective: This pilot study aimed to assess the potential of the Meta Nodam program, a novel metaverse-based educational initiative to enhance adolescents' resistance to e-cigarette use and increase their engagement in preventive education.

Methods: The Meta Nodam program was developed on the Roblox platform, designed to promote autonomous engagement and health-related decision-making among adolescents. The study included 120 participants in a 2-session intervention over 2 weeks, each session lasting 45 minutes. Changes in key cognitive outcomes (e-cigarette use intentions, attitudes, norms, self-efficacy, and interest development) were examined using pre- and postintervention surveys. In addition, focus group interviews with 10 participants were conducted to gain deeper insights into participants' experiences.

Results: Quantitative analysis showed a significant within-group increase in e-cigarette–related self-efficacy (t_{119}=–3.171; P=.002), whereas no statistically significant pretest-posttest differences were observed in intentions (t_{119}=–0.846; P=.40) or attitudes (t_{119}=−0.080; P=.94). Qualitative findings explained and expanded these results by indicating that immersive metaverse experiences made e-cigarette–related risks more tangible, encouraged peer discussion, and promoted reflection on e-cigarette–related decision-making. Participants also described the program as engaging and reported interest in further exploring information about the health risks of e-cigarette use.

Conclusions: Owing to the short duration of the metaverse experience, limited to 2 sessions over 2 weeks, the program did not measurably alter adolescents' attitudes or intentions regarding e-cigarette use. However, it was associated with enhanced e-cigarette–related self-efficacy and demonstrated the applicability, usefulness, and attractiveness of the metaverse program. This study highlights the potential of digital platforms such as the metaverse for health education, emphasizing user engagement, interaction, and experiential learning in preventive education. Future research should consider broader participant demographics and more robust experimental designs to more rigorously evaluate the potential of such interventions.

KEYWORDS

e-cigarette; adolescent; metaverse; pilot study; smoking prevention; focus group; health education; user engagement

Introduction

Recent global statistics indicate that e-cigarettes have the highest use rate among tobacco-related products used by adolescents [1]. E-cigarettes are linked to health risks such as myocardial infarction, upper respiratory irritation, immune system disruption, and reduced fertility [1,2]. The use of e-cigarettes by adolescents demonstrates a "gateway effect" that leads to other health issues [3]. Notably, the inclusion of nicotine not only induces addiction but also impairs brain development in adolescents [4], and the capability of users to adjust the quantity of nicotine solutions puts them at high risk of nicotine exposure. In South Korea, national data also show that adolescent e-cigarette use remains a pressing concern. Although the prevalence of conventional cigarette smoking among Korean adolescents continues to decline, e-cigarette use shows an opposite trend. According to the 2023 Korea Youth Risk Behavior Web-based Survey, the rate of e-cigarette use among adolescents steadily increased from 1.9% in 2020 to 2.9% in 2021, reaching 3.3% in 2022 [5]. These consistently rising rates

XSL•FO
RenderX

underscore the necessity for targeted prevention efforts within this population.

Existing tobacco-related youth prevention programs are focused primarily on conventional tobacco products [6]. Although some studies have included e-cigarettes in broader adolescent behavioral interventions [7,8], there has been no focus on e-cigarettes. A systematic review of interventions for the prevention of youth tobacco and nicotine use revealed that no studies targeted e-cigarettes [9]. This underscores a critical oversight as most existing programs encompass general tobacco use rather than focusing on e-cigarette use. Although recent strategies targeting e-cigarette use have evolved, they often repurpose traditional smoking prevention techniques [10]. Unlike traditional cigarettes, e-cigarettes foster a positive social norm around their use, largely due to perceptions of reduced harm and the customizable nature of flavors and scents, appealing to youth's desire for personalization and variety. Additionally, the sleek, technology-oriented design of e-cigarettes, coupled with their discreet use and portrayal on social media, enhances their attractiveness and social acceptability among peers. This unique appeal, combined with the communal aspect of vaping, underscores the need for specifically tailored interventions that address the nuances of e-cigarette use among youth, challenge positive norms, and highlight the health risks involved.

Given adolescents' growing perception of e-cigarettes as appealing [11], prevention efforts must address the key cognitive determinants of decision-making—specifically, attitudes, perceived social norms, and refusal self-efficacy—within the social contexts where vaping occurs. These cognitive factors are not isolated; they are shaped by multilevel influences, including peer behavior, school and family norms, retail access, and media exposure. Refusal self-efficacy, a concept rooted in the social cognitive theory by Bandura [12,13], refers to the belief in one's capability to successfully decline e-cigarettes despite peer pressure or temptation.

To reinforce this efficacy, repeated mastery experiences in diverse contexts are essential. Metaverse environments are particularly well suited for this purpose, offering immersive, realistic, yet safe simulations of high-risk situations that are difficult to replicate in real life [14-16]. Within these virtual spaces, adolescents can practice refusal skills and observe how peer reactions and environmental cues influence their attitudes and norms through collaborative gameplay and problem-based scenarios. Therefore, developing metaverse-based educational programs that incorporate these multilevel influences into their design to specifically target changes in adolescents' attitudes, norms, and self-efficacy represents a promising strategy for e-cigarette use prevention.

An examination of existing adolescent educational programs using the metaverse reveals that traditional lecture-based content is frequently transferred directly into virtual realms. However, this approach has been criticized for not fully exploiting the potential of metaverse environments, which offer significant freedom and diverse experiential possibilities [14,17]. Such programs often limit opportunities for real-life experiential learning and fail to leverage the extensive capabilities of the metaverse, especially in contexts where practically any scenario can be simulated [18]. Additionally, research on the actual experiences of adolescents within these highly interactive and immersive metaverse environments remains scarce [19]. To address this gap, a pilot study was conducted to investigate the potential of the metaverse for raising awareness and delivering preventive health education to adolescents. The immersive and interactive nature of metaverse environments uniquely supports experiential learning and the strengthening of refusal self-efficacy, crucial components for effective health education. This pilot study aimed to evaluate the feasibility and user engagement of an interactive metaverse program and examine preliminary within-group changes in key cognitive outcomes (self-efficacy, attitudes, norms, and intentions) related to e-cigarette use among adolescents.

Methods

Research Design

This study used an explanatory sequential mixed methods pilot design in which the quantitative phase was conducted first followed by a qualitative phase to provide a more in-depth understanding of the quantitative findings. In the quantitative phase, a single-group pretest-posttest design was used with 120 participants to evaluate the feasibility and acceptability of the intervention and assess preliminary changes in key cognitive outcomes. After the intervention and postintervention survey, qualitative data were obtained from 10 participants through focus group interviews to explore participants' experiences within the metaverse and provide contextual insights into how the program influenced their perceptions of and attitudes toward e-cigarettes. The qualitative themes were then used to explain and expand upon the quantitative results. Integration occurred during the interpretation and presentation of the findings by linking quantitative outcomes with related qualitative themes.

Development of Meta Nodam

The Meta Nodam program was developed to leverage the immersive capabilities of the metaverse, allowing adolescents to safely experience and navigate the multilevel factors influencing e-cigarette use within a simulated environment. The program was developed and implemented on the Roblox platform. The name Meta Nodam combines "Meta," referencing its metaverse-based platform, with "Nodam," a Korean term meaning "no tobacco," reflecting the program's purpose of promoting healthy decision-making regarding e-cigarette use.

The development of Meta Nodam was grounded in the multilevel determinants of adolescent e-cigarette use identified by Han and Son [20]. Recognizing that e-cigarette use is driven by a complex interplay of individual, interpersonal, and environmental factors, the program used the metaverse to simulate these multilevel influences within a safe, virtual space. While the intervention environment mirrored these broader contextual factors, the educational strategies were specifically designed to enhance individual-level cognitive determinants—attitudes, norms, and self-efficacy—as the proximal mechanisms for driving behavior change.

XSL•FO
RenderX

The Meta Nodam program incorporated its learning objectives into a set of interconnected metaverse spaces that adolescents could explore. These included Fashion Square (Figure 1C), Play Zone (Figure 1A), Living Zone (Figure 1B), Forest Zone (Figure 1E), and Treatment Zone (Figure 1D). Each zone provided a distinct contextual experience relevant to how adolescents encounter e-cigarette–related cues in their daily lives. Fashion Square served as the central gathering space where participants interacted with peers' avatars and expressed identity through customization, offering natural opportunities to observe social dynamics. The Play Zone and Living Zone reflected familiar social environments in which adolescents often encounter peer influence and normative cues. These spaces allowed adolescents to observe others' behaviors and reflect on how social expectations shape their own decisions.

Figure 1. Screenshots of the Meta Nodam metaverse environment. The labeled panels show the interconnected virtual spaces used in the program: (A) Play Zone, (B) Living Zone, (C) Fashion Square, (D) Treatment Zone, and (E) Forest Zone.

The Forest Zone incorporated a symbolic representation of the negative consequences of sustained e-cigarette use through encounters with zombies. This design provided an experiential but age-appropriate way to illustrate potential harms associated with nicotine use. Virtual e-cigarette vending machines were strategically placed throughout the Play, Living, and Forest Zones to create realistic decision-making points. When participants approached a machine, they were required to make a choice—interact with it or not. If they chose to interact, they were transported to the Treatment Zone, where their activities were temporarily restricted and they were informed about the consequences of the action. This mechanism encouraged participants to reflect on their decision and reinforced the link between choices and outcomes.

Nonplayer characters (NPCs) were integrated throughout the environment to deliver informational messages about health risks, model social reactions, and simulate peer influence. Some NPCs provided direct health-related information intended to support shifts in attitudes toward e-cigarettes. Others expressed approving or disapproving views of vaping, enabling participants to consider how social expectations and peer cues can shape normative beliefs. NPC conversations and scripted scenarios were carefully designed to resemble situations that adolescents may encounter in their everyday lives.

The program's interactive components were strategically designed to function as pedagogical tools, transforming abstract health concepts into concrete virtual experiences. The combination of informational messages, symbolic representations, peer interactions, situational cues, and

XSL•FO
RenderX

decision-making moments created an integrated experiential learning environment that supported the targeted cognitive constructs. Opportunities to make choices in ambiguous or socially pressured situations were included to strengthen self-efficacy by allowing adolescents to practice navigating tempting or uncomfortable scenarios within a safe virtual space. The structured yet exploratory nature of the metaverse world enabled repeated engagement with these learning opportunities while maintaining a sense of autonomy.

The program was delivered over 2 structured 45-minute sessions conducted in person in school classrooms. Students used laptops with stable internet connections to access the Meta Nodam environment simultaneously, allowing for real-time interactions with peers' avatars. The first session focused on orientation, initial exposure, and exploration of the metaverse environment. It included a 20-minute prebriefing via Zoom (Zoom Video Communications) explaining the program's objectives and instructions, followed by 20 minutes of exploration within the metaverse and a short debriefing. The second session was designed to provide further guided and unguided exploration, peer interaction, reflection on e-cigarette–related decision-making, participation in a fashion contest, and a concluding debriefing along with the postsurvey. Teachers monitored students' activities through their own computers, providing technical support and ensuring safety while minimizing disruptions to the immersive experience.

Pilot Test of Meta Nodam

The pilot test of the Meta Nodam program was conducted as a preliminary investigation among 120 girls' middle school students. This sample size was determined using the G*Power program (version 3.1.9.7) based on a 2-tailed paired *t* test with an 80% power level and a significance level of .05. The effect size, set at 0.257, was based on the impact of a virtual reality game program aimed at preventing adolescent e-cigarette use [21]. To account for a potential dropout rate of approximately 20%, as observed in similar school-based smoking prevention programs [22], 120 participants were initially recruited.

The pilot included pre- and postintervention surveys and focus group interviews with 10 highly engaged students to gain qualitative insights into their experiences. These interviews were conducted in 2 groups, each consisting of 5 highly engaged students. Highly engaged students were selected because the qualitative phase of this pilot study aimed to obtain detailed feedback on program experience, usability, engagement, and areas for improvement. Students who had actively explored the metaverse environment were expected to provide more specific descriptions of program functions, immersive elements, difficulties, and suggestions for refinement. The 2-session, 90-minute format was selected to align with the regular class period structure of the participating middle school and examine the feasibility of implementing the program in a real school setting. As this was a pilot study, the program was intended to assess feasibility, acceptability, engagement, and preliminary cognitive responses rather than long-term cognitive or behavior change. Surveys were administered before the first session and after the second session, each taking approximately 6 to 9 minutes to complete.

Measurement and Data Collection

The first section of the questionnaire assessed self-efficacy in resisting e-cigarette use, a key factor in understanding participants' confidence in handling temptations related to e-cigarette use. This was measured using a tool adapted from Condiotte and Lichtenstein [23]. This scale demonstrated good internal consistency, with Cronbach α values of 0.970 (pretest) and 0.973 (posttest). The next section focused on e-cigarette–related characteristics, particularly the influence of peers' e-cigarette use, which is a critical determinant in adolescent behavior. The aim of this section was to capture the social environment of the participants regarding e-cigarette use. To further categorize the participants, e-cigarette use patterns were assessed by inquiring about both lifetime and recent e-cigarette use, thereby classifying participants as lifetime or current e-cigarette users.

Participants' intentions toward future e-cigarette use were evaluated using modified questions from Pierce et al [24-26] to gauge their susceptibility to e-cigarette use. The Cronbach α for this scale was 0.748 (pretest) and 0.840 (posttest).

Attitudes toward e-cigarettes were measured using an instrument adapted from de Vries et al [27] and modified by Kim and Choi [28]. This section of the questionnaire explored the participants' perceptions of the benefits and risks associated with e-cigarette use. The Cronbach α for this scale was 0.921 (pretest) and 0.842 (posttest). Additionally, e-cigarette–related norms were assessed by adapting a tool from Primack et al [29] to evaluate the perceived social acceptance and prevalence of e-cigarette use within the participants' social circles. The Cronbach α for this measure was 0.617 (pretest) and 0.665 (posttest).

After the intervention, the survey included additional items to evaluate the impact on participants' interest development using an instrument adapted from Wang and Adesope [30]. The subdomains of this instrument assessed various facets of interest development, including triggered situational interest, maintained situational interest, emerging individual interest, and well-developed individual interest, each rated on a scale from 1 to 7, where 1 indicated the lowest level of interest and 7 indicated the highest. The Cronbach α for this scale was 0.941 (posttest).

To complement the quantitative data, qualitative insights were gathered through focus group interviews with participants who showed high engagement in the program and were willing to discuss their experiences extensively. This approach was used to obtain rich, experience-based feedback on program usability, immersion, perceived educational value, and areas for refinement. These interviews began with the following broad question: "How was your experience with the Meta Nodam program?" This open-ended approach allowed participants to share their detailed experiences freely, providing a deeper understanding of the program's impact from their perspective. The researchers facilitated natural discussions among participants, asking clarifying questions only when necessary to confirm or explore specific points in greater depth.

XSL•FO
RenderX

Ethical Considerations

This study was approved by the institutional review board of Pusan National University (PNU IRB/2022_165_HR). Participants who voluntarily expressed interest were thoroughly informed about the study's purpose, content, procedures for withdrawal, privacy protections, and compensation measures in case of research-related harm. As all participants were under 18 years of age, written informed consent was obtained from each adolescent participant as well as their legal guardians through a detailed explanatory letter and consent form. Participants whose guardians declined consent or who chose not to take part were allowed to opt out without any consequences; however, apart from students who were absent from school, there were no cases of withheld consent in this study. Participants received a snack voucher worth KRW 1500, approximately US $1.10 (KRW 1=US $0.00073 as of June 11, 2026), after completing each of the pre- and postintervention surveys as a token of appreciation for their time. This compensation was not linked to their survey responses. The consent procedure ensured informed and voluntary participation, adhering to the highest standards of research ethics and safeguarding the rights and well-being of adolescent participants and their guardians.

Data Analysis

For quantitative data, statistical analysis was performed using SPSS (version 23; IBM Corp). Descriptive statistics were used to assess demographic details, and paired *t* tests were used to compare pre- and postintervention measures of e-cigarette–related cognitive outcomes, including self-efficacy, intentions, attitudes, and normative beliefs, with the significance threshold set at a *P* value of less than .05.

Content analysis was carried out on qualitative data from the focus group interviews to extract themes and patterns. All discussions were audio recorded, transcribed verbatim, and subjected to an inductive content analysis process. Two researchers independently performed line-by-line coding, compared their codebooks, and resolved discrepancies through discussion until full agreement was reached. Codes were then grouped into subcategories and distilled into overarching themes that reflected common perceptions of program usefulness, realism, and perceived changes in refusal confidence. Data saturation was reached after conducting 2 focus group interviews (totaling 10 participants) as no new themes emerged. An audit trail documenting analytic decisions and periodic peer debriefings enhanced dependability, whereas member checking with 30% (3/10) of the participants confirmed that the derived themes accurately represented their views.

The quantitative and qualitative findings were then integrated at the interpretation stage. Specifically, quantitative results were first reviewed for each outcome domain, and related qualitative themes were subsequently linked to these outcomes to determine whether the qualitative findings explained, complemented, or expanded the quantitative findings. This integrated interpretation was used to organize the Results section around preliminary cognitive responses and program experiences.

Results

Participant Characteristics

This study involved female middle school students, none of whom had ever used or were currently using e-cigarettes. Regarding friends' e-cigarette use, 75% (90/120) reported no use among their peers, whereas 25% (30/120) acknowledged that some friends used e-cigarettes. Among the 10 students who participated in the focus group interviews, none had personal experience using e-cigarettes, although 3 (30%) mentioned having friends who used e-cigarettes.

Engagement and Participation Experience in the Metaverse Program

The overall postintervention interest development score averaged 5.59 (SD 0.97), suggesting that participants were engaged with the program content. Among interest subdomains, triggered situational interest was highest (mean 6.11, SD 1.07), followed by maintained situational interest (mean 5.86, SD 1.23), well-developed individual interest (mean 5.55, SD 0.85), and emerging individual interest (mean 5.33, SD 1.10; Table 1). These findings should be interpreted as exploratory, reflecting short-term responses observed within the context of a brief, 2-session pilot program.

Table . Pretest-posttest changes in e-cigarette–related cognitive outcomes and interest development from the Meta Nodam program.

Variable and subcategory	Pretest, mean (SD)	Posttest, mean (SD)	*t* test (*df*)	*P* value
Self-efficacy (0-10)	9.65 (0.91)	9.86 (0.58)	−3.171 (119)	.002
Intention (4-16)	15.57 (1.06)	15.64 (1.07)	−0.846 (119)	.40
Attitudes (12-60)	54.68 (7.43)	54.74 (6.55)	−0.080 (119)	.94
Normative belief				
Perceived prevalence (0-300)	125.92 (50.03)	120.25 (52.64)	1.695 (119)	.09
Approval by parents or peers (3-12)	4.52 (2.34)	4.78 (2.97)	−0.922 (119)	.36
Popularity among the successful or elite (4-16)	12.78 (1.95)	12.77 (2.45)	0.086 (119)	.93
Interest development (1-7)		5.59 (0.97)		
Triggered situational interest	—[a]	6.11 (1.07)	—	—
Maintained situational interest	—	5.86 (1.23)	—	—
Emerging individual interest	—	5.33 (1.10)	—	—
Well-developed individual interest	—	5.55 (0.85)	—	—

[a]Not applicable.

The focus group interviews also showed that the metaverse environment enhanced engagement and learning compared with traditional methods. Participants described the program as enjoyable, gamelike, and immersive, which helped maintain their interest in e-cigarette use prevention education.

Participants noted that, unlike traditional smoking prevention education, which they found boring, the metaverse program was enjoyable and encouraged active participation. The program's playful approach was key to maintaining interest:

> *We usually play in the metaverse for fun or as a hobby. But this time, we first encountered it through an educational program. At first, I thought it would be boring like the typical education we received in elementary school, where they just keep telling us facts and why smoking is bad. But this program turned education into a game, which made it much more interesting and engaging for us.* [Participant 2]

Participants also reported sustained engagement and broadened interest beyond the assigned sessions. The program was so engaging that some participants continued to interact with it even after the sessions ended, sparking broader educational interests beyond e-cigarettes:

> *After just one session, I found the storyline to be really extensive and interesting. So, I kept playing two or three more times over the week. The game had a lot of addicts, and shooting them with a gun to deal with them was surprisingly fun. It made me curious about why they became addicted in the first place, which encouraged me to look into it more.* [Participant 3]

E-Cigarette Refusal Self-Efficacy

Analysis of the quantitative data indicated a statistically significant within-group increase in self-efficacy related to making decisions about e-cigarette use, with scores rising from 9.65 (SD 0.91) before participation to 9.86 (SD 0.58) after participation (t=–3.171; P=.002; Table 1).

The qualitative findings provided contextual insights into this increase by showing that participants did not experience e-cigarette–related situations as abstract health messages but as personally relevant scenarios through their avatars. In particular, the avatar-based experience appeared to help participants place themselves in virtual situations involving e-cigarette use and consider how they might respond to similar temptations or peer-related situations in real life:

> *Experiencing the effects of smoking in the metaverse felt more real than just hearing about it. The metaverse experience was more impactful because my avatar in the game represented me. It felt like I was the one smoking and being taken to a confined space, which made the experience very novel and engaging.* [Participant 6]

The postintervention survey also appeared to provide an additional opportunity for participants to reflect on how they would respond to e-cigarette offers from peers. Rather than only recalling information about e-cigarette risks, participants described reconsidering their own behavioral responses in peer-related situations, including refusing use and discouraging peers from using e-cigarettes:

> *When I was filling out the survey, there were many question items like "I won't smoke even if a friend*

XSL•FO
RenderX

offers." Seeing these question items made me think about my actions. Now, if a friend smokes, I'll stop them and make sure I don't join in. [Participant 1]

Attitudes and Intentions Toward E-Cigarettes

No statistically significant pretest-posttest differences were observed in intentions, attitudes, or normative beliefs (Table 1). However, the qualitative findings suggested that participants developed greater awareness of e-cigarette–related risks and reflected on how e-cigarette use could affect them and their peers.

Participants described the metaverse scenarios as making the risks and consequences of e-cigarette use more vivid. In particular, the symbolic portrayal of addiction appeared to help participants recognize the difficulty of escaping e-cigarette dependence:

I remember the zombies saying things like "help me," which made me realize how hard it must be to escape e-cigarette addiction. It really showed how difficult it can be to break free. [Participant 8]

Participants also reported that the program created opportunities for more open conversations with peers about the risks of e-cigarettes. These discussions appeared to extend participants' risk awareness beyond individual reflection to peer-related communication and prevention-oriented dialogue, although such changes were not captured as statistically significant pretest-posttest changes in attitudes, intentions, or normative beliefs:

First of all, I think the biggest change was in our awareness. In the metaverse, when we finish an activity, we talk to our friends about it. For example, we might say, "Did you know about the dangers of e-cigarette usage?" This creates an atmosphere where we can comfortably talk about these issues. If someone jokes about a friend who might be an e-cigarette user, we can now openly say, "Don't use it; it's not good for you." Before, everyone would whisper and talk secretly, but now, since we all learned together and understand how bad it is, it's more effective when several friends talk about it together. This has been the biggest real-world change. [Participant 2]

Metaverse Program Usability and Refinement

Focus group interviews provided feedback on the usability of the metaverse program and areas for refinement. Participants identified the need for clearer guidance, more realistic and direct educational content, increased interaction, and longer session duration.

Participants suggested the addition of a guide or tutorial for the metaverse environment, including a mini map, to enhance their experience and ease of use:

At first, I didn't know what was going on at all. It would be helpful to have some kind of tutorial or help guide. Also, having a mini-map on the screen would be great to help navigate the structure, maybe placed in the corner. [Participant 4]

Participants recommended making the virtual environment more realistic and incorporating more direct educational messages about e-cigarettes to increase the impact of the program:

I think it would be better if there was more content about e-cigarettes. Like, when you get stuck in the treatment room and have to talk to the NPC, it would be cool if you got more info about e-cigarettes at that point. Maybe even add a quiz or something. [Participant 1]

When I go to the convenience store near school with my friends, there are so many e-cigarette ads that really stand out. It's like They are made for students like us to see. If you could show scenes like this in the metaverse, I think it would help us realize the dangers of e-cigarettes. [Participant 3]

Participants also expressed a desire for increased interaction with NPCs and students from other schools, as well as a longer program duration to fully explore the metaverse:

It would be great if we could interact with the NPCs. Besides that, I think it would be beneficial if this kind of game-based smoking prevention program could be implemented in other schools as well, not just ours. [Participant 5]

The teacher explained everything well, but I felt like two sessions were not enough. It would have been better if the program had been longer. [Participant 2]

Discussion

Principal Findings

This pilot study of the Meta Nodam program provided preliminary insights into how a metaverse-based intervention may support adolescents' engagement, awareness, and cognitive readiness to resist e-cigarette use. The most notable quantitative finding was a statistically significant within-group increase in e-cigarette refusal self-efficacy. This finding was contextualized by the qualitative results, which showed that participants experienced e-cigarette–related situations as personally relevant through their avatars and reflected on how they might respond to peer offers or temptations in real life.

This improvement in self-efficacy may be related to the pedagogical strategies embedded within the metaverse environment. According to self-efficacy theory [12,13], mastery experiences are an important source of confidence. Meta Nodam was designed to provide simulated decision-making experiences in realistic but safe scenarios, allowing students to encounter e-cigarette–related cues and consequences without real-world risks. Qualitative findings suggested that the avatar-based experience made these situations feel personally meaningful and prompted participants to consider their own responses to similar situations. These findings suggest a possible pathway through which virtual rehearsal and reflection may support e-cigarette refusal self-efficacy.

The observed pattern aligns with earlier studies showing that virtual and immersive environments can effectively enhance

XSL•FO
RenderX

adolescents' knowledge and confidence [21]. Unlike traditional didactic education, which often relies on passive information transfer, the metaverse allowed for situated learning, where students actively navigated peer influence and environmental cues. Accumulating evidence supports this approach, suggesting that immersive or virtual reality–based lessons elicit higher engagement and learning outcomes than traditional methods among secondary school learners [14,16]. In this respect, Meta Nodam offers a promising strategy to supplement conventional prevention approaches by providing digital native youth with a safe, interactive space to build behavioral competence.

The absence of statistically significant changes in attitudes and intentions regarding e-cigarette use contrasts with findings from some earlier prevention programs [7,28]. However, several contextual factors may help explain this pattern. Many participants in this study already reported low intention to use e-cigarettes and generally negative attitudes toward vaping before the intervention, suggesting limited room for measurable shifts. Moreover, the program consisted of only 2 short sessions, which may not have been sufficient to influence more stable cognitive constructs. Nonetheless, qualitative data revealed that many participants reflected more deeply on vaping risks, expressed heightened awareness, and reported increased comfort discussing e-cigarette issues with peers following the program. These qualitative impressions may reflect subtle early shifts that were not detectable in the quantitative measures over such a brief time frame. As a pilot study, these findings highlight the need for further research with longer or more intensive implementations and more diverse samples to more fully examine the potential for cognitive and attitudinal shifts.

The evaluation of interest development scores indicated strong engagement and intrinsic motivation among participants, consistent with outcomes observed in prior metaverse-based educational programs [31]. Triggered situational interest showed the highest postintervention levels, suggesting that the novelty and interactive nature of the metaverse environment successfully captured students' attention. This finding aligns with those of research demonstrating the motivational benefits of gamified or interactive learning environments [18,32]. Participants' qualitative responses also supported this as several reported exploring the program beyond assigned sessions and described becoming curious about issues related to e-cigarette use. The program's autonomy-enhancing features, symbolic representations, and opportunities for experiential learning may have contributed to these patterns. Additionally, the implementation of scenario-based role-play allowed students to actively rehearse refusal skills within contexts that closely mirrored real-life situations [21,32]. This practical application likely contributed to the students' perceived increase in confidence in managing vaping temptations.

Regarding the program design, participants differentiated Meta Nodam from existing metaverse educational platforms that often replicate traditional classroom environments, such as those on Gather Town [33]. In contrast, this program was appreciated for its experiential and narrative-driven elements that transcended simple knowledge transmission. However, feedback indicating a desire for more explicit educational content suggests that future iterations should aim for a refined balance between open-ended exploration and structured instructional density. This aligns with user-centered design principles [34], which emphasize that harmonizing learner autonomy with clear educational goals is essential for maximizing both engagement and learning efficacy.

Successful implementation also relied heavily on the educator's role. Teacher-led prebriefing sessions were identified as a critical component for orienting students and framing the experience as an educational intervention rather than purely recreational. As real-time interventions during the simulation can disrupt immersion [14], providing clear guidance beforehand proved to be the most effective strategy. However, adopting such high-technology tools imposes practical demands on educators, including the need for technical proficiency and additional preparation time [14,35], highlighting the necessity for adequate infrastructure and teacher support systems.

This pilot study offers preliminary indications that metaverse-based approaches may be promising for supporting adolescents' awareness and confidence regarding e-cigarette use. The immersive and interactive nature of the program may help create opportunities for reflective learning and peer dialogue. However, several limitations must be considered. First, as this study was designed as a pilot trial to evaluate feasibility and immediate preliminary responses, the findings reflect short-term changes only. Therefore, these results should be interpreted as exploratory evidence rather than definitive proof of the program's long-term effectiveness. The brief 2-session, 90-minute intervention exposure was an important limitation and may have been insufficient to produce measurable changes in relatively stable cognitive constructs such as attitudes and intentions. The single-gender, single-school sample also restricts generalizability to more diverse populations. Technical requirements, teacher workload, and system stability pose additional considerations for broader implementation. Furthermore, initial program deployment revealed operational challenges such as software bugs and the breadth of the virtual world relative to available time, suggesting opportunities to streamline content in future iterations. Addressing these limitations—through longer interventions, additional or booster sessions, repeated role-play or refusal practice, stronger integration of structured educational content, improved technical support, follow-up assessments, and multisite evaluation—will be essential to fully understand the potential role of metaverse-based programs in adolescent tobacco use prevention.

Conclusions

This pilot study suggests that the Meta Nodam program may offer an engaging and interactive means of supporting adolescents' awareness and confidence related to e-cigarette use. By situating educational content within a metaverse environment, the program provided opportunities for students to explore realistic social situations, interact with peers, and reflect on vaping-related decisions in a safe and immersive setting. While no measurable changes were observed in attitudes or intentions during this short 2-session format, participants demonstrated increased self-efficacy and described positive engagement with the program's activities.

XSL•FO
RenderX

Given its exploratory nature, the findings should be interpreted cautiously. Nonetheless, the results indicate that metaverse-based environments may hold promise as a complementary tool within school-based prevention efforts, particularly for digital native adolescents who may benefit from interactive and experience-driven learning. Further refinement and evaluation—including longer program duration, expanded educational content, and more diverse samples—are needed to more fully understand how metaverse-based programs can support adolescents' decision-making and contribute to broader strategies aimed at preventing e-cigarette use among youth.

Acknowledgments

The authors express their sincere gratitude to Mi-Young Jung, a school nurse at Hanseong Girls' Middle School, for her invaluable assistance in the development and implementation of the program. They also extend their thanks to Chae-won Lim and the members of an extracurricular club program for high school students affiliated with the Korea Advanced Institute of Science and Technology (KAIST), whose support was instrumental in creating the program. During the revision process, generative artificial intelligence was used to assist with language refinement and organization of the manuscript. The authors reviewed, verified, and edited all artificial intelligence–assisted text and take full responsibility for the accuracy, integrity, and final content of the manuscript.

Funding

This research was supported by the Basic Science Research Program through the National Research Foundation of Korea funded by the Ministry of Education (RS-2023-00249649).

Authors' Contributions

GH contributed to conceptualization, methodology, investigation, formal analysis, data curation, writing—original draft, and writing—review and editing. HS contributed to conceptualization, methodology, supervision, validation, and writing—review and editing. Both authors reviewed and approved the final manuscript.

Abstract

Background: The global prevalence of dementia continues to rise and demands scalable, nonpharmacological interventions. Digital cognitive training has expanded, but many older adults, who have limited digital literacy, struggle to sustain use. We designed an intervention that integrates social interaction, reward-based engagement, and an artificial intelligence (AI) conversational agent, which aims to reduce these barriers and support continuous participation.

Objective: This study examined whether a 12-week digital cognitive training program improves cognitive function in older adults. It also tested whether a group chat service, which enables interaction among participants and with an AI agent, increases engagement and social support.

Methods: We recruited 133 participants (mean age 64.75, SD 6.76; range 55-75 years) who had no diagnosis of dementia. All participants used the *Care & Cure* program for 12 weeks. The program includes an AI chatbot (*Sammy Talk*) and a group chat service (*Our Town*), which supports peer interaction. We measured cognitive function using the Korean Mini-Mental State Examination—Version 2 (K-MMSE-2). We also assessed degrees of social support (Medical Outcomes Study—Social Support Survey), depression (Short Form Geriatric Depression Scale—Korean Version), and engagement (Twente Engagement with eHealth Technologies Scale), and analyzed usage logs to examine participation patterns.

Results: Participants showed improved cognitive function after the intervention (Hedges g=0.350, P<.001). Active users (n=67), who engaged more frequently with the program, showed greater improvement than nonactive users (n=66), especially among those who had lower baseline cognitive scores (Hedges g=0.523, P<.001). Social support increased, particularly emotional and informational support (t_{132}=−6.509, P<.001). Participants reported higher engagement (t_{132}=2.008, P<.05) and lower depression scores (t_{132}=3.093, P<.01). Regression results showed that group chat participation, which promotes interaction with the AI agent, increased engagement in cognitive training (t_{131}=12.395, P<.001). Increased engagement was associated with higher social support (t_{131}=4.102, P<.001) and improved cognitive function (t_{131}=2.467, P<.05). Cognitive training alone did not produce a significant effect. Participants showed low adherence, which indicates a need for strategies that sustain long-term use.

Conclusions: The *Care & Cure* program improved cognitive function and strengthened social support in older adults. Social interaction, which increases engagement, played a central role. These findings suggest that digital cognitive interventions should incorporate social mechanisms to achieve meaningful effects.

Introduction

Background

The global prevalence of dementia is rising, with recent estimates indicating that approximately 50 million people currently live with dementia. It is estimated that the number will increase to 152 million by 2050 [1]. Dementia has a significant impact on personal, family, and economic levels, costing the world about 1.3 trillion dollars [2]. Prevention is essential for dementia management. Among nonpharmaceutical interventions, digital cognitive training has become more popular because prevention is essential for dementia management. Among nonpharmaceutical interventions, digital cognitive training has gained increasing popularity as long-term clinical studies demonstrate that older adults who engage in regular digital cognitive training could delay dementia onset by preserving memory, attention, calculation, language, visuospatial, and executive functions [3-7]. This preservation helps build cognitive reserve that protects against age-related cognitive decline [8,9]. In practice, traditional cognitive training programs are constrained by several limitations. These include (1) limited accessibility for older adults who have mobility issues, (2) heavy reliance on social workers, and (3) substantial financial costs, which are incurred by individuals through personal expenses for participation and by society through health care and social services for people living with dementia [6,10,11].

Many studies suggest that digital cognitive training programs with remote access can overcome these barriers [3-7]. These programs demonstrate greater scalability since they can reach a larger number of users simultaneously without requiring additional resources or staff. For example, while traditional cognitive training requires more therapists or social workers for each new group of users, digital cognitive training programs can be used by many more users with minimal additional cost. This efficiency in scaling makes them more cost-effective, creating a more sustainable and widely accessible option [12-14].

However, current digital training programs have limited accessibility from home mainly because of inadequate consideration of older adult users' digital literacy [15,16]. Low digital proficiency among older adults restricts their access to digital training programs [17]. Even older users with the ability to use digital training programs at home and with the necessary technological infrastructure often struggle with prolonged engagement [18]. Older adults face many challenges, including physical limitations, difficulty processing information, and digital service interfaces that are not easy to use [19]. These barriers worsen clinical results as the disease progresses, increase medical costs, and impose a greater patient burden [20].

Several solutions address these challenges, including simplified user interfaces that reduce cognitive load, gamification elements designed to promote user engagement, personalized digital literacy support, sending push notifications, using chatbots, and using tools to help people connect with others. These features (1) enhance usability, (2) reduce cognitive demand and screen fatigue, and (3) ultimately improve compliance and clinical outcomes [21]. Among these solutions, chatbots and group-based interventions have shown relatively strong potential for enhancing user engagement and effectiveness in digital cognitive training programs demonstrated by numerous studies [21-23].

Conversational agents, also known as chatbots, have the potential to resolve these barriers [24]. A substantial number of studies have shown that conversational agents used for health care interventions elicit moderate to high levels of participant satisfaction and acceptance, largely due to social support features [25-29]. These agents show promise to advance patient-centered care by supporting users in managing their own health [24,25]. Additionally, group-based interventions enhance program engagement by fostering interaction among members [27]. It is widely accepted that conversational agents provide effective social support when integrated with group interventions [28,29]. Two recent studies have validated the effectiveness of a fully automated mobile conversational agent in providing social support [28,29]. In health care settings, the Shared Medical Appointments model, which integrates group-based interventions, continues to gain wider acceptance as a way to improve patient engagement in treatment programs [30-33].

Under this circumstance, we propose *Care & Cure*, a chatbot-based service. The *Care & Cure* service offers 15 different cognitive training programs through *Sammy Talk*, along with a group chat feature called *Our Town*, where participants can interact with one another. This group interaction is intended to improve user engagement with *Sammy Talk*. At the core of this service is *Sammy*, a software robot that delivers personalized cognitive training and fosters social support through conversational interactions. By integrating these features, *Care & Cure* aims to meet both cognitive training and social needs of older adults.

Objectives

The primary objective of this study is to evaluate whether the *Care & Cure* program enhances cognitive function in older adults. The secondary objective is 2-fold: (1) to assess how social support impacts cognitive function and (2) to determine whether increased engagement with *Our Town* encourages greater usage of *Sammy Talk* and interaction with the artificial intelligence (AI) agent. To achieve these objectives, we analyzed the utilization patterns of both *Our Town* and *Sammy Talk* to assess their effects on cognitive function and social support. As an additional evaluation beyond the primary focus on cognitive functions, we examined the effect of social support functionality embedded in both *Sammy Talk* and *Our Town* on emotional well-being, specifically depressive symptoms, which emerged as a complementary benefit to the cognitive improvements.

Methods

Study Design

This was a single-arm, prospective, exploratory study. The protocol and all related materials were approved by the Yonsei University Institutional Review Board (IRB; 7001988 - 202401-HR-1397-06) prior to the study's initiation.

Study Recruitment

We recruited participants from Suncheon, a midsized city in South Jeolla Province, South Korea, with a population of approximately 280,000. The city's older adult population reflects South Korea's aging demographics, with about 20% of residents aged 65 years or older [34]. Suncheon is recognized for facilities that support senior citizens through welfare centers, nursing homes, and silver towns that provide housing and health care services for older adults [35] (see Section 1 in Multimedia Appendix 1 for more details).

Suncheon Nonghyup, a key institution in the city, provides substantial support to the older adult community. Its well-established network facilitated the recruitment process (see Multimedia Appendix 1, Section II for more details). The central office of the farmers' cooperatives distributed formal recruitment documents to local branches. Through this network, we recruited participants who met the inclusion criteria: adults aged 55 and 75 years and proficient in using a smartphone. All participants provided written informed consent prior to participating in the study.

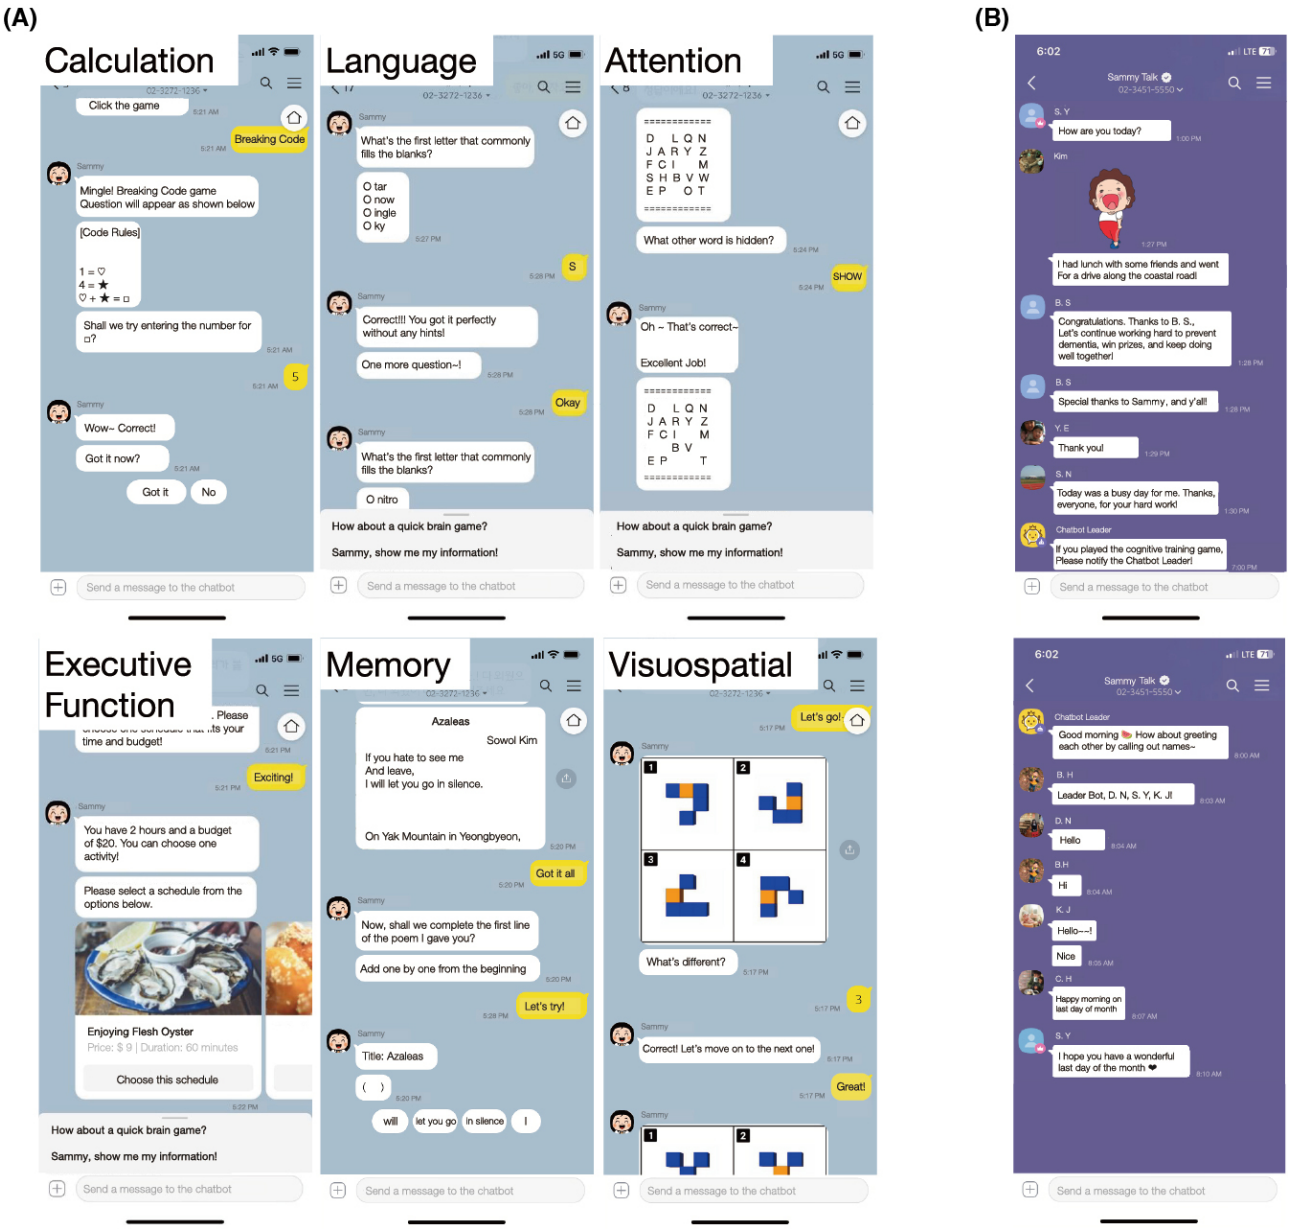
Inclusion and Exclusion Criteria

The inclusion criteria were adults (1) aged 55-75 years who could read and write Korean (for more rationale, see Multimedia Appendix 1, Section III) and (2) owned a smartphone with text typing proficiency. We excluded adults who (1) lacked formal education or were illiterate, (2) had severe visual or auditory impairments, and (3) experienced difficulty using a smartphone.

Prior to recruitment, we evaluated these criteria through a preliminary screening survey. Participants provided demographic information, including age, educational background, and literacy levels. They also demonstrated smartphone proficiency by performing basic tasks such as navigating the interface and sending messages. Additionally, the survey assessed visual and auditory impairments. This screening process identified participants who met all study requirements.

Intervention

Our intervention delivered cognitive enhancement games specifically designed by neurologists through 2 key components on the *KakaoTalk* platform: *Sammy Talk*, a conversational agent providing cognitive games, and *Our Town*, a group chat feature. We chose *KakaoTalk* because more than 70% of South Korea's senior population use it [36]. The *Care & Cure* program, designed to prevent dementia, integrates both components into this widely used messaging platform.



- A software robot, *Sammy*, functions as a conversational agent providing cognitive training through chatbot interactions. Conversational agents, which have demonstrated effectiveness in remote treatment delivery [37], support participants with communication difficulties through verbal or textual interactions [38,39] and are widely used for purposes such as memory enhancement [40] and CBT-based interactive tools for alleviating depression and anxiety [28]. For this reason, we developed *Sammy* as a conversational agent to offer 15 training games targeting 6 cognitive domains: calculation, language, attention, executive function, memory, and visuospatial processing [41-52] (Figure 1A; see Multimedia Appendix 1, Section IV). The game difficulty adapts across 5 levels as participants provide correct answers in *Sammy Talk*. Participants receive 4 games for cognitive improvement at 8 AM. A detailed description is available in Multimedia Appendix 1, Section IV.
- *Our Town* provides a virtual space where participants interact through group chat, promoting regular engagement with other members. Each group includes more than 5 members, and they receive notifications, and the members are expected to interact 3 times a day. An AI chatbot integrated into *Our Town* facilitates these interactions by moderating the group, encouraging participants to engage in *Sammy Talk*, and inquiring about their daily gaming activities and general well-being. Participants receive feedback and rewards based on their daily, weekly, or monthly game completion rates (Figure 1B).

The *Sammy Talk* chatbot functions as an autonomous digital facilitator, delivering morning greetings and encouraging cognitive training activities. The chatbot sends automated prompts 3 times a day (8 AM, 1 PM, and 7 PM) in *Our Town* to promote user engagement with digital cognitive games and ensure task completion. To complement *Sammy Talk*'s limited autonomous functions, a human facilitator motivates less active members, monitors individual participation, and provides personalized feedback with external rewards. The facilitator tracks participant messages in *Our Town* and monitors game performance through an administrative website.

For rewards, the group with the highest weekly participation rate receives gift cards worth KRW 5000 (approximately US $3.70, based on the exchange rate at the time of the study) for each participant and a group certificate. Additionally, when all group members complete their required 4 daily games, they receive restaurant gift cards worth KRW 10,000 per participant (approximately US $7.40, based on the exchange rate at the time of the study) for offline meetups. This integrated approach, combining an autonomous chatbot and human facilitation, fosters an environment that actively encourages engagement and consistent participation in cognitive training.

XSL•FO
RenderX

Figure 1. Overview on the proposed application. (A) Snapshots of *Sammy Talk* represent different cognitive domains in the following order: Calculation, language, attention, executive function, memory, and visuospatial function. (B) Snapshots of *Our Town*.

The interactions in *Our Town* exhibit straightforward structures with moderate turn-taking patterns. A daily interaction usually begins when the chatbot sends an automated morning greeting, which prompts individual responses from group members. These responses emerge sequentially, as members choose either personalized greetings or emoji-based communication. The exchanges primarily focus on 3 elements: mutual well-being inquiries, weather-related small talk, and positive message sharing. The structural simplicity of these interactions, which consist of brief greetings and basic phrases, ensures comfortable participation. Members demonstrate varied communication preferences: some address each participant individually, while others prefer concise responses or emojis. Each interaction typically consists of 5-10 turns, which reflects varying engagement levels. The uncomplicated, conversational nature of *Our Town* creates an accessible environment that accommodates diverse schedules and active communication styles.

A 2-day educational session took place at the *Suncheon Nonghyup* headquarters to establish baseline training. During this session, participants received an introduction to both the *Sammy Talk* program and *Our Town* group chat, alongside a comprehensive guidebook. The research team provided telephone instructions for those unable to attend in person. Subsequently, all participants received a text message with the program access link. The team installed *Sammy Talk* and *Our Town* directly onto the smartphones of session attendees.

Outcome Assessment

The evaluation included 4 areas: cognitive function, emotional well-being, participant engagement, and application usage. We used 2 cognitive assessment scales: the Korean-Mini Mental State Examination—Version 2 (K-MMSE-2) [53] (see Multimedia Appendix 1, Section V for more details). These assessments took place at baseline and within 7 days after the 12-week intervention. The K-MMSE-2 uses a 30-point scale,

XSL•FO
RenderX

where scores of 24 or above indicate normal cognition, 18 - 23 suggest mild cognitive impairment, and below 17 indicate severe cognitive impairment. For emotional function assessment as a supplementary outcome, we used the Short Form Geriatric Depression Scale—Korean version (SGDS-K) [54] and the Medical Outcomes Study–Social Support Survey (MOS-SSS) [55] (see Multimedia Appendix 1, Section V for more details). The SGDS-K uses a 15-point scale, where scores of 5 or below indicate normal mood, scores of 6 - 9 suggest moderate depression, and scores of 10 or above indicate severe depression. The MOS-SSS ranges from 19 to 95 points, with higher scores indicating stronger perceived social support. Changes in depression symptoms and social support served as secondary outcomes, with assessments occurring pre- and postintervention.

In addition to these, we measured participation willingness using the Twente Engagement with eHealth Technologies Scale (TWEETS) [55] (see Multimedia Appendix 1, Section V for more details), which uses a 9-point scale where higher scores indicate greater engagement willingness. The analysis on app engagement relied on log data acquired from the administrative websites of both *Sammy Talk* and *Our Town* (see Multimedia Appendix 1, Section V for more details). For *Sammy Talk*, engagement assessment included play frequency and duration across daily, weekly, and monthly intervals. For *Our Town*, engagement metrics comprised the number of chat exchanges and user-agent interaction duration across identical time intervals. The overall usage metrics included total *Sammy Talk* hours and *Our Town* chat bubble counts throughout the intervention period (Table 1).

Table . Measurement tool.

Category	Measurement		Standard
Cognition	Cognitive function	K-MMSE-2[a]	30
Emotion	Depression	SGDS-K[b]	15
Emotion	Social support	MOS-SSS[c]	19

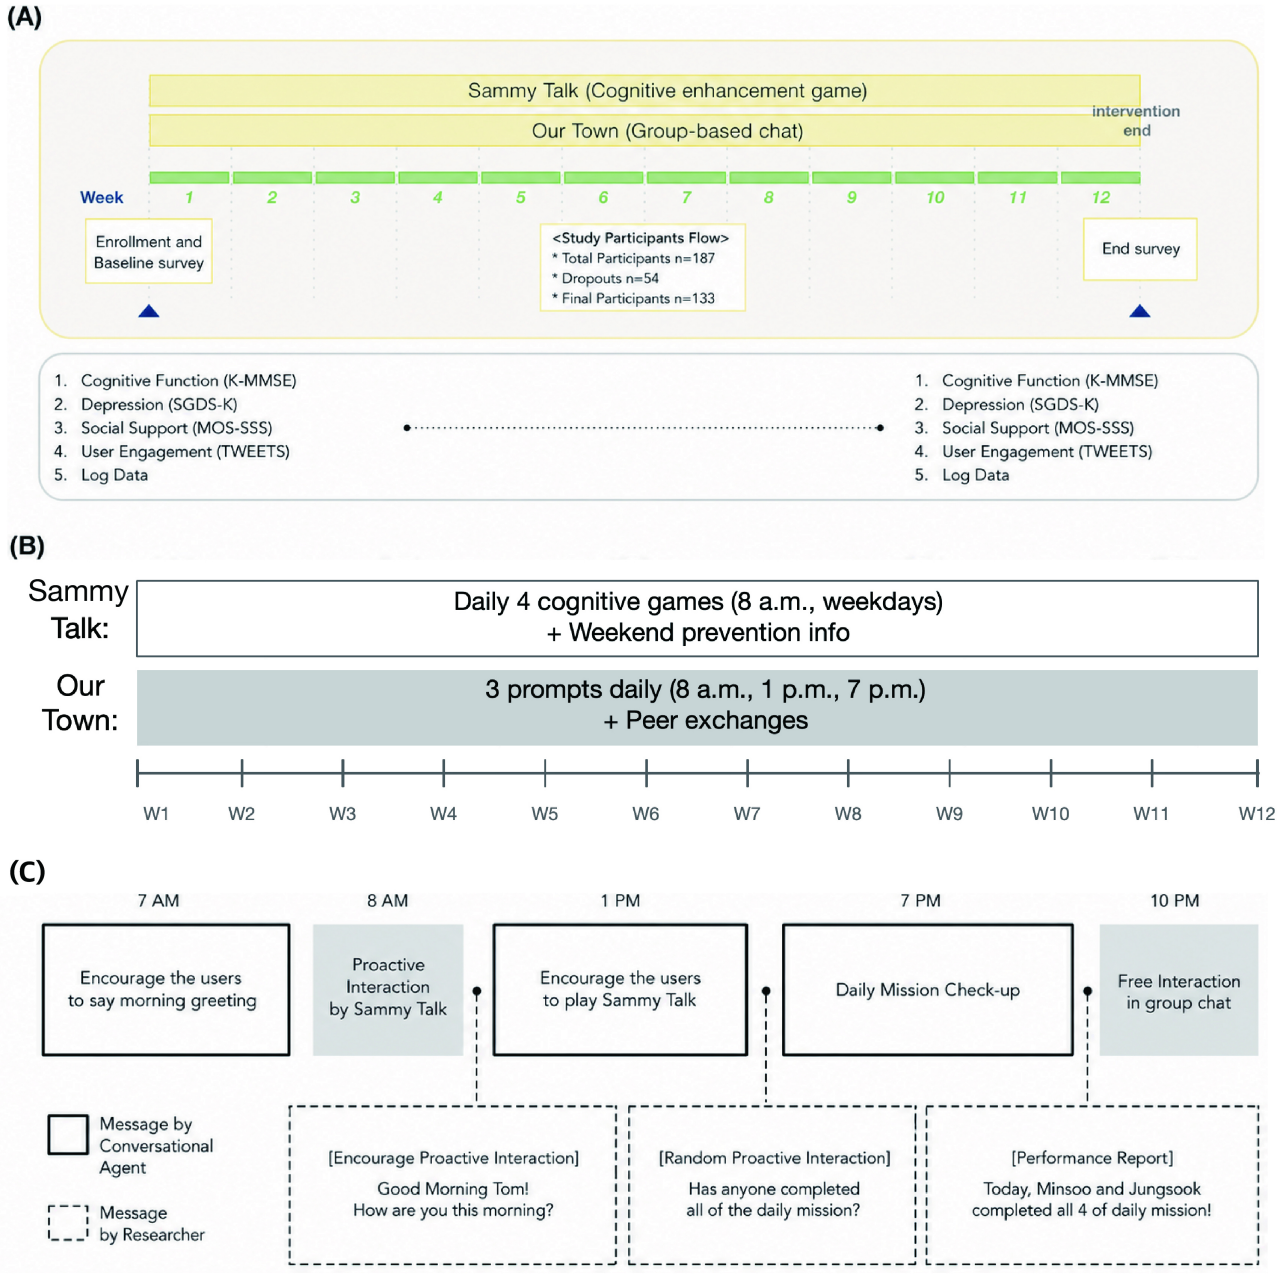
Log data	User engagement	Number of interaction in group chat	Number

[a]K-MMSE-2: Korean-Mini Mental State Examination—Version 2.

[b]SGDS-K: Short Form Geriatric Depression Scale—Korean version.

[c]MOS-SSS: Medical Outcomes Study–Social Support Survey.

[d]TWEETS: Twente Engagement with eHealth Technologies Scale.



We arranged in-person meetings for pre- and postsurveys based on practical and methodological considerations: participant age preferences, assessment administration requirements, facility availability, and geographical accessibility. The target population, aged 55 - 75 years, typically preferred face-to-face surveys over online formats. The *Suncheon Nonghyup* branch offered appropriate facilities, including halls and meeting rooms, for administering the K-MMSE-2, which required direct facilitator-participant interaction. The branch's proximity to participants' residences enhanced accessibility. Facilitators conducted presurveys during *Care & Cure* program introduction sessions, while postsurveys coincided with reward collection visits, ensuring effective data gathering.

Study Procedures

We conducted the human subjects experiment for 12 weeks (Figure 2A). During this period, 133 participants (1) engaged in daily message exchanges through *Our Town* and (2) completed 4 daily sessions of *Sammy Talk*. Each day at 8 AM, participants received their daily activity instructions. Weekday activities consisted of 4 preselected games, whereas during weekends and holidays, the system delivered dementia prevention information and notifications at 8 AM. We conducted the 12-week intervention in a structured sequence of activities. The flowchart illustrates how customized cognitive training in *Sammy Talk* and group-based interactions in *Our Town* progressed in parallel and reinforced each other (Figure 2B). Participants maintained *Sammy Talk* engagement throughout the 12-week period. All participants completed these activities in their homes (Figure 2C).

Statistical Analysis

We analyzed data from 133 participants using SPSS (version 28.0; IBM SPSS Inc). All participants completed the 12-week intervention, which included cognitive training games on *Sammy Talk* and the group chat platform *Our Town*. The study divided participants into 2 groups based on their engagement levels: active users (n=66) and nonactive users (n=67). Total usage included both *Sammy Talk* (which counted the number of games played) and *Our Town* (which counted the number of group chat posts). The median value of 65 sessions served as the dividing point: participants who recorded more than 65 sessions were classified as the active group, and those who recorded 65 sessions or fewer were classified as the nonactive group. We applied a “50% of the time” threshold, which ensured an even distribution between the 2 groups. This approach aligns with the methodologies used by Horwitz et al [56], who categorized participants into top and bottom 50% engagement groups in digital mental health interventions. This approach was also supported by Yardley et al [57] and Bucci et al [58], who identified that higher engagement correlated with improved clinical outcomes.

For comprehensive understanding of the impact of the training regarding the K-MMSE-2 scores, we additionally conducted a sensitivity analysis that categorized participants into lower (n=66) and higher (n=67) K-MMSE-2 groups, using baseline K-MMSE-2 median and SD. Participants with baseline K-MMSE-2 scores ≤27, which represented the median score, were categorized as the lower K-MMSE-2 group, while those who scored >27 were categorized as the higher K-MMSE-2

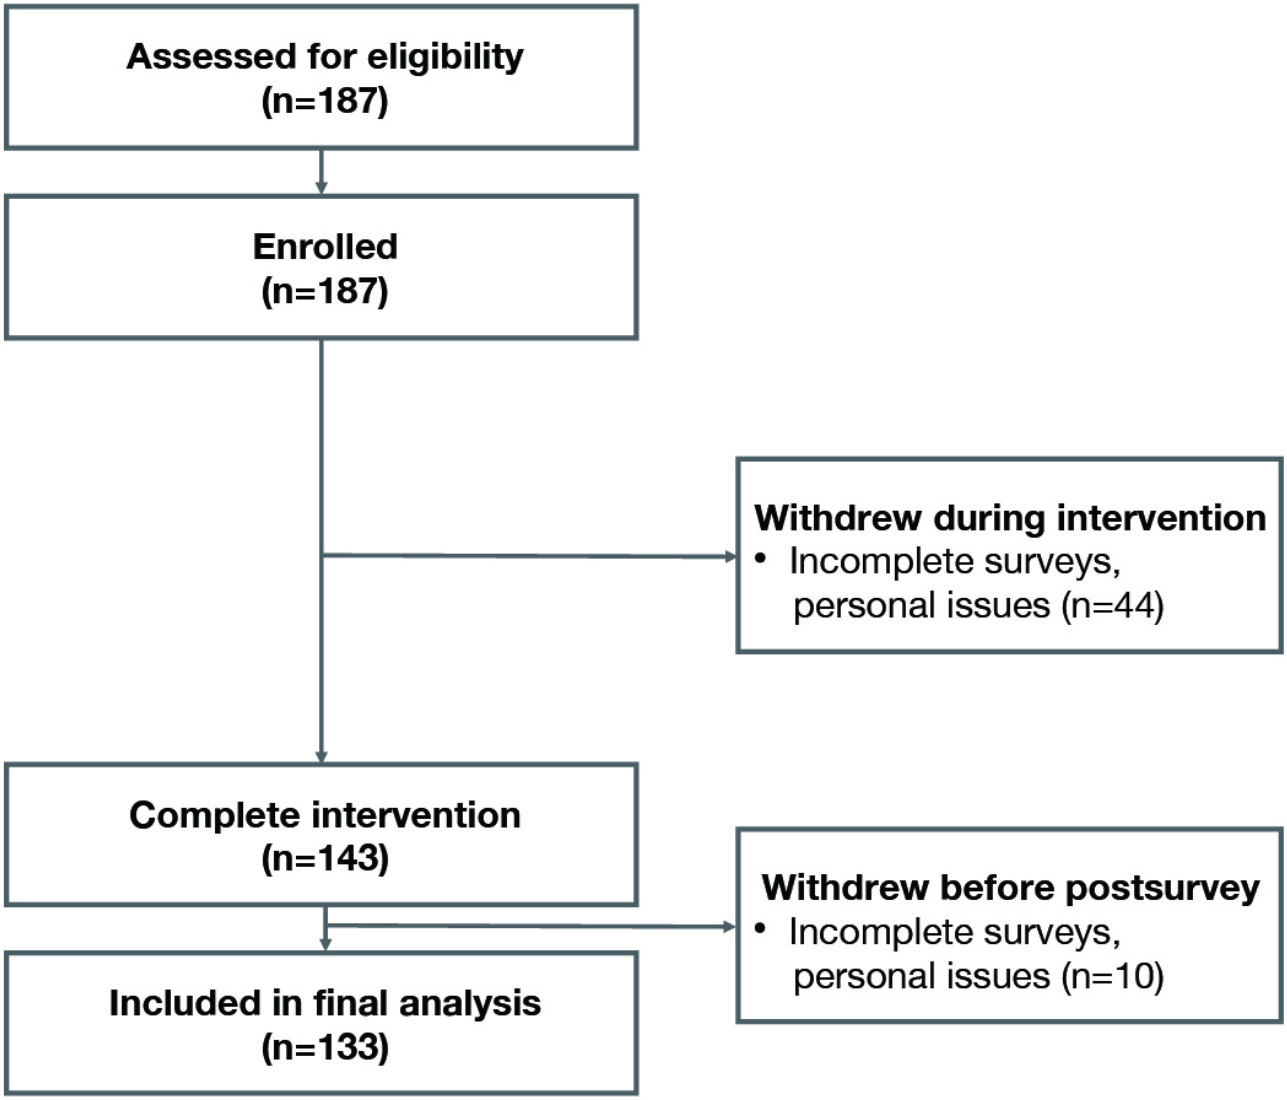
XSL•FO
RenderX

group. We also applied an alternative classification: participants whose baseline scores fell more than 1 SD below the mean were classified as having lower K-MMSE-2 status.

The analysis consisted of several components. Descriptive statistical analyses provided demographic information. Paired-sample *t* tests identified significant differences in cognitive function, emotional status, and participation between pre- and postintervention periods. Additional paired *t* tests compared outcomes between lower- and higher K-MMSE-2 groups and between high- and low engagement groups. Path analysis, through simple regression analyses, examined how group interventions affected *Sammy Talk* engagement, social support improvement, and cognitive function. Repeated-measures ANOVA assessed the mean and variability of daily *Sammy Talk* and *Our Town* usage across 3 months. Descriptive statistics supplemented this assessment for detailed data interpretation.

Ethical Considerations

This study was approved by the Yonsei University IRB (IRB no. 7001988 - 202401-HR-1397-06). All participants provided written informed consent prior to participation. The collected data were fully anonymized and securely stored, with access restricted to the research team. Participants received small incentives, such as gift cards worth KRW 5000 (approximately US $3.70) and restaurant vouchers worth KRW 10,000 (approximately US $7.40), based on the exchange rate at the time of the study, as compensation for their participation.



Results

Baseline Characteristics of the Participants

Initially, we recruited 187 participants for the study. Of these, 44 participants withdrew during the intervention period from the primary measure because they did not complete the survey or due to personal circumstances, leaving 143 participants. After the 12-week intervention, 10 more participants withdrew for similar reasons before completing the second measure, resulting in 133 participants available for final statistical analysis. Participants who did not complete the postintervention survey (n=54) were excluded from the final analysis. No statistical adjustments were applied for missing data from participants who withdrew before completion. Therefore, all statistical analyses were conducted using complete cases only. Figure 3 illustrates the flow of participant recruitment, retention, and exclusion throughout the study.

XSL•FO
RenderX

Figure 3. Flow diagram of study participants.

These 133 participants ranged in age from 55 to 75 years (mean 64.76, SD 6.76 years). Based on previous studies reporting medium effect sizes (Hedges *g*=0.5) and using G*Power (α=.05, power=0.80), we estimated that a minimum sample size of 128 would be required. This estimate is also consistent with the numbers of participants actually analyzed in similar studies involving older adults (100, 103, 145, 132, and 180 participants, respectively) [59-63]. To account for a potential dropout rate of approximately 30%, we aimed to recruit at least 180 participants. Ultimately, 187 were enrolled (Table 2).

Table . Summary of our study and comparable digital cognitive intervention studies.

[a]N/A: not applicable.

The demographic profile showed that out of 133 participants, 69 (51.9%) were female, 119 (89.5%) had been married, and 51 (38.3%) held elementary school diplomas. Among them, out of 133 participants, 91 (68.4%) reported living with a spouse (Table 3). No missing data were observed for the baseline demographic variables, including cognitive function score (K-MMSE-2), depression score (SGDS-K), social support measure (MOS-SSS), or participation measure (TWEETS),

XSL•FO

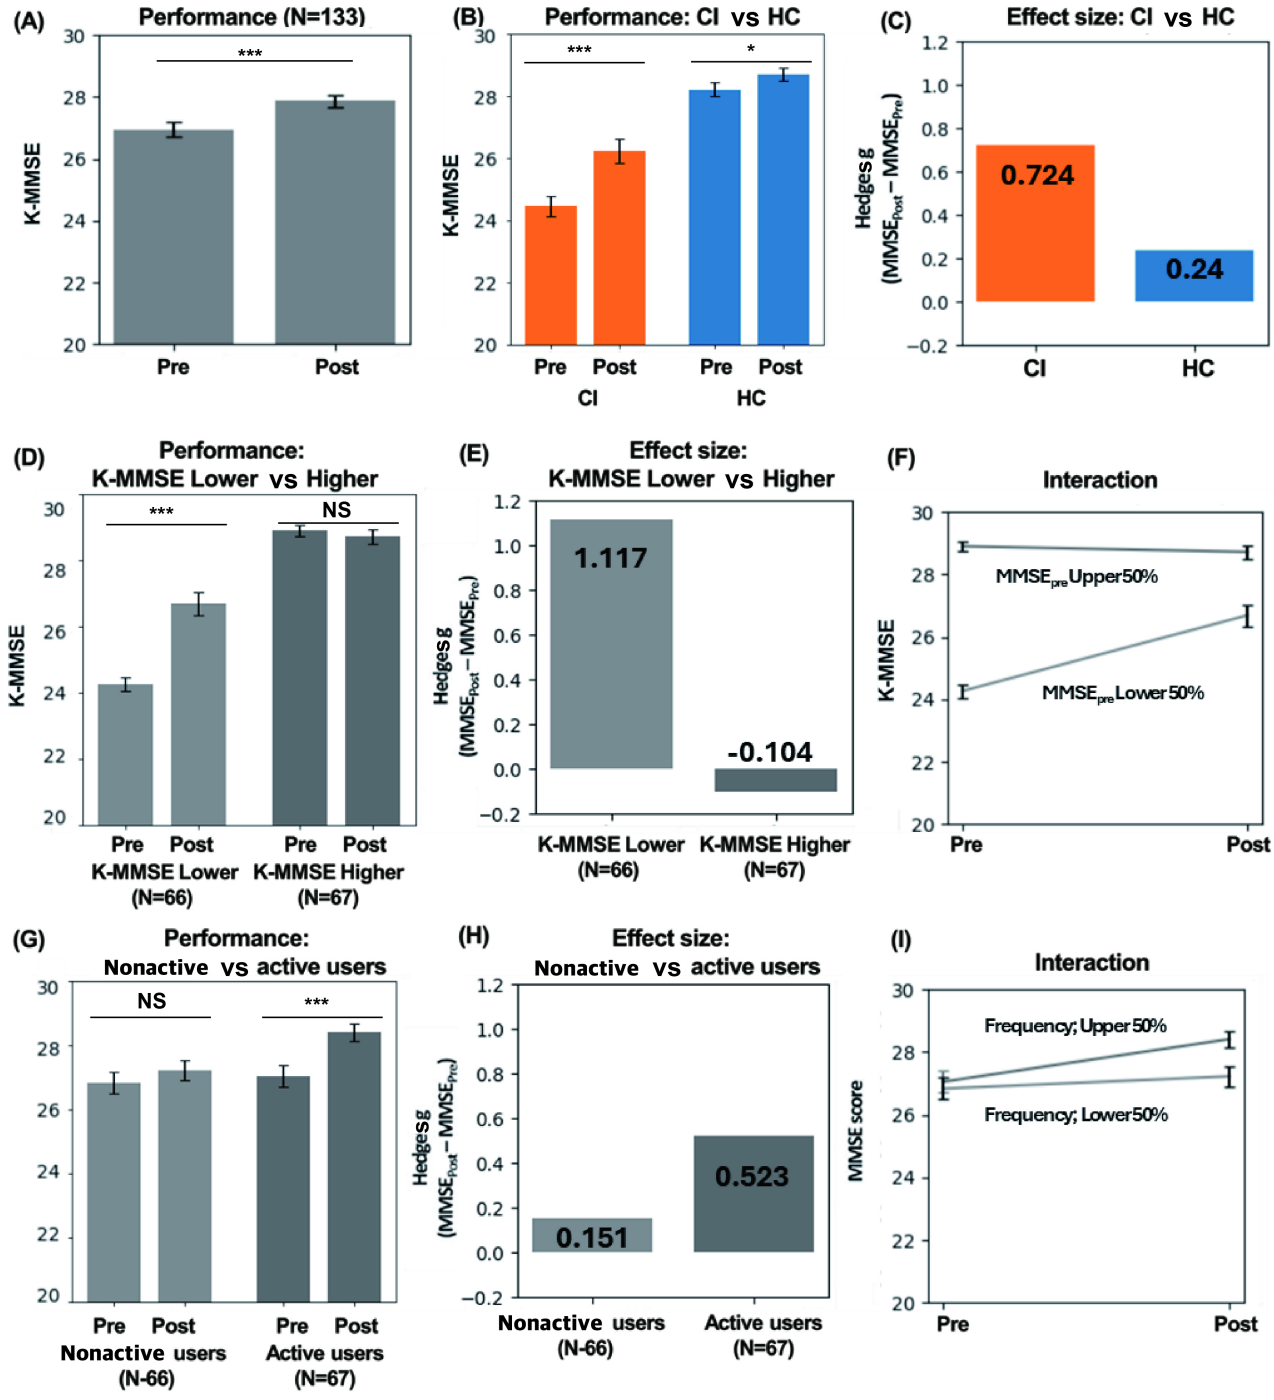
Married couple with children	31 (23.3)
Living with relatives other than spouse/children (eg, siblings) or with nonrelatives	6 (4.5)



Primary Result

Overall Change in Cognitive Function

For all 133 participants, K-MMSE-2 scores showed significant improvement after using the *Care & Cure* program (Figure 4A; pretrial: mean 26.95, SD 2.77; posttrial: mean 27.87, SD 2.46; t_{132}=−4.106, *P*<.001) with a weak effect size (Hedges *g*=0.350). The cognitive impairment risk group included 15 participants with baseline K-MMSE-2 scores ranging from 19 to 23, corresponding to the K-MMSE-2 normative range for mild cognitive impairment (18-23). The healthy control (HC) group included 118 participants with baseline scores of 24 or higher, corresponding to the cognitively normal range in the K-MMSE-2 norms. The cognitive impairment group showed greater improvement in cognitive function than the HC group (Figure 4B; cognitive impairment: *P*<.001; HC: *P*<.05). Effect sizes for each group are presented in Figure 4C. The cognitive impairment group demonstrated a strong effect size (Hedges *g*=0.724), whereas the HC group showed a weak effect (Hedges *g*=0.240).

XSL•FO
RenderX

Figure 4. Overall results. (A) Pre- and postintervention comparison of cognitive function. (B) Performance enhancement comparing participants in the cognitive impairment (CI) risk group (K-MMSE-2 scores 19 - 23) versus those in the HC group (K-MMSE-2 scores ≥24). (C) Effect size. (D) Performance comparison between participants below and above baseline K-MMSE-2 median scores. (E) Effect size. (F) Interaction effect. (G) Performance comparison between low (nonactive) and high (active) app usage frequency groups (based on end-of-experiment user logs). (H) Effect size. (I) Interaction effect. We note that "K-MMSE" in the plot refers to K-MMSE-2 (independent samples *t* test; **P*<.05,***P*<.01,****P*<.001; note: K-MMSE-2 baseline values were adjusted from 0 to 23 - 26 for readability; error bars indicate standard error of the mean). Orange bars indicate the CI group, blue bars indicate the HC group, and gray bars represent overall or subgroup comparisons. CI: cognitive impairment; HC: healthy control; K-MMSE-2: Korean-Mini Mental State Examination—Version 2; MMSE: Mini Mental State Examination; NS: not significant.

Performance Changes in K-MMSE-2 Subject to Baseline Cognitive Function

Similar patterns emerged between groups categorized by baseline K-MMSE-2 median scores. For sensitivity analysis, we divided participants into 2 groups based on their baseline K-MMSE-2 scores: the lower K-MMSE-2 group (n=66) and the higher K-MMSE-2 group (n=67). Participants whose K-MMSE-2 scores fell below the baseline median formed a lower group, while the remaining participants were assigned to the higher group.

Independent samples *t* tests examined cognitive improvement differences between groups. The analysis showed that the K-MMSE-2 lower group demonstrated significant score increases posttreatment (independent *t* test; *P*<.001), whereas the K-MMSE-2 higher group showed no statistically significant

XSL•FO
RenderX

changes (independent *t* test; *P*<.241) (Figure 4D). Effect size analysis showed substantial impact in the K-MMSE-2 lower group (Hedges *g*=1.117), while the higher group displayed an ignorable negative effect (Hedges *g*=−0.104; Figure 4E). The interaction effect between baseline cognitive level and time is presented in Figure 4F.

Performance Changes in K-MMSE-2 Based on the Application Usage Frequency

The active user group (n=67) showed significant increases in K-MMSE-2 scores after the intervention, whereas the nonactive user group (n=66) did not show statistically significant changes in K-MMSE-2 scores (independent *t* test; *P*<.001) (Figure 4G). The lower frequency group (nonactive group) showed a weak effect (Hedges *g*=0.151), while the higher frequency group demonstrated a moderate effect (Hedges *g*=0.523; Figure 4H). The interaction effect between usage frequency and time is presented in Figure 4I.

Performance Differences in K-MMSE-2 According to Age

To investigate the influence of age, we again divided participants once more into 2 age groups based on the median age (66 years): the lower age group (age ≤66 years; n=70) and the higher age group (age>66 years; n=63). Independent *t* tests examined cognitive improvement differences using K-MMSE-2 Delta scores. Both age groups showed increased K-MMSE-2 Delta scores, although these changes lacked statistical significance (lower age group: mean 0.96, SD 2.27 years; higher age group: mean 0.87, SD 2.90 years; t_{131}=−0.187, *P* value not applicable). Effect size analysis revealed negligible differences between groups (Hedges *g*=0.03). See Figure S2 in Multimedia Appendix 1 for more details.

Secondary Result

Impact of Group Intervention on Engagement, Social Support, and Cognitive Function

To investigate the impact of group chat usage and cognitive training on cognitive function, simple regression analyses were conducted on 2 separate occasions. In the initial regression model, usage of the *Our Town* (group chat), measured as the number of interactions, significantly influenced usage of cognitive training ($F_{1,131}$=153.646, *P*<.001). The explanatory power of the regression model was approximately 54.0% (R^2=0.540). The Durbin-Watson statistic was 1.502, which is close to 2, indicating no significant concerns regarding the assumption of independence of residuals. Regarding the significance of the regression coefficients, engagement in *Our Town* (group chat) demonstrated a statistically significant positive effect on the usage of cognitive training (β=.735, *P*<.001). This finding suggests a positive and significant relationship between increased engagement in the group chat and greater usage of cognitive training tools.

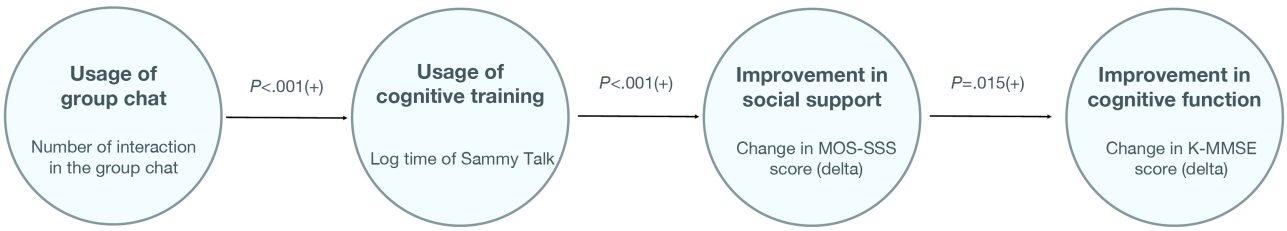
In the second regression model, usage of the cognitive training tools, measured as total log time, did not significantly influence improvement in cognitive function, as assessed by the K-MMSE-2 Delta scores ($F_{1,131}$=0.158, *P*=.692). The explanatory power of the second regression model was minimal, accounting for only 0.1% (R^2=0.001). The Durbin-Watson statistic was 2.050, which is close to 2, indicating no significant concerns regarding the assumption of independence of residuals. Regarding the significance of the regression coefficients, cognitive training usage did not statistically significantly influence cognitive function improvement (β=−.035, *P*=.692). This finding suggests that cognitive training usage did not contribute to cognitive function enhancement (Figure 5 and Table 4).

Figure 5. Impact of group intervention on engagement and cognitive function. K-MMSE-2: Korean-Mini Mental State Examination—Version 2; NS: not significant.

XSL•FO
RenderX

Table . Summary of regression models examining group chat usage, cognitive training, and cognitive function.

	Model	*B*	SE	β	*t* test (*df*)	*P* value	*F* test (*df*); *P* value	R^2	Durbin-Watson (95% CI)
1	Group chat usage → cognitive training usage	1.138	0.092	.735	12.395 (131)	<.001	153.646 (1,131); <.001	0.54	1.138(0.956 to 1.320)
2	Cognitive training usage → cognitive function improvement	−0.001	0.003	−.035	−0.397 (131)	.69	0.158 (1,131); .69	0.001	-0.001(-0.007 to 0.005)



We conducted additional regression analyses to examine how social support mediated the relationships between group chat usage, cognitive training, and cognitive function improvement. In the initial regression model, *Our Town* usage (measured by the number of interactions) significantly influenced cognitive training usage ($F_{1,131}$=153.646, *P*<.001). The explanatory power of the regression model was approximately 54.0% (R^2=0.540). The Durbin-Watson statistic was 1.502, which is close to 2, indicating no significant concerns regarding the assumption of independence of residuals. Regarding the significance of the regression coefficients, engagement in *Our Town* (group chat) demonstrated a statistically significant positive effect on the usage of cognitive training (β=.735, *P*<.001). This finding suggests a clear positive relationship between increased engagement in the group chat and greater usage of cognitive training tools.

In the second regression model, frequent cognitive training usage, defined as total interaction time with the conversational agent, significantly influenced social support improvement, as indicated by social support scores ($F_{1,131}$=16.830, *P*<.001). The explanatory power of the second regression model was 11.4% (R^2=0.114). The Durbin-Watson statistic was 1.946, which is close to 2, indicating no significant concerns regarding the assumption of independence of residuals. Regarding the significance of the regression coefficients, frequent engagement with the conversational agent demonstrated a statistically significant positive effect on social support improvement (β=.337, *P*<.001). This finding suggests that participants who interacted more frequently with the conversational agent reported greater perceived social support.

In the third regression model, improvements in social support had a statistically significant effect on cognitive function enhancement, as measured by the K-MMSE-2 Delta scores ($F_{1,131}$=6.830, *P*<.05). The explanatory power of the regression model was 4.4% (R^2=0.044). The Durbin-Watson statistic was 2.084, which is close to 2, indicating no significant concerns regarding the assumption of independence of residuals. Regarding the significance of the regression coefficients, higher social support scores were associated with greater improvements in cognitive function (β=.211, *P*<.05). This finding suggests that participants with strong social support experienced greater gains in cognitive function.

Conversely, cognitive training usage did not have a statistically significant impact on cognitive function enhancement (*P*=.692). These findings suggest that cognitive function does not improve when individuals use cognitive games as a stand-alone intervention. However, combining cognitive games with group interventions that increase social support and motivation leads to cognitive function improvement (Figure 6 and Table 5).

Figure 6. Impact of group intervention on engagement, social support, and cognitive function (as a part of path analysis). K-MMSE: Korean-Mini Mental State Examination; MMSE: Mini Mental State Examination.

Change in Social Support, Willingness to Participation, and Depression

Social support was divided into four categories: (1) emotional or informational, (2) material, (3) affectional, and (4) positive social interaction support. Emotional or informational support showed the highest pre-post difference with statistical significance (t_{132}=−6.509, *P*<.001) and a moderately strong effect size (Hedges *g*=0.70). Willingness to participate was assessed across 3 dimensions: affect, behavior, and cognition. Affect captured participants' emotional attitudes toward their involvement, such as expressing enjoyment when using *Sammy Talk* for cognitive training or showing enthusiasm about interacting with other members in *Our Town*. Next, behavior referred to observable participation such as attendance or task engagement, including frequency of playing arithmetic and memory games in *Sammy Talk* or actively posting messages and responding to others in *Our Town* social platform. Finally, cognition reflected participants' beliefs and understanding of the program's value, such as recognizing the *Sammy Talk*'s cognitive exercises could improve their mental abilities or believing that social interactions in *Our Town* could enhance their well-being and reduce isolation. Willingness to participate demonstrated significant differences in cognitive factors (t_{132}=2.159, *P*<.05) with a nearly moderate effect size (Hedges *g*=0.43). Within the subcategories of willingness to participate, affect showed significant pre-post differences (t_{132}=2.008, *P*<.05) with a moderate effect size (Hedges *g*=0.51), whereas behavioral measures showed no significant differences (t_{132}=0.244, *P*=.81). Depression levels exhibited significant pre-post differences (t_{132}=3.093, *P*<.01) with a weak effect size (Hedges *g*=0.21). Table 6 presents these results in summary.

Table . Comparison of social support, emotional relief with program use before and after.

Engagement Analysis: Sammy Talk and Our Town

To examine the engagement patterns, we conducted a repeated-measures ANOVA on the average daily usage frequency of *Sammy Talk* (conversation-based intervention) and *Our Town* (community-based intervention) over 3 months (Figure 7). The analysis showed significant differences in average daily usage frequency between *Sammy Talk* and *Our Town* during the third month (P<.001). Results indicated a significant main effect of usage duration ($F_{2,264}$=20.282, P<.001) and a significant interaction between intervention types (eg, *Sammy Talk* and *Our Town*) and usage duration ($F_{2,264}$=17.859, P<.001). *Our Town* demonstrated steadily increasing average daily usage, which reached the highest in month 3 (mean 0.90, SD 0.11), followed by month 2 (mean 0.56, SD0.08) and month 1 (mean 0.24, SD 0.05). In contrast, *Sammy Talk* usage frequency varied, with highest engagement observed in month 2 (mean 0.52, SD 0.08), followed by month 3 (mean 0.47, SD0.11) and month 1 (mean 0.42, SD 0.05).

Figure 7. Changes in participant *Sammy Talk* and *Our Town* usage frequency following intervention implementation. *P<.05,**P<.01,***P<.001.

Discussion

Principal Findings

The *Care & Cure* program demonstrated effectiveness in improving cognitive function across all 133 participants, with particularly strong enhancement among individuals with lower K-MMSE-2 scores. This aligns with the program's evidence-based development, which incorporated clinical expertise from neurologists at Mokdong Ewha Womans University Hospital.

The *Sammy Talk* content followed validated clinical frameworks across multiple cognitive domains. The calculation games were derived from the *WRAT-3 Arithmetic subset* and *Digit Symbol Substitution Test* [41,42]. Visuospatial tasks incorporated the *Mental Rotation Test* [43], whereas attention-focused games used crossword puzzles and the *Montreal Cognitive Assessment letter—a tapping test* [44,45]. Executive function games were adapted from the *University of California, San Diego Performance-Based Skills Assessment* (*UPSA-3*) and the *Trail Making Test* [46,47]. Memory tasks integrated the *Korean Naming Test*, *Chinese idioms*, and *Rey-Osterrieth Complex Figure Test* [48-51]. Language games incorporated the *Montreal Cognitive Assessment* initial letter fluency test and *Scrambled Sentences Test* [44,52]. However, the specific cognitive impact of individual game components remains to be clarified in future research.

Participants with lower baseline K-MMSE-2 scores (hereafter referred to as the lower group) showed larger effect sizes, as

XSL•FO
RenderX

they had greater potential for measurable improvement. By contrast, those with higher baseline scores (hereafter referred to as the higher group) showed little change, having already approached their cognitive performance ceiling. This difference reflects a well-known ceiling effect among cognitively normal participants. Previous studies examining short-term interventions have consistently reported that people with cognitively normal conditions achieve only limited gains, whereas those with cognitive impairment show greater improvement [64-66]. Moreover, participants in the lower group faced a higher risk of decline and therefore benefited more from the clinically validated content designed by neurologists to target multiple cognitive domains, including calculation, attention, language, memory, visuospatial ability, and executive function. This finding is consistent with previous research using validated clinical tasks, which confirmed that participants in the lower group achieved greater improvements than those in the higher group [64,65].

Higher usage frequency of *Care & Cure* corresponded with enhanced cognitive function. *Our Town* appeared to moderate this effect by increasing *Sammy Talk* engagement. Participants who engaged more often in *Our Town* engagement dedicated more time to *Sammy Talk* and achieved superior cognitive function scores. The group chat format likely enhanced engagement through shared performance goals, achievement reports, and peer encouragement. These findings align with previous research on group chat–based cognitive enhancement programs [31,32].

Nonetheless, *Our Town* did not directly enhance cognitive function; rather, its impact emerged through social support mechanisms. The integration of *Our Town* and *Sammy Talk* (a software robot) in the *Care & Cure* program enhanced social support, which in turn improved cognitive function. While *Our Town* did not bring about direct cognitive benefits, it served as an indirect motivational means by sending consistent reminder messages to participants. Participants exchanged greetings and shared daily experiences in *Our Town* while learning practical knowledge and conversation-related vocabulary through *Sammy Talk*. This encouraged more frequent communication both online and offline. These repeated interactions in turn created a social support network through daily greetings, experience sharing, and conversational practice. The AI chatbot provided additional support by offering affective encouragement and fostering positive exchanges, leading participants to report higher social support scores. This finding aligns well with previous studies demonstrating that AI chatbots deliver social support and reduce depressive symptoms among older adults [67,68]. Social support and emotional stability function as preventive factors that preserve cognitive function by reducing loneliness and chronic stress, both recognized contributors to memory decline and executive dysfunction [67-71]. Conversations and social interactions demand memory recall, language use, and problem-solving, repeatedly stimulating cognitive processes and strengthening cognitive reserve [72-74].

On a secondary issue, the *Care & Cure* program effectively reduced emotional distress, with participants experiencing emotional changes through enhanced social support. Program engagement, measured through *Our Town* chat interactions, showed increasing participant responses to the chatbot-based software agent, reaching 3.8 times the initial level by month 3 (Figure 6). This increased engagement suggested more frequent conversations with both the software agent and other participants, potentially facilitating positive social exchanges and providing emotional, affectionate, and informational support. However, chat interaction frequency alone provides limited insight into intervention adherence. Future research should examine more precise adherence measurements. The study suggests that increased social support influenced participants' depressive symptoms [75-78].

Postanalysis on Dropout

Nearly 3 out of 10 participants (28.8%) dropped out of the study, with education emerging as the primary differentiating factor. Education, rather than age or sex, accounted for this difference, as people who completed the intervention had significantly more years of education than those who dropped out (t_{131}=2.43, P=.016). These results show that education level, which reflects accumulated social and cognitive resources, was associated with dropout, whereas age and sex were not. Participants with limited education and digital literacy often struggled to use the digital cognitive training program. Lower educational attainment, which often limits digital literacy, reduced participants' ability to use messenger applications and type messages, preventing them from joining group chats or completing training tasks [18,20,21]. Those who lacked primary school education and could not perform basic arithmetic operations were unable to complete calculations tasks and eventually dropped out. Participants with very low education levels may therefore be more likely to drop out of digital cognitive training programs [18,20,21]. Although not statistically significant, males were likely to drop out more frequently than females, suggesting that future studies should consider strategies to improve male retention (see Multimedia Appendix 1, Section VI for more details).

Limitations

Despite the significant improvement in participants' cognitive capacity through the use of our proposal in general, the research has some limitations to address. First, the single-arm design without a control group reduces confidence in attributing changes to the intervention. Without a comparison group, it would be very difficult to establish that observed improvements resulted solely from the intervention, as changes might be able to reflect natural progression, practice effects from repeated testing, or placebo effects. In addition, it would be challenging to determine whether improvements are clinically meaningful compared with standard care or alternative interventions. Second, participant interaction with the software robot in *Our Town* (the group chat component) was lower than anticipated, with its primary effect manifesting through increased usage of *Sammy Talk*. Third, the sample was drawn from a single midsize Korean city with relatively homogeneous demographic characteristics, limiting the generalizability of findings to other regions or populations. Fourth, the program's reliance on *KakaoTalk* as the delivery platform might restrict applicability beyond the Korean context. These methodological considerations highlight areas for future investigation, including randomized controlled trials with appropriate control groups,

XSL•FO
RenderX

multisite studies across diverse populations, and head-to-head comparisons with standard assessment tools to establish clinical superiority.

Conclusions and Future Research Direction

The *Care & Cure* program demonstrated effectiveness for cognitive enhancement, with more frequent participation corresponding to greater improvement. The program showed particular efficacy among cognitively impaired participants. Additional benefits included reduced depressive symptoms, enhanced social support, and increased participation willingness.

Our hypothesis proposed that increased *Our Town* usage would enhance *Sammy Talk* engagement, subsequently improving cognitive function. The data confirmed that higher *Our Town* usage directly increased *Sammy Talk* participation. However, increased *Sammy Talk* usage alone did not yield statistically significant cognitive improvements. When examining social support as a mediator between *Sammy Talk* usage and cognitive enhancement, results indicated that social support directly influenced cognitive improvement. This relationship requires further investigation to understand underlying mechanisms.

While the top 50% of program participants showed greater K-MMSE-2 improvements, the causal relationship between *Sammy Talk* usage and cognitive enhancement lacked statistical significance. Future research should examine the relationship between *Our Town* and *Sammy Talk* usage patterns while addressing the methodological issues raised in this study. Controlled trials with comparison groups are necessary to establish causal effects. For example, a potential future study could compare an intervention group using both *Sammy Talk* and *Our Town*, with a control group attending a traditional face-to-face dementia prevention program. Researchers should also test strategies to increase participation in group chat functions, which serve as sources of social support [79-81]. Gamification approaches, such as small financial rewards, goal setting, or competition elements, may enhance motivation to engage [82,83]. Additionally, context-based reminders drawing on Ecological Momentary Interventions or Ecological Momentary Assessments could encourage more consistent use of both *Sammy Talk* and *Our Town* [84-86].

Next, future studies had better recruit participants from varied regions and sociodemographic groups to extend findings beyond a single Korean midsized city. For instance, researchers could target English-speaking populations from middle-class and low-class households or urban groups with higher digital literacy and educational attainment [87,88]. Moreover, researchers should conduct longitudinal follow-up studies that track participants for at least 1 year to examine whether cognitive benefits persist and to determine whether digital training combined with social support prevents long-term cognitive decline [89,90]. For example, participants could use the intervention for 1 year or more, with outcomes measured at regular intervals to evaluate intervention effectiveness over time. Finally, since this program relied on *KakaoTalk* as its delivery platform, which limits generalizability beyond Korea, future studies should better adapt the same model to other messaging services that provide chatbot Application Programming Interfaces, such as *WeChat*, *WhatsApp*, or *Facebook Messenger*, to test how the intervention performs across different cultural and technological contexts [91,92].

Finally, future works should also take into account education as a covariate, which requires stratified randomization and sensitivity analyses to ensure the robustness of findings. Researchers should also design tasks that assess cognition without relying on arithmetic, so that individuals without formal schooling can participate fully in the longitudinal intervention. Finally, incorporating competitive gamification elements, which may appeal particularly to males who often demonstrate stronger achievement motivation than females, could enhance digital program retention by using leaderboards or quizzes that provide modest rewards and recognize performance [93-95]. By pursuing these directions, future research would be able to clarify how digital cognitive training and social interaction interplay with each other, and identify practical strategies that strengthen engagement and broaden applicability across populations.

Abstract

Background: Unguided internet-based cognitive behavioral therapy (ICBT) is a low-cost and scalable treatment for major depressive disorder (MDD), but its long-term effects in Chinese populations remain unclear.

Objective: This study aimed (1) to explore the short- and long-term effectiveness of unguided ICBT in treating adults with MDD; (2) to investigate the short- and long-term effects on disease-related symptoms, individual and social functioning, and quality of life; and (3) to assess the acceptability and satisfaction with the ICBT.

Methods: An 8-week randomized controlled trial (ChiCTR2100046425) was conducted between August 2021 and June 2023 in Shenzhen, China, with 159 participants in the immediate ICBT group (7-module ICBT course plus usual care) and 158 in the waitlist control (WLC) group (usual care). The WLC group later completed the same ICBT course and follow-up assessments. Outcome measures (depressive and anxiety symptoms, psychological distress, social functioning, self-efficacy, quality of life, and stigma) were assessed before and after treatment and at 3-, 6-, and 12-month follow-ups for ICBT participants. Remission and response, adherence, and satisfaction were evaluated by predefined standards.

Results: Among 300 participants analyzed (mean age 28.49, SD 7.0 years; female: n=225, 75%), dropout rates were 22.4% (34/152) in the immediate ICBT group versus 6.3% (10/158) in the WLC group. At posttreatment, the immediate ICBT group showed greater reduction in depressive symptoms versus WLC (mean difference −3.65, SE 0.60; P<.001; d=0.50), with higher remission (80/121, 66.1% vs 58/148, 39.2%; P<.001) and response rates (50/121, 41.3% vs 27/148, 18.2%; P<.001). At 12-month follow-up, the depressive symptoms were improved compared with that at pretreatment (mean difference −3.90, SE 0.32; P<.001; d=0.70), and no significant change was observed in comparison with the outcomes at posttreatment (mean difference −0.81, SE 0.33; P=.33; d=−0.15). ICBT treatment also exhibited similar short- and long-term effects on secondary outcomes, with significant improvement of disease-related symptoms, individual and social functioning, and quality of life. Moreover, the majority of the participants treated with ICBT reported high acceptability of and satisfaction with the ICBT course.

Conclusions: Unguided ICBT effectively reduces depressive symptoms and enhances functioning in Chinese patients with MDD, with sustained benefits over 12 months. Its scalability and low-cost nature make it a promising option for resource-limited settings.

Introduction

Background

Major depressive disorder (MDD) affects approximately 332 million people globally in 2021 [1]. As the second leading cause of nonfatal disability [1], MDD is associated with severe emotional symptoms, low self-efficacy, impaired social functioning, and diminished quality of life [2]. Additionally, MDD has imposed a significant economic burden on individuals and societies, which is predominantly from productivity loss [3,4]. Although there are efficacious treatments for MDD with robust clinical evidence (ie, psychotherapies and pharmacotherapies) [5], the treatment gap is still substantial. In low- and middle-income countries, more than 70% of patients remain untreated [6,7]. Social discrimination and personal stigma, high treatment expenditure, side effects of antidepressants, and the inconvenience of traditional in-person psychotherapies have prevented people from accessing these conventional forms of treatment [8].

Internet-based cognitive behavioral therapy (ICBT), a scalable, confidential, low-cost, and flexible modality of cognitive behavioral therapy (CBT) delivered through the internet with guided and unguided forms, has been introduced to the treatment of MDD to overcome the treatment barriers mentioned earlier [9]. Although CBT has been recommended as a first-line treatment for MDD by many treatment guidelines [10-12], the levels of evidence and applicable scenarios of ICBT vary across these guidelines. In China, mental health resources are severely limited, with per capita mental health investment standing at US $1.07 and only 2.19 certified psychiatrists per 100,000 people, far below the high-income country averages of US $35.06 and 13.06 psychiatrists [13]. The structural imbalance in the distribution further compounds the shortage, with hospitals and professionals disproportionately clustered in provincial capitals and the more developed eastern regions [14]. Moreover, despite the high prevalence of MDD in China (6.8%), the service coverage rate remains strikingly low at only 9.5% [15]. The unguided form, defined as self-help ICBT with different levels of technical support, offers greater potential for scalability compared to guided ICBT. Consequently, the earlier-mentioned mental health realities in China provided the impetus for our team to develop an unguided ICBT course for MDD called Morning Mood on WeChat Mini Program.

There is a growing body of evidence that unguided ICBT showed superior outcomes in alleviating depressive symptoms compared to control treatments (ie, treatment-as-usual and waitlist control [WLC]) in short-term clinical end points (ie, posttreatment) [16-31]. However, a large variance is observed in reported short-term effect sizes, ranging from no effect [23] to large effect sizes [22,28,29]. Moreover, the long-term efficacy of unguided ICBT remains understudied, with existing studies yielding inconsistent conclusions regarding whether sustained improvements occur beyond the intervention period [23,26,32-35]. Newby et al [26] found that the depressive outcomes at the posttreatment stage were favored over the 3-month follow-up stage, with a within-group effect size of −0.21, while Gilbody et al [23] reported that the within-group effect size between the posttreatment and 12-month follow-up stage was 0.35. Regarding binary outcomes, both response rates (defined as ≥50% reduction in symptom severity) and remission rates (defined as symptom levels below clinical thresholds) exhibited considerable variability across studies. Posttreatment analyses revealed that unguided ICBT achieved response rates of 37% - 58.6% and remission rates of 30.5% - 64%, representing more improvements over control conditions [18,20,25,27,32,34,36,37]. Only 1 study reported a response rate at 12-month follow-up of 51.4% [32]. In addition, existing studies focusing on unguided ICBT for MDD are largely represented by Western studies, thereby limiting the ability to generalize the results to patients from different races, ethnicities, and cultural backgrounds [38]. In China, only 1 randomized controlled trial (RCT) has verified the short-term effectiveness of clinician-supported unguided ICBT (the Chinese-translated version of MoodGYM) in patients with MDD [31]. However, previous research has explored the effect of ICBT for depressive symptoms or subthreshold depression. During the COVID-19 pandemic, unguided ICBT has been proven effective for patients with depressive symptoms and COVID-19 [39]. Another study demonstrated that unguided ICBT significantly reduced depressive severity among undergraduate students with mild to severe symptoms of depression [40]. Beyond unguided form, guided ICBT has also shown a moderate antidepressant effect among individuals with subthreshold depression, regardless of age [41,42]. Furthermore, a trial in Hong Kong confirmed that both web- and app-based guided ICBT led to significant improvements in depressive symptoms [43]. Furthermore, the aforementioned studies have primarily focused on depressive symptomatology outcomes, limiting possible insights into other relevant depression domains (eg, anxiety symptoms, self-efficacy, quality of life, and functional outcomes) [44]. Given the earlier-mentioned limitations, there is a need to evaluate the short- and long-term effectiveness of unguided ICBT for MDD, especially in China.

Objectives

Herein, this study aimed (1) to evaluate the short- and long-term effectiveness of unguided ICBT in treating adults with MDD, (2) to further evaluate the short- and long-term effects on specific depressive symptoms as well as individual and social functioning, as well as quality of life, and (3) to assess the acceptability and satisfaction with the ICBT.

Methods

Study Design

This study was an 8-week nonblinded pragmatic RCT with 12-month follow-up, investigating whether an unguided ICBT course as an adjunct to usual care could reduce depression symptoms in adult patients with MDD and its long-term effectiveness. Eligible participants were randomized to either (1) the immediate ICBT group (ICBT group I), receiving the ICBT intervention with nonspecialists' support plus usual care, or (2) the WLC group, receiving usual care only. After the 8-week control period, WLC participants crossed over to receive the ICBT intervention (ICBT group II). Both ICBT groups (I and II) were assessed at baseline, posttreatment, and at 3, 6, and

XSL•FO
RenderX

12 months after the intervention to examine immediate and long-term effects.

Ethical Considerations

This trial was registered with the Chinese Clinical Trial Registry (ChiCTR2100046425). The study protocol, patient information sheets, and informed consent forms were approved by the Medical Ethics Committee of Shenzhen Nanshan Center for Chronic Disease Control, China (ethics approval ll20210012). The CONSORT (Consolidated Standards of Reporting Trials) with the eHealth extension was adopted to guide and report the trial (Checklist 1) [45]. All participants provided informed consent. Deidentified data were used for the whole analysis. Financial incentives (US $6.82 electronic cash) were distributed to those who completed the trial.

Participants and Procedure

All participants were recruited from the Department of Depressive Disorder at Shenzhen Kangning Hospital and the Department of Psychiatry at Shenzhen Nanshan Center for Chronic Disease Control. MDD diagnosis was determined by using the Mini-International Neuropsychiatric Interview (M.I.N.I.), which was administered according to the *Diagnostic and Statistical Manual of Mental Disorders-Fourth Edition* (DSM-4) criteria [46,47]. The enrollment period spanned from August 2021 to June 2023. The key inclusion criteria were (1) Chinese residents, (2) aged between 18 and 60 years, (3) met criteria for MDD in DSM-4, (4) had access to the internet, (5) a score of Patient Health Questionnaire-9 (PHQ-9) more than 5, (6) no severe suicidal risk according to section C of the M.I.N.I., and (7) in a stable condition (if taking antidepressants, dosage had to be stable for at least 30 days before enrollment). The key exclusion criteria were (1) met DSM-4 criteria for bipolar disorder or other psychotic disorders, (2) had an ongoing alcohol or substance abuse disorder, (3) was pregnant or lactating, (4) underwent physiotherapy or psychotherapy treatments at the time of enrollment, and (5) any other condition deemed by the psychiatrists to interfere with ICBT (eg, cognitive impairment).

A 2-stage procedure was adopted for the selection of eligible participants. Outpatients who visited the department of depressive disorder and psychiatry were first screened by psychiatrists to identify potential study participants. Trained researchers (YJ and H Zhao) then conducted structured diagnostic interviews (ie, M.I.N.I.) to make the MDD diagnosis. Both researchers hold master's degrees and have medical backgrounds. They underwent standardized M.I.N.I. interview training organized by the National Center for Mental Disorders, which comprised theoretical instruction, simulated interviews, and a reliability test. Furthermore, both researchers completed a 1-year clinical practicum at the Department of Psychiatry, Nanshan Center for Chronic Disease Control (ie, Nanshan Mental Health Center). Throughout the data collection period, they received regular supervision from senior psychiatrists to ensure diagnostic consistency. Randomization was performed using a computer-generated sequence with randomly permuted block sizes (4 and 6). This sequence was managed centrally and applied sequentially to participants in biweekly batches throughout the recruitment period to ensure ongoing group balance. Due to the nature of the interventions, the blind method was hard to carry out.

Eligible participants were then instructed to complete baseline assessments through online questionnaires. Sociodemographic information (eg, age, sex, and ethnicity), lifestyle features (eg, exercise, drinking, and smoking), clinical characteristics (eg, antidepressant use, first of onset, and age of MDD onset), and baseline symptoms (eg, somatic pain, resilience, and insomnia severity) were collected.

Interventions

The ICBT intervention in this trial was tailored for the Chinese population, aiming at teaching practical CBT skills for depression. A total of four phases were carried out for intervention development and cultural adaptation: (1) literature review on the ICBT intervention and cultural adaptation framework, (2) preliminary content setting, (3) face-to-face group discussion and content adaptation, and (4) expert consultations and finalized adaptation.

Guided by the ecological validity model, cultural adaptations were made across 8 dimensions (ie, language, persons, metaphors, content, concepts, goals, methods, and contexts) to ensure relevance, acceptability, and comprehensibility [48]. In terms of language, the intervention was delivered in Mandarin, using idioms and communication styles that align with local habits to prevent misinterpretation. For persons, all illustrative characters designed with names, appearances, and attire were in line with Chinese people's characteristics, and video cases featured individuals from diverse age groups to enhance relatability. Metaphors were replaced with localized, everyday analogies to improve understanding. The content, including scenarios and activities, was tailored to align with common daily practices, social customs, and economic realities. Concepts of stressors and depressive symptoms were refined to resonate with the population's lived experiences. To mitigate mental health stigma, the intervention's goals were framed around "mood management" rather than depression treatment. The core therapeutic methods, such as behavioral activation, were preserved, but the suggested activities were customized according to culturally relevant options. Finally, the context of delivery was adapted by designing the intervention as a WeChat Mini Program, leveraging a ubiquitous platform in China to maximize accessibility and minimize barriers to engagement.

The ICBT course consists of 7 lessons, covering psychoeducation, behavioral activation, cognitive restructuring, affect regulation, and relapse prevention. The detailed content of each lesson and the corresponding screenshots are displayed in Multimedia Appendix 1. Participants in the ICBT group were required to complete 1 lesson per week; one week after completing the prior lesson, the subsequent lesson would be open automatically. This setting was used to prevent participants from completing multiple lessons in a short period, which might potentially impact the effectiveness. General support involving technical support and daily reminders provided by nonspecialists (eg, nurses, lay health workers, and social workers) via telephone or WeChat was applied to prompt engagement. The active treatment phase comprised 7 weeks, while the total

XSL•FO
RenderX

intervention period, which included a final week for outcome consolidation, was defined as 8 weeks.

Participants in the WLC group were treated with usual care, and no additional care was offered during the 8-week study period. After completing the posttreatment assessment, participants in the WLC group were asked whether they were willing to receive ICBT intervention at no cost. The login accounts and passwords for Morning Mood were then provided to the intended individuals. All participants with antidepressant prescriptions were instructed to be on a stable dose for the past 4 weeks before enrollment and maintain the antidepressant regimen (unchanged drug type and dosage) during the intervention phase. Only necessary adjustments due to severe adverse reactions are permitted.

Outcome Measures

The primary outcome was depressive symptoms measured by the Chinese version of PHQ-9, which was with good reliability and validity [49]. Its Cronbach α was 0.91 in this study. Remission was defined as a PHQ-9 score less than 10, where the threshold was set and adopted by the Improving Access to Psychological Therapies of the United Kingdom to distinguish clinical cases and noncases [50,51]. Response was defined as symptom improvement (ie, the reduction of PHQ-9 score of 50% or more) [34].

The secondary outcome measures included anxiety symptoms, nonspecific psychological distress, social function impairment, general self-efficacy, quality of life, and depression stigma, which were assessed by the Chinese version of the Generalized Anxiety Disorder-7 (GAD-7), the Kessler 10-Item Psychological Distress Scale (K-10), the Sheehan Disability Scale (SDS), the General Self-Efficacy Scale (GSES), the Short Form Six-Dimension (SF-6D), and Depression Stigma Scale (DSS), respectively. These measurement tools have good reliability and validity [52-57]. In this study, the corresponding Cronbach α was 0.94, 0.96, 0.94, 0.71, 0.95, and 0.84, respectively. All outcomes were evaluated at pre- and posttreatment, with further follow-up at 3, 6, and 12 months after ICBT intervention.

Participants' satisfaction and acceptability for ICBT treatment were investigated after the treatment by the following three questions: (1) "Do you think the courses in this project have been helpful for you?" (2) "Are you satisfied with the courses in this project?" and (3) "Would you be willing to recommend this project to people in need?"

Statistical Analysis

The sample size was determined by a priori power analysis. A total of 86 participants per group (n=172) was thought to be sufficient to detect a moderate between-group effect size (Cohen *d*=0.50, defined as the standardized difference between groups obtained by calculating the mean difference and dividing by the pooled SD) on repeated measures for PHQ-9, with a power of 90% and 2-tailed α of .05. The expected sample size was calculated based on a previous meta-analysis of individual patient data that investigated the effectiveness of unguided ICBT versus inactive controls for depressive symptoms [34]. Taking the attrition into consideration, the target sample size should be 228 patients when the anticipated dropout rate is set at 25% [39].

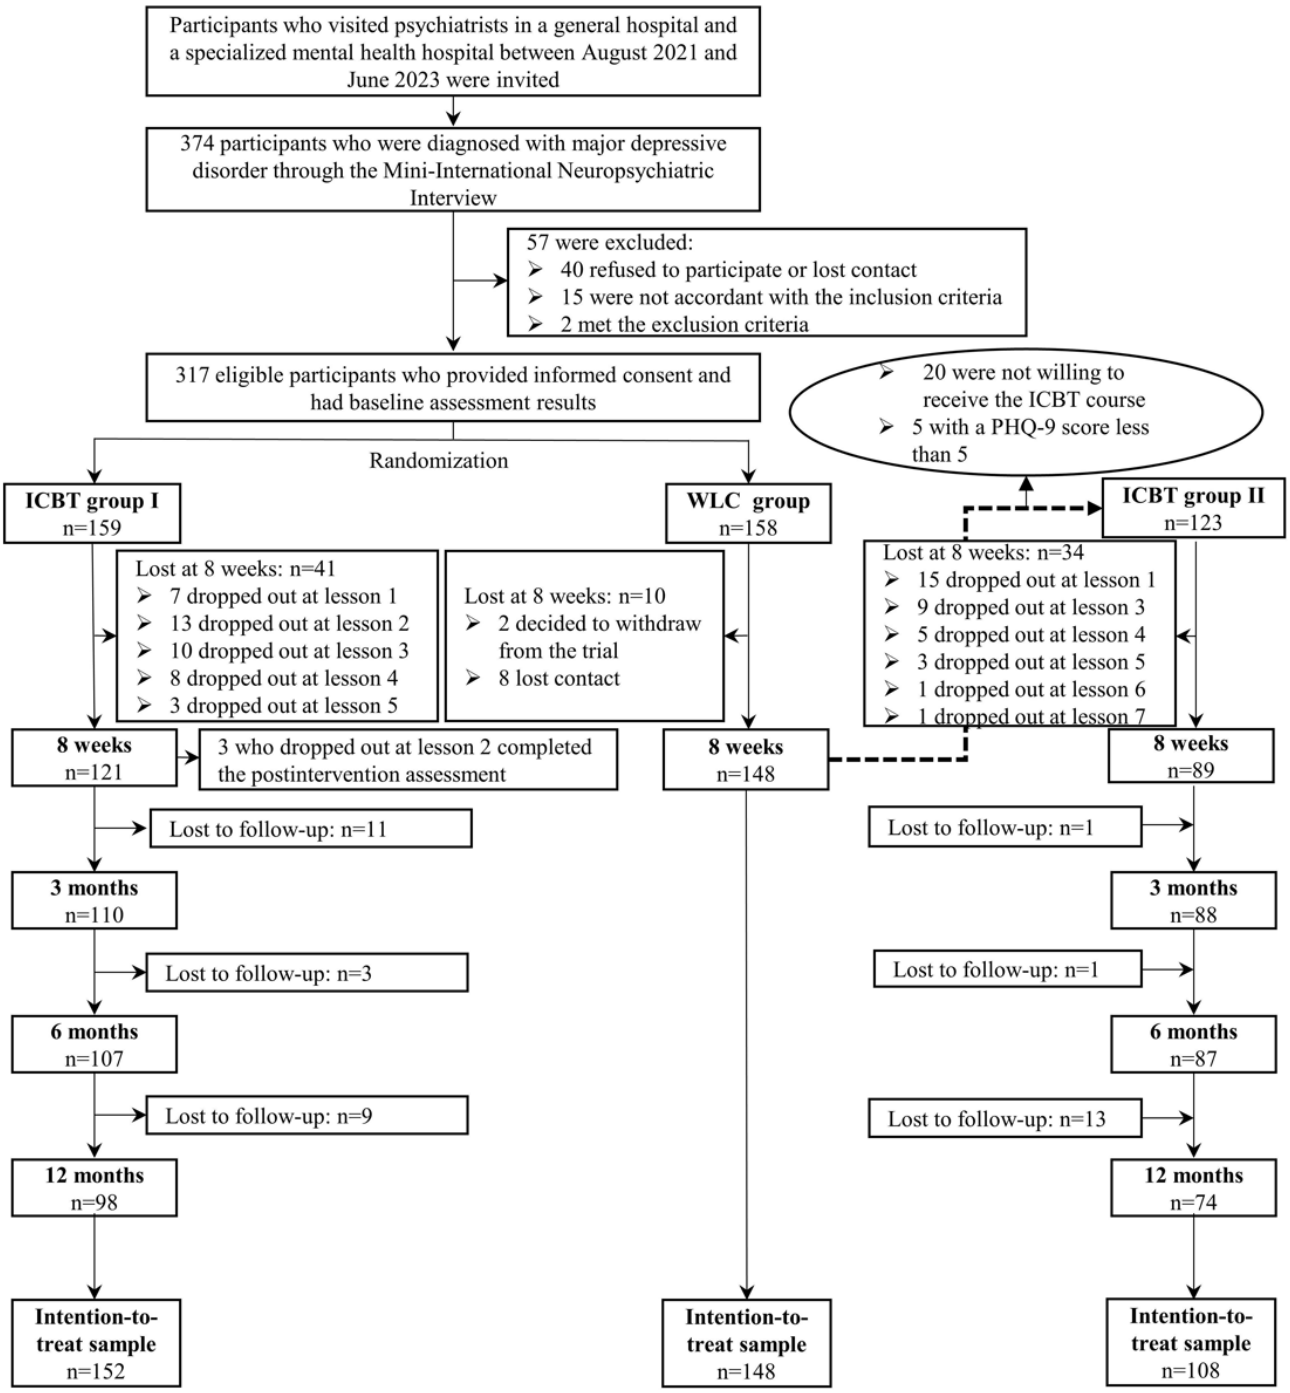
Participants who did not start lesson 1 in the immediate ICBT group and who could not be contacted in the WLC group after randomization were excluded from the main analysis, which followed the modified intention-to-treat (mITT) principle [58-60]. Sensitivity analyses were conducted in the intention-to-treat (ITT) sample (ie, all randomized participants) and the per-protocol set (PPS; ie, participants who completed all modules in the immediate ICBT group and who completed the posttreatment assessment in the WLC group). According to the statistical principles for clinical trials, the primary analysis in a clinical trial should adhere to the ITT principle by including all randomized participants. In practice, the mITT approach is often used as a refinement for ITT. This approach justifiably excludes a limited number of participants, such as those who violated major eligibility criteria, never received any dose of the study treatment, or provided no data after randomization [61]. Excluding patients who received no treatment is methodologically sound, as such analyses can serve as an unbiased estimator for the principal stratum effect (ie, the effect in the population of patients who would initiate treatment) [62]. Furthermore, the mITT analysis complements the ITT findings by providing a more precise estimate of the treatment effect among patients who actually started the intervention [58]. Missing data of posttreatment assessment in the ITT sample were addressed via multiple imputation using chained equations (*MICE* package in R [53]), with pooled estimates derived from Rubin's rules [63,64]. Baseline characteristics and outcome measures were described as mean (SD) for continuous variables and frequencies (percentages) for categorical variables. The differences between the 2 groups were compared using 2-tailed *t* tests, chi-square tests, and Mann-Whitney tests.

The 8-week model (ie, random intercept linear mixed models [LMMs]) was applied to evaluate the effectiveness of the ICBT by estimating the mean between-group differences (the ICBT group I: n=152 and the WLC group: n=148) in 9 outcomes at the pre- and posttreatment time points (8 weeks). In this model, treatment groups, the time point of measurement, and the treatment by time point interaction were treated as fixed effects, and the individual patient effect was set as a random effect with a normal distribution and expected value 0. Parameters were estimated using maximum likelihood. In addition, the follow-up model (ie, marginal LMM with random intercept) was used to estimate the outcome changes in the ICBT group (ICBT group I: n=152 and ICBT group II: n=108). The fixed effect of time was used to estimate the marginal means of each outcome at 8 weeks, 3, 6, and 12-month follow-ups. Post-hoc pairwise comparisons of these marginal means across time points were conducted with Bonferroni correction. There were 18 models, one up to 8 weeks across arms ("8-week model") and one including combined intervention group data ("follow-up model") per outcome variable (depressive symptoms, anxiety symptoms, psychological distress, social function impairment, health-related quality of life, general self-efficacy, depression stigma, personal depression stigma, and perceived depression stigma). Model fit was evaluated using Schwarz's Bayesian criterion. Within-group and between-group effect sizes (Cohen *d*) were calculated based

XSL•FO
RenderX

on the method suggested for LMM analysis [65,66]. It was reported that the effect be categorized as small (>0.20), moderate (>0.50), and large (>0.80) according to Cohen *d* [67]. Sensitivity analyses for long-term effectiveness evaluation were conducted, respectively, among participants treated with ICBT in the ICBT group and the WLC group.

The remission and response rates in the ICBT and WLC groups were also estimated by treatment arms (ICBT vs WLC) and time points (posttreatment, 3-, 6-, and 12-month follow-ups). Chi-square tests were performed to assess the frequency differences in remission and response between the 2 groups. All analyses were performed using R language (version 4.2.2; R Foundation for Statistical Computing), and a *P* value less than .05 was considered statistically significant.



Results

Overview

A total of 374 participants with MDD were recruited for this trial between August 2021 and June 2023, of whom 317 cases entered the trial and were randomized (ICBT group I: n=159; WLC group: n=158). In the ICBT group I, 7 participants did not start lesson 1 and thus were excluded. According to the criteria for completion and attrition defined in Multimedia Appendix 2, the treatment completion rate was 77.6% (118/152), and the attrition rate at 12-month follow-up was 35.5% (54/152). The average number of ICBT lessons completed was 5.89 (SD 2.13). In the WLC group, the dropout rate was 6.3% (10/158). After the 8-week waitlist phase, participants in the WLC group were provided access to the ICBT intervention (ICBT group II). In total, there were 108 (73%) who initiated the intervention. The remaining participants were excluded for the following reasons: 20 (13.5%) declined to receive treatment, 5 (3.4%) no longer met the inclusion criteria (PHQ-9 score<5), and 15 (10.1%) only registered at Morning Mood and did not start lesson 1. In this group, the treatment completion rate was 82.4% (89/108), and the attrition rate at 12-month follow-up was 31.5% (34/108). The detailed completion and dropout information are presented in Figure 1. The mITT sample used for the short-term effectiveness analyses consisted of 152 patients in the ICBT group I and 148 patients in the WLC group. For the long-term effectiveness evaluation, a total of 260 participants receiving ICBT intervention in the 2 ICBT groups were included, with 152 from group I and 108 from group II.

Figure 1. Study flowchart. ICBT: internet-based cognitive behavioral therapy; PHQ-9: Patient Health Questionnaire-9; WLC: waitlist control.

Baseline Characteristics

Table 1 outlines the baseline characteristics of the mITT sample. The mean age was 28.49 (SD 7.00) years, and the female-to-male ratio was 3:1. Most participants were Han ethnic (283/298, 95%), highly educated (247/299, 82.6%), employed (192/297, 64.6%), and nonmarried (201/285, 70.5%). Participants whose monthly household income was below 10,000 Chinese Yuan (1 Chinese Yuan=US $0.1419 in 2023) accounted for the largest part (96/281, 34.2%). In modifiable lifestyle behaviors, the majority of the participants did not smoke cigarettes (186/299, 62.2%), lived with other people (210/283, 74.2%), drank alcohol (249/299, 83.3%), and had no exercise habits (218/299, 72.9%). In terms of clinical features, more than half of the participants were in their first episodes of MDD (175/292, 59.9%), did not take antidepressants (163/300, 54.3%), or did not have comorbidities at baseline (190/298, 63.8%). The mean (SD) of baseline outcome measures including PHQ-9, GAD-7, K-10, SDS, SF-6D, GSES, and DSS were 13.40 (4.83), 10.25 (4.60), 29.73 (7.48), 13.81 (6.81), 0.56 (0.21), 19.61 (5.71), and 52.08 (9.14), respectively. Baseline characteristics were comparable between the ICBT and WLC groups, suggesting that the randomization was successful. Table S1 in Multimedia Appendix 3 and Table S1 in Multimedia Appendix 4 display the baseline characteristics of the ITT sample and the PPS.

[r]DSS: Depression Stigma Scale.

Outcome Measures at Posttreatment

Table 2 depicts observed and estimated means of outcomes by treatment arms and time points, and the mean differences between groups calculated by 8-week models. The 8-week model suggested significant interaction effects of time-by-intervention-arm for PHQ-9 (β=−3.65; *P*<.001), GAD-7 (β=−2.85; *P*<.001), K-10 (β=−4.87; *P*<.001), SDS (β=−5.57; *P*<.001), GSES (β=1.42; *P*=.01), DSS (β=−2.93; *P*=.03), and personal DSS (β=−1.80; *P*=.008), except for SF-6D (β=.01; *P*=.50) and perceived DSS (β=−1.21; *P*=.21; Table S1 in Multimedia Appendix 5).

Figure 2 illustrates the change in estimated outcome measures across time by treatment arms. In both treatments, the scores of PHQ-9, GAD-7, and K-10 decreased over time, while the scores of SF-6D, GSES, and perceived DSS increased after treatment. Compared with the WLC group, larger improvements were obtained in these outcomes for those who received ICBT treatment. The changes in SDS, DSS, and personal DSS of the 2 groups moved in opposite directions, with a reduction in social function impairment, depression stigma, and personal stigma showing in the ICBT group.

Figure 2. Estimated means and 95% CIs for time by treatment group interaction effects at 8 weeks. Linear mixed models with random intercept, including treatment groups (ie, internet-based cognitive behavioral therapy and waitlist control), time points of measurement (ie, pre- and posttreatment), and the treatment by time point interaction as fixed effects, are applied to calculate estimated means, mean differences in pre- and posttreatment changes between the 2 groups, and their *P* values. Patient-specific effects enter the model as a random effect with a normal distribution and an expected value of 0. DSS: Depression Stigma Scale; GAD-7: General Anxiety Disorder-7; GSES: General Self-Efficacy Scale; K-10: Kessler 10-Item Psychological Distress Scale; PHQ-9: Patient Health Questionnaire-9; SDS: Sheehan Disability Scale; SF-6D: Short Form Six-Dimension.

The within- and between-group effect sizes measured by Cohen *d* were calculated based on the estimated means (Table S2 in Multimedia Appendix 5). For depressive symptoms, the between-group effect size was moderate (*d*=0.50; 95% CI 0.26 - 0.75). The within-group effect size was large for the ICBT group (*d*=1.02; 95% CI 0.76 - 1.27), whereas in the WLC group, the effect size was small (*d*=0.34; 95% CI 0.11 - 0.57). For secondary outcomes, the between-group effect sizes were small (*d* range=0.07 - 0.43). The within-group effect sizes in the ICBT group ranged from small to large, with GAD-7 (*d*=0.89; 95% CI 0.63-1.14) and K-10 (*d*=0.87; 95% CI 0.61-1.12) exhibiting large sizes, SDS (*d*=0.58; 95% CI 0.33-0.83) showing moderate size, and the left displaying small sizes (*d* range=0.01 - 0.39). The within-group effect sizes in the WLC group were small, with a *d* range of 0.10-0.31.

Sensitivity analyses of short-term effectiveness outcomes using the ITT sample (Tables S2-S4 and Figure S1 in Multimedia Appendix 3) and the PPS population (Tables S2-S4 and Figure S1 in Multimedia Appendix 4) yielded results concordant with those of the primary analysis.

Outcome Measures at Follow-Up

Table 3 presents the observed and estimated means of outcomes among all participants receiving ICBT treatment in the ICBT I and II groups by time points. Figure 3 demonstrates the change course of all outcome measures during the intervention and follow-up period. Follow-up models demonstrated that improvements in outcomes were maintained across 12-month follow-ups except for DSS and its subscales. The results of paired comparisons are displayed in Table S3 in Multimedia Appendix 5. Paired comparisons confirmed no significant change from posttreatment to 12-month follow-up on PHQ-9 (Bonferroni adjusted estimated mean difference −0.81; SE=0.33; *P*=.33), GAD-7 (Bonferroni adjusted estimated mean difference −0.63; SE=0.31; *P*=.63), K-10 (Bonferroni adjusted estimated mean difference −1.11; SE=0.55; *P*=.64), SDS (Bonferroni adjusted estimated mean difference 0.88; SE=0.47; *P*=.33), GSES (Bonferroni adjusted estimated mean difference 0.12; SE=0.38; *P*>.99), DSS (Bonferroni adjusted estimated mean difference −0.49; SE=0.69; *P*=.95), and perceived DSS (Bonferroni adjusted estimated mean difference 0.58; SE=0.47; *P*=.74), while significant increases in SF-6D (Bonferroni adjusted estimated mean difference −0.04; SE=0.01; *P*=.04) and personal DSS (Bonferroni adjusted estimated mean difference −1.06; SE=0.36; *P*=.03; Table 3).

[q]Estimated means are based on the follow-up models.

Figure 3. Estimated marginal means and 95% CIs across all time points for participants receiving ICBT intervention in both ICBT and waitlist control groups. Marginal linear models are applied to calculate estimated marginal means, mean differences, and their *P* values. Red dashed lines mean that no available data can be used for the intervention period. DSS: Depression Stigma Scale; GAD-7: General Anxiety Disorder-7; GSES: General Self-Efficacy Scale; ICBT: internet-based cognitive behavioral therapy; K-10: Kessler 10-Item Psychological Distress Scale; PHQ-9: Patient Health Questionnaire-9; SDS: Sheehan Disability Scale; SF-6D: Short Form Six-Dimension.

The within-group effect sizes for different outcome measures across time points are presented in Table S4 in Multimedia Appendix 5. During the follow-up period, the effect sizes for PHQ-9 were maintained at moderate levels ($d \geq 0.50$) compared with that of the pretreatment stage. For GAD-7, K-10, and SDS, moderate effect sizes were also observed over 12 months (d range=0.52 - 0.73). The remaining secondary outcomes (eg, SF-6D and GSES) had shown small effect sizes both at posttreatment and follow-ups. Compared with the posttreatment stage, the effect sizes for all outcomes at follow-up were small, ranging from 0.01 to 0.18.

The results of the 2 sensitivity analyses for the long-term effectiveness evaluation were almost consistent with those of the main analysis (Tables S5-S8 and Figures S1 and S2 in Multimedia Appendix 5). For personal DSS, both the main analysis and sensitivity analyses showed down first and then up, with only the main analysis reporting statistical significance.

Remission and Response

Table S9 in Multimedia Appendix 5 displays the numbers and rates of participants reaching remission from depression and responding to treatment by trial arms and across time points. At posttreatment, a total of 80 complete remissions and 50 responders were observed in 152 patients who received ICBT treatment. The remission and response rates reached 66.1% (80/121) and 41.3% (50/121), respectively. The clinical symptomatic remissions in the WLC group were significantly lower than those of the ICBT group, with complete remissions in 58 (39.2%) cases (P<.001) and response in 27 of the 148 (18.2%) patients (P<.001). During the follow-up period, the remission and response rates in the ICBT group remained high, with rates of 58.2% and 32.7%.

XSL•FO
RenderX

Treatment Acceptability and Satisfaction

A total of 119 participants completed the course evaluation regarding perceived helpfulness, satisfaction, and recommended intention. In total, 98 (82.4%) reported that the course was helpful, 117 (98.3%) reported feeling satisfied with the course, and 111 (93.2%) participants were willing to recommend the course to others around them.

Discussion

Principal Findings

This study assessed the short- and long-term effectiveness of an unguided ICBT course in Chinese patients with MDD and evaluated participants' acceptability and satisfaction with ICBT. Compared to WLC, depressive symptoms, disease-related symptoms, individual and social functioning, and quality of life in the ICBT group were significantly improved at the posttreatment stage, with the between-group effect size of PHQ-9 reaching 0.50. Remission and response rates of the ICBT group were statistically higher than those of the WLC group (80/121, 66.1% vs 58/148, 39.2%; P<.001; 50/121, 41.3% vs 27/148, 18.2%; P<.001). Moreover, these positive results in the ICBT group were maintained after the intervention. At 12-month follow-up, the depressive symptoms were improved compared with that at pretreatment (mean difference 3.90, SE 0.32; P<.001; d=0.70), and no significant change was observed in comparison with the outcomes at posttreatment (mean difference −0.81, SE 0.33; P=.33; d=−0.15). Patients treated with ICBT reported high acceptability with an engagement rate of 77.6%. Above 90% of participants in the ICBT group reported high treatment satisfaction. To our knowledge, this was the first study that investigated both the short- and long-term effectiveness of unguided ICBT supported by nonspecialists for MDD in China.

Comparisons With Previous Work

The result that unguided ICBT as an additional treatment to usual care was more effective than usual care alone at posttreatment was well supported by the findings of most previous meta-analyses and RCTs on unguided ICBT [16,17,30,31,34]. The demonstrated effectiveness of the Morning Mood for Chinese clients with MDD can be attributed to its strict adherence to CBT principles and thoughtful cultural adaptation. First, the program successfully delivers core CBT components in a structured, sequential manner. This allows users to systematically learn and practice skills to break the cycle of negative thoughts and behaviors that maintain depression, even without a therapist guiding each step. Second, the program was delivered in the participants' native language, ensuring clarity and facilitating a deeper understanding of complex psychoeducational content. Third, culturally resonant materials were used, such as incorporating familiar idioms and real-life scenarios that reflect the typical stressors and automatic thoughts experienced by the mainland Chinese population. This likely fostered a stronger connection with the content and improved the self-application of CBT skills. Fourth, the program's design aligns with modern digital consumption habits, prioritizing video-based demonstrations and interactive exercises over text-heavy narratives, which suits contemporary learning preferences. Finally, the integration of mindfulness and relaxation exercises resonated with the traditional Chinese philosophy of mind-body harmony, thereby complementing the Western CBT framework and making the therapeutic concepts more intuitively understandable and personally meaningful to the target audience.

The ICBT group exhibited a statistically significant improvement in depressive symptoms than the WLC group, with a medium between-group size of 0.50. However, the effect size calculated in this study was lower than that of a meta-analysis (0.65) [17]. The relatively poor performance could be attributed to the supporting provider and implementing environment, which led to different treatment effects [16]. Previous investigations usually provided support by clinicians and were implemented in clinical settings [68], while this study differed by providing support through nonspecialists and being conducted in a more practical setting. It is acknowledged that unguided ICBT with clinician support leads to better treatment compliance due to the authority of doctors [23,42]. Moreover, the clinical setting has contextual factors, favoring the deployment and uptake of the intervention [51]. Therefore, higher effect sizes were reported in previous research. However, given the shortage of mental health specialists in China, unguided ICBT supported by nonspecialists might be more pragmatic and workable, with the potential of increasing accessibility, availability, and affordability of MDD treatment. More measures should be taken to enhance treatment outcomes when putting Morning Mood into large-scale use.

This study has also proven the sustained long-term effectiveness within the ICBT treatment conditions, with no significant difference in depressive symptoms between the posttreatment and follow-up stages. High remission and response rates were also observed both at posttreatment and follow-up under the ICBT intervention. This finding was consistent with the existing research [18-20,22,25,26,28,29]. However, 1 meta-analysis [35] and 2 large RCTs [21,23] reported a significantly large magnitude of effect at follow-up compared to the posttreatment outcome despite the varied within-group effect size. This could be partially explained by the study characteristics. In our study, patients were diagnosed with MDD, and more than half of them had antidepressant treatments, indicating a more severe disease condition. It is mentioned that the short- and long-term treatment effects of unguided ICBT are better in individuals with mild to moderate depressive symptoms [34]. The long-term effect of ICBT on depressive symptoms and absolute treatment outcomes suggested that intensified measures might be needed to consolidate the desired therapeutic effects for the long term in our future application.

Our results showed that at posttreatment, participants in the ICBT group experienced a significantly larger reduction of anxiety symptoms, nonspecific psychological distress, and depression stigma than individuals in the WLC group, while a greater improvement of self-efficacy and social functioning. Existing research on ICBT for MDD reported similarly favorable effects except for depression stigma [69-73]. These results provided new supportive evidence for the addition of unguided ICBT to usual care in developing countries.

XSL•FO
RenderX

We also found that ICBT produced long-term positive effects on anxiety symptoms, nonspecific distress, social functioning, general self-efficacy, and quality of life. However, few studies have comprehensively investigated these outcomes in the long run. As comorbidity depression with anxiety and other psychiatric disorders are common [74,75], ICBT interventions for depression have been proposed to be potentially effective in improving general mental health, including anxiety symptoms and nonspecific distress, which aligns with the findings in previous research [20,30,32]. General self-efficacy, which essentially reflects the subjective thoughts of participants, was considered to be an indicator of cognitive and behavioral changes in patients with MDD. It was found that ICBT intervention has significantly increased the individuals' self-efficacy even after the acute treatment phase. The ultimate aim of the ICBT intervention is to develop the psychological and emotional skills to restore social functioning and improve quality of life. This self-developed ICBT course has finally reached its goals, which agrees with the results of prior research [23,32,35]. Together, these results indicate that ICBT for MDD has widespread favorable outcomes.

The majority of ICBT completers were satisfied with the course, and the engagement rate of the ICBT intervention in this study was high, with 77.6% (118/152) of individuals completing the course. A previous study reported that the average completion rate of a self-guided intervention with general support was 65% [16]. Several factors could account for the notably higher rate in our study. Compared with clinicians, nonspecialists have more time and energy to dedicate to the provision of general support to prompt engagement. Furthermore, the ICBT course in our study was designed for Chinese people with good cultural adaptability and was embedded on the WeChat app with good user convenience. Taken together, these findings showed that unguided ICBT supported by nonspecialists could enhance the treatment effect in multiple dimensions.

Implications

This trial provides evidence on the short- and long-term effectiveness of the unguided ICBT intervention (ie, Morning Mood) for MDD in China across multiple dimensions: depressive symptoms, disease-related symptoms, psychosocial functioning, and quality of life. The high adherence rate (77.6%) in our study suggests that the program's delivery format and support intensity align well with the needs of individuals with MDD in China. The unguided ICBT supported by nonspecialists shows a positive effect for MDD in conditions that require fewer resources, with the cost-effectiveness being proven in a previous study [76]. Therefore, it is indicated that integrating the unguided ICBT into the primary community health centers or other care pathways is a good choice in China, where trained therapists are limited, social discrimination is serious, and the accessibility of mental health care services is poor [77]. Second, the small to moderate between-group effect sizes in short-term outcomes emphasize the necessity of optimizing the efficacy by recognizing those who respond well to the intervention and those who show no response to treatment, which could further increase the cost-effectiveness [78]. Third, the suboptimal enduring remission rate (58.2%) underscores proactive monitoring in real-world applications to take timely intervention measures and prevent further deterioration.

Strengths and Limitations

This study has several strengths. First, the ICBT program in this study is developed based on Chinese culture and habits of Chinese expressions, with examples demonstrated in the course being selected from real life; thus, the effect of cultural and linguistic incompatibility was excluded. Moreover, the ICBT intervention is delivered through the WeChat Mini Program, which makes the implementation more convenient than web- or app-based forms. Participants do not need to download an additional app or search on the Internet. To some extent, this study has provided more robust evidence of ICBT for depression in China. Second, in our study, the unguided ICBT intervention is supported by nonspecialist health workers (ie, any type of health worker, like a nurse, lay health worker, or medical social worker, who is not a specialist in mental health). This form of ICBT has no requirement for qualified mental health specialists and thus is easier to implement. The results of our study provide a reference for solving the problem of the treatment gap in resource-limited countries like China. Third, measurement tools with good reliability and validity have been used to evaluate the short- and long-term effectiveness of ICBT from multiple dimensions, including depressive symptoms, disease-related symptoms, individual and social functioning, and quality of life. Few previous studies have comprehensively explored these perspectives.

There are also some limitations in this study. First, due to ethical considerations, participants in the WLC group are arranged to receive ICBT treatment after an 8-week intervention period. That is, no control exists during the follow-up phase. As a result, it is difficult to distinguish the effect of ICBT from usual care and the natural course. A further RCT with long-term follow-ups in all treatment arms should be conducted to solve this problem. Second, the participants in our study were recruited from mental health clinics in Shenzhen, China, and were diagnosed with MDD. The majority of them were female and received high levels of education. Therefore, the generalization of the present findings may be limited. Third, due to data qualification of the sample, we could only compare the proportions of participants taking antidepressants in the ICBT and WLC groups. It is thought that drug types, dosage, and duration influence the treatment outcomes.

Conclusions

This study has demonstrated the short- and long-term effectiveness of unguided ICBT with general support delivered by nonspecialists for patients with MDD from multiple dimensions, including depressive symptoms, anxiety symptoms, nonspecific psychological distress, social functioning, quality of life, and general self-efficacy. Participants report high acceptability of and satisfaction with the ICBT course. Taken together, these results add to existing literature consolidating unguided ICBT supported by nonspecialists as an effective treatment to solve the substantial treatment discrepancies in low-resource settings. Additional studies with larger samples are needed to examine potential factors that could enhance the long-term effectiveness of ICBT.

Abstract

Background: Despite the high prevalence of depressive disorders, access to effective treatment remains limited due to financial, geographic, and social barriers. Online self-help groups offer a promising and scalable form of peer-based support beyond traditional clinical settings. Integrating cognitive behavioral therapy (CBT) techniques such as cognitive restructuring and behavioral activation into self-help groups may enhance their effectiveness.

Objective: This study evaluated the efficacy of a cognitive behavioral therapy–based online self-help group (COS) that integrates structured CBT techniques with peer-led group support as a low-intensity intervention for individuals with depressive symptoms. A randomized controlled trial (RCT) comparing COS with a CBT-based mobile application was conducted. Additionally, a separately recruited waitlist control group was included as a supplementary comparison condition.

Methods: Participants were recruited online. After eligibility screening via a structured clinical interview, participants were randomly assigned to a COS group (n=79) or a CBT-based mobile application group (n=39). An additional waitlist control group (n=48) was recruited separately during the second phase of the study. The COS intervention involved 7 videoconferencing sessions that incorporated peer-led group discussions, sharing lived experiences, and core CBT techniques such as cognitive restructuring. The primary outcome measure was depressive symptoms, assessed using the Beck Depression Inventory-II, and the secondary outcome was suicidal ideation, estimated using the Beck Scale for Suicide Ideation, measured at baseline, postintervention, and 3-month follow-up. Linear mixed models were used to evaluate group × time interaction effects. Reliable change indices were also calculated to assess clinical significance. All statistical tests were 2-tailed.

Results: Among participants assigned to the COS group, 61% (48/79) completed all 7 sessions, and 84% (66/79) attended 5 or more sessions. A significant time × group interaction was observed for depressive symptoms ($F_{4,288.47}$=7.23, P<.001). The COS group exhibited a substantial reduction in depressive symptoms from baseline to postintervention ($t_{285.76}$=10.77, two-tailed; P<.001), with a large within-group effect size (d=1.38); this improvement was maintained at the 3-month follow-up. Suicidal ideation also significantly decreased in the COS group ($t_{277.11}$=4.55, two-tailed; P<.001), with sustained effects at follow-up. Clinically meaningful improvement in depressive symptoms, as defined by the reliable change index, was observed in 75% (56/75) of COS participants. While both the COS and app-based CBT groups achieved comparable reductions in depressive symptoms, only the COS group demonstrated a significant reduction in suicidal ideation.

Conclusions: This RCT provides evidence that a structured, CBT-informed online self-help group can reduce depressive symptoms and suicidal ideation. The COS program offers a scalable, accessible alternative to traditional therapy, particularly in settings with limited access to mental health professionals.

Introduction

Depressive disorders have far-reaching public health consequences, contributing to work absenteeism, increased economic burden, elevated suicide risk, and higher all-cause mortality [1-3]. The duration of untreated depression is a critical determinant of clinical outcomes; shorter durations are associated with faster remission and better treatment response [4]. Thus, timely access to effective intervention is essential for mitigating the course and consequences of depressive illness [5,6].

Despite this urgency, approximately 30% of individuals diagnosed with depression receive no treatment at all [7]. Common barriers include financial hardship, geographic inaccessibility, stigma, and a shortage of qualified mental health professionals [8,9]. These systemic barriers underscore the need for alternative models of care that are both accessible and scalable. Digital health technologies, including videoconferencing and mobile applications, have expanded access to mental health care by providing flexible, cost-effective, and evidence-based interventions for underserved populations [10-13]. Among these, online self-help groups are promising platforms for delivering support outside traditional clinical settings [14].

Traditional self-help groups are typically peer-led and rooted in shared lived experiences [15], fostering mutual support among individuals facing common challenges [14,16,17]. Participation in these groups has been associated with reduced depressive symptoms [18,19], improvements in quality of life [20], decreased feelings of loneliness [21], and overall reductions in mental health problems [22,23]. These benefits, supported by meta-analyses and systematic reviews [18,20,22,24], underscore the potential value of self-help groups as scalable, low-barrier interventions.

However, the utility of traditional in-person self-help groups is often curtailed by significant structural impediments. Community-based local groups depend on physical proximity, regular attendance, and a sufficient number of members to maintain operations, which often serve as barriers to entry and sustainability [25]. Individuals residing in rural areas, or those burdened by mobility limitations, physical illness, caregiving responsibilities, or irregular working hours, often find in-person attendance untenable [25-27]. Furthermore, in smaller communities, concerns regarding anonymity or privacy may deter participation, while low population density may preclude the formation of groups entirely. These persistent barriers underscore the urgent need for delivery formats capable of extending the reach of self-help interventions beyond local constraints.

The application of digital health technologies, particularly real-time videoconferencing, offers a robust solution to these challenges. By enabling participation irrespective of location, reducing the burden of travel, and facilitating flexible scheduling, these technologies effectively mitigate traditional barriers while enhancing anonymity [28,29]. Crucially, synchronous online formats preserve key therapeutic elements of self-help groups: mutual support and real-time emotional exchange among individuals with lived experiences. Consequently, online self-help groups represent a vital mobile health innovation, leveraging the technology to connect participants nationwide and expanding access to structured psychological support where traditional models fall short.

The term “online self-help group” encompasses a diverse range of formats, ranging from large, asynchronous text-based discussion forums to synchronous, small group-based mutual support sessions. This study focuses specifically on the latter—synchronous, videoconferencing-based groups designed to foster real-time interaction and support. Despite the promise of this format, there is a notable gap in the literature [30]: to date, few randomized controlled trials (RCTs) have rigorously evaluated the clinical efficacy of synchronous online self-help groups in treating depression. Moreover, a key limitation of typical self-help groups is their lack of structured therapeutic content, resulting in wide variability in group facilitation, composition, and outcomes [31]. This inconsistency poses challenges to their reliability and scalability as interventions for individuals with clinically significant depressive symptoms. In this study, we developed a semistructured manual for a cognitive behavioral therapy–based online group self-help program (COS). We then examined its efficacy among individuals experiencing depressive symptoms through an RCT. The COS program integrated core cognitive behavioral therapy (CBT) components, including cognitive restructuring and coping skills, to enhance therapeutic consistency and effectiveness within a peer-led group format. This hybrid model builds on prior work, such as SMART Recovery [32], showing that structured CBT elements can improve psychological outcomes in mutual aid settings.

A noninteractive, CBT-based mobile application served as the active comparator. While this application has demonstrated efficacy in reducing depressive symptoms through interventions targeting dysfunctional thoughts [33], it is designed for individual use and does not offer the social support and accountability that characterize group-based interventions such as the COS program. In addition, a separately recruited waitlist control group was included to account for potential symptom improvement attributable to the natural course of depression.

Consequently, we hypothesized that the COS program would be at least as efficacious as the CBT-based mobile application intervention for general CBT-based outcomes, such as depressive symptoms, stress, and dysfunctional attitudes, and that the peer-based format of COS might offer additional benefits for outcomes involving emotional or interpersonal processes. Furthermore, we expected that a higher proportion of individuals in the COS group would demonstrate clinically meaningful improvement.

To our knowledge, few RCTs have evaluated online self-help groups for depression, and prior studies have typically examined only unstructured peer-support interventions. This study contributes to this literature by examining a semistructured, CBT-informed online self-help group and by including an active digital CBT comparator. We anticipate that the findings will highlight the potential of online self-help groups as a scalable, low-barrier intervention that can help overcome the logistical

XSL•FO
RenderX

and geographic challenges often related to accessing traditional, evidence-based practices.

Methods

Study Design

This study primarily used a 2-arm RCT in which participants were randomly assigned to either the COS or the cognitive behavioral therapy–based mobile application (APP) group at a 2:1 ratio, using block randomization. Participants of the RCT were recruited between May and November 2021. Interventions were delivered between August and December 2021, and follow-up assessments were completed in March 2022.

To complement the primary RCT design, a nonrandomized waitlist control group was recruited during the second phase of the study from December 2021 to April 2022. This waitlist control group provided a baseline for the natural course of depression. While the active comparator (APP) has demonstrated efficacy in reducing depressive symptoms [33], relying exclusively on this digital intervention prevents a direct assessment of absolute efficacy relative to a no-treatment control. Therefore, following the completion of enrollment for the randomized arms, a waitlist control group was recruited to distinguish the intervention effect from spontaneous remission.

Participant enrollment proceeded in two distinct phases due to operational and timeline constraints. During the initial recruitment period, the research team prioritized the randomized comparison between the COS and APP groups, as this constituted the primary objective of the trial. To minimize potential confounding, identical inclusion and exclusion criteria were applied across phases, and sociodemographic characteristics were monitored rigorously.

Recruitment and Screening Procedures

Participants for the RCT were recruited between May and November 2021 through online advertisements disseminated via social media platforms (eg, X and Instagram) and university-based online community platforms in Korea. Interested individuals were invited to contact the research team via direct message or email to receive detailed study information and to schedule an initial telephone screening.

Inclusion criteria were as follows: (1) aged between 19 and 55 years, (2) diagnosed with any depressive disorder based on the Structured Clinical Interview for DSM-5 – Clinician Version (SCID-5-CV) or having a PHQ-9 (Patient Health Questionnaire-9) score of ≥5 indicating mild depression [34], (3) fluent in Korean, and (4) able to use a real-time videoconferencing program. Participants undergoing pharmacotherapy were eligible only if their dosage had been stable for at least 1 month.

Exclusion criteria included current psychotic symptoms (ie, hallucinations and delusions), concurrent psychological interventions, or high suicide risk. Individuals with high suicide risk, defined as those reporting suicide ideation with planning during the SCID-5-CV, were excluded and referred to appropriate services. No participants were excluded on this basis.

Recruitment followed a 2-step screening procedure. Interested individuals first completed a brief telephone screening that assessed medication stability, current psychological intervention, and commitment to the study schedule. Eligible participants received a brief explanation of the study after eligibility screening (SCID-5-CV) and provided informed consent via an online signature. Of 186 individuals initially screened, 141 underwent online SCID-5-CV interviews and initial assessments. SCID-5-CV interviews were conducted by graduate students in clinical and counseling psychology or licensed clinical psychologists, all of whom received more than 2 weeks of SCID-5-CV administration training. A total of 127 participants were randomized to the COS or APP group.

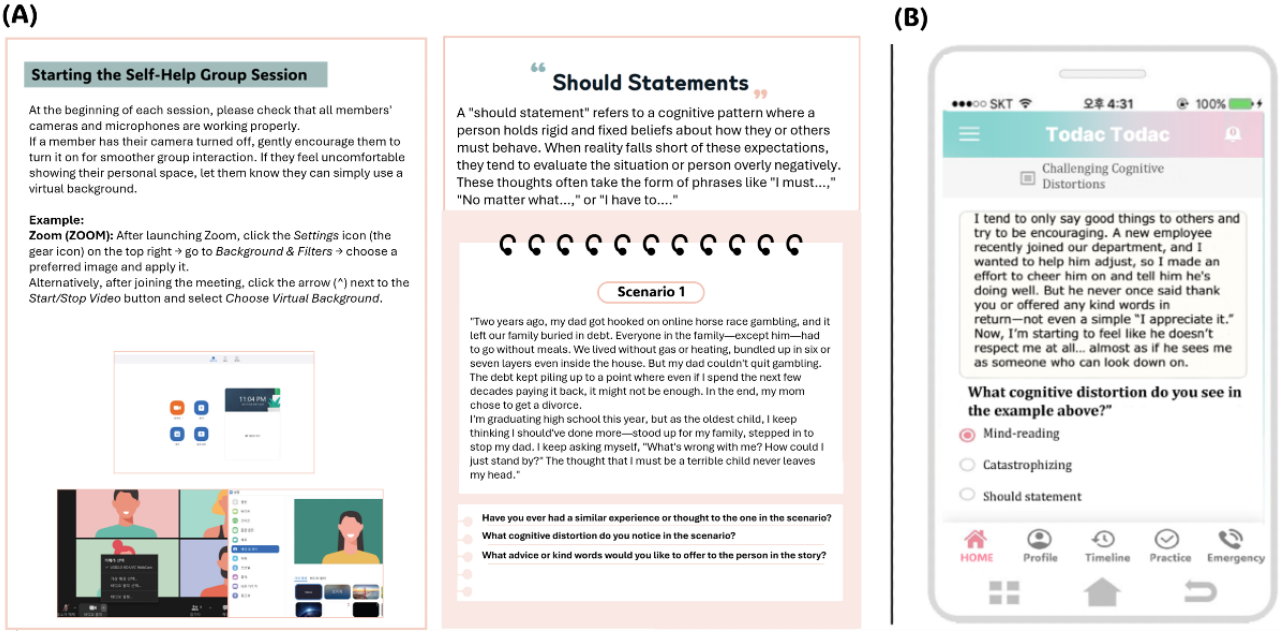
For the recruitment and screening of the waitlist control group, the same inclusion and exclusion criteria used for the RCT were applied to the waitlist control, except that the requirement for real-time videoconferencing ability was waived. During this phase, 74 individuals were screened, 55 completed eligibility procedures, and 48 were enrolled. The study adhered to the CONSORT (Consolidated Standards of Reporting Trials) 2010 guidelines [35], and the CONSORT checklist is provided as Checklist 1.

Sample Size Calculation

The sample size was determined based on power estimates and feasibility considerations. We adopted a statistical power of 0.80 and a significance level of α=.05. The assumed effect size was set to f=0.25, a conservative estimate informed by prior meta-analyses of digital psychological interventions and peer support–based approaches, both of which generally report small-to-moderate improvements in depressive symptoms [36,37]. Using f=0.25 for detecting a group × time interaction in a repeated-measures design, a total of approximately 66 participants were required. Given the 2:1 randomization ratio between the COS and APP groups, we aimed to recruit at least 99 participants to ensure adequate power.

Randomization

Block randomization was performed using a computer-generated list, with a fixed block size of 3. Participants were randomly assigned to the COS or APP group at a 2:1 ratio.



Interventions

The COS Program

The COS program is a semistructured, 7-session, CBT-based online self-help group protocol designed to alleviate depressive symptoms. The COS manual and workbooks were developed and reviewed by licensed clinical psychologists to ensure fidelity to the self-help group format and CBT principles and accuracy of therapeutic content. Figure 1A shows a sample page from the participant workbook provided in the COS program.

XSL•FO
RenderX

Figure 1. (A) Sample page from the participant workbook provided in the COS program. (B) Screenshot of the cognitive distortion exercise featured in the cognitive behavioral therapy–based mobile application. These materials were originally developed in Korean and translated into English. COS: cognitive behavioral therapy–based online self-help group.

Each group typically consisted of 4 - 6 participants and 1 facilitator, with each session lasting approximately 50 minutes. Sessions were held twice weekly via videoconferencing platforms such as Zoom. A face-to-face pilot version of the COS program was conducted in 2020 to refine content and structure prior to web-based adaptation [38]. The first session of COS focused on rapport-building, sharing lived experiences with depression, and psychoeducation. Subsequent sessions (2-7) focused on introducing various cognitive distortions (eg, catastrophizing, mind reading, overgeneralization, "should" statements, tunnel vision, and black-and-white thinking). In each session, participants read a series of scenarios written in the manual of the COS program, reflecting on each cognitive distortion and suggesting possible alternatives for the protagonist. After reading the given scenario, the participants were encouraged to share personal experiences related to these negative and distressing emotions related to each cognitive distortion. These activities were designed to provide participants insight into their negative automatic thoughts and emotional support from others with similar experiences.

Although the COS program was fundamentally designed to permit participants to assume the facilitator role, a designated facilitator who was either a graduate psychology student or a licensed clinical psychologist was assigned in this study. This was implemented to ensure strict adherence to protocols that monitor participant safety, in accordance with research ethical standards. To facilitate the intended peer-led model, the program includes a publicly available participant manual and a step-by-step facilitator guidebook, alongside a brief introductory video provided through the Korean National Center for Mental Health. Crucially, substantive discussions, including the sharing of lived experiences and the restructuring of cognitive distortions, remained participant-led. All facilitators received 30 to 40 minutes of training on COS procedures before implementation. Their role was strictly limited to logistical management, such as opening the videoconferencing sessions, introducing session activities, and timekeeping, alongside the monitoring of participant safety. Facilitators were trained to monitor participant safety and to notify the research team immediately if a participant reported active suicidal thoughts. In such cases, they were instructed to administer the P4 screener [39] to assess suicide risk and to contact the research team for a follow-up safety evaluation. No instances of active suicidal ideation were reported during the study.

The CBT-Based Mobile Application

We used a CBT-based mobile application as an active comparator. The efficacy of the app was confirmed in an RCT [33]. Similar to the COS program, the app presented short stories illustrating frustrating situations that highlighted various cognitive distortions, followed by quizzes designed to identify these distortions and reduce related negative emotions (Figure 1B). Participants in the APP group were instructed to use the app for approximately 270 to 360 minutes (5 minutes per session × 3 sessions daily × 24 days), ensuring comparable total usage time to the COS program. Weekly reminders were sent to encourage adherence to the app usage schedule. Participants were considered to have completed the APP program if they used the app for at least 18 days (270 minutes), completing 3 or more sessions per day.

Outcome Measures

The primary outcome was depressive symptoms, assessed using the Beck Depression Inventory-II (BDI-II), a widely used measure of depression [40]. Scores from 0 to 13 indicate no or minimal depressive symptoms, 14 to 19 mild, 20 to 28 moderate depression, and 29 to 63 severe depressive symptoms.

The secondary outcome was suicidal ideation, measured using the Beck Scale for Suicide Ideation (BSS). The BSS consists of 21 items that assess the severity of suicidal symptoms [41].

XSL•FO
RenderX

Exploratory outcomes included cognitive and psychosocial variables. Dysfunctional attitudes, a predisposing cognitive structure underlying depression, were measured using the Dysfunctional Attitude Scale (Form A) Revised (DAS-17) [42,43]. Daily life stressors were measured using the Perceived Stress Scale (PSS) [44]. Loneliness and perceptions of social support were assessed using the UCLA Loneliness Scale version 3 (UCLA-LS) [45,46] and the Perceived Available Support (PAS) scale of the Berlin Social Support Scale (BSSS) [47], respectively. Protective factors against suicide risk were assessed using the Reasons for Living Inventory for Young Adults (RFL-YA) [48]. Finally, general self-efficacy was measured using the General Self-Efficacy Scale (GSES) [49], given its known association with depression. All outcome measures were administered via Qualtrics as online self-report questionnaires.

Statistical Analysis

An intent-to-treat analysis was conducted to compare the immediate and 3-month efficacy of the programs using a linear mixed model (LMM). Prior to the main analysis, the appropriateness of the LMM for the repeated-measures design was confirmed by evaluating within-participant dependence using unconditional mixed-effects models. Intraclass correlation coefficients (ICCs) were calculated for this preliminary assessment. A significant (P<.05) interaction between time and condition in the hypothesized directions indicated that one group showed greater improvement.

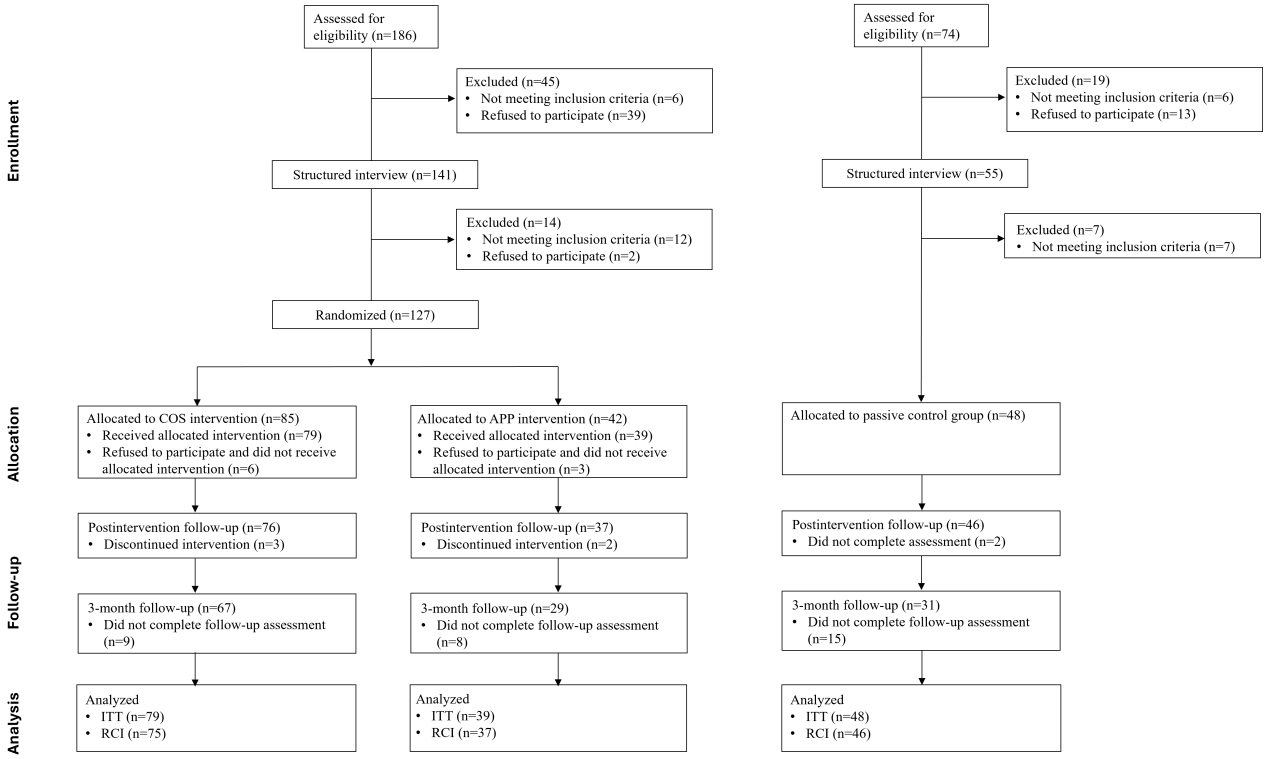
Prior to the main analysis, we examined the missingness mechanism for the primary outcome, BDI-II. Little's missing completely at random (MCAR) test was insignificant (χ^2_3=0.96, P=.62), and baseline BDI-II scores did not predict missingness (P=.24), supporting a missing at random (MAR) mechanism. Missing data were not imputed because the mixed-model approach provided equal or better power without imputing missing data for the intent-to-treat analysis under MAR assumptions [50]. To test the efficacy of the intervention, we evaluated the differences in scores between groups at each time point (T_1, T_2, and T_3). In the LMM, all the analyses included concurrent medication and social contact frequency as covariates. For post hoc analyses, both uncorrected P values and Holm-Bonferroni corrected P values (P_{holm}) were reported. Effect sizes were calculated using Cohen d. Within-group effect sizes for within-group changes were adjusted for correlations between repeated measurements to account for the dependency between time points [51-53].

To determine the statistical significance of the changes in the primary outcome measures between baseline and postintervention, we calculated a reliable change index (RCI) [54,55]. The RCI was computed using the RCI calculator [56]. A significant RCI indicates that the observed change in an individual participant's score over time is statistically meaningful. We used chi-square analysis to compare the proportions of individuals in each group demonstrating meaningful improvements or deterioration. All statistical tests were 2-tailed.

Ethical Considerations

The study protocol was reviewed and approved by the Institutional Review Board (IRB) of Korea University (KUIRB-2021-0157-06), and the trial was retrospectively registered with the Clinical Research Information Service (KCT0007673), a primary registry of the WHO International Clinical Trials Registry Platform.

All participants provided written informed consent after being informed about the study's objectives, procedures, and potential risks and benefits. Participants were explicitly informed that their involvement was voluntary and that they retained the right to withdraw from the study at any time without penalty. To ensure privacy, all participant data were anonymized prior to analysis, with identifiable information removed. Data were stored securely on password-protected servers, with access restricted strictly to authorized research personnel. Compensation was provided for each component of the study, including the screening interview, intervention sessions, and assessments at baseline, postintervention, and the 3-month follow-up. Participants who completed all study components received a maximum total compensation of approximately KRW 115,000 (about US $78 as of December 5, 2025).



Results

Adherence and Baseline Sociodemographic and Clinical Characteristics

Figure 2 presents the CONSORT participant flowchart. Of the 127 individuals randomized, 6 in the COS group and 3 in the APP group declined to participate prior to the start of the trial, resulting in 79 participants in the COS group and 39 in the APP group completing the baseline assessment (Table 1). In terms of adherence, 84% (n=66) of participants in the COS group attended 5 or more sessions of the program, and 82% (n=32) of those in the APP group used the app for at least 18 days.

[a]COS: cognitive behavioral therapy–based online self-help group.

[b]APP: cognitive behavioral therapy–based mobile application group.

[c]BDI-II: Beck Depression Inventory-II.

[d]BSS: Beck Scale for Suicide Ideation.

There were no significant differences across groups in age, sex, sexual orientation, socioeconomic status, or educational level (all *P*>.05). Individuals receiving concurrent pharmacotherapy accounted for 20% of all participants. Chi-square analysis revealed no significant differences between the groups (*P*=.55). Baseline depressive symptoms (as measured by the BDI-II) and suicidal ideation (as measured by the BSS) also did not differ significantly across groups (both *P*>.05).

Primary Outcomes

Initial unconditional mixed-effects models indicated substantial within-subject clustering in depressive symptoms (ICC=0.59), supporting the use of LMM. Consistent with the study design, the primary comparison focused on the 2 randomized groups, COS and APP, while the waitlist group served as a nonrandomized comparison group to assess natural symptom fluctuation.

The LMM analysis revealed significant main effects of time ($F_{2,289.99}$=86.76, *P*<.001), group ($F_{2,163.68}$=3.32, *P*=.04), and

XSL•FO
RenderX

time × group interaction ($F_{4,288.47}$=7.23, P<.001) for depressive symptoms, as measured by the BDI-II (Table 2). Figure 3A illustrates changes in depressive symptoms across T_1, T_2, and T_3 for each group.

Figure 3. (A) Estimated mean BDI-II scores over time. (B) Estimated mean BSS scores over time. APP: cognitive behavioral therapy–based mobile application group; BDI-II: Beck Depression Inventory-II; BSS: Beck Scale for Suicide Ideation; COS: cognitive behavioral therapy–based online self-help group; P_{holm}: Holm-Bonferroni corrected *P* values; Waitlist: waitlist control group.

After each program (T_2), both the COS and APP groups showed significant reductions in depression from baseline (COS: difference=11.84, $t_{285.76}$=10.77, two-tailed, P_{holm}<.001; APP: difference=10.26, $t_{283.29}$=6.6, two-tailed, P_{holm}<.001) (Table 3). Mean BDI-II scores decreased from the moderate range at baseline (COS: T_1 mean 27.03, SD 10.01; APP: T_1 mean 26.72, SD 11.31) to the mild range at postintervention (COS: T_2 mean 14.57, SD 10.99; APP: T_2 mean 16.35, SD 10.87) after the program in both groups (Table 4). Within-group comparisons indicated large effect sizes in both groups (*d*=1.38 for COS; *d*=0.93 for APP).

At the 3-month follow-up (T_3), depressive symptoms in the COS group did not show a statistically significant change compared to T_2 (difference=−0.72; $t_{283.76}$=−0.62, two-tailed; *P*=.53). In the APP group, depressive symptoms decreased from T_2 to T_3 (difference=3.85; $t_{288.53}$=2.25, two-tailed; *P*=.03), although this reduction did not remain significant after Holm-Bonferroni correction (P_{holm}=.30). The difference between the COS and the APP group at T_3 was not significant (difference=3.18; $t_{168.7}$=1.43, two-tailed; *P*=.15), indicating comparable longer-term outcomes between the two randomized groups.

As secondary evidence, both the COS and the APP groups were compared with the waitlist control group. At T_2, the COS group showed a significantly greater reduction in depressive symptoms compared with the waitlist control group (difference=−6.9; $t_{279.71}$=−3.51, two-tailed; *P*<.001, P_{holm}=.01, *d*=0.68), indicating a medium effect size. The APP group also showed lower depressive symptoms than the waitlist controls at T_2, but this did not meet the Holm-Bonferroni correction (difference=−5.51; $t_{279.9}$=−2.39, two-tailed; *P*=.02, P_{holm}=.25).

At T_3, the COS group showed lower depressive symptoms than the waitlist control group (difference=−5.43; $t_{330.55}$=−2.56, two-tailed; *P*=.01), but this difference did not remain significant after Holm-Bonferroni correction (P_{holm}=.17). The APP group showed significantly lower depressive symptoms than the waitlist control group at T_3 (difference=−8.6; $t_{338.28}$=−3.42, two-tailed; *P*<.001, P_{holm}=.02).

RCI Analysis

The RCI analysis included participants who completed both the T_1 and T_2 assessments. In the COS group, 76 participants completed the T_2 assessment; however, one individual did not complete the baseline assessment and was therefore excluded, resulting in a sample of 75 participants. The APP and waitlist control groups had 37 and 46 participants, respectively. In the COS group, 75% (56/75) showed a significant change from pre- to postinterventions. About 57% (21/37) of participants in the APP group and 35% (16/46) in the waitlist control group demonstrated significant changes over the same period. The difference in the proportion of participants with reliable change between the COS and APP groups was marginally significant (P=.054).

XSL•FO
RenderX

Secondary Outcomes

Within-subject dependence in suicidal ideation was identified (ICC=0.72), supporting the use of LMM. For suicidal ideation (as measured by the BSS), the LMM analysis revealed a significant main effect of time (P<.001) and a trend toward a time × group interaction (P=.09). The main effect of the group was not statistically significant (P=.80).

Figure 3B presents changes in suicidal ideation over time (T_1 – T_3) by group. Post hoc within-group comparisons indicated a reduction in suicidal ideation from T_1 to T_2 in the COS group (difference=3.13; $t_{277.11}$=4.55, two-tailed; P<.001, P_{holm}<.001; d=0.71), with no significant change between T_2 and T_3 (difference=−1.07; $t_{274.21}$=−1.5, two-tailed; P=.13). In the APP group, the change from T_1 to T_2 was not statistically significant (difference=1.2; $t_{272.63}$=1.27, two-tailed; P=.21). The comparison between T_1 and T_3 indicated a reduction, but did not reach the threshold for significance after Holm-Bonferroni correction (difference=2.63; $t_{278.73}$=2.53, two-tailed; P=.01, P_{holm}=.44). As secondary evidence, the waitlist control group showed minimal change in suicidal ideation over time. Neither the comparison between T_1 and T_2 (difference=0.69; $t_{273.74}$=0.80, two-tailed; P=.43) nor the comparison between T_2 and T_3 (difference=−0.16; $t_{276.51}$=−0.16, two-tailed; P=.87) reached statistical significance.

Exploratory Outcomes

Intraclass correlations for the exploratory outcomes also demonstrated notable within-participant dependence, with ICCs ranging from 0.48 to 0.73.

There were significant main effects of time and time × group interaction for all exploratory outcomes (all P<.05), with the exception of perceived available support (as measured by PAS) (P=.75) (Multimedia Appendix 1).

At postintervention, both the COS and APP groups showed significant improvements in multiple domains: reduced perceived stress (PSS), dysfunctional attitudes (DAS-17), and loneliness (UCLA-LS), as well as increased self-efficacy (GSES), perceived social support (PAS), and reasons for living (RFL-YA) (all P<.05). In contrast, the waitlist control group showed no significant change across any of these outcomes between T_1 and T_2 (all P>.05).

Most improvements observed at T_2 were sustained at the 3-month follow-up, with no significant changes from T_2 for any outcomes except DAS-17 and UCLA-LS in the COS group. Specifically, DAS-17 scores increased (P=.02), and loneliness scores decreased (P=.04) from T_2 to T_3; however, neither result remained significant after applying the Holm-Bonferroni correction (P_{holm}=.56 and P_{holm}=.98, respectively).

At T_3, the APP group showed higher GSES and RFL-YA scores than the waitlist control group (P=.006 and P=.03, respectively); however, these differences did not reach statistical significance after correction (P_{holm}=.16 and P_{holm}=.95, respectively). No significant between-group differences were observed for other variables at follow-up.

Discussion

Principal Findings

The primary objective of this RCT study was to evaluate the efficacy of a CBT-based online self-help group program (COS) for individuals experiencing depressive symptoms. Findings indicated that participants in the COS group showed a significant reduction in both depressive symptoms and suicide ideation, with these effects largely maintained at the 3-month follow-up. Notably, 75% (56/75) of those in the COS group exhibited clinically meaningful improvement in depressive symptoms, as determined by the RCI. At baseline, depressive symptoms in the COS group were of moderate severity, but following the intervention, their average symptom levels fell within the mild range. This level of improvement is comparable to outcomes typically achieved through standard, therapist-delivered CBT [57].

Although we expected the COS program to be at least as efficacious as the APP intervention for general CBT-based outcomes and potentially superior for outcomes influenced by peer interaction, the results revealed that the app-based program yielded similar improvement in reducing depressive symptoms, perceived stress, dysfunctional attitudes, and loneliness. This parity in outcomes is likely attributable to the shared therapeutic components across the COS and APP conditions. In both programs, participants engaged in cognitive restructuring exercises, including the identification of cognitive distortions within hypothetical scenarios and the generation of more adaptive, alternative thoughts. These fundamental CBT techniques were consistently applied in both conditions and may have contributed to the comparable levels of improvement observed.

Beyond the shared therapeutic elements, several intervention-related features may help explain why COS and APP yielded largely comparable outcomes. The interpersonal features unique to COS, such as validation, reciprocal feedback, and collaborative cognitive restructuring, may require a longer intervention period or greater group contact for their unique benefits to emerge fully. In this study, the COS program consisted of 7 sessions delivered over 3 weeks, which is considerably shorter than most peer support or group-based depression interventions that typically span 10 to 12 sessions [36]. The relatively brief structure may have limited the development of group processes that could otherwise differentiate COS from APP.

Implementation fidelity is another relevant consideration [58]. The APP condition delivered identical content with consistent pacing for every participant, ensuring high consistency. Conversely, the COS format, although manualized, naturally introduced variability in discussion depth, interaction patterns, and pacing across groups. While this variability may have supported peer engagement, it may also reduce the consistency with which CBT skills were practiced compared to the standardized app.

Despite the similarity in outcomes, the COS group demonstrated a marginally higher proportion of participants achieving

XSL•FO
RenderX

clinically significant change, as indicated by the RCI, compared to the APP group. Furthermore, the analysis for suicide ideation revealed a trend-level time × condition interaction, with a significant reduction emerging only within the COS group. Post hoc comparisons indicated a statistically significant decrease in suicidal ideation from T_1 to T_2 only in the COS condition, even though the intervention did not explicitly target suicidality; in contrast, no significant within-group changes were detected in the APP or waitlist control groups. This finding is particularly salient, given the elevated suicide risk commonly associated with depressive disorders [59,60]. The reduction in suicidal ideation may be attributable to the relational dynamics of the self-help group format. One possible explanation is the supportive and interactive nature of the group setting, which may have provided emotional validation, normalization, and interpersonal connection—factors that have been identified as protective in the context of suicide risk [61]. Previous research has demonstrated that group-based interventions can be effective in reducing suicidal thoughts, with social support and a sense of belonging identified as key mechanisms [62,63]. Recently, peer-led interventions have gained increasing attention in suicide prevention efforts and have been recommended for their potential to meaningfully integrate lived experience into mental health care [64]. However, their adoption in practice remains limited. The COS program may offer a scalable and accessible intervention that not only aligns with these emerging recommendations but also addresses the current gaps in service delivery.

The COS program was specifically designed to integrate structured CBT techniques within a peer-led, self-help group framework. This hybrid model aimed to combine the clinical efficacy of CBT with the emotional resonance and empowerment afforded by lived-experience sharing, which is characteristic of self-help groups [65]. Importantly, since this low-intensity psychological intervention was manualized, brief in duration, and minimally dependent on professional facilitation [66], these features render the COS program particularly amenable to digital dissemination, offering a scalable and resource-efficient option for addressing the treatment gap in depression care.

Limitations

This study has several limitations that must be acknowledged. First, although the COS program was designed for peer-led delivery, trained facilitators with psychological knowledge were present during sessions to ensure participant safety and adherence to the intervention protocol. While this approach helped maintain fidelity and manage potential risks, it may have reduced the ecological validity of a fully peer-led mode. We envision that future implementation will use a stepped-care approach, in which professionals initially lead the groups before transitioning leadership to peers. Consequently, future studies should evaluate the comparative efficacy of the COS program when delivered exclusively by peers versus professionals. This will help establish the viability of this scalable model and its clinical effectiveness in real-world settings. Second, the waitlist control group was recruited independently from the randomized intervention groups. Although efforts were made to match key sociodemographic characteristics, the absence of full randomization may have introduced unmeasured confounding variables, including differences in participants' motivation or expectations, as well as potential time-related confounds that limit the strength of causal inferences. Third, all outcomes were measured using self-report instruments. Although standardized instruments with strong psychometric support were used, the exclusive reliance on self-report measures may introduce reporting bias. Future studies may benefit from incorporating clinician-administered assessments or objective indicators, such as behavioral or physiological measures. Fourth, blinding procedures could not be implemented due to the behavioral nature of the intervention and its peer-supported, online-delivery format. Although outcome assessments were completed directly by participants, thereby limiting the risk of assessor-rated bias, the absence of participant blinding remains a methodological limitation that should be considered when interpreting the results. Fifth, the participants were predominantly female and consisted largely of young adults, with an average age in the late twenties. This consideration is particularly pertinent for outcomes such as suicidal ideation, where gender differences in prevalence and expression are well documented. Although the inclusion criteria permitted participation up to age 55 years, the reliance on online recruitment methods likely contributed to this skew. Consequently, this demographic profile may limit the generalizability of the findings to older adults or populations with different digital usage patterns. Finally, the study did not include long-term follow-up beyond 3 months. Future studies should assess whether the observed improvements are sustained over extended periods, including follow-ups of at least 12 months, and further evaluate the real-world applicability of fully peer-led implementations.

Conclusions

This study contributes valuable evidence supporting digital approaches to depression and suicidality. The continued use of remote, group-based psychological interventions may help address persistent barriers to accessing conventional services. Within this context, the development and evaluation of scalable, evidence-based digital programs remain an important public health objective, particularly for populations with limited access to mental health professionals. Notably, the findings highlight the potential of structured self-help group interventions that can be delivered with minimal professional involvement, offering a practical and accessible option for expanding psychological support.

Editorial Notice

This randomized study was retrospectively registered. The authors noted that the registration was conducted retrospectively due to an administrative oversight during the initial stages of the study. The editor granted an exception from ICMJE rules mandating prospective registration of randomized trials because the risk of bias appears low, and the study information registered with the authors' ethics committee matches the trial reporting. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness, as retrospective registration does not prevent authors from changing their outcome measures retrospectively.

Abstract

Background: Nurse burnout is a pervasive global problem. Cognitive behavioral therapy (CBT) has been shown to reduce burnout; however, most digital CBT programs use standardized approaches that overlook individual differences in burnout profiles. With advances in artificial intelligence (AI), algorithm-based recommendation systems now enable personalized intervention delivery by matching specific CBT modules to users.

Objective: This study aimed to test the effects of an AI-selected mobile CBT-based intervention on nurse burnout and to describe participants' experiences with the intervention. Specifically, it evaluated whether an AI-selected CBT-based intervention differentially reduced burnout subdomains compared with an information-only control group and explored how nurses perceived and engaged with the AI-selected program.

Methods: This study adopted a mixed methods design, integrating a 2-group randomized controlled trial and qualitative content analysis exploring participants' experiences. For this randomized controlled trial, a total of 125 nurses were enrolled and randomly assigned to either the experimental group (n=62) or the control group (n=63) between October 2024 and December 2024. The experimental group received an AI-selected mobile CBT-based intervention, in which an AI algorithm assigned CBT modules based on participants' burnout profiles (client-related, personal, and work-related), job stress, and coping characteristics. The control group received information related to burnout management. Primary outcomes, client-related, personal, and work-related burnout, were assessed at baseline, 2 weeks, and 4 weeks. Secondary outcomes, including coping strategies, job stress, and stress response, were assessed at baseline and 4 weeks. Between-group differences in burnout over time were examined using repeated measures analysis of variance, with adjustment for job stress and stress response. Within-group changes and postintervention group differences were analyzed using *t* tests. Open-ended survey responses and follow-up interviews (n=5 in the experimental group) were analyzed using thematic content analysis.

Results: Follow-up completion rates were 84.6% (137/162) at both 2 and 4 weeks. The experimental group showed a greater reduction in client-related ($F_{1,121}$=7.548; P=.007), personal ($F_{1,121}$=6.533; P=.01), and work-related burnout ($F_{1,121}$=38.194; P<.001) than the control group, reflecting more pronounced within-group improvements over time. No significant between-group differences were observed for coping strategies, job stress, or stress response. Qualitative findings suggested that some participants were receptive to the AI-selected CBT-based intervention and reported increased self-awareness and reflective engagement with coping strategies that they might not have selected independently.

Conclusions: The findings suggest that participants were receptive to AI-selected CBT-based interventions, suggesting the potential of such interventions as a supportive approach for alleviating nurse burnout. Future research should explore the sustainability of these effects and optimize the intervention duration to enhance engagement and impact.

Introduction

Nurses play an essential role in delivering health care services and represent nearly half of the global human resources in the health sector [1]. However, many nurses are increasingly vulnerable to burnout due to prolonged exposure to physical and psychological stressors in clinical settings [2]. Several meta-analyses have estimated that the prevalence of burnout among nurses ranges from 11% to 56% [3-5], and in Korea, 55.9% of frontline nurses experience burnout [6].

Nurse burnout is multifaceted and often categorized into 3 subdomains: client-related burnout (exhaustion related to patient care), personal burnout (emotional and physical exhaustion), and work-related burnout (stress stemming from job demands) [7]. Given the ongoing nursing shortage [8] and rising health care demands [9], accessible and effective interventions are required to address burnout. These interventions should consider not only general experiences of burnout but also its distinct subdomains, which may vary according to individual roles and work contexts.

Cognitive behavioral therapy (CBT) is a structured, problem-focused intervention that aims to modify maladaptive and irrational cognitions underlying emotional and behavioral issues [10]. Beyond traditional protocol-based CBT, an expanding body of research has applied CBT-based or CBT-informed psychological interventions, including mindfulness-based approaches [11], laughter therapy [12], storytelling [13], and reflective writing [14], to address burnout-related symptoms. CBT has been widely recognized as an effective intervention for reducing burnout symptoms among nurses by helping them restructure their dysfunctional thoughts and behaviors across various clinical settings. Meta-analytic evidence suggests that CBT is particularly effective in alleviating emotional exhaustion [15] and depersonalization [16], which are 2 core subdomains of burnout. These findings highlight the potential of CBT-based interventions to effectively address key aspects of nurse burnout.

With the rapid advancement of mobile technology, mobile health (mHealth) interventions have become increasingly common in supporting mental health [17]. These platforms offer scalable, flexible, and cost-effective alternatives to traditional face-to-face therapy, making them particularly useful for health care professionals, such as nurses, who often face temporal and spatial barriers to accessing psychological support [18]. Application-based CBT programs, such as Wysa [19] and Woebot [20], have shown effectiveness in reducing symptoms of depression and stress. Artificial intelligence (AI)–based recommendation systems are increasingly being integrated into mHealth platforms to enable the delivery of personalized interventions [21]. Originally developed and widely adopted in industries such as retail and entertainment, collaborative filtering and content-based recommendation algorithms are currently being utilized in health care settings to tailor interventions based on user profiles, symptom severity, and behavioral patterns [22]. These intelligent systems have the potential to enhance user engagement and therapeutic outcomes by offering interventions that optimally match individual needs [23].

Despite growing evidence supporting the effectiveness of CBT-based interventions in reducing burnout among nurses, most studies have focused on evaluating the effects of a single standardized program [16]. These approaches often adopt a one-size-fits-all model, overlooking the multidimensional nature of burnout and the diverse needs of individual users. Few interventions have addressed burnout subdomains as distinct targets for tailored support. Moreover, there is a notable lack of research that applies user-based recommendation systems to suggest interventions based on nurses' individual characteristics, such as their burnout profiles or professional backgrounds. This gap highlights the need for an adaptive and tailored system that can enhance the effectiveness and relevance of digital mental health interventions in the nursing workforce.

This study evaluated the effectiveness of an AI-selected mobile CBT-based intervention designed to reduce burnout among nurses. The intervention used a user-based recommendation system to enhance its impact by suggesting 1 of 4 CBT-based modules tailored to the user's burnout subdomain, as well as demographic and work-related factors. Previously, we conducted a 3-group randomized trial using this system [24], which demonstrated significant improvements in some burnout subdomains.

Since then, the algorithm has been further optimized, but it remains unclear how participants perceive and engage with programs selected by AI. To address both issues, we designed this study to evaluate the intervention using quantitative and qualitative approaches, thereby providing a more comprehensive understanding of its effectiveness and user acceptance.

Methods

Study Design

We adopted a mixed methods design, integrating a 2-group randomized controlled trial (single-anonymized) and qualitative content analysis exploring participants' experiences. The study was conducted in accordance with the CONSORT (Consolidated Standards of Reporting Trials) guidelines for reporting randomized controlled trials [25] (Checklist 1). In addition, the qualitative component of this study was reported in accordance with the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist [26].

Randomization

Randomization was conducted using an online tool (randomizer.org, a service provided by the Social Psychology Network), ensuring an equal 1:1 allocation between the experimental and control groups. Participants were not informed about the randomization before enrollment to reduce selection bias and preserve objectivity during the intervention process.

Participants and Sample Size

Participants were recruited through 2 large South Korean online nurse communities (1500 registered nurse-verified members). Recruitment notices containing the study purpose, procedures, and inclusion criteria were posted as online announcements. Nurses who wished to participate accessed a Google Forms survey link, reviewed the study information, and provided

XSL•FO
RenderX

electronic informed consent. Inclusion criteria were nurses who had completed preceptorship and worked independently for at least 1 month; those not providing direct care or with prior exposure to mobile burnout interventions were excluded. Additionally, participants were allowed to withdraw from the study after enrollment if (1) personal- or health-related circumstances made continued participation impossible, (2) they chose not to complete the study, or (3) they had difficulty participating in the study due to safety or ethical reasons.

We estimated the required sample size using G*Power (version 3.1.9.7) [27], based on a previous study [28], with an effect size of 0.13, α=.05, power=0.95, and 3 repeated measures, resulting in 130 participants. Allowing for a 20% attrition rate [29], the recruitment target was set at 162 participants (81 per group). To ensure data quality, baseline variables were screened for univariate outliers. Observations more than 1.5 to 3 IQRs from the median were removed, resulting in the exclusion of 12 cases (experimental=4; control=8). Of the 162 eligible participants randomized, 137 (84.6%) completed both the 2-week (posttest 1) and 4-week (posttest 2) follow-up assessments. For the final quantitative analyses, 125 participants (experimental=62, control=63) were included after the data-cleaning process for missing values and outliers, indicating a 77.2% retention rate for a fully remote intervention.

Interventions

Experimental Group

The intervention designed by the research team was delivered via a mobile app called Nurse Healing Space. This app comprises 4 distinct modules that target burnout reduction: (1) mindfulness meditation, (2) storytelling and reflective writing, (3) laughter therapy, and (4) acceptance and commitment therapy (Table 1). The experimental group received AI-selected CBT-based intervention modules at 2-week intervals. Over the 4-week intervention period, the AI algorithm sequentially selected 2 modules from the 4 available CBT-based interventions. Participants engaged in 3 sessions per week, with each session lasting approximately 10 to 15 minutes. Animated female characters appeared in the videos to guide participants through the activities. For the mindfulness meditation, users followed guided instructions regarding body movements, breathing techniques, and meditative practices. Storytelling and reflective writing involved watching narratives shared by fellow nurses, followed by reflective writing about their personal experiences. In laughter therapy, participants were led through songs and dance routines designed to elicit positive affect and laughter. The acceptance and commitment therapy component focused on emotional acceptance and thought regulation, as modeled in the videos. All program content was developed with input from domain experts to ensure both clinical relevance and psychological effectiveness.

Table . Program components of intervention.

Week and session	Programs			
	Mindfulness meditation	Storytelling and reflective writing	Laughter therapy	Acceptance and commitment therapy
Week 1				
Session 1	Body scan (upper body), self-compassion meditation	Work is piling up	Look like my mom, bee dance	Hello my heart (introduction)
Session 2	Body scan (lower body), yoga meditation	I am a person too	Don’t make a wry face, bee dance	Thinking is just thinking (cognitive diffusion)
Session 3	Sitting up straight meditation, relaxation meditation	There aren’t enough hours in the day	When I go to Los Angeles, creative movement	This is the moment (being present in the moment)
Week 2				
Session 4	Body scan (upper body), yoga meditation	Am I an emotional outlet?	Look like my mom, open chest 1, 2, 3	Look back at me (self as context)
Session 5	Body scan (lower body), sitting up straight meditation	The working environment is too poor	Don’t make a wry face, free movement	Worthy life (the best 3 moments of my life)
Session 6	Self-compassion meditation, relaxation meditation	There is a shortage of nurses	When I go to Los Angeles, creative movement	Let’s do it together (committed action and willingness)

The algorithm was developed to provide personalized burnout interventions by identifying the most similar prior participant using both profile similarity scores and burnout patterns. The development, operation, optimization, and intervention content of the AI algorithm are discussed in greater detail in a separate study [30].

After completing Program 1, participants’ burnout levels were reassessed. If the most elevated burnout dimension showed a reduction of 50 points or more, the data were considered valid and incorporated into the algorithm. Otherwise, the data were considered invalid and excluded from AI model training, although the participants continued to receive the subsequent intervention modules without restriction. As data accumulated,

XSL•FO
RenderX

the AI continually updated its artificial neural network through iterative learning. Based on the reassessed burnout dimension scores after Program 1, the AI algorithm recommended a second 2-week program (Program 2) using the same algorithm. The variables were reassessed after Program 2. Following this, the AI algorithm updated its artificial neural network upon recognizing valid data. Participants in the experimental group completed a pretest survey (107 items: demographic and work-related characteristics and study variables), followed by Program 1 for 2 weeks, posttest 1 (19 items: burnout), Program 2 for 2 weeks, and posttest 2 (97 items: study variables).

Control Group

Participants in the control group were provided with online informational materials covering all 4 intervention programs (mindfulness meditation, storytelling and reflective writing, laughter therapy, and acceptance and commitment therapy) through a blog platform. We sent the URL to participants after they had completed the pretest survey. The control group also completed the same sequence of assessments as the experimental group: a pretest survey, posttest 1 at week 2, and posttest 2 at week 4. After completing the final assessment, participants in the control group were given access to *Nurse Healing Space*.

Measurement

Demographic and Work-Related Characteristics

Data included age, sex, marital status, job title, hospital size, clinical experience, department, overtime, shift type, and turnover intention (0 - 10 scale).

Primary Outcome

We assessed burnout using the Korean-adapted Copenhagen Burnout Inventory [7,31]. This 19-item instrument measures client-related, personal, and work-related burnout on a 5-point Likert scale. Each item is transformed to a 0 to 100 score, and subscale scores are calculated as the mean of the corresponding items, with higher scores indicating greater burnout. The possible score range for each subscale is 0 to 100. Cronbach α in this study was 0.936.

Secondary Outcomes

We measured coping using the Korean version of the Coping Strategy Indicator [32,33]. The 33-item scale includes social support-seeking, problem-focused, and avoidance-focused coping, rated on a 3-point Likert scale. Subscale scores are calculated by summing the corresponding item scores (possible range: 11 - 33), with higher scores indicating greater use of each coping strategy. Cronbach α in this study was 0.888. We measured job stress with a 23-item scale developed for Korean nurses [34,35]. It covers 6 subdomains: workload overload, role conflict as a professional, lack of professional knowledge and skills, interpersonal relationship problems, inappropriate treatment and compensation, and night shift. These are rated on a 5-point Likert scale. Item scores range from 1 to 5, and the overall job stress score is calculated as the mean of the item scores, with higher scores indicating greater job stress. The possible score range is 1 to 5. Cronbach α in this study was 0.881. We measured stress response with the 22-item Stress Response Inventory-Modified Form [36,37], covering somatization, depression, and anger, rated on a 5-point Likert scale (0 - 4). Total scores range from 0 to 88, with higher scores indicating greater stress response. Cronbach α in this study was 0.936.

Data Collection

Data were collected between October 8 and December 31, 2024. Quantitative data were assessed at baseline, 2 weeks, and 4 weeks. Participants advanced to the next program only after completing the previous one. Although each module was designed to last 2 weeks, actual usage varied: Program 1 ranged from 14 to 20 days (mean 15.80, SD 1.30 d) and Program 2 ranged from 14 to 18 days (mean 15.55, SD 1.0 d). The integrated management platform enabled the research team to monitor participants' study progress and completion status at each stage of the study. To support continued participation, weekly reminder messages were sent during the intervention period, and participants received compensation after completion of each survey assessment point.

Qualitative data were collected to explore participants' experiences with the AI-recommended interventions. As part of the survey, all experimental group participants completed a short open-ended questionnaire. Following the completion of the intervention, participants in the experimental group were contacted via text messages to assess their willingness to participate in one-on-one follow-up Zoom interviews, and 5 agreed to participate. Each interview lasted approximately 30 minutes (Textbox 1). The semistructured interview guide was collaboratively developed by the research team and reviewed by an experienced qualitative researcher. The follow-up interviews were conducted by the first author, a female clinical nurse and doctoral student with approximately 10 years of inpatient experience and prior qualitative research experience. No prior relationship was established between the interviewer and participants before the study, and participants were informed of the interviewer's role as a researcher and the purpose of the study prior to participation. To minimize potential interviewer bias, the interviewer maintained reflexive memos during data collection, adhered to the semistructured interview guide, and engaged in peer debriefing with an experienced qualitative researcher. These procedures helped enhance the credibility and trustworthiness of the qualitative findings. With participants' consent, all Zoom interviews were audio-recorded for transcription and analysis purposes. No video recordings were made, and participants were informed that they could freely disable their cameras during the interview.

Textbox 1. Interview questions.

1. If you were to describe the program you completed to a friend, what would you say?
2. In what ways did the program help reduce your burnout?
3. What positive experiences did you have while participating in the recommended program?
4. What negative experiences did you have while participating in the recommended program?
5. What was the most significant change you noticed before and after completing the program?
6. What are your thoughts on the use of artificial intelligence (AI) in health programs?
7. During the intervention period, were you aware that the program you received had been selected by an AI algorithm?
8. How do you feel about receiving and following a program recommended by an AI algorithm?
9. How do you think your experience would differ if you chose a program yourself compared with following one recommended by an AI algorithm?

Data Analysis

We analyzed data using SPSS Statistics (version 27; IBM Corp). Descriptive statistics summarized participants' characteristics and study variables. We tested baseline homogeneity between groups using chi-square tests and *t* tests. Group differences in burnout over time were examined using repeated-measures ANOVA, with job stress and stress response as covariates due to their significant correlations with burnout. We assessed within-group changes in coping strategies, job stress, and stress response using independent *t* tests. Within-group changes in burnout from baseline to posttest 2 were further examined using paired-sample *t* tests, and effect sizes were calculated using Cohen *dz*. An intention-to-treat (ITT) analysis was not conducted. This study used a sequential AI-based intervention in which outcome data at each assessment point were required to inform subsequent algorithm-selected module recommendations and to ensure the validity of adaptive intervention delivery. Accordingly, the primary quantitative analyses were conducted using participants with complete outcome data across assessment points. The absence of an ITT analysis is acknowledged as a methodological limitation of this study.

Qualitative data were analyzed using content analysis to identify participants' experiences with the AI-based CBT intervention. For this qualitative component, an inductive content analysis approach was used. The first author repeatedly read the interview transcripts and open-ended responses to become familiar with the data and generated initial open codes. These codes were then organized into broader categories through an iterative comparison process. To enhance the credibility of the findings, a peer debriefing procedure was conducted, in which an experienced qualitative researcher reviewed the coding structure and provided feedback. Throughout the analysis, reflexive memos were maintained to document analytic decisions and reduce potential researcher bias. These steps helped strengthen the dependability and confirmability of the qualitative findings, which served to complement and contextualize the quantitative results.

Ethical Considerations

This study was approved by the institutional review board of the principal investigator's institution (institutional review board number ewha-202407-0025-01) and registered in the Clinical Research Information Service (KCT0009853; October 16, 2024). All participants received detailed information about the study's purpose, procedures, risks, and benefits through an online study information page, and electronic informed consent was obtained prior to enrollment. Participants were informed of their right to withdraw from the study at any time without penalty. To ensure privacy and confidentiality, all collected data were deidentified and stored in encrypted, password-protected files. Contact information used for randomization and compensation delivery was stored separately from outcome data, and only authorized research personnel had access to the deidentified dataset. All participants received a token of appreciation valued at KRW 5000 (approximately US $4) for each survey completed (baseline, posttest 1, and posttest 2). In addition, experimental group participants who took part in the optional follow-up interview received an additional KRW 20,000 (approximately US $15) gift card as compensation.

Results

Homogeneity of Demographic Characteristics and Study Variables Between Groups

Baseline comparisons indicated no significant differences in demographic characteristics between groups (Table 2). However, job stress (t_{123}=3.80, P<.001) and stress response (t_{123}=3.77, P<.001) differed significantly and were therefore included as covariates in subsequent analyses to adjust for potential confounding effects (Figure 1).

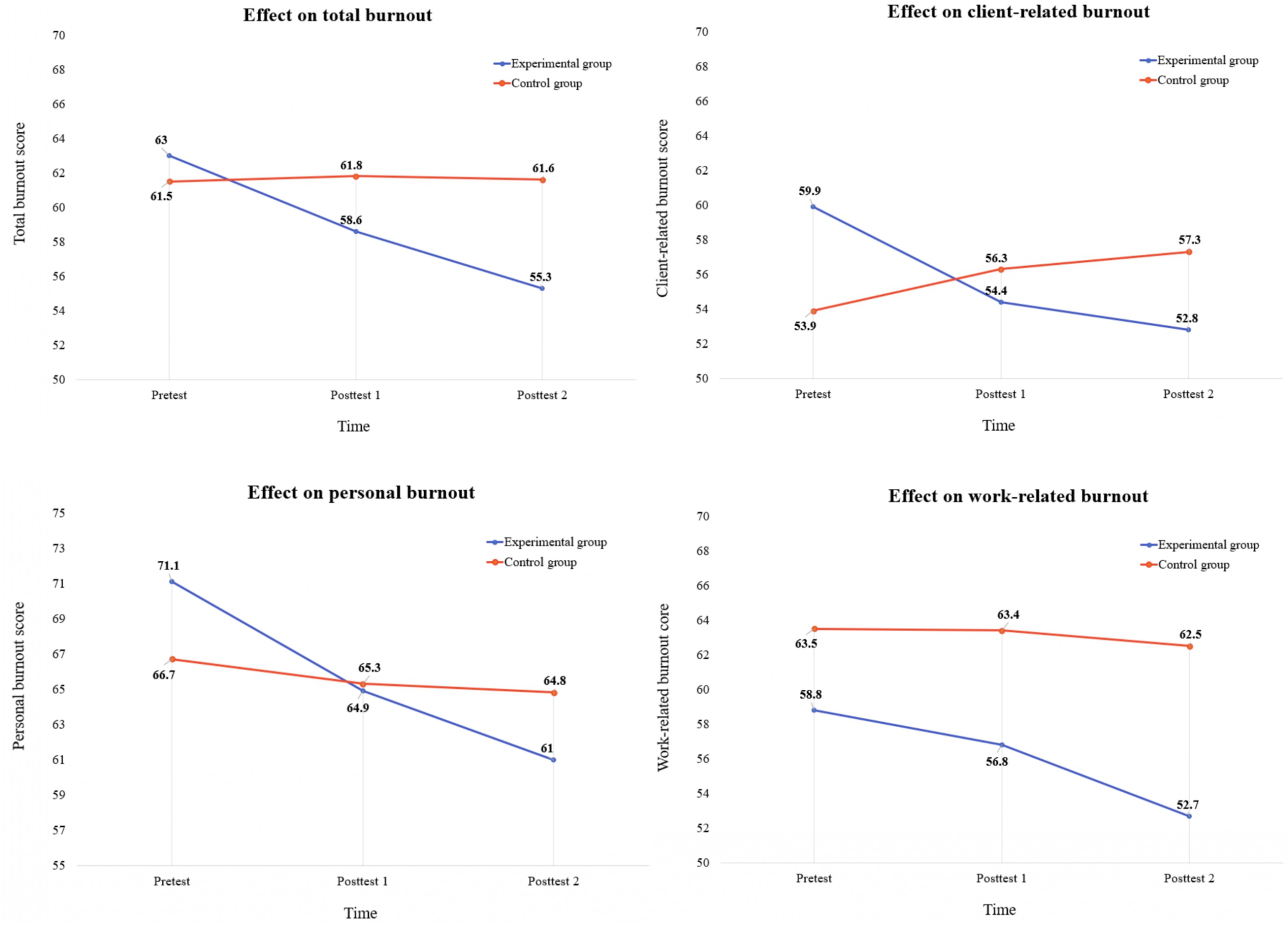
Figure 1. CONSORT (Consolidated Standards of Reporting Trials) diagram profile flow.



Effects of the Intervention on Nurse Burnout

Figure 2 and Table 3 present the repeated-measures ANOVA results with covariates. The experimental group showed significantly greater reductions than the control group in client-related burnout ($F_{1,121}$=7.548, P=.007), personal burnout ($F_{1,121}$=6.533, P=.01), and work-related burnout ($F_{1,121}$=38.194, P<.001), reflecting significant group effects. No significant time or interaction effects were observed. In addition, paired-sample t tests indicated significant within-group reductions from baseline to posttest 2 in the experimental group across total burnout and all burnout subdomains, with small-to-moderate effect sizes. However, no significant within-group changes were observed in the control group.

Participant Experiences With the Intervention

Overview

We identified 2 overarching themes: experiences with the AI algorithm and perceptions of the burnout reduction program. Subthemes within each theme reflected participants' emotional, cognitive, and behavioral responses during the intervention.

Experiences With the Burnout Reduction Program

Participants described the program as an opportunity for self-reflection, emotional relief, and the development of coping strategies applicable to daily life.

Reflecting on Oneself

Several participants noted that guided activities, such as reflective writing and mindfulness meditation, enabled them to reassess their emotional state and recognize personal growth. These activities facilitated intentional self-observation and reflection on past experiences. For example, 1 participant explained:

> *During reflective writing, I looked back on past memories. It was tough then, but now I could see how much I have grown.*

Another participant stated:

> *The meditation gave me space to empty my mind and reflect. Having time just for myself was the biggest change.*

Feeling Calmer Overall

Participants reported feeling more relaxed and emotionally composed through the program's cognitive and physical relaxation components, which, in some cases, carried over into their clinical practice. One participant noted:

> *I do not know if it helped with burnout directly, but I felt more at ease. I felt calmer.*

Another participant shared:

> *When dealing with patients, I responded more gently instead of reacting harshly. I could keep calm even in busy environments.*

Creating a Mental Space for Recovery

Participants described how emotional residue from clinical work often lingered after shifts, exacerbating burnout. The program provided temporary psychological detachment from work-related stressors and created a mental space for recovery. One participant explained:

> *I used to just eat or sleep after work, but even after sleeping, the stress did not go away. This program helped me forget about it for a while.*

Another participant noted:

> *Focusing on the video and sound helped me forget things, even if just briefly.*

Strengthening Self-Efficacy Through Personalized Coping

Participants reported increased confidence in managing stress and preventing burnout. By identifying coping techniques suited to their needs and integrating them into daily life, they strengthened their sense of self-efficacy. One participant shared:

> *Stretching helped me regulate my emotions, and now I stretch as a daily habit.*

Another participant explained:

> *When I am struggling, I try taking deep breaths or moving my body—my own way of coping.*

Experiences With the AI Algorithm

Participants were often introduced to interventions they had not previously considered. They also expressed a strong sense of trust in the AI-based recommendation process.

Exposure to New Programs Beyond Preexisting Preferences

Participants noted that the AI algorithm encouraged them to engage in programs they would not have selected independently, thereby reducing reliance on habitual or preference-driven choices. One participant reflected:

> *As people, we tend to choose what we already know. But because the AI recommended something different, I could experience a variety of options.*

Another participant added:

> *It was a refreshing experience. I could try methods I would not have chosen myself, and they turned out to work surprisingly well for me.*

Trust in AI-Based Recommendations

Participants expressed confidence in the AI-generated recommendations, emphasizing that the suggestions felt objective and tailored to their personal condition. These comments suggest that some participants were receptive to the AI-recommended programs, even when the content differed from what they would have personally preferred. One participant noted:

> *When friends recommend something, I sometimes dismiss it because they do not really know me. However, with AI, it feels like it is based on a thorough understanding of my condition.*

Another participant added:

> *If I chose a program myself, I would have picked something I liked, not necessarily what I needed. The AI seemed to know what was appropriate for me at the moment.*

Discussion

Principal Findings

In this study, a greater reduction was observed in all 3 burnout subdomains in the experimental group compared with the control group. However, these results should be interpreted in light of the absence of significant time and group interaction effects. These findings suggest a potential role for tailored interventions in supporting burnout reduction, although confirmatory evidence demonstrating significant interaction effects is still needed. Previous studies have suggested the role of CBT in mitigating

XSL•FO
RenderX

burnout [15,16] and extending it by integrating AI-based personalization into mHealth delivery. Previous studies applied standardized programs to all participants without accounting for individual differences in burnout profiles or coping strategies [38,39]. A recent meta-analysis also confirmed that mobile CBT-based interventions generally reduce stress and burnout among nurses but noted heterogeneity in effects due to intervention type and user engagement [40]. This study assists in addressing these gaps by using an AI algorithm that tailors CBT-based interventions to users' demographic, work-related characteristics, and psychological profiles.

Although several mHealth interventions, such as Wysa and Woebot, have demonstrated effectiveness in reducing psychological symptoms through chatbot-delivered CBT, these platforms typically tailor content based on brief, momentary self-reported mood or symptom check-ins [19,20]. By contrast, this study used a data-driven recommendation algorithm informed by multidimensional baseline self-report data, including burnout subdomains, job stress levels, and coping styles, to guide the selection of CBT-based modules. This approach was intended to support a relatively more condition-specific and theoretically grounded personalization strategy rather than real-time mood-based content adaptation. The theoretical grounding of this approach is based on a multidimensional conceptualization of burnout, which assumes that different burnout subtypes are associated with distinct cognitive and behavioral mechanisms [7]. Accordingly, the recommendation algorithm was designed to align users' burnout profiles and coping characteristics with CBT-based modules targeting specific therapeutic mechanisms, such as cognitive restructuring, behavioral activation, and emotion regulation [15,16]. Moreover, while many digital mental health interventions primarily rely on quantitative outcome metrics, this study additionally incorporated a qualitative component to capture participants' lived experiences with the AI-assisted program. The thematic analysis highlighted users' reflections on increased self-awareness [41], trust in AI recommendations, and emotional relief, thereby providing contextual insight into the observed quantitative results.

Despite the generally favorable trends observed, the magnitude of the observed changes in burnout was modest, which necessitates a cautious interpretation of the direct effectiveness of the AI-based mobile CBT-based intervention. This pattern is consistent with findings from a recent systematic review of person-directed psychoeducational interventions for nurses, which reported that CBT-based approaches generally contribute to reductions in burnout while also demonstrating considerable variability in effect sizes and limited evidence regarding the long-term sustainability of effects [42]. Furthermore, the fully remote and self-guided nature of the intervention may have contributed to variability in how participants engaged with the program, which could partially account for the modest intervention effects observed in this study. Future studies should incorporate more comprehensive adherence-reporting methods, including objective indicators of behavioral engagement, such as module completion rates, frequency of session participation, usage duration, and interaction logs. Such approaches may help clarify the relationship between intervention engagement and treatment outcomes in fully remote CBT-based interventions. Despite these limitations, the qualitative results of this study provide important contextual insight into how such interventions may exert their influence. Rather than indicating immediate or substantial symptom reduction, participants described gradual changes in self-awareness, coping orientation, and engagement with stress-related situations. These experiential changes suggest that AI-selected mobile CBT-based interventions may operate by facilitating early-stage cognitive and behavioral adjustments, which may precede more pronounced reductions in burnout over time. Integrating these qualitative insights with the quantitative outcomes allows for a more nuanced interpretation of the intervention effects, particularly in the context of digital and mobile-based burnout interventions for nurses.

Although mobile and AI-assisted interventions are often assumed to reduce dropout by improving accessibility and flexibility, the attrition rate in this study approached 20% [11], which is comparable to rates reported in face-to-face CBT-based interventions. This finding suggests that the mobile format alone may not be sufficient to substantially reduce dropout among nurses. Factors such as high baseline occupational stress, shift work, and limited cognitive and emotional resources may have constrained sustained engagement, even in a self-guided and flexible intervention context [2]. These findings indicate that although mobile delivery may lower structural barriers, additional strategies, such as adaptive reminders, enhanced human support, or shorter intervention modules, may be necessary to further improve retention in future digital burnout interventions for nurses.

A particularly noteworthy finding of this study is that participants reported engaging in coping strategies they might not have selected on their own, specifically because they were recommended by the AI algorithm. From the interviews, participants reported that AI-generated recommendations encouraged engagement with unfamiliar coping strategies that were later perceived to be helpful. Such accounts indicate that the AI recommendations may have contributed to prompting participants to move beyond their habitual coping tendencies and consider alternative strategies. Prior research suggests that individuals experiencing burnout tend to exhibit reduced cognitive flexibility due to emotional exhaustion, often resorting to avoidant and passive coping strategies, such as denial, self-blame, and behavioral disengagement [43,44]. Although these strategies may temporarily conserve psychological energy, they ultimately fail to address the root causes of stress and can perpetuate a cycle of worsening burnout. Within this context, our findings suggest that the AI-selected intervention did more than merely provide additional options. By tailoring recommendations to participants' burnout subdomains and psychological profiles, it may have helped reduce preference-driven selection and encouraged consideration of strategies that participants might otherwise have overlooked. In this sense, the AI algorithm functioned not only as a personalization tool but also as a facilitator that broadened participants' coping repertoires and supported openness to new and potentially more adaptive approaches.

Moreover, the participants who were interviewed expressed a high level of trust in the AI-generated recommendations. This

XSL•FO
RenderX

trust appeared to stem from their perception that the recommendations were objective and data-driven; however, this interpretation should be viewed cautiously, as the study did not include a comparison condition involving recommendations from human professionals. Prior research has shown that some individuals tend to attribute greater objectivity to algorithmic guidance [45], and trust is known to be a key factor influencing engagement with and continued use of digital mental health interventions [46]. In this study, participants' trust in the AI-assisted program may have supported openness toward continued participation, although the relative advantage of AI-generated recommendations over human-delivered recommendations cannot be inferred from the current study design. Furthermore, this study suggests that AI-based mental health interventions may represent a promising complementary approach to conventional group-based or offline burnout programs, which often face structural limitations. Traditional interventions rely on fixed formats, predetermined schedules, and in-person settings, making them less accessible or feasible for professionals with demanding schedules, such as shift-working nurses. A systematic review reported that many burnout interventions were group-based and conducted offline, and they consistently noted barriers, such as scheduling difficulties, participant dropout, and lack of long-term effectiveness [42]. By contrast, the AI algorithm applied in this study delivered tailored CBT-based modules by automatically analyzing multidimensional user data, including burnout subtypes, stress levels, and coping styles. This approach enabled precise and flexible intervention without time or location constraints.

Such technological adaptability is not limited to specific professions but offers the scalability and inclusiveness needed to support high-risk occupational groups (eg, teachers, firefighters, and social workers) as well as vulnerable populations (eg, adolescents, older adults, and informal caregivers). As data from more diverse groups accumulate and algorithmic learning advances, AI interventions may become increasingly capable of addressing a broader range of mental health conditions, such as anxiety, depression, sleep disorders, and posttraumatic stress disorder. In this regard, AI-powered digital interventions may offer a scalable and sustainable approach that simultaneously enhances accessibility and personalization—2 essential elements in the future of mental health services.

Limitations

This study has several limitations that should be considered when interpreting the findings. First, all outcome measures were self-reported, thereby raising concerns about potential reporting bias, including social desirability. Second, participants were recruited without a minimum screening threshold for burnout symptoms. Although the mean baseline burnout scores exceeded 50, indicating generally elevated burnout levels among participants, the absence of a formal screening process means that participants were not explicitly selected based on a confirmed need for intervention. Although this design allows for the examination of the AI-selected mobile CBT-based intervention in real-world nurses who are vulnerable to burnout, it limits the ability to draw conclusions about intervention effects among individuals with suspected or clinically significant burnout. Future studies should consider targeting participants with elevated burnout levels to more directly test intervention efficacy. Third, although participants' access to the intervention platform and participation status were monitored digitally, this study did not include objective adherence indicators reflecting the depth of engagement with the intervention, such as total usage duration, module completion rates, session completion frequency, or detailed interaction logs. As a result, it was not possible to determine the extent to which participants actively engaged with the intervention content throughout the study period. Because this study used a fully remote, self-guided intervention format, the absence of more robust adherence data limits the interpretation of the observed intervention effects and may partially explain the relatively modest or inconsistent effects observed across several outcomes. Future studies should incorporate more comprehensive adherence-reporting methods, including objective behavioral engagement indicators, to better evaluate the relationship between intervention engagement and treatment outcomes. Fourth, although this study was conducted as a single-blind randomized controlled trial, complete participant blinding could not be fully guaranteed. Because the control group received only informational materials while the experimental group engaged with interactive AI-selected modules, participants may have inferred their group assignment. Such potential unblinding may have influenced their expectations or engagement levels, thereby introducing performance bias. Fifth, this study did not include a comparison group receiving recommendations from human professionals. As a result, interpretations regarding the relative superiority or added benefit of AI-generated recommendations should be made with caution. Sixth, baseline levels of job stress and stress response were significantly higher in the experimental group than in the control group, and these variables were statistically adjusted for using analysis of covariance. However, such baseline heterogeneity may have influenced responsiveness to the intervention, thereby complicating interpretation of the observed group differences. Participants with higher baseline psychological distress may have responded differently to the intervention compared with less distressed participants. Future studies should consider stratified randomization or subgroup analyses to better account for baseline psychological differences. Seventh, this study did not use an ITT analysis. Excluding participants with missing data or outliers may have reduced the benefits of randomization and introduced potential selection bias. Future studies should consider applying ITT approaches, such as mixed-effects modeling or multiple imputation, to better preserve randomization and enhance the robustness of the findings.

Conclusions

This study evaluated the effectiveness of an AI-selected, mobile, CBT-based intervention in reducing nurse burnout and explored participants' experiences with how the AI-selected program supported them during the intervention period. By tailoring program selection based on individual characteristics and burnout-related factors, the intervention was designed to address some limitations of standardized approaches. Nurses who received the AI-selected intervention showed reductions in

XSL•FO
RenderX

burnout, suggesting the potential use of personalized digital mental health interventions as a supportive approach for nurse burnout management. These findings highlight the potential of AI technology to enhance individualized care in occupational mental health and support further studies to examine its long-term effects and applicability across diverse health care settings.

Acknowledgments

The authors sincerely thank all the nurses who participated in this study for their time and valuable contributions. During the preparation of this manuscript, generative artificial intelligence (AI) tool ChatGPT (GPT-5.5; OpenAI) was used to assist with language polishing and improving sentence clarity. The AI tool was not used for idea generation, interpretation of results, or reference creation. All content generated with AI assistance was carefully reviewed, edited, and verified by the authors. The authors take full responsibility for the accuracy and integrity of the manuscript.

Funding

This work was supported by the National Research Foundation of Korea grant funded by the South Korean government (Ministry of Science and Information and Communication Technology) (RS-2024-00351194).

Abstract

Background: Excessive alcohol consumption among adolescents and young adults is a serious health problem. Dynamically tailored interventions could reduce their excessive drinking. We therefore developed “What Do You Drink” (WDYD), a 17-week dynamically tailored mHealth (mobile health) intervention providing personalized support on alcohol consumption.

Objective: We aim to evaluate the effectiveness, acceptability, and use of WDYD in reducing alcohol consumption of adolescents and young adults at risk.

Methods: We conducted a 2-arm, parallel-group randomized controlled trial using ecological momentary assessments. Recruitment was via an educational alcohol program, an online lifestyle monitor, social media advertisements, or news items on websites. Participants downloaded the standalone WDYD app, and when having given active informed consent, were randomized to the intervention or control group. Participants in the intervention group received dynamically tailored feedback sessions on alcohol consumption (wk 0 - 5, 7, 9, 13, and 17) and goal-monitoring reminders. Both groups completed an online baseline survey, 2 follow-up surveys (wk 9 and 33), and various ecological momentary assessments (7 daily assessments during wk 1, 7, 13, 19, 25, 31, and 33). Participants provided consent before randomization, in which they were informed that 2 study groups existed. After randomization, no disclosure of group assignment was provided, although participants could potentially infer it from receiving tailored sessions vs no tailored sessions. Primary outcomes were excessive drinking, binge drinking, and weekly alcohol consumption. Secondary outcomes were intrinsic motivation, self-confidence, and mood. Acceptability of WDYD was measured by survey questions; use was tracked via app data logs.

Results: Analyses were based on data from 1767 participants; 720 in the intervention group and 1047 participants in the control group. Almost half of them were female (2276/4795, 47.5%), and most (3471/4595, 72.4%) participants were aged 18 - 24 (median 19.40, IQR 2.92) years. The dropout rate was high, up to 96% (4603/4795) in the final 33rd week. No significant effect of WDYD was found on primary outcomes and mood, except for week 1 (excessive drinking: standardized β=−0.35, SE 0.15; 95% CI −0.64 to −0.05; binge drinking: standardized β=−0.36, SE 0.16; 95% CI −0.68 to −0.04; mood: standardized β=0.20, SE 0.06, 95% CI 0.08 to 0.32). Both groups reduced their alcohol consumption. Significant positive effects were found for intrinsic motivation and self-confidence up to 25 weeks (wk 25: standardized β=0.54, SE 0.24; 95% CI 0.06 to 1.02 for motivation; standardized β=0.72, SE 0.26; 95% CI 0.22 to 1.23 for self-confidence). Participants evaluated WDYD as acceptable and usable.

Conclusions: WDYD did not significantly reduce excessive drinking compared to control, but improved motivation and self-confidence. High dropout rates highlight challenges in sustaining engagement in long-term mHealth interventions. Future research should explore strategies to enhance retention and optimize dynamic tailoring.

Introduction

Background

Excessive alcohol drinking among adolescents and young adults is a large public health concern in Western countries [1]; it is negatively associated with short-term and longer-term negative outcomes, with regard to health, academic performance, social relationships, and finishing school [1]. Specifically among adolescents and young adults, alcohol consumption occurs in groups and is strongly influenced by the group [2-4]. In the Netherlands, various studies show that adolescents and young adults engage in excessive drinking [5-7]. In accordance with the guidelines, excessive drinking is defined as heavy drinking (ie, drinking at least 8 [women] or 15 [men] alcoholic beverages per week) and/or binge drinking (ie, drinking at least 4 [women] or 6 [men] drinks at 1 occasion [8,9]). Preventing excessive drinking is important to improve the health of individuals and to reduce societal costs.

Potential for mHealth Interventions

mHealth (mobile health) interventions can be a useful means to reach young people and to prevent them from drinking excessively [10]. mHealth interventions use mobile phones to deliver interventions and improve health, which are generally prevalent among young people (in the Netherlands, 99.1% uses a mobile phone for internet [11]). They are also widely accessible and can safeguard the users' anonymity [12]. In addition, mHealth enables the effective combination of information and communication technology with behavior change methods [13]. Although mHealth can be useful, usable, and effective, currently available alcohol apps generally contain few behavior change strategies [14]. Empirical evidence is lacking for alcohol prevention mHealth interventions among adolescents and young adults specifically [10]. Research emphasized the need for tailoring [15], personalization [16], and intervening in real-life contexts [10] for this target group.

WDYD Intervention

In this study, we aimed to evaluate an evidence-based 17-week dynamically tailored mHealth intervention, "What Do You Drink" (WDYD; Trial Registration: onderzoekmetmensen.nl Trial 28135 [17,18]). Dynamic tailored interventions, also called just-in-time adaptive interventions [19-21], are interventions where the information about the individual is used to determine when and how to intervene; that is, feedback and support are provided based on prior assessments of behavioral and psychological factors. In other words, to make these intervention-related decisions, not only static information (eg, baseline characteristics), but also time-varying information (eg, mood or response to intervention) is used [20]. Thus, dynamically tailored interventions are adapted over time to the dynamic changes of individuals, based on their varying needs. A meta-analytic review has shown that dynamic, tailored, just-in-time adaptive interventions are more effective than nondynamic, non–just-in-time adaptive interventions [19,21]. Moreover, dynamically tailored interventions should reduce dropout, a general problem of digital health interventions [10].

In addition, WDYD is based on behavior change techniques that have shown to be effective in changing health behavior and reducing alcohol consumption [22-24]. Examples of general methods used in WDYD are goal setting, action planning, behavioral feedback, and self-monitoring. In addition, based on daily assessments of behavioral (alcohol consumption) and psychological factors (motivation, self-confidence, and mood), users were provided with weekly tailored support based on a diversity of behavioral change techniques (eg, planning and problem solving, behavior substitution, modeling, and motivational interviewing techniques [18]).

Objectives

The primary objective was to evaluate the effectiveness of WDYD in reducing excessive alcohol consumption among adolescents and young adults (≥16 y) at risk. Secondary objectives were to assess changes in determinants of drinking behavior (intrinsic motivation, self-confidence, and mood) and to examine the acceptability and use of WDYD.

Hypotheses

We hypothesized that, compared to the control group (no intervention), participants receiving WDYD would (1) show greater reductions in excessive alcohol use, binge drinking, and weekly alcohol consumption (primary outcomes); (2) demonstrate positive changes in determinants of drinking behavior (secondary outcomes); and (3) evaluate the intervention as acceptable and usable, with measurable engagement reflected in app usage logs.

Methods

Ethical Considerations

Human Subjects Ethics Review

This study was approved by the Ethical Committee of the Faculty of Social Sciences of Radboud University Nijmegen (approval number ECSW2016-1403-390).

Informed Consent

Participants provided active informed consent within the app before study enrollment. Individuals younger than 16 years of age were excluded from participation; consent included confirmation that participants were aged 16 years or older (see Multimedia Appendix 1 for consent documents). Participants received a summary of this study's purpose (ie, personalized education about alcohol intake), duration (ie, approximately 6 months), and procedures (including participation via an app, questionnaires, and ecological momentary assessments [EMAs], information about the study groups, and possible interventions). They were also informed that participation was voluntary and that they could withdraw at any time without providing a reason.

XSL•FO
RenderX

Privacy and Confidentiality

Participants were quasi-anonymous. Registration required an email address, which was linked to a unique participant code and stored separately. The Information and Communication Technology provider managing the app had access to both datasets; researchers only accessed deidentified data. Email addresses were shared with researchers solely for reward distribution and could not be linked to participant codes. Data protection measures were outlined in the terms of use and privacy statement included in the consent process (see Multimedia Appendix 1). No cookies or third-party tracking tools were used to prevent multiple registrations, and no additional identity verification measures were implemented.

Compensation

Participants were compensated for their participation. Those who completed both follow-up surveys received a minimum of €25 (US $29.15; €12.50 [US $14.63] per completed survey) and up to €80 (US $93.92) in bol.com vouchers, depending on overall study completion rates. Compensation procedures were communicated during the consent process (see Multimedia Appendix 1).

Design

This study was a 2-arm, parallel-group, online-only randomized controlled trial conducted in the Netherlands between September 2018 and October 2019. The target population was adolescents and young adults aged ≥16 years who drank excessively. Participants could enroll between September 2018 until the end of January 2019 by downloading the stand-alone WDYD app from the iOS App Store (Apple Inc)or Google Play Store (Google LLC). Within the WDYD app, participants were randomly assigned (1:1) to the experimental group (ie, WDYD intervention) or control group (no intervention), using a preprogrammed algorithm embedded in WDYD (see reference for the language code [25]). During consent, participants were informed that 2 study groups existed. Individual allocation was unknown at the time of consent, because randomization occurred after participants provided consent. After randomization, no allocation disclosure was provided. However, participants could infer their group assignment from the presence (intervention) or absence (control) of tailored sessions. The trial lasted 33 weeks and consisted of an online survey at baseline, followed by additional online surveys at 9 and 33 weeks. To account for the fluctuating nature of alcohol drinking and contextual influences [26,27], participants were also asked to report their alcohol intake each day using EMA over 7 weeks (wk 1, 7, 13, 19, 25, 31, and 33), each consisting of 7 consecutive daily assessments. Surveys and EMAs were administered via the WDYD app, with push notifications as reminders.

The trial was conducted with version 2.0.0 of the WDYD app (d.d. August 27, 2018). Two updates were made to WDYD during the trial: (1) small textual changes (September 12, 2018), and (2) a bug fix and removal of text about participation rewards at the end of the enrollment period (January 30, 2019).

Participants

The eligibility criteria were based on the Dutch Health Council guidelines for excessive drinking [9] and being 16 years or older. Adolescents (aged 16 - 18 years) indicating any amount of routine alcohol consumption were considered excessive drinkers. For adults, excessive drinking was defined as:

- Men: drinking more than 2 drinks per day (heavy drinking) or 6 or more glasses in 1 day (binge drinking).
- Women: drinking more than 1 glass per day (heavy drinking) or 4 or more glasses in 1 day (binge drinking).

Participants also had to be 16 years of age or older at the time they signed up.

Initially, WDYD was developed as an intervention with a primary focus on students in secondary vocational education who drank excessively (aged 16 to 24 years). The intervention was developed in cocreation with these students using a user-centered approach [18]. Due to low enrollment in a prior pilot (n=253; 19.3% of the 1310 participants needed), recruitment was expanded to all Dutch adolescents and young adults who drank excessively.

Multiple recruitment channels were used:

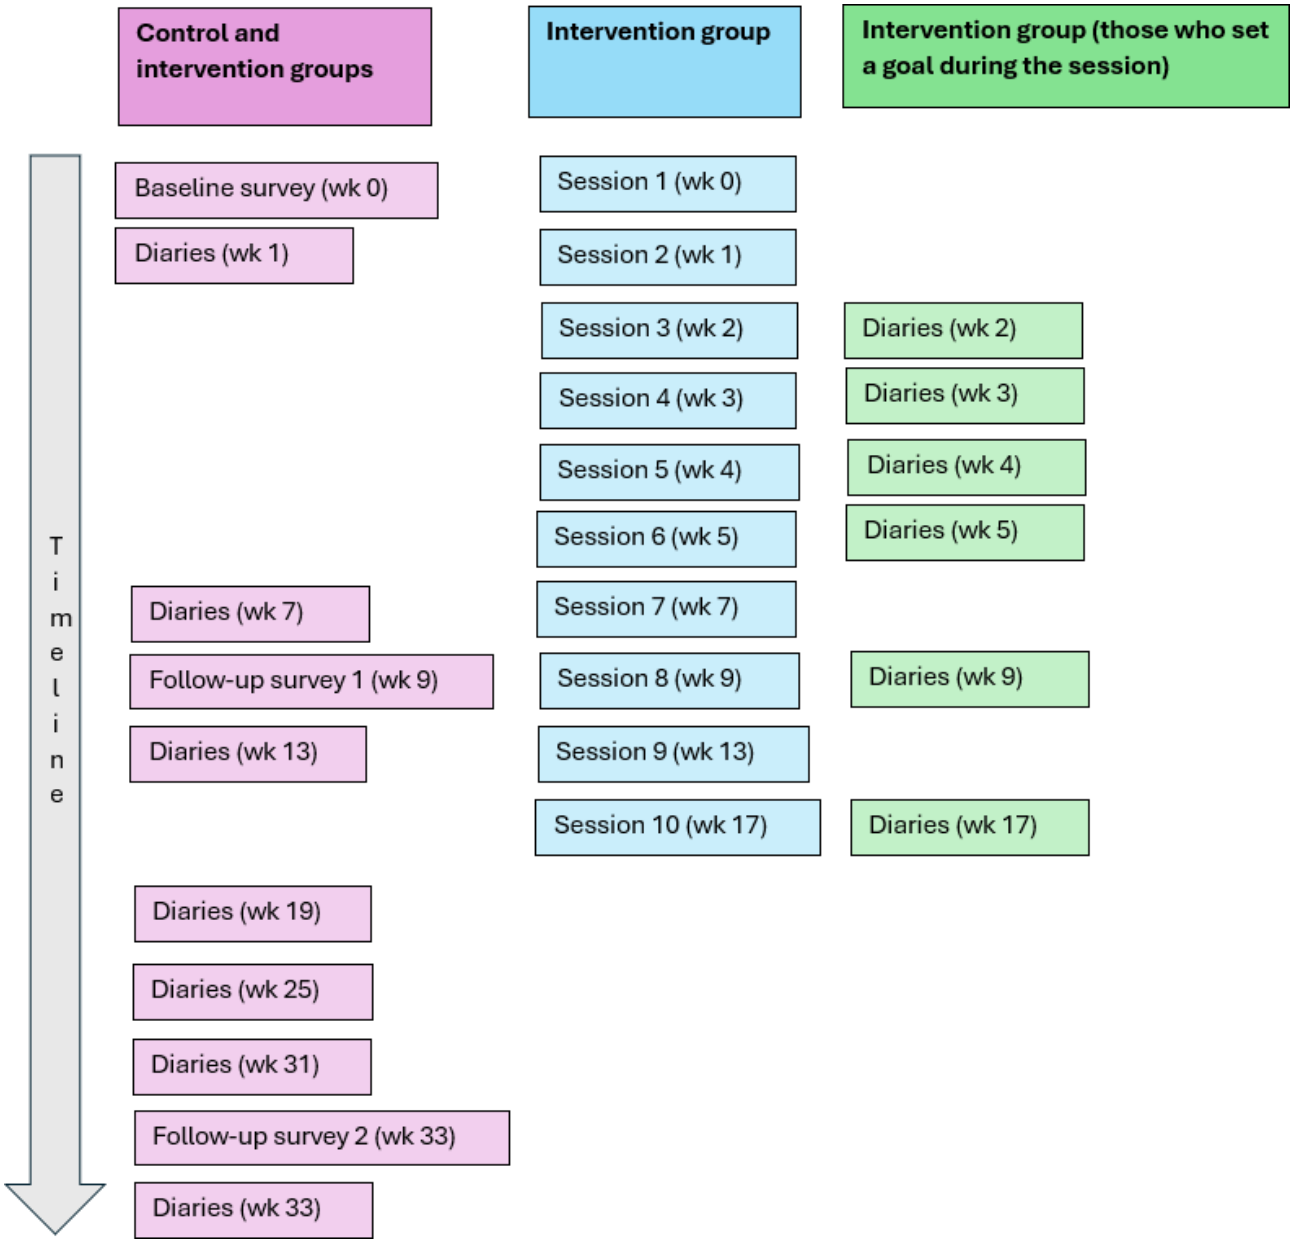
1. Students in secondary vocational education were recruited via an online lifestyle monitor (“TestYourLifestyle”; *Testjeleefstijl* in Dutch) specifically designed for schools and students in secondary vocational education [28]. The monitor is used annually by multiple schools as part of their health-education curriculum. The monitor consists of various lifestyle modules (eg, physical activity, nutrition behavior, sexual behavior, or smoking), including alcohol consumption. Within the monitor, students can create a user account, receive module-specific questions followed by brief tailored normative feedback (ie, comparison of their behavior to the Dutch guidelines), behavior-related risk information, and information about websites or programs related to the lifestyle topic. To recruit students in secondary vocational education for this study, students who drank alcohol excessively according to the monitor received an invitation to participate with a link to further information about this study and the possibility to download the WDYD app to subscribe and provide informed consent for participation. During the recruitment period (September 2018 to January 2019), the alcohol module of the lifestyle monitor was completed by 12,004 students. Of these students, 55.1% (6619/12004) exceeded the heavy-drinking guideline, and 52.4% (6290/12004) reported binge drinking, making them eligible for participation in WDYD. The lifestyle monitor is implemented at the school level, but detailed information on the number of participating schools and class-level participation rates was not available.
2. Students in secondary vocational education were also recruited via teachers who implemented an educational program on alcohol consumption. The Secondary Vocational Education Council distributed an email invitation and published a news item on its website aimed at teachers responsible for citizenship education, a compulsory subject in secondary vocational education. Interested teachers could sign up via email to deliver the educational program in their classes. Unfortunately, the number of teachers and schools that received the initial invitation is not known. After completing the educational

XSL•FO
RenderX

program, teachers were asked to invite their students to participate in the WDYD study by providing access to this study's information page and the WDYD app.

3. Via a social media campaign (Instagram or Facebook) targeting people aged 16 - 24 years in the Netherlands.
4. Via news items and flyers by the Addiction Prevention and Care Institute [29].
5. As the eligibility of participants who drank excessively could not be established via the recruitment channels before enrollment, we intentionally oversampled and subsequently excluded individuals who did not meet the inclusion criteria.

Intervention



WDYD was developed systematically using the Intervention Mapping planning protocol [30] and an iterative, user-centered design process [31]. The development is described elsewhere [18]. WDYD (version 2.0.0) delivered a 17-week dynamically tailored mHealth program.

Regarding content and access to the intervention, WDYD offered a total of 39 different exercises and 22 videos targeting five key goals: (1) motivation, (2) self-confidence, (3) mood, (4) planning, and (5) relapse prevention, using evidence-based techniques (eg, motivational interviewing [32], behavioral modeling [33], goal setting [34], self-monitoring [35], implementation intentions [36], cognitive-behavior therapy [37], and provision of rewards [38]) and engagement strategies [22,23,39]. In addition, participants could monitor their goal progress in WDYD, in which historic daily alcohol intake was registered, as well as whether they had reached their self-set goal. Screenshots of the intervention are shown in Multimedia Appendix 2.

Exercises were tailored based on EMA data. Participants who set a goal were asked to daily monitor their alcohol drinking behavior, mood, motivation, and self-confidence. They received push notifications to remind them to provide a daily report. The intervention group received tailored weekly sessions and reminders; this started with 6 weekly sessions (wk 0 - 5), after which the frequency of sessions reduced to 2 biweekly sessions (wk 7 and 9), and 2 monthly sessions (wk 13 and 17). See Figure 1 for an overview of the intervention content and timing.

XSL•FO
RenderX

Figure 1. Flow of the WDYD intervention content and timing. WDYD: What Do You Drink.

Control Group

The control group completed surveys (baseline, wk 9, and wk 33) and EMAs only (7 daily assessments during wk 1, 7, 13, 19, 25, 31, and 33), without receiving any feedback or support. They reported their day-to-day alcohol consumption and mood in the EMAs. Motivation and self-confidence to drink less were only asked on the first day of each EMA week.

The control group was also invited to fill in the online baseline survey, and the first and second online follow-up surveys (wk 9 and 33).

Procedure

Participants were invited to participate in this study via various recruitment strategies (see Participants section) and invited to download the WDYD app; access was open and free of charge. Participants who downloaded the app could sign up and provide informed consent in the app. After consent, participants completed a baseline survey measuring sociodemographic variables, and primary and secondary outcomes. Participants in the experimental group received tailored feedback sessions. Invitations for follow-up surveys at weeks 9 and 33, with an estimated completion time of, respectively, 10 and 5 minutes, were sent via push notifications at 7 PM, followed by up to 3 reminders (ie, at d 1, 4, and 7). At the start of a survey, participants were informed about the expected duration of each survey. Participants were given 30 days to complete the follow-up surveys.

Outcome Variables

Outcomes were measured via closed online surveys at baseline, 9, and 33 weeks, and via EMAs consisting of brief daily assessments for 7 consecutive days (wk 1, 7, 13, 19, 25, 31, and 33). All measurements were administered within the WDYD app and pretested for usability and technical functionality.

XSL•FO
RenderX

Primary Outcomes

Weekly alcohol consumption was measured as the number of standard drinks per week, assessed at baseline using daily intake questions [40,41] and during EMA bursts using the question: "How many glasses of alcoholic drinks did you drink yesterday?" (range: 0 - 100) [40]. Weekly alcohol intake was calculated based on a minimum of 4 EMAs in a given week.

Binge drinking was defined as drinking more than 3 (women) or more than 5 (men) standard alcohol units on at least 1 day of the week; the day with the highest reported number of glasses consumed was used to determine whether binge drinking occurred.

Excessive drinking was defined as binge drinking (ie, drinking 4 [women] or 6 [men] or more glasses in 1 day) and/or heavy drinking (ie, drinking any amount of alcohol when under the legal drinking age of 18 years, and for adults to drink a maximum of 1 [women] or 2 [men] glasses of standard alcohol units on an average day [9]). Heavy drinking was determined by comparing the extrapolated number of glasses of alcoholic drinks in a week (more than 7 glasses for women, and more than 14 glasses for men).

Secondary Outcomes

Intrinsic motivation was measured by the question: "How important is it for you to drink less alcoholic drinks" (0=not at all important to 10=very important) [32].

Self-confidence was assessed with the question: "How confident are you that you can drink less alcoholic drinks" (0=not at all confident to 10=very confident) [41,42].

Mood was assessed with the question: "How do you feel?" (0=very bad to 10=very good [41,43,44]. These were measured at baseline (except for mood), week 1 (except for motivation and confidence), and weeks 7, 13, 19, 25, 31, and 33. For mood, the weekly average was calculated if participants filled out a minimum of 4 daily assessments.

Motivation and self-confidence were measured on the first day of each EMA week. Mood was measured daily in an EMA week, and an average weekly mood index was created based on a minimum of 4 EMA entries.

Sociodemographic Variables

Sociodemographic variables were measured at baseline. These variables were age, gender, migrant background, ongoing educational level, and highest completed educational level. Both education variables were rescored to low (less than secondary or vocational education), intermediate (secondary through preuniversity education) or high (professional or university education). Specifically for students in secondary vocational education, we assessed their qualification level (1-4), school year (1-4), and pathway (practical, vocational training, or combination).

Program Evaluation and Use

Program Evaluation

Participants in the intervention group were asked to evaluate WDYD in the first follow-up survey (week 9).

WDYD usability was assessed by 5 items, for example, "How do you perceive the user-friendliness of WDYD?" on a 10-point scale (eg, 1=not at all user-friendly to 10=very user-friendly),

Information quality was also assessed by 5 items (eg, "How do you perceive the credibility of the information in WDYD?" with 10-point scales (eg, 1=not at all credible to 10=very credible).

Personalization was assessed by 8 items (eg, "WDYD took into account my personal preferences," scales 1=totally agree to 5=totally disagree).

Finally, participants were asked to grade the overall acceptability of WDYD on a scale from 1 (very bad) to 10 (excellent) [45].

Program Use

For participants in the intervention group, use of WDYD was logged in the app. Session completion was calculated as the average number of sessions completed across all participants in the intervention group.

Exercises completed were calculated by dividing the number of completed exercises within a given category by the total number of exercises participants had chosen.

Power Calculation

The sample size was based on a priori power calculation for detecting a reduction in excessive drinking in the intervention group compared to the control group. We anticipated a small effect size (Cohen d=0.20) based on a previous study of an earlier version of WDYD [27] and a just-in-time adaptive alcohol intervention [39]. In the previous study, the EMA procedure, including the rewarding of participants, resulted in a 20% dropout [27]. When anticipating a conservative dropout rate of 40% [46], a small effect size (d=0.20), a power of 0.80, and a 2-sided α of .05, a total of 655 participants were required per group at baseline.

Statistical Analyses

Data were analyzed using R (R Foundation) [47]. Logistic regression analyses were also used to analyze the dropout probability at the start (ie, within the first week), and throughout this study (ie, within 33 wk), with primary, secondary, and sociodemographic variables at baseline as predictors. Descriptive statistics (%, n, mean, SD, median, or IQR) were used to analyze baseline characteristics of the sample (ie, sociodemographic and outcome variables) and to evaluate usability and acceptability of WDYD. A logistic regression analysis was used to evaluate the randomization by analyzing the probability of intervention group assignment using the primary, secondary, and sociodemographic variables observed at baseline. Baseline logistic regression analyses were used to examine differences between recruitment strategies in drinking behavior at baseline.

Effects of WDYD on primary and secondary outcomes were analyzed using multilevel generalized linear regression models using the R package *lme4* [48]. A multilevel logistic regression model was used for dichotomous outcomes (ie, excessive drinking and binge drinking), a multilevel negative binomial regression model for count outcomes (ie, number of glasses), and a linear multilevel regression model for continuous

XSL•FO
RenderX

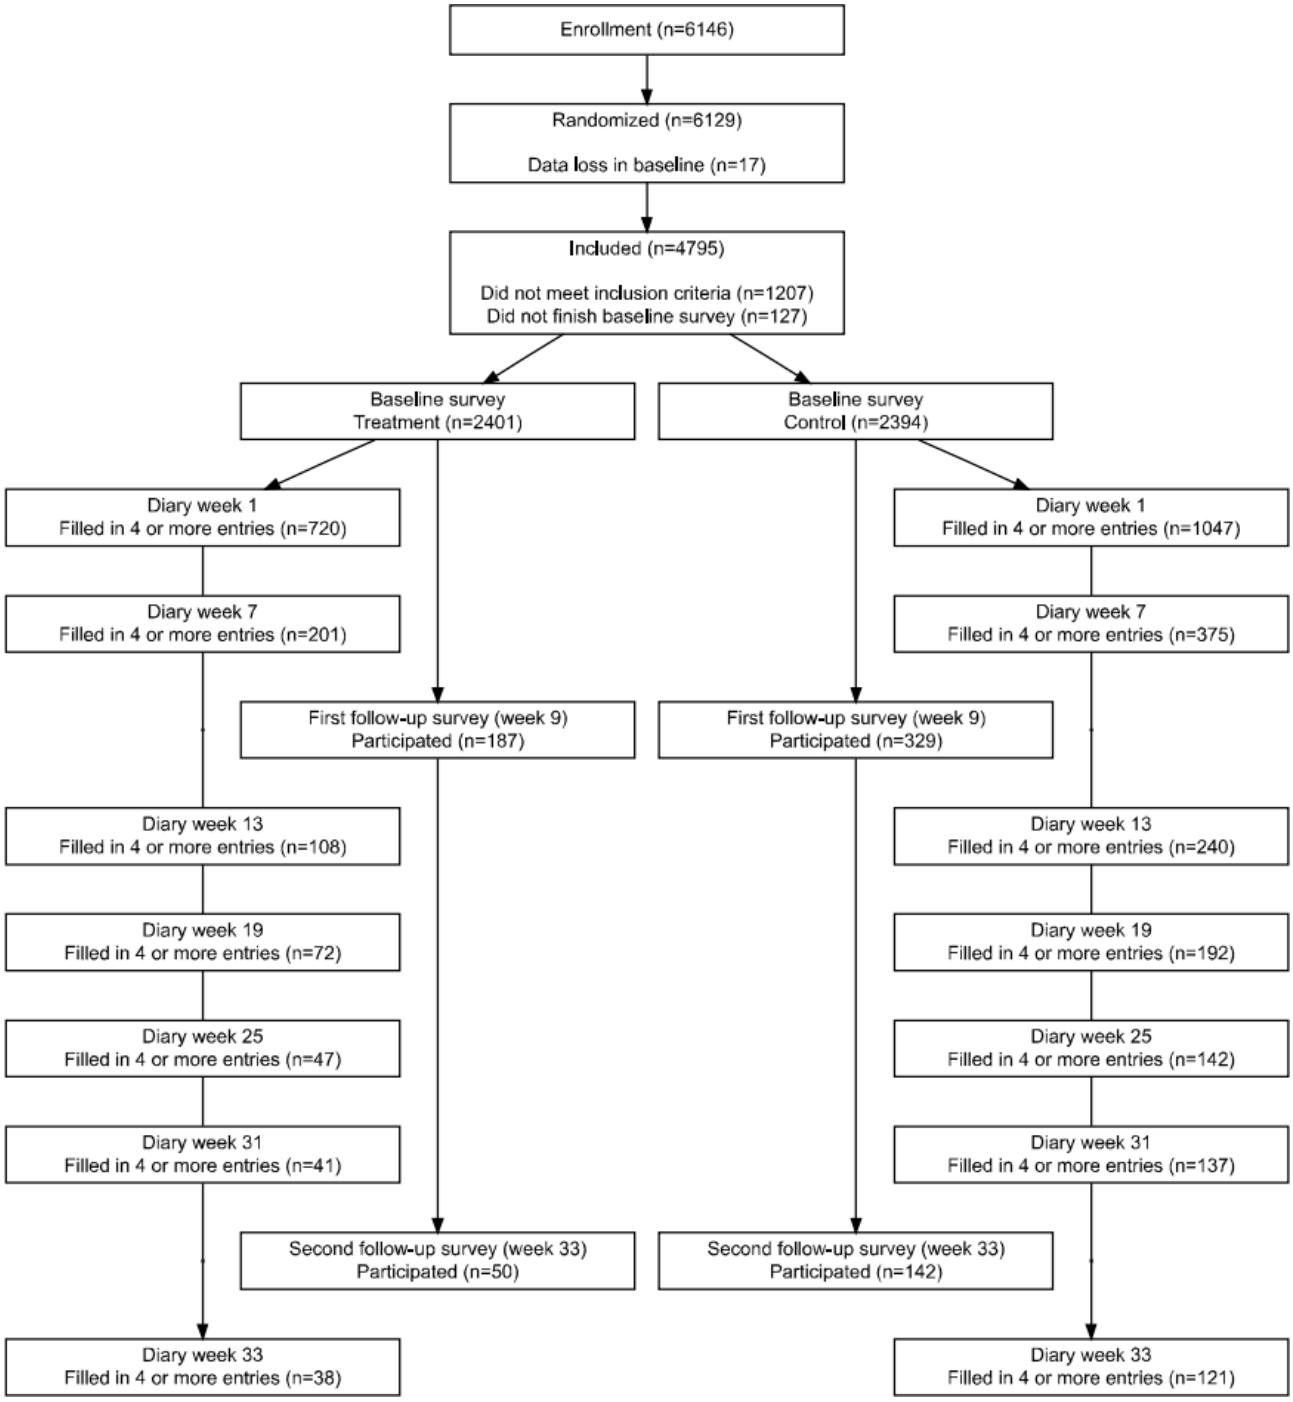
outcomes (ie, mood, motivation, and self-confidence). In these models, time (categorical: a dummy for every diary week with baseline as reference category), group (intervention vs control), and the interaction between time and group were used as predictors. In addition, a random intercept was included in each model to account for within-person clustering over time.

Missing values were imputed using multiple imputation with multilevel predictive mean matching using 100 imputations and 25 iterations, using the R package *mice* [49]. The imputation model contained the primary and secondary outcomes (alcohol consumption, mood, intrinsic motivation, and self-confidence) from the daily assessment data, group, enrolled in secondary vocational education, time, number of sessions attended (0 - 10), gender, and intention to reduce excessive drinking at baseline and week 9. We performed additional complete case analyses on both primary and secondary outcomes to check for differences between analyses based on multiple imputation and those based on complete cases only.

Results

Response Rates and Dropout

The flow of participants through this study is shown in Figure 2. A total of 6146 people downloaded the WDYD app between September 1, 2018, and January 31, 2019, and agreed to participate in this study. Most participants (4168/6146, 68.1%) indicated having been recruited via Facebook (Meta) or Instagram (Meta). Other recruitment sources included referrals from friends or relatives (637/6146, 10.4%), nonsocial media websites (465/6146, 7.6%), the online lifestyle monitor (327/6146, 5.3%), and through their teacher (272/6146, 4.4%). Finally, 4.6% (280/6146) participants found this study through another channel.



We were unable to determine the group allocation of 17 participants due to data loss of group allocation at baseline. The remaining 6129 participants were randomized into the intervention (n=3088) or control group (n=3041). After filling in the baseline survey, 1334 participants did not meet the inclusion criteria and were excluded from further analysis. Of the participants who met the inclusion criteria, 36.9% (1767/4795) completed the first week of daily assessments, 10.8% (516/4795) completed the first follow-up survey (wk 9), and 4% (192/4795) completed the second follow-up survey (wk 33). Participants who were enrolled in secondary vocational education (exp(β)=2.034, *P*<.001) and had a higher peak daily alcohol consumption (exp(β)=1.040, *P*<.001) were more likely to drop out within the first week of this study. Over the entire 33 weeks of this study, participants assigned to the intervention group (exp(β)=2.96, *P*<.001), enrolled in secondary vocational education (exp(β)=3.59, *P*<.001), and had a higher mean weekly alcohol consumption (exp(β)=1.034, *P*<.001) were more likely to drop out.

Participants were excluded from all analyses when they did not meet the inclusion criteria (ie, excessive drinking and ≥16 y of age; see Participants section; n=1207) or if they did not complete the baseline questionnaire (n=127). The number of participants that dropped out of this study was large, especially in the first diary week (n=3028). We excluded participants who dropped out within the first diary week from the main analysis, as not enough information was observed to allow for imputation. In addition, the number of participants who completed the measurements during weeks 31 and 33 was insufficient for reliable imputation. As a result, our imputation model was unable to produce stable imputed outcomes. For this reason, we restricted our analysis to data collected up to week 25.

The final sample for the main analyses consisted of 1767 participants ($n_{intervention}$=720, $n_{control}$=1047). Missing values of these participants were imputed for analyses. Trace plots showed that the imputed datasets had converged, and density and scatterplots between observed and imputed data showed plausible imputed values.

XSL•FO
RenderX

Figure 2. Flow of participants in the WDYD study. WDYD: What Do You Drink.

Baseline Characteristics

Baseline characteristics of participants are depicted in Table 1. There were no significant differences between participants in the intervention and control groups regarding sociodemographic characteristics, primary and secondary outcomes (data not shown). Small differences were found in drinking behavior by recruitment strategy. Participants reporting higher weekly alcohol consumption were more likely to be recruited via social media (exp(β)=1.01, *P*<.001) and less likely via teachers (exp(β)=0.95, *P*<.001) or the lifestyle monitor (exp(β)=0.92, *P*<.001). No other significant baseline differences were observed in drinking behavior, and no interaction effects of recruitment strategy with group assignment were found. Slightly more than half of the participants were male (2519/4795, 52.5%), 72.4% (3471/4795) participants were aged 18 to 24 years, most of them attended or had completed a higher educational level (2673/4795, 56.3%), and 34.6% (1659/4795) of them attended secondary vocational education.

[a]WDYD: What Do You Drink.

[b]This variable was the inclusion criterion.

Intervention Effects

Effects of WDYD on primary and secondary outcomes based on multiple imputation are depicted in Table 2 and Figure 3. In both groups, binge drinking and mean weekly alcohol consumption significantly increased from baseline to week 1. After week 1, both groups decreased their alcohol consumption, but this did not significantly differ from baseline. There were no significant differences between groups on the primary outcomes at different time points (wk 1, 7, 13, 19, and 25), with the exception of a positive effect in favor of the intervention group for binge drinking and excessive drinking at week 1. Participants in the intervention group were less likely to drink excessively or binge compared to the control group in week 1. At later time points (wk 7, 13, 19, and 25), we do not have enough evidence to suggest that both groups differ. Figure 3 shows that there is a large amount of uncertainty in our model parameters, especially at later points in time when less data was available.

With regard to the secondary outcomes, motivation and self-confidence increased in both groups from weeks 7 to 25. Positive effects of WDYD were found for motivation and self-confidence at weeks 7, 13, 19, and 25; participants in the intervention group had significantly increased their motivation and self-confidence to consume less alcohol than those in the control group. As for mood, participants in the intervention group reported a more positive outcome in week 1 than participants in the control group; this difference was small but significant. After week 1, the difference between groups was no longer significant. Week 3 shows similar uncertainty in estimation for motivation, self-confidence, and mood.

We did conduct additional moderation analyses and found no evidence of educational attainment moderating the treatment effect (data not shown).

Effects on the primary and secondary outcomes were additionally evaluated using complete case analysis; results (data not shown) were similar to those based on multiple imputation of missing values.

Figure 3. Predicted outcomes of WDYD for the control and intervention groups according to the multilevel model based on multiple imputation. Bands indicate the 95% pointwise CIs for the control and intervention groups. The CI for the intervention group has the coefficient of time and group fixed at its mean predictor values. Pred: predicted; WDYD: What Do You Drink.

Program Evaluation and Use

The program evaluation and use of WDYD among intervention participants are depicted in Table 3. Participants were very positive about WDYD; they evaluated the overall acceptability of WDYD with a mean grade of 7.17 (SD 1.07; 0=very bad to 10=excellent). The usability of WDYD was evaluated as good (with mean grades of 6.78, SD 1.73, or higher at a 10-point scale). The informativity and usefulness of WDYD were evaluated as satisfactory (means 5.69, SD 2.04, and 5.46, SD 2.05, respectively), and the credibility and understandability as good (means 7.25, SD 1.41, and 7.97, SD 1.44, respectively). The amount of information was perceived as adequate (mean 5.78, SD on a scale from 0=too little to 10=too much). In addition, participants positively evaluated the design principles of WDYD (eg, acceptation and freedom of choice).

The average number of sessions followed reflects the high dropout rate (mean 1.67, SD 2.12). Within the intervention sessions, most participants received a motivation exercise (1475/4298, 34.3%) or a planning exercise (1465/4298, 34.1%).

[b]0=too little, 10=too much, with 5 as the center.

Discussion

Principal Results

This study evaluated the effect, use, and acceptability of a dynamically tailored mobile intervention, WDYD, to reduce excessive alcohol drinking among at-risk adolescents and young adults. Regarding the primary outcomes, we found no support for our hypothesis that WDYD was more effective than the control group in reducing alcohol consumption. No effect of WDYD was found on mean weekly alcohol consumption. Positive effects of WDYD were found only in the first week for excessive drinking. In addition, there was an increase in binge drinking in the first week in both groups, but this increase was significantly smaller in the intervention group. After this first week, alcohol consumption seemed to decrease over time in both groups, but differences between groups were nonsignificant at all time points. The increase in binge drinking in the first week was possibly due to the measurement difference between baseline and the following weeks. At baseline, alcohol consumption was based on a participant's self-reported alcohol intake during a typical week, whereas at the follow-up measurements, participants were asked to report their consumption of the day before (1-day recall) for 7 consecutive days. A 1-day recall leads to more accurate estimates than a

XSL•FO
RenderX

7-day recall because it is less susceptible to recall bias [50], and this difference is even more pronounced with binge drinking [40].

The reduction in alcohol consumption over time in both groups in this study is in contrast with the study about a previous web-based version of WDYD [27], which showed that both groups increased their alcohol consumption over time, with the intervention group showing a significantly lower increase than the control group. Differences between this study and the previous study may partly explain the variation of observed effects. The previous study used a web-based brief, single-session tailored feedback intervention. Effects were measured during 30 weekly 7-day recall EMAs over 6 months among a highly educated sample of young adults (ie, students in higher professional education or university) recruited via flyers and included when they were ready to change their alcohol consumption. In this study, the reduction of alcohol consumption in both groups over time, as well as the absence of a significant intervention effect on alcohol consumption, could be explained by the use of daily 1-day recall EMAs; the study's participants, including those in the control group, self-monitored their alcohol drinking behavior daily for 7 weeks during this study. Self-monitoring is shown to be an important behavior change technique in predicting positive outcomes regarding alcohol reduction research [14,23]. Therefore, it is highly likely that the difference in outcomes between groups would have been greater if the control group had engaged in less frequent self-monitoring. Moreover, a difference between the studies lies in the inclusion criteria. First, the 2 studies targeted different populations. The previous study focused on highly educated young adults (ie, students in higher professional education and university), whereas this study primarily targeted adolescents and young adults from secondary vocational education and expanded recruitment to a broader group of Dutch adolescents and young adults. These populations differ in educational level, lifestyle context, and potentially in digital literacy, which may influence engagement and responsiveness to tailored feedback. Second, the previous study included participants who were already ready to change their alcohol consumption [27], a factor known to predict intervention responsiveness and behavior change outcomes [51,52]. In contrast, this study did not preselect participants based on their readiness to change, resulting in a more heterogeneous sample in terms of readiness. This combination of a different target group and broader variation in readiness may have reduced intervention effects compared to the earlier trial.

This study shows that there was a large variation between individuals in alcohol use and its determinants over time. This is in line with earlier research [27,53] and supports the dynamically tailored nature of WDYD. At the same time, it emphasizes a need for additional data analyses besides the evaluation of group-level effects. Specifically, an analysis method that accounts for differences between and within individuals over time to learn why and for whom the intervention is effective and to improve future dynamically tailored interventions [54].

An important flaw of this study was the high dropout rates, with 63.1% (3028/4795) within the first week, rising to 96% (4603/4795) at the final week 33, even though we applied several strategies to prevent dropout (eg, rewards, therapeutic alliance, and dynamic tailoring [10,21]). Dropout was higher among students in secondary vocational education and those who consumed more glasses of alcohol weekly. High dropout is a common problem in mHealth interventions, especially in the first 2 weeks of the study and among those most at-risk, and this needs attention (eg, [10,55]). EMA is a promising means to provide dynamic tailoring; however, it also places a cognitive burden upon participants and presents difficulties in keeping participants engaged [21]. Although sensor technology may be a promising strategy to reduce this burden, this is not yet available, reliable, or practical for the outcomes measured in this study [56]. WDYD was a stand-alone intervention and did not use in-person contact. Both in-person contact (eg, with a counselor) or a combined or stepped-care intervention (eg, mHealth combined with an educational program at school) could be promising ways to reduce dropout while also improving effectiveness [39,57,58]. In addition, although WDYD included pictures, videos, and a design that was tailored to accommodate low literacy levels, it relied on text to provide tailored feedback. As health literacy is related to dropout, future mHealth interventions could rely more on audio and video feedback [57]. Additionally, providing tailored information by a conversational agent using generative artificial intelligence (AI) could be a promising way to reduce dropout and increase intervention effects [59,60]. Possibly, the WDYD intervention was too static, thereby limiting engagement. Emerging developments in generative AI offer additional opportunities to personalize interventions at scale. AI-driven conversational agents can deliver dynamic, context-aware feedback, simulate motivational interviewing, and adapt content based on real-time user data. These technologies could enhance engagement, reduce attrition, and provide more nuanced support for behavior change compared to static tailoring. However, ethical considerations such as privacy, transparency, and bias mitigation must be addressed before widespread implementation in mHealth interventions.

Despite not finding significant effects on the primary outcomes, and dropout being a serious problem, WDYD could be seen as a promising intervention. This is especially true when taking into account that young and lower-educated adolescents and young adults are a difficult group to reach, as the majority (90%) lack motivation to reduce their alcohol consumption [27]. First, the combination of recruitment strategies used in this study showed that we are able to reach young adults who drink excessively; the use of social media advertisements resulted in the largest number of participants. Second, we found positive effects of WDYD on the secondary outcomes, intrinsic motivation, and self-confidence toward drinking less alcohol. Both outcomes significantly increased in the intervention group compared to the control group, and this effect lasted over 25 weeks. Third, additional analyses revealed that increases in intrinsic motivation and self-confidence among active users of WDYD were significantly associated with reductions in alcohol consumption (data not shown). WDYD can thus be an effective means to improve motivation and self-confidence toward reducing alcohol consumption, and this increase seems to have promising effects on alcohol consumption itself. In addition,

XSL•FO
RenderX

the user-based assessments revealed that the intervention was evaluated very positively. WDYD was evaluated as usable (eg, user-friendly and easy in navigation), credible, understandable, and provided an adequate amount of information. The informativity and usefulness were evaluated as sufficient. Dynamic tailoring was successfully implemented in the intervention design, as participants indicated that WDYD accounted for their personal preferences, discussed topics they found important, and provided freedom in choosing their alcohol consumption. This was also the case for motivational interviewing because participants felt accepted for who they are and felt addressed pleasantly.

A small proportion of participants were recruited via channels that may have provided prior exposure to alcohol-related information, such as the online lifestyle monitor (327/6146, 5.3%) or educational programs delivered by teachers (272/6146, 4.4%). Although this may have reduced contrast between intervention and control conditions, moderation analyses showed that the recruitment method did not significantly influence group effects (data not shown).

Limitations

This study had multiple limitations. First and foremost, dropout rates were high, particularly in the intervention group. This selective attrition may have introduced bias. To mitigate this, we applied multiple imputation [61]. However, due to difficulties imputing data from weeks 31 and 33 after baseline, these time points were omitted from the imputation model, and analyses were limited to data up to 25 weeks. Additionally, we did not examine reasons for dropout, which could have provided important information to reduce dropout in the future [57].

Second, although the intervention was originally developed for students in secondary vocational education, recruitment challenges led us to broaden our inclusion criteria to all Dutch adolescents and young adults engaging in excessive drinking. As a result, only 34.6% (1659/4795) of the sample consisted of students in secondary vocational education, and 6% (284/4795) had a low educational level. While moderation analyses showed no significant interaction between educational level and treatment effects (data not shown), caution is warranted when generalizing results to students in secondary vocational education or students from lower-educated populations. Sampling from a more diverse population may have introduced more variability in drinking behavior and decreased receptiveness to our intervention, which could affect the interpretation of our outcomes.

Third, a small proportion of participants (5.3%) were recruited via an online lifestyle monitor or via teachers delivering alcohol education (4.4%). These participants may have already been exposed to normative feedback or alcohol-related risk information before this study. This prior exposure could have reduced the contrast between the intervention and control conditions, potentially reducing observed effects.

Fourth, we used single-item measures to assess the primary and secondary outcomes. Although these items were selected based on prior studies and some of these items showed comparable or adequate performance compared to multi-item scales [42-44], single-item measures are generally more susceptible to measurement error and have lower psychometric quality [62]. In addition, the items used were not validated before our study, which may limit the reliability and generalizability of our findings. However, in studies using EMA, multiple-item scales may enhance reactivity and participant burden [63], justifying our choice for brevity.

Finally, there was a potential risk of contamination between conditions. Although participants were individually randomized into the control or experimental condition within the WDYD app, it is possible that participants in the control group were acquainted with those in the intervention group and discussed intervention content. To assess this, we asked participants in the control group 12 questions about the intervention at the first follow-up (9 weeks after baseline). The answers provided no strong indication of contamination. The distribution of correct answers resembled random guessing, and no participant answered more than 8 of 12 items correctly (data not shown).

Strengths

Strong points of this study are the participatory design, use of intervention mapping as a framework for systematic development, the focus on a high-risk group for whom hardly any interventions are available, the use of EMAs to account for the fluctuating nature of alcohol consumption and to account for recall bias [26,50], and the use of multilevel multiple imputation analyses to account for dropout [61]. The current study adhered to the CONSORT (Consolidated Standards of Reporting Trials) statement [64,65], thereby improving the quality of reporting.

Conclusions

The dynamically tailored mHealth intervention WDYD targeting adolescents and young adults with excessive alcohol consumption did not show favorable changes in alcohol intake, and dropout rates were high. Nevertheless, WDYD might be useful for adolescents and young adults to improve intrinsic motivation and self-confidence to reduce their alcohol consumption as important first steps toward behavior change. As such, the intervention has been implemented in the Netherlands as part of a larger campaign. To reduce dropout rates in mHealth interventions, future research should explore underlying reasons for dropout, as well as using in-person contact, a combined intervention (eg, mHealth with educational program), and audio- or visual-feedback to improve user retention.

Acknowledgments

Abstract

Background: Regular physical activity is a crucial and an important modifiable lifestyle factor reducing the risk of recurrent incidents after stroke or transient ischemic attack (TIA). Mobile health (mHealth) has emerged as a promising approach for providing long-term support for physical activity. However, little is known about how individuals poststroke or TIA adhere to and engage with mHealth interventions.

Objective: This study aimed to (1) describe adherence to supervised sessions in an mHealth intervention targeting physical activity, (2) describe engagement with self-managed mHealth support for physical activity during and after the intervention, (3) compare characteristics of participants with high and low adherence and app engagement, and (4) examine whether high adherence and app engagement were associated with maintained physical activity after having completed the intervention and at a 12-month follow-up.

Methods: In this study, a secondary analysis of data from the experimental arm of a feasibility randomized controlled trial was conducted. The experimental group received a 6-month mHealth version of the i-REBOUND intervention, which included supervised mHealth support for physical activity and behavior change, followed by a 6-month postintervention period with access to self-managed mHealth support. The control group received mHealth consultations via video conferencing. Adherence measures included attendance at supervised exercise and counseling sessions, while app engagement was measured by weekly interactions with self-managed mHealth support during and after the intervention. Participants' level of physical activity (steps per day) was measured using accelerometers at baseline, and at 6- and 12-month postbaseline. Logistic regression analysis examined the associations between high adherence and app engagement during the intervention and postintervention period and maintained physical activity (ie, >7000 steps/day) across the 12-month study period.

Results: Of the 57 participants enrolled, 51 (89%) completed the intervention; the average age was 71 years, 34/51 (67%) were female, and 47/51 (92%) had mild stroke symptoms. Adherence to supervised mHealth support was high (supervised exercise sessions: 79%, counseling sessions: 98%), while engagement with self-managed mHealth support was high during the intervention (83%) but declined postintervention (38%). A larger proportion of females (24/31, 77%) demonstrated high adherence to the intervention compared to males (7/31, 23%, χ^2_1=4.1; *P*=.04). High adherence (≥80%) during the intervention was associated with maintained physical activity between baseline and the 6-month follow-up (OR 12.07, 95% CI 2 - 72.76; *P*=.01), while high app engagement (≥80%) during postintervention was associated with maintained physical activity between the 6- and 12-month follow-up (OR 5.10, 95% CI 1.02 - 25.52; *P*=.05).

Conclusions: Supervised mHealth support was well received with high adherence, while modules for self-management of physical activity faced challenges in engaging the participants. Future studies could benefit from qualitative and cocreative approaches to better understand and refine self-managed mHealth support for individuals poststroke or TIA.

Introduction

Stroke affects 15 million people annually and is the third leading cause of death and disability worldwide [1]. A previous stroke or transient ischemic attack (TIA) increases the risk of a recurrent stroke, often with more severe health consequences [2]. Physical activity is an important modifiable lifestyle factor that contributes to a risk reduction of recurrent stroke and long-term disability for up to five years after a mild stroke or TIA [3]. Despite the crucial role of physical activity in secondary prevention [2], access to long-term support for physical activity after a stroke or TIA remains limited [4,5]. Many individuals poststroke fail to meet recommended physical activity levels, spend extended periods sedentary [6], and often require therapist-led support to maintain long-term engagement in physical activity.

Interventions combining onsite supervised physical exercise with support for physical activity through behavior change techniques appear to be particularly effective in improving cardiovascular health (eg, systolic blood pressure) [7]. However, barriers such as lack of access to professional support, long travel times, and inadequate public transportation limit people poststroke or TIA from attending on-site physical activity services [8,9]. Mobile health (mHealth), that is, health care delivered via mobile devices, is a promising intervention modality for promoting physical activity poststroke [10], offering a flexible solution with the potential to support long-term physical activity. Yet, individuals poststroke may face challenges in using mHealth technology due to limited digital literacy and stroke-related impairments such as fatigue, lack of motor skills, or cognitive difficulties, which can hinder their ability to effectively interact with mobile devices [11]. Despite these challenges, individuals poststroke are generally satisfied with digital services and show a willingness to engage with technology-based support, indicating that mHealth may be a feasible and acceptable option for this population [12]. In the context of secondary stroke prevention, mHealth provides an underutilized opportunity to enhance access to physical activity support and reduce the risk of secondary complications after stroke or TIA [10,13].

The health outcomes of digital interventions, such as mHealth, are influenced by the individuals' adherence to (ie, the extent to which the participant followed the intervention as designed) and engagement with the intervention [14-16]. Engagement is a multifaceted concept involving both *what* users are engaged with (ie, the targeted health behavior and the digital intervention) and *how* they engage with the digital intervention [17,18]. In terms of *how*, Perski et al [19] conceptualize engagement as having both behavioral and experiential dimensions. The behavioral dimension refers to the extent of active interaction with the intervention, while the experiential dimension encompasses subjective experiences such as feelings and interest [19]. A recent scoping review suggested higher adherence to mHealth interventions among males, older individuals, and those with secondary education [15]. Limited research has explored adherence to and engagement with mHealth interventions in individuals poststroke or TIA [10], and the factors influencing these behaviors remain largely unknown. A better understanding of adherence and app engagement can inform future development of mHealth interventions to promote and maintain physical activity poststroke or TIA.

This study builds on "i-REBOUND—let's get moving," a telehealth intervention developed in Australia to support home-based exercise and the promotion and maintenance of physical activity in people poststroke or TIA [20]. To improve reach, i-REBOUND was developed into a fully digital mHealth intervention [21], which provides 6 months of supervised support for physical activity and behavior change, followed by a 6-month postintervention period with access to self-managed mHealth support. Effective mHealth interventions depend on individuals' adherence and app engagement to ensure sufficient exposure to the intervention and, ultimately, to achieving the health outcomes. Thus, optimizing and tailoring support for future mHealth interventions requires a deeper understanding of how individuals adhere to and engage with these technologies. While a previous feasibility trial demonstrated that the i-REBOUND intervention was safe, acceptable, and accessible for people poststroke or TIA across Sweden [22], it did not assess participant adherence or engagement over time, nor the association with physical activity outcomes. Therefore, the present secondary analysis examines patterns of adherence to and engagement with the mHealth intervention and the association with maintained physical activity after the intervention. The specific aims were to (1) describe adherence to supervised exercise and individual counseling sessions during the intervention, (2) describe engagement with the self-managed mHealth support for physical activity during intervention and postintervention, (3) compare the characteristics of participants with high and low levels of adherence and engagement in the mHealth intervention, and (4) examine whether high adherence and app engagement were associated with maintained physical activity between baseline and the 6-month follow-up, and between the 6- and 12-month follow-up.

Methods

Study Design

The present study was a preplanned secondary analysis of data from the experimental arm of a feasibility randomized controlled trial (ClinicalTrials.gov: NCT0511195). The trial included individuals poststroke or TIA randomized into an experimental group receiving the mHealth version of the i-REBOUND intervention or a control group receiving mHealth consultations

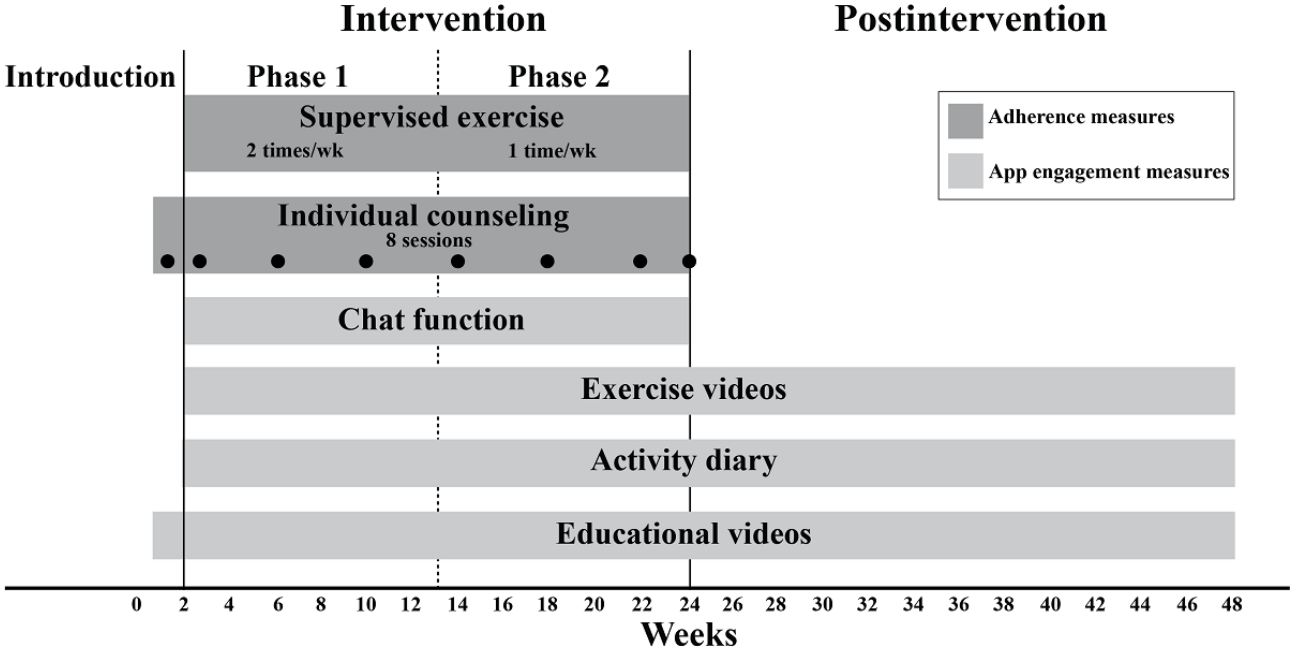
XSL•FO
RenderX

via videoconferencing [21,22]. The analysis focused on participants' adherence to and engagement with the mHealth intervention and was therefore limited to the experimental arm. The data were collected between September 2021 and December 2023. This study was reported in accordance with the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist (Checklist 1) [23].

Ethical Considerations

The study was approved by the Swedish Ethical Review Authority (dnr 2020 - 05062 and 2021 - 03622). Participation in the study was voluntary, and participants could withdraw at any time without consequence. No compensation was provided. Individuals who expressed interest received both verbal and written information before providing written informed consent. This consent also included approval for the secondary analysis conducted in the present study. A detailed description of the inclusion procedure and ethical considerations is available in the study protocol [21]. All data were anonymized to ensure participant confidentiality.

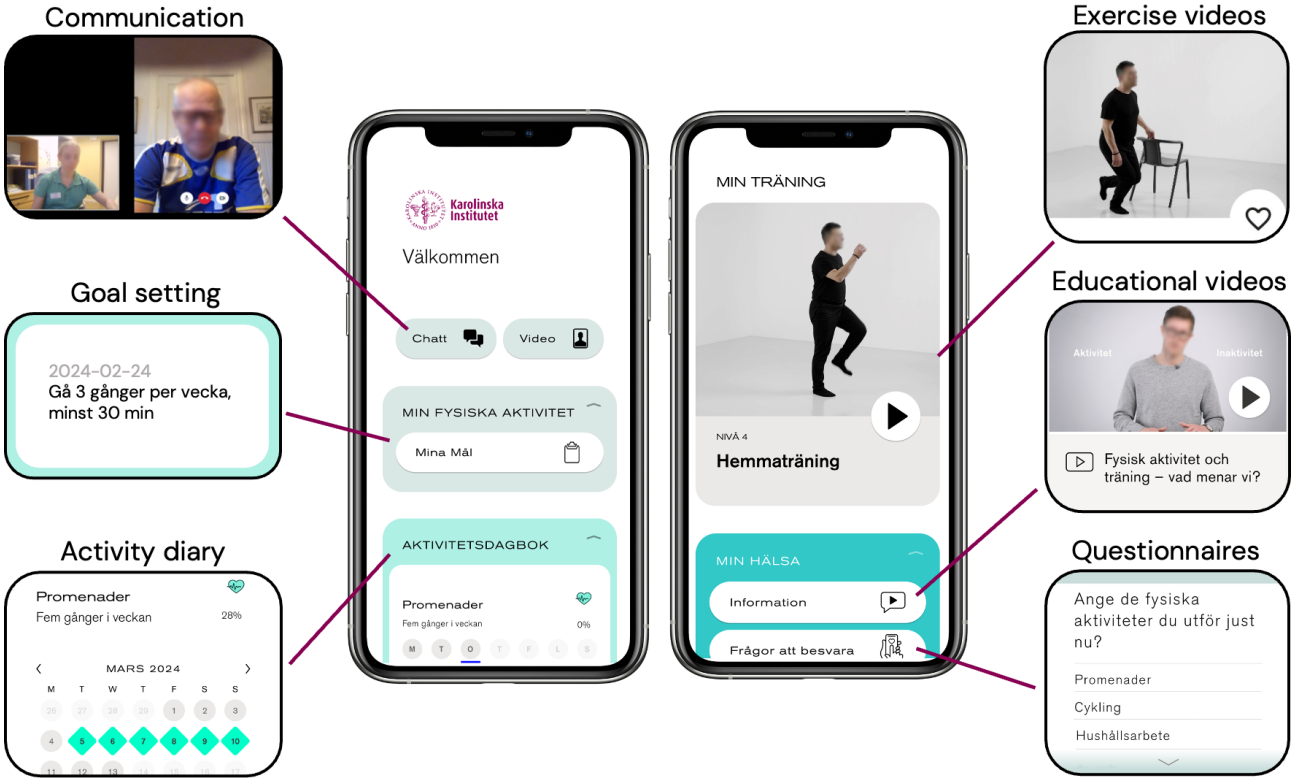
Participants



Participants were recruited through advertisements at collaborating clinics, social media, patient organizations, and the webpage of Karolinska Institutet. Inclusion criteria were (1) clinical diagnosis of stroke or TIA between 3 months and 10 years prior to study enrollment, confirmed by the participants' physician, (2) living at home, (3) being able to walk a short distance indoors with or without a walking device, (4) being able to use a smartphone including e-signature identification with or without the help of a relative or carer, and (5) having access to a stable internet connection. Exclusion criteria were (1) already meeting the recommended physical activity levels of at least 150 minutes per week of moderate physical activity or at least 75 minutes per week of vigorous-intensity physical activity, (2) severe health conditions compromising engagement in the intervention, or (3) enrolled in a concomitant clinical trial or participating in rehabilitation (eg, aerobic exercises) at the time point of recruitment.

Intervention

The mHealth Version of the i-REBOUND Intervention



The mHealth intervention provided support for physical activity and behavior change to individuals poststroke or TIA across 48 weeks, divided into an intervention and postintervention period (Figure 1). Full intervention details are outlined in the study protocol [21]. The intervention was delivered via the STAAR (Stroke Treatment Through Active and Accessible Rehabilitation) app, which was managed by the medical technology company Empowered Health and available on iOS and Android devices. Participants accessed all intervention components through the app, including an overview of their individual goals, educational videos, an activity diary for self-monitoring, and prerecorded exercise videos (Figure 2). Supervised sessions were delivered via video calls within the app, and written communication occurred through a chat function. Two physical therapists with at least 5 years of experience in stroke rehabilitation delivered the intervention through a web-based digital clinic connected to the app. Baseline assessments were conducted using digital questionnaires administered via the app.

Figure 1. Illustration of the mobile health intervention and postintervention across the 48-week study period.

XSL•FO
RenderX

Figure 2. Overview of the mobile health intervention components and the Stroke Treatment Through Active and Accessible Rehabilitation (STAAR) app's interface.

Supervised mHealth Support

During the first week, the mHealth intervention was introduced in 2 sessions with the physical therapist, including a medical history review, discussions about resources for physical activity and home exercises, and a practice exercise session. Phase 1 of the intervention (wk 2 - 12) offered 2 supervised exercise sessions per week, and phase 2 (wk 13 - 24) offered 1 session. The supervised 30-minute exercise sessions aimed to reach physical activity at moderate intensity (ie, Borg Rating of Perceived Exercise Exertion Scale >12 [24]) and were delivered individually or in groups based on participants' physical capacity.

Support for behavior change consisted of individual monthly counseling sessions with the physical therapist. These sessions included discussions on goals, self-management strategies, and barriers and facilitators to physical activity. In addition to the supervised exercise sessions, participants were encouraged to engage in any physical activity of their choice. The final counseling session during the last week of the intervention period focused on developing an individualized self-management plan and setting goals for the postintervention period, supporting maintenance of exercise routines and engagement in physical activity.

Self-Managed mHealth Support

Educational videos on physical activity and exercise recommendations, individually prescribed exercise videos, and an activity diary were available throughout the intervention and postintervention period as behavioral change techniques to support the promotion of physical activity in analogy with the behavior change technique taxonomy (v1) by Michie et al [25] (see Multimedia Appendix 1). Participants were encouraged to engage with the self-managed mHealth support across the intervention and postintervention periods, although no specific instructions for intended usage were provided. Individual exercises, with prerecorded instructional videos for strength and/or aerobic training, were prescribed by the physical therapist based on the needs and preferences of each participant. The digital activity diary encouraged self-management by enabling participants to self-monitor their physical activity. Participants selected activities to monitor, such as outdoor walking, and designated days to perform them, marking each activity as "performed" or "not performed" in the diary. Participants had the option to receive mobile phone reminders for the selected activities through the activity diary. During postintervention, the study participants had access to self-managed mHealth support, but no physical therapist contact was offered.

Measures

Baseline Measures

Baseline data collection included demographics (age, sex, level of education, employment status, stroke/TIA diagnosis, and living situation) and assessment of level of stroke-disability according to Modified Rankin Scale; ranging from 0 to 5, where 0 indicates no disability and 5 indicates severe disability [26].

Digital questionnaires were administered via the STAAR app to assess functioning. Self-efficacy for exercise was assessed by the 9-item Exercise Self-Efficacy Scale [27]. For each item, participants indicate their confidence to execute the behavior on a 100-point percentage scale divided into 10-point increments, ranging from 0% (not at all confident) to 100% (highly confident). Fatigue was assessed by the Fatigue Severity

XSL•FO
RenderX

Scale 9-item version scored on a 7-point Likert scale, ranging from 1 (“disagree”) to 7 (“fully agree”), with the median score of the 9 items used for analysis [28]. Levels of depression, anxiety, and stress were assessed by the Depression, Anxiety, and Stress Scale 21 [29]. Each of the 21 items is rated on a 4-point Likert scale ranging from 0 (“did not apply to me at all”) to 3 (“applied to me very much, or most of the time”), 7 items each pertaining to depression, anxiety, and stress. Scores for the subscales were calculated by summing the scores of each domain. Self-perceived impact of stroke was assessed using the 8 subscales (strength, memory, emotion, communication, activities of daily living/instrumental activities of daily living, mobility, hand function, social and participation) of the Stroke Impact Scale [30]. The score ranges from 0 to 100; higher scores indicate a lower perceived impact. Recovery after stroke was assessed with a visual analog scale, in which participants were asked to score their global perceived stroke recovery from 0 (“no recovery”) to 100 (“complete recovery”) [30].

Measures of Adherence to Supervised Exercise and Individual Counseling Sessions

Adherence to supervised exercise and individual counseling sessions during the intervention was documented in the digital clinic by the physical therapist. The intended adherence was 2 supervised exercise sessions per week in phase 1 and one exercise session per week in phase 2, along with eight counseling sessions across phases 1 and 2. Individual adherence rates in percentage were calculated by dividing exercise sessions attended by the total sessions offered in phase 1 (n=22) and phase 2 (n=12). The same approach was applied to calculate adherence to the counseling sessions offered (n=8). Based on their adherence to supervised exercise, participants were categorized into high adherence (>80%) and low adherence (<80%) groups [22].

App Engagement Measures

Participants’ weekly app engagement was tracked via user logs and assessed during the intervention and postintervention, with an “active week” defined as at least one interaction with the chat function (only intervention period), prescribed exercises, or activity diary. Overall app engagement was then calculated as the percentage of active weeks over the 48-week study period, excluding the introductory week. Based on this metric, participants were categorized into high app engagement (≥80%) and low app engagement (<80%) groups. Disengagement was defined as the point at which participants ceased interacting with self-managed mHealth support (ie, the activity diary and the prescribed exercise videos) for the remainder of the study until completion. Time to disengagement was calculated as the number of weeks from the start of the postintervention period to the participant’s last recorded engagement.

Participants were categorized by activity diary use as low (<19 wk), sporadic (20 - 39 wk), or frequent (>40 wk) engagers and by engagement with prescribed exercises as limited (≤5 sessions), sporadic (6 - 19 sessions), or frequent (>20 sessions) engagers. Participant categorization by engagement with activity diary and prescribed exercises was guided by a pragmatic approach, with thresholds selected based on the observed distribution of data. Engagement with educational videos across the entire study period was calculated as the number of viewed videos divided by the total number available (n=8).

Physical Activity Measures

To explore the relationship between intervention adherence, app engagement, and maintenance of physical activity in daily life, physical activity was measured objectively using the activPAL accelerometer (PAL Technologies Ltd) at baseline, and at 6- and 12-month postbaseline [31]. The activPAL device demonstrates reliability and validity in measuring step count [32] and is recommended for assessing physical activity after a stroke [33]. Participants received the monitor by mail with instructions to wear it on their nonaffected or dominant leg (as applicable) for 7 consecutive days (24 h/d) before returning it via prepaid post. Participants with at least 3 days of physical activity data, each containing a minimum of 10 hours of data, were included in the analysis [34]. The outcome was the number of steps per day. As no minimal clinically important difference in steps has been established for the stroke population, we used at least 7000 steps/day as a criterion for optimal cardiovascular risk reduction [35]. This cut-off was also deemed a reasonable and achievable target at the 6- and 12-month follow-ups, given that the baseline physical activity level in our sample was approximately 6000 steps per day. Changes in physical activity between baseline and the 6-month follow-up, and between the 6- and 12-month follow-up, were grouped into 4 categories:

1. Unchanged—low physical activity (<7000 steps/d at baseline and 6-mo follow-up, <7000 steps/d at 6-mo and 12-mo follow-up)
2. Declined physical activity (≥7000 steps/d at baseline and <7000 at 6-mo follow-up, >7000 steps/d at 6-mo follow-up and <7000 at 12-mo follow-up)
3. Unchanged—active (≥7000 steps/d at baseline and 6-mo follow-up, ≥7000 steps/d at 6-mo and 12-mo follow-up)
4. Improved physical activity (<7000 steps/d at baseline and ≥7000 at 6 mo follow-up, <7000 steps/d at 6 mo follow-up and ≥7000 at 12 mo follow-up).

Participants in categories 3 and 4 were classified as having maintained their level of physical activity.

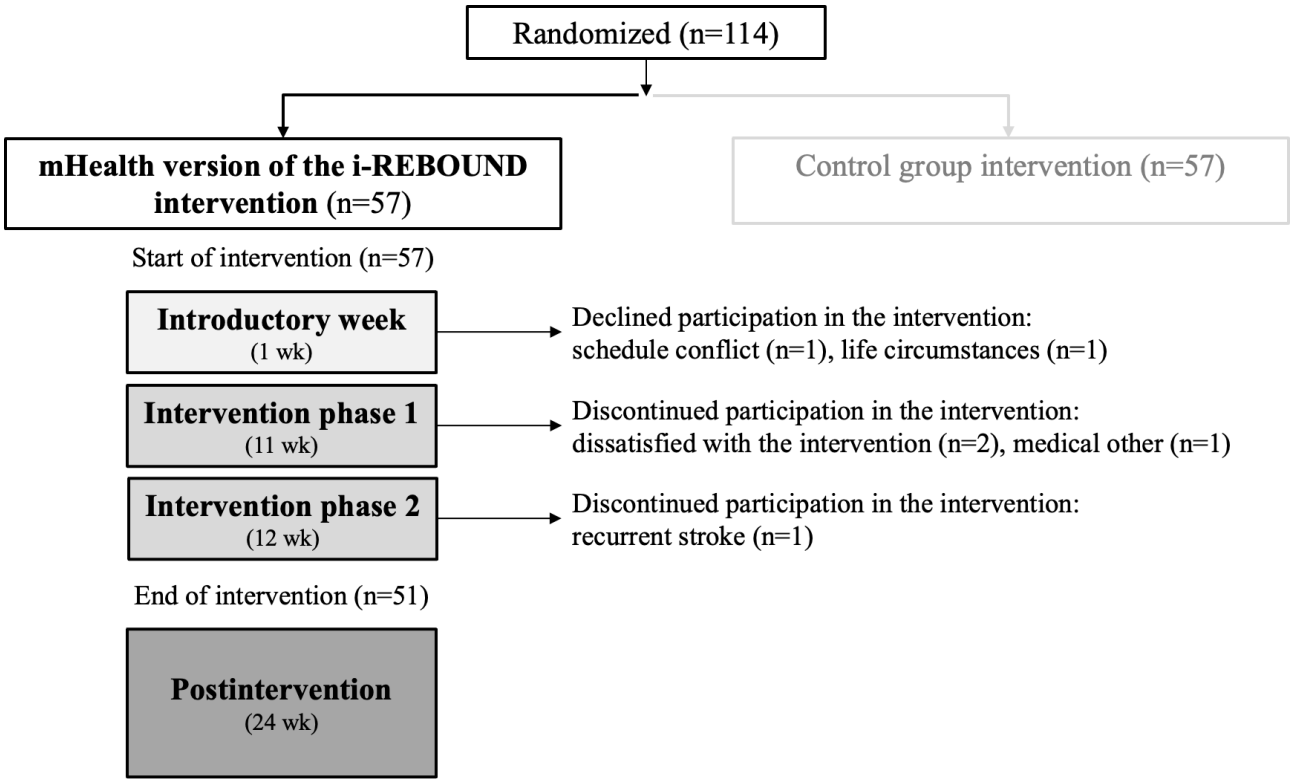
Data Analysis

IBM SPSS Statistics software (version 24.0; IBM Corp) was used for statistical analyses. Baseline characteristics and descriptive statistics for aims 1 to 3 were calculated and presented as mean (SD), median (IQR), and frequencies (%).

For the first and second aim, descriptive statistics described the adherence to and engagement in the mHealth intervention across the study period. Participants who completed the introductory week and began intervention phase 1 were included in the analysis. Those who discontinued the intervention were considered lost to follow-up, with data analyzed up to the week of discontinuation.

For the third aim, between-group differences regarding demographic characteristics between the sub-groups with high and low adherence, and high and low app engagement, were analyzed using Mann-Whitney *U* test for continuous variables and chi-square test for binary variables.

XSL•FO
RenderX



For the fourth aim, logistic regression analysis was used to examine the associations between high adherence during the intervention, high app engagement during the intervention and postintervention periods, and maintained physical activity levels (categories 3 and 4, as described earlier) from baseline to the 6-month follow-up and from the 6-month to the 12-month follow-up. These analyses included age (years) and use of a walking aid as covariates, as they have been shown to be associated with the level of physical activity in people poststroke [36]. The α level was set at .05 for all analysis.

Results

Characteristics of Participants

Of the 57 participants enrolled, 51 (89%) completed the intervention (Figure 3). The mean age of the participants completing the intervention was 71 (SD 8) years, and the median time since stroke or TIA was 2.4 (IQR 1.2-5) years. Of the 51 participants who completed the intervention, 34 (67%) were female, 27 (53%) had a university degree, 8 (16%) were employed, and 47 (93%) reported no or mild poststroke or TIA symptoms (ie, Modified Rankin Scale score 0 - 1) (Table 1).

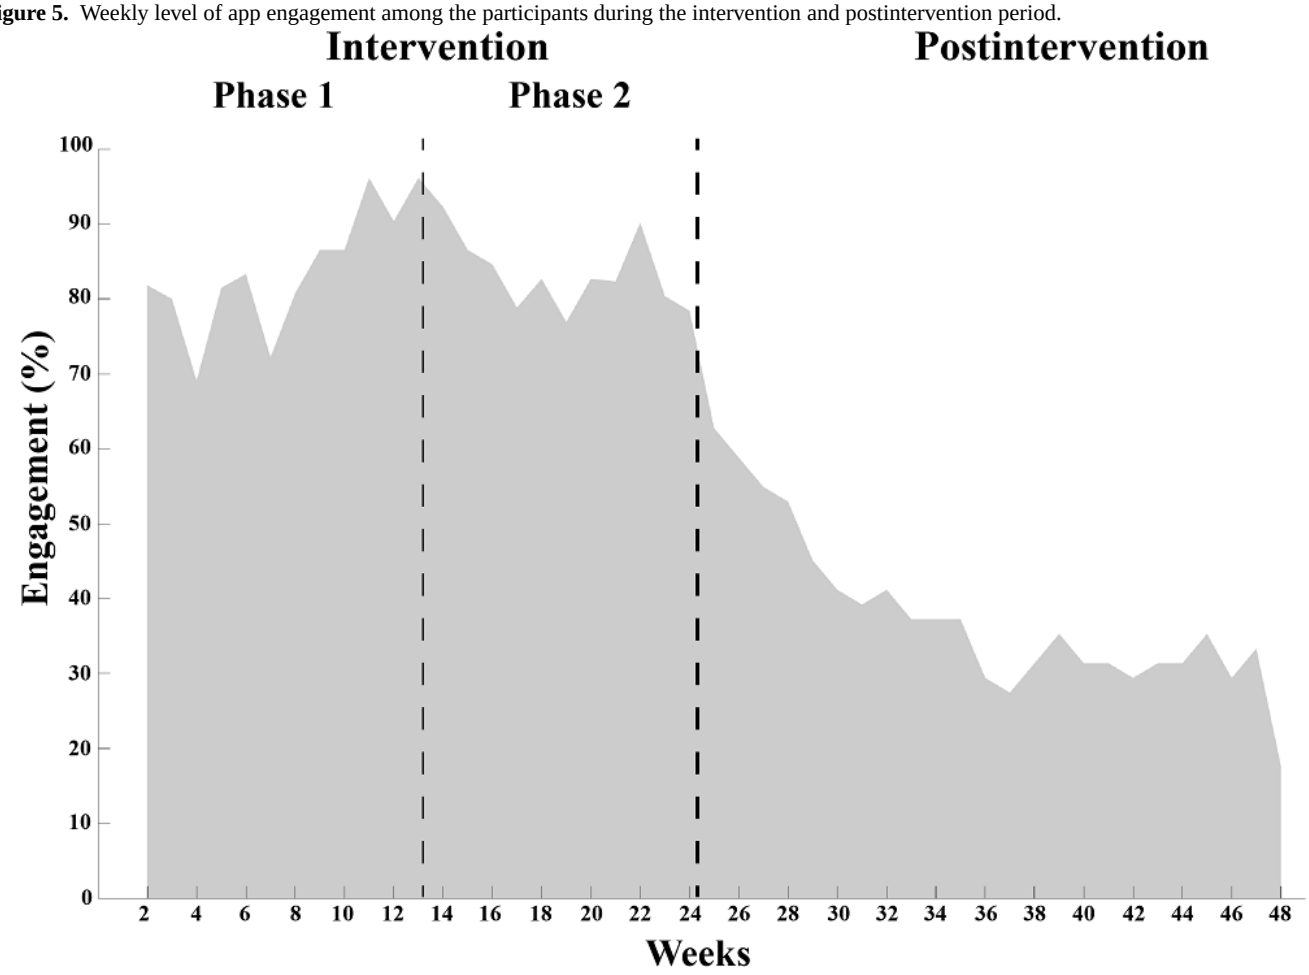
Adherence to Supervised Exercise and Individual Counseling Sessions

The mean adherence to supervised exercise across the intervention period was 79% (min-max: 29% - 100%) (Figure 4), with 911 of 1151 sessions attended in phase 1 and 489 of 618 sessions attended in phase 2. The mean adherence rate to individual counseling sessions across the intervention was 97% (min-max: 50% - 100%) and among those who completed the intervention, 82% (42/51) attended all counseling sessions.

XSL•FO
RenderX

Figure 4. Weekly adherence to supervised exercise during intervention phases 1 - 2.



Engagement With Self-Managed mHealth Support

App engagement was higher during the intervention phase, with an average of 84% of participants using the app weekly (min-max: 69% - 94%), compared to the postintervention period (average 38%; min-max: 18% - 63%) (Figure 5). The majority of participants (42/51, 82%) disengaged during the postintervention period, with an average time to disengagement of 8 weeks (min-max, 0 - 23).

XSL•FO
RenderX

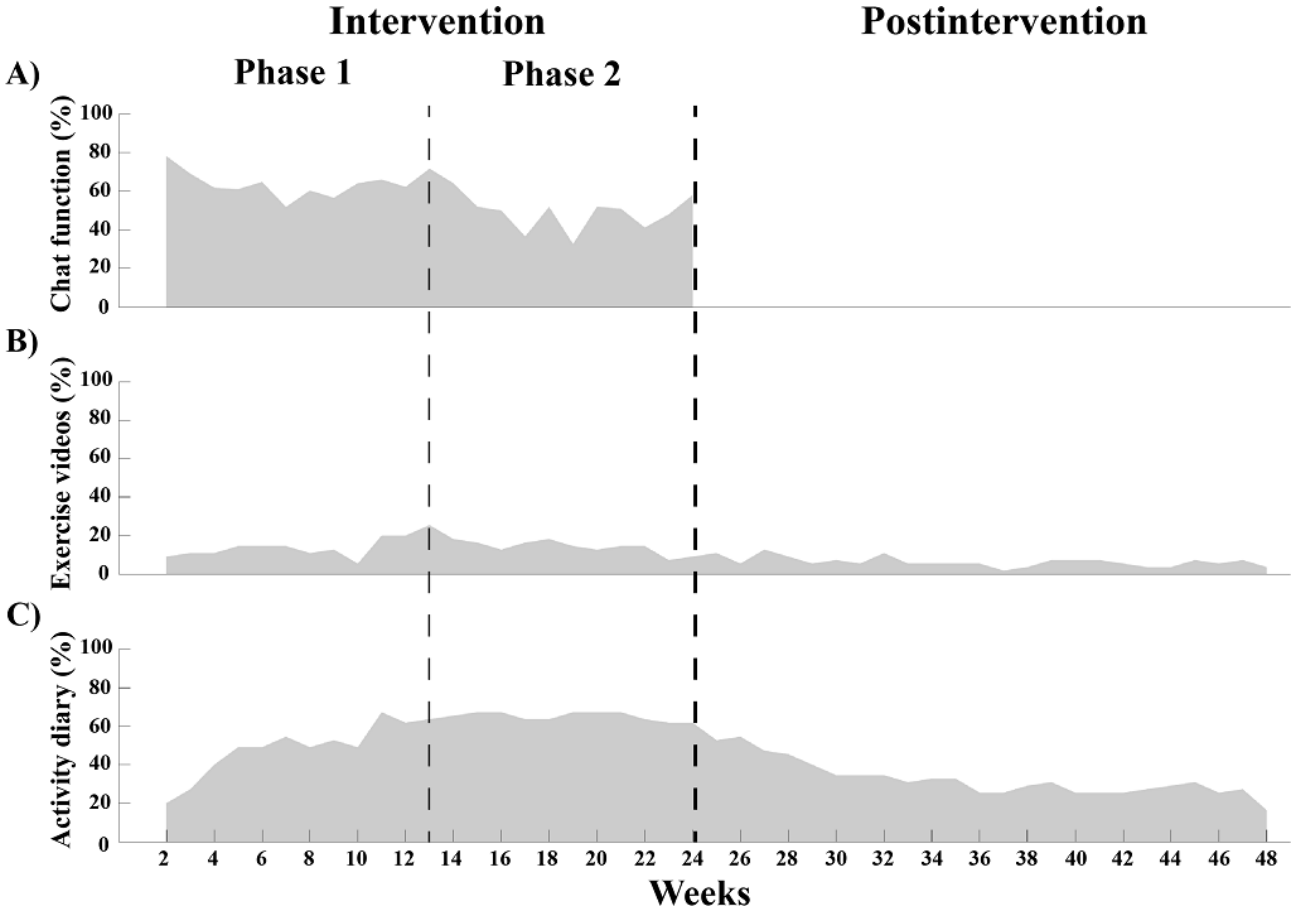


Figure 5. Weekly level of app engagement among the participants during the intervention and postintervention period.

Engagement with the chat function and with the activity diary were the most common types of app engagement (Figure 6). The average weekly engagement with the chat function was 63% in phase 1, decreasing to 50% in phase 2 (Figure 6A). On average, participants sent 1.6 weekly chat messages during the intervention. Forty-three of 55 participants (78%) used the activity diary to some extent across the study period (Figure 6C). In total, 103 activities were monitored, and the most frequently monitored activities were outdoor walking (n=29, 28%), aerobic exercise (n=13, 13%), and unspecified physical exercise (n=12, 12%). Among the 43 participants using the activity diary, 14 (33%) demonstrated low usage (<19 wk), 17 (40%) sporadic usage (20 - 39 wk), and 12 (28%) frequent usage (>40 wk). Fifty of 55 participants (91%) were prescribed individual exercises, and among those, 33 (66%) had limited engagement (<5 sessions), 12 (24%) sporadic engagement (6 - 19 sessions), and 5 (10%) frequent engagement (>20 sessions). The mean engagement with educational videos was 67% (min-max: 0% - 100%), with each participant viewing 5 of 8 videos on average, and 53% (29/55) participants watching all content.

XSL•FO
RenderX

Figure 6. Weekly engagement in the chat function (A), exercise videos (B), and activity diary (C) during the intervention and postintervention periods.

Comparison of Characteristics of Users With Different Levels of Adherence and App Engagement

Of the 51 participants completing the intervention, 31 (61%) had high adherence (ie, ≥80%) and 15 (29%) had high app engagement (ie, ≥80%). Most personal and contextual factors, as well as clinical and functional measures, showed no significant differences between participants with high versus low adherence or high versus low app engagement in the mHealth intervention (Table 2). A higher proportion of females (24/31, 77%) demonstrated high adherence to the intervention compared to males (7/31, 23%, χ^2_1=4.1; *P*=.04).

[a]ADL/iADL: activities of daily living/instrumental activities of daily living.

Factors Associated With Maintained Physical Activity

Valid physical activity data were available for 45 participants (88%) at 6 months and 42 participants (82%) at 12 months among those who completed the intervention. Twenty-four participants (53%) maintained their physical activity between baseline and the 6-month follow-up, whereas 19 (45%) maintained their physical activity between the 6- and 12-month follow-ups (Table 3). High adherence during the intervention was associated with maintained physical activity between baseline and the 6 months follow-up (Odds ratio [OR] 12.07, 95% CI 2-72.76; *P*=.01), and high app engagement during the postintervention was associated with maintained physical activity between 6 and 12 months (OR 5.10, 95% CI 1.02-25.52; *P*=.05). High app engagement during the intervention was not associated with maintained physical activity between baseline and the 6-month follow-up (OR 2.80, 95% CI 0.55-14.28; *P*=.22), nor was high adherence during the intervention associated with maintained physical activity between the 6- and 12-month follow-ups (OR 3.53, 95% CI 0.68-18.35; *P*=.13).

XSL•FO
RenderX

Table . Study participants demonstrating ≥7000 steps/day at 6- and 12-month follow-up, as well as a classification of the change between baseline and the follow-ups.

	Classification of change[a]	
	Baseline to 6-month follow-up (n=45), n (%)	6- to 12-month follow-up (n=42), n (%)
Unchanged—low physical activity	16 (36)	16 (38)
Declined physical activity	5 (11)	7 (17)
Unchanged—physically active	17 (38)	17 (40)
Improved physical activity	7 (15)	2 (5)

[a]Unchanged—low physical activity (ie, <7000 steps/d at baseline and 6-mo follow-up, <7000 steps/day at 6-mo and 12-mo follow-up); declined physical activity (ie, >7000 steps/day at baseline and <7000 at 6-mo follow-up, >7000 steps/d at 6-mo follow-up and <7000 at 12-mo follow-up); unchanged—active (ie, ≥7000 steps/d at baseline and 6-mo follow-up, ≥7000 steps/d at 6-mo and 12-mo follow-up); and improved physical activity (ie, <7000 steps/d at baseline and ≥7000 at 6 mo follow-up, <7000 steps/d at 6 mo follow-up and ≥7000 at 12 mo follow-up).

Discussion

Principal Findings

This study investigated adherence and app engagement during and 6 months after an mHealth intervention for people poststroke or TIA. Adherence to supervised sessions remained high (>75%) across the intervention, and more females adhered to the supervised exercise than males. Engagement with self-managed mHealth support was initially high but decreased postintervention. High adherence during the intervention was associated with maintained physical activity between baseline and the 6-month follow-up, while high postintervention engagement was associated with maintained physical activity between the 6- and 12-month follow-ups.

Findings in Context

Adherence to supervised exercise during the intervention averaged 79%, which is comparable to adherence rates in nondigital [37] and digital interventions for people poststroke or TIA [20,38]. Adherence to counseling sessions (97%) was higher compared to a previous study showing decreasing adherence to long-term nondigital physical activity support in people poststroke [39]. The current study's digital format provided an accessible and flexible solution that may have contributed to the high adherence rates. High adherence to supervised phases of exercise programs is common [40]. In this study, weekly interactions with a physical therapist as part of the mHealth intervention likely contributed positively to adherence. Additionally, most participants attended group exercise sessions, which may have further promoted adherence by creating a sense of accountability and commitment to the group [12,38]. Low app engagement within physical activity apps is a well-known challenge in mHealth interventions [41], yet our findings showed high engagement (84%) with self-managed support modules during the intervention, particularly the chat function and activity diary. However, app engagement postintervention decreased to 38%. As with adherence, app engagement during the intervention was likely promoted by regular interaction with a physical therapist, whereas the lack of such contact postintervention may have contributed to the decreasing patterns of engagement [19,42]. Similar patterns of declining engagement have been observed in unsupervised mHealth interventions for people with chronic conditions [43]. While the supervised sessions followed a structured schedule, engagement with the self-managed mHealth support was optional and guided by the participant's preferences. A recent review suggests that clear guidance on the frequency and type of mHealth engagement can promote maintained participant engagement [43]. Thus, the lack of explicitly defined goals of app engagement in the current mHealth intervention might further explain the decreasing app engagement postintervention.

In line with a meta-analysis of digital physical activity interventions in adults [16], our results suggest that adherence during the intervention and app engagement postintervention is important for maintaining physical activity after the intervention period. This study found no significant differences in high adherence or app engagement between sub-groups, such as age or education level, which has previously been shown to influence mHealth intervention adherence [15]. However, our results suggest that females may have adhered to supervised sessions more than males, potentially because females tend to be more proactive and engaged in health-related issues [44]. The results from this study support that adherence to and engagement with an mHealth intervention might be important factors influencing the intervention's impact on maintained engagement in physical activity.

Several aspects of the self-managed mHealth support could be improved to enhance the app engagement in the current mHealth intervention, as well as long-term engagement in physical activity beyond the intervention period. Personalized app content commonly benefits app engagement [41]. However, despite access to an activity diary with self-selected activities and individually prescribed exercises, only 28% (12/43) and 10% (5/50), respectively, frequently engaged with these modules in the present study. Engaging mHealth features, such as prompts, gamification, and regular content updates, have been shown to significantly enhance app engagement [19,41,42]. These elements were not incorporated into the current intervention; however, integrating them in future development could be a valuable strategy to encourage maintained app engagement among individuals poststroke or TIA. Another promising approach to enhance engagement in people poststroke or TIA, particularly those with lower digital health literacy, is to develop strategies that actively involve caregivers in participating in the mHealth intervention and mediating treatment delivery. This approach has been tested in on-site interventions [45] but has

XSL•FO
RenderX

been rarely implemented in digital formats in stroke trials. Furthermore, a potential refinement of the intervention design could be development of distinct phases, each with specific goals for supporting behavior change. This might include an initiation phase focusing on establishing routines for exercise and physical activity (like the present intervention), followed by a maintenance phase in which therapist support occurs less frequently. This design could be especially important for people poststroke or TIA, who often require long-term support to establish and maintain behavior change [39]. Advancing toward more independent self-management of physical activity would also require extending the intervention's focus to support participants in developing strategies for sustaining behavior change after the intervention, which should be embedded within the individual counseling and educational materials. We believe that refinement of the mHealth version of the i-REBOUND intervention should be cocreated with people poststroke or TIA and target multiple domains, including technology, intervention design, and the establishment of clear expectations for adherence and engagement [46].

Limitations

The findings should be interpreted cautiously given the relatively small sample size. In addition, the participants were mostly female, highly educated, and with mild stroke symptoms, which limits the generalizability of the findings to other stroke or TIA populations [47]. Furthermore, the 7000 steps/day cut-off for physical activity, while clinically relevant for optimal cardiovascular risk reduction [35], is a crude measure for detecting change over time. Moreover, participants in the sample exhibited a notably high level of physical activity at baseline, exceeding the average daily step count of 4078 for individuals with stroke [6]. User logs yielded an in-depth examination of the participants' mHealth engagement behavior but could not sufficiently capture the multifaceted nature of engagement. For a more comprehensive understanding of engagement, exploration of participants' subjective experiences is required, which we acknowledge as a limitation of the present study. A strength was the 48-week study period, which allowed for a thorough investigation of changes in adherence and engagement patterns over time. However, adherence and engagement levels were classified solely as 'low' (<80%) or 'high' (>80%). For more substantiated levels, future studies should determine adequate levels for effective mHealth engagement and adherence and set predefined benchmarks [43].

Conclusion

Supervised mHealth support was well received, with high adherence. In contrast, the self-management modules for physical activity faced challenges in engaging participants. High adherence during the intervention was associated with physical activity maintenance immediately afterward, while high app engagement postintervention was linked to maintenance at the 12-month follow-up. These exploratory findings may be hypothesis-generating and inform future research. To enhance engagement with mHealth interventions and support maintained physical activity after the supervised phase, future studies could benefit from qualitative and cocreative approaches to better understand and refine self-managed mHealth support for individuals poststroke or TIA.

Acknowledgments

We thank all participants in the study and the physical therapists who delivered the intervention. To assist with language refinement and editorial improvements during manuscript writing, a generative artificial intelligence tool (Microsoft Copilot) was used. All intellectual content, including the study design, interpretation, and conclusions, is entirely the authors' own.

Abstract

Background: Internet-based cognitive behavioral therapy (iCBT) for the treatment of depression has proven to be an effective and accessible option. However, iCBTs tend to have low adherence rates, which may negatively impact their effectiveness. One such iCBT program is the browser-based, proven-effective iFightDepression (iFD) tool. An app-based version of the iFD tool is the iFD app, which was developed to improve usability with a smartphone. The iFD app provides enhanced usability and a more optimized user experience on mobile devices. Additionally, it offers more comfortable interaction with worksheets, reduced text with added videos, and quicker access to the program via the smartphone icon. These improved usability on smartphones and could have an impact on adherence.

Objective: This study investigated (1) whether adherence parameters, that is, the *number of worksheets*, the *number of sessions*, and the *number of workshops*, significantly differed between users of the iFD app and the iFD tool and (2) exploratorily whether symptom reduction (delta Patient Health Questionnaire-9 [PHQ-9] scores) differed after 5 to 9 weeks between the iFD app and the iFD tool, after controlling for covariates.

Methods: We used *t* tests to compare data from 56 participants using the iFD app for 8 weeks with data from 172 participants using the iFD tool in a previous 6-week study. Exploratively, symptom reduction was compared between formats. A multiple regression model was calculated with the delta PHQ-9 score as the dependent variable and format, baseline PHQ-9 score, adherence, current psychotherapy, antidepressants, age, and sex as independent variables.

Results: There was no significant difference between the iFD tool and the iFD app in terms of the *number of sessions per week* ($t_{67.393}$=0.920; *P*=.36; corrected *P*=.36), the *number of workshops* ($t_{76.368}$=–1.217; *P*=.30; corrected *P*=.36), and the *number of worksheets per week* (t_{74}=0.984; *P*=.33; corrected *P*=.36). We found no difference in delta PHQ-9 scores between the iFD app and the iFD tool, and baseline PHQ-9 scores were the only significant predictor (*b*=–0.61; *P*<.001).

Conclusions: Despite the improved availability of the app version in daily life, there were no significant differences in the use parameters we analyzed and no differences in symptom reduction. This study provides the first evidence that adherence to iCBT content is comparable for browser- and app-based interventions and that symptom reduction is similar for both formats. However, this study used a convenience sample, and therefore, the results must be interpreted with caution. Notably, in the study of the iFD tool, guidance was provided by the study assistants in a standardized manner. In the pilot study on the iFD app, the amount of guidance varied substantially, as it was provided by the participants' health care practitioners. These differences in guidance could also have an influence on adherence.

Introduction

Internet-based cognitive behavioral therapy (iCBT) for the treatment of depression has proven to be an effective and accessible option [1]. However, adherence rates tend to be low [2,3], which may negatively impact effectiveness [4]. One such iCBT is the browser-based, proven-effective [5] iFightDepression (iFD) tool, which has been available since 2014. To improve its usability on smartphones and thus potentially increase adherence, an app-based version of the iFD tool, the iFD app, was developed based on the content of the iFD tool. The iFD tool is accessible via mobile web browsers on smartphones; however, the iFD app provides enhanced usability and a more optimized user experience on mobile devices. Further advantages are that the worksheets can be filled in more conveniently, the amount of text has been reduced in favor of new information videos, and the access is faster through the icon on the smartphone.

Smartphone apps are particularly attractive for health-related applications because, unlike desktop computers or laptops, people tend to carry their smartphones everywhere and to keep them on at all times. In a survey, participants were divided into focus groups and interviewed using open-ended questions about their experiences with apps designed to support a healthy lifestyle [6]. The focus groups were recorded, transcribed, and analyzed to identify frequent topics. One topic that frequently emerged was that participants appreciated health apps on smartphones because they provide a "quick and efficient link to a wealth of information 'on the go'."

This raises the question of whether the improved availability and usability of a program on a smartphone has a positive effect on adherence and thus potentially on symptom reduction. Although the dose-response relationship remains a subject of debate due to mixed findings [4], some studies have found no significant impact of adherence on efficacy [7-9], while many others indicate a positive correlation between adherence and treatment effectiveness [10-12]. Nevertheless, it is certainly worthwhile to investigate potential factors that could improve adherence. Outside the field of depression, the evidence appears to support the assumption that a program delivered as a smartphone app may enhance treatment adherence. A study comparing an app to a browser-based and paper diary–based weight loss program showed that the app group had a higher frequency of program use than the browser-based and the paper diary–based program [13]. However, in this case, the content of the 2 programs was similar but not identical. The study was not statistically powered to detect a change in weight loss; however, the results were displayed to give an idea of the effect size. After 6 months, participants in the smartphone group demonstrated a statistically significantly greater reduction in body weight compared with those in the website group. However, no significant difference was observed when comparing the smartphone group to the paper diary group.

To the best of our knowledge, there is only 1 study regarding digital interventions on depression comparing app-based vs browser-based access to identical programs. Watts et al [14] compared the adherence of a mobile app group with a computer group in a program for depression. However, in this study, only the *number of completed lessons* was analyzed and found not to be significantly different based on the format. In this study, we examine various use parameters beyond just the *number of completed lessons*. The frequency of log-ins is also a noteworthy factor, as frequent use may indicate a deeper integration of these programs into daily routines. The number of completed worksheets is also a significant parameter, as a higher completion rate may suggest more active engagement with the content. In combination, the various use parameters provide a more comprehensive insight into how engaged and active users are. This allows us to provide a more informed comparison of adherence between the two formats. The aim of our study is to discover whether the app-based format can achieve higher adherence rates than the browser-based format. The following questions were investigated in this study:

1. Do adherence parameters, that is, the *number of completed worksheets*, the *number of sessions*, and the *number of workshops completed*, significantly differ between users of the iFD app and the iFD tool?
2. Does symptom reduction (delta Patient Health Questionnaire-9 [PHQ-9] score) differ between users of the iFD app and the iFD tool after 5 to 9 weeks, after controlling for covariates such as, age, sex, and adherence (this was an exploratory question)?

Methods

Study Design

This study is a secondary analysis of data from 2 different studies. We analyzed data from 56 participants from a pilot study (authors KS, CA, and UH; unpublished data, April 2023) of the newly developed iFD app, along with data from 172 participants from the intervention group of a randomized controlled trial (RCT) using the iFD tool published in 2020 [5]. Participants of the pilot study were instructed to use the iFD app for 8 weeks in addition to treatment as usual (TAU). TAU could include psychotherapy, antidepressants, or watchful waiting. The pilot study was conducted from June 2022 to January 2023. Participants in the intervention group of the RCT (who used the iFD tool) were instructed to use the iFD tool for 6 weeks. All participants were treated by either a physician or a psychotherapist. The RCT was conducted between June 2016 and August 2018.

Sample and Recruitment

The participants of the pilot study of the iFD app were referred by practitioners experienced with the iFD tool who agreed to test the app with their patients. Participants of the pilot study were aged 18 years or above and received a diagnosis of mild to moderate depression (F32.0, F32.1, F32.9, F33.0, F33.1, and F33.9) or dysthymia (F34.1) from a physician or psychotherapist. In Germany, both licensed psychological psychotherapists and physicians are authorized to diagnose depressive disorders. The practitioners provided the patients' diagnosis to the study team after the patients had given their written informed consent. At the beginning of the study, participants had a PHQ-9 [15,16] score between 5 and 19.

XSL•FO
RenderX

Recruitment for the RCT of the iFD tool took place throughout Germany via the online channels of the German Foundation of Depression and Suicide Prevention. The participants of the intervention group from the RCT were aged 18 years or above and had a current diagnosis of mild or moderate depressive disorder (F32.0, F32.1, F33.0, and F33.1) or dysthymia (F34.1), according to the Mini International Neuropsychiatric Interview and PHQ-9 (score 5‐14), indicating mild to moderate symptoms.

Sociodemographic data for users of the iFD app and the iFD tool are summarized in Table 1.

Table . Overview of sociodemographic characteristics.

Variables	Study iFightDepression app (n=56)	Study iFightDepression tool (n=172)	Comparison, *P* value (BH[a]-adjusted *P* value)
Age (years)			.97 (.97)
Mean (SD)	42.79 (14.39)	42.86 (12.36)	
Median (IQR)	44.5 (29.0-57.0)	43.5 (33.8-52.0)	
Female, n (%)	34 (60.7)	137 (79.6)	<.001 (<.001)[b]
Baseline PHQ-9[c] score, mean (SD)	11.84 (4.12)	9.81 (3.51)	.002 (.002)[d]
Current psychotherapy use, n (%)	40 (71.4)	97 (56.4)	.07 (.08)
Current antidepressant use, n (%)	27 (48.2)	114 (66.3)	<.001 (<.001)[b]

[a]BH: Benjamini-Hochberg.

[b]These results are significant (*P*<.001).

[c]PHQ-9: Patient Health Questionnaire-9.

[d]This result is significant (*P*<.01).

Ethical Considerations

The study protocol for the RCT of the iFD tool was reviewed and approved by the Ethics Committee at the Faculty of Medicine, University of Leipzig, on February 11, 2015 (case number 080-15-09032015). The protocol of the pilot study of the iFD app was reviewed and approved by the Ethics Committee at the Faculty of Medicine, Goethe University Frankfurt, on June 11, 2021 (reference number 2021-53). Furthermore, we received confirmation from the Ethics Committee at the Faculty of Medicine, Goethe University Frankfurt, on June 4, 2025 (reference number 2025-2467-Waiver), that no further approval from the ethics committee was required for the secondary analysis. The original informed consent obtained from participants for both studies covered the secondary analysis without the need for additional consent. Data were used in a pseudonymized form for the statistical analysis. The interventions were offered free of charge, and no reimbursement was offered to participants.

Guidance

Guidance for the iFD app was provided by the practitioners managing the participants' TAU. The study team asked the practitioners to check in with participants at each appointment during TAU about their experience with the iFD app and to discuss how their work with it was progressing. The practitioners were qualified iFD guides, that is, they had completed a 70-minute webinar and actively used the iFD tool. Few practitioners were using the iFD tool for years and therefore completed the webinar several years ago. Among other things, the iFD workshops were explained in detail in the webinar. Although the webinar referred to the iFD tool, the content of the workshops in the iFD app has not changed. Shortly before the start of the study, the practitioners were given a brief introduction to the iFD app, where differences from the iFD tool were explained. Furthermore, calls at 3 time points were scheduled by the study assistants to collect feedback on the app and discuss any changes in treatment. The study assistants also asked how often and for how many minutes they had spoken to the practitioners about the iFD app to estimate the amount of guidance provided by the practitioner.

The guidance for the iFD tool was provided by the study assistants (psychologists and psychotherapists). The study assistants guided the participants in 5 telephone calls, which were supervised by a senior psychiatrist who was involved in the development of the iFD tool. All study assistants were qualified through the standard webinar process and used a guide for the calls based on the webinar content. The focus of the guideline calls was to motivate the participants rather than discuss the content. The study assistant then noted the duration of the phone calls to determine the amount of guidance.

Measures

The PHQ-9 completion was mandatory at first log-in in both studies and could be completed again at any time during the intervention. Once a week, patients were asked to complete the questionnaire to monitor their symptoms. The instructions in the iFD tool were adjusted so that the measurement now referred to the period starting from the last time the PHQ-9 was completed. In the iFD app, the original instruction—referring to the past 2 weeks—was retained. The sum scores of the baseline PHQ-9 and the last PHQ-9 completed within the time span of 5 to 9 weeks after registration were used in the current analysis. This time span was chosen based on the time span of the 2 studies (6-week RCT iFD tool and 8-week pilot study iFD app, with a buffer of 1 week).

XSL•FO
RenderX

Anonymized log files were used to examine user behavior. These log files contained time-stamped logs of all activity within the iFD tool or app. From these, composite measures of use were created. We determined the *number of sessions per week*, *the number of workshops completed* (at least 70.0% of the material was seen or read), and *the number of completed worksheets per week* to measure and compare adherence.

Statistical Analyses

For the comparison of the parameters of adherence between the iFD tool and the iFD app, we used the Welch 2-sample *t* test, chosen for its robustness with unequal variances [17]. *P* values were corrected using the Benjamini-Hochberg method [18].

To compare symptom reduction, a multiple regression analysis was performed with *age*, sex, *baseline PHQ-9*, *format* (app vs browser), *workshops completed*, *sessions per week*, *completed worksheets per week*, *amount of guidance* (min), *current psychotherapy* (yes or no), and *current antidepressants* (yes or no) as predictor variables for the delta PHQ-9. Delta PHQ-9 refers to the mean difference between PHQ-9 scores at registration and the last PHQ-9 filled 5 to 9 weeks after registration. It was used as a measure of symptom change. Negative values indicate a reduction in symptoms, while positive values reflect an increase. Only participants who completed the PHQ-9 questionnaire at least once within 5 to 9 weeks were included in the analysis.

The assumptions of multiple regression were assessed and tested. Normality of the residuals was evaluated using graphical methods, specifically a histogram and a Q-Q plot. The histogram displayed a bell-shaped curve characteristic of a Gaussian distribution, indicating approximate normality. In the Q-Q plot, the majority of data points aligned closely with the reference line, with several lying directly on it. However, the Shapiro-Wilk test indicated a significant deviation from normality (P=.01). Given the known high statistical power and resulting high sensitivity of the Shapiro-Wilk test in larger samples (N>50) to even the slightest deviations from normality, the graphical results were considered sufficient to justify the use of linear regression [19-22]. The nonsignificant Breusch-Pagan test (P=.70) indicated that homoscedasticity was present [23]. All predictors were correlated with each other in pairs to test for multicollinearity. The highest correlation (0.77) was observed between the *number of sessions* and the *number of completed worksheets*. This indicated that multicollinearity was not present, as there is an assumption that correlation values above 0.8 are a sign of multicollinearity [24]. However, the variance inflation factor (VIF) in the full model with the interactions indicates multicollinearity for the predictors' *format*, *completed worksheets*, and *number of sessions*, as well as the interactions (VIF>10) [25]. Accordingly, we conducted a stepwise hierarchical regression analysis to localize multicollinearity and compare the models. In the first step (model 1), only the covariates (age, sex, amount of guidance, current psychotherapy, and current antidepressant use) were included as predictors in the model. In the second step (model 2), the format was added. In step 3 (model 3), the use parameters were included. Models 1 to 3 indicated no critical multicollinearity (VIF <2.6). In step 4 (model 4), interaction terms between format and use parameter were included. The interactions did not significantly improve the model and led to increased multicollinearity (VIF >10) [25]. Therefore, a regression model without interactions was used (Table 2). The full model including interaction terms is available in Table S2 in Multimedia Appendix 1.

Table . Summary of the multiple regression model predicting delta Patient Health Questionnaire-9 scores (negative values indicate a reduction in symptoms; N=167; R^2[a]=0.26; adjusted R^2=0.21).

	B[b]	*P* value
Constant	3.71	.10
Age (years)	–0.01	.66
Sex (male)	–0.39	.59
Antidepressants (yes)	0.44	.48
Psychotherapy (yes)	0.46	.47
Baseline Patient Health Questionnaire-9	–0.61	<.001[c]
Guidance	0.02	.24
Format (browser)	–1.48	.14
Worksheets completed	–0.05	.43
Number of sessions	0.04	.78
Workshops completed	0.06	.83

Results

Comparison of Adherence Parameters

We found no significant differences between the iFD tool and the iFD app in terms of the *number of sessions per week* ($t_{67.393}$=0.920; *P*=.36; corrected *P*=.36), the *number of workshops completed* ($t_{76.368}$=–1.217; *P*=.30; corrected *P*=.36), and the *number of completed worksheets per week* ($t_{74.099}$=0.984; *P*=.33; corrected *P*=.36).

Comparison of Symptom Reduction

Overall, 37 (n=56, 66.1%) participants from the iFD app pilot study and 130 (n=172, 75.6%) participants from the RCT of the iFD tool completed the PHQ-9 at least once within 5 to 9 weeks. The sociodemographic data of the completers are summarized in Table S1 in Multimedia Appendix 1. Table 3 shows the PHQ-9 scores in both groups before and after the intervention. Table 4 presents a comparison of sociodemographic characteristics between participants who completed at least 1 PHQ-9 assessment within 5 to 9 weeks (completers) and those who did not and were excluded from further analysis (noncompleters).

Table . Patient Health Questionnaire-9 (PHQ-9) scores at the start of the intervention and after the participants had completed the PHQ-9 at least once within 5 to 9 weeks[a].

Group	PHQ-9: intervention start, mean (SD)	Last PHQ-9 after 5-9 weeks, mean (SD)	Within-group effect size[b] (95% CI)
Study iFD app (n=37)	12.62 (4.11)	8.84 (4.51)	0.88 (0.39 to 1.36)
Study iFD tool (n=130)	9.52 (3.37)	6.98 (3.89)	0.70 (0.45 to 0.95)

[a]The between-group effect size comparing the iFD app and iFD tool groups was 0.27 (95% CI –0.09 to 0.64).

[b]Effect size is calculated as Cohen *d*.

Table . Comparison of sociodemographic characteristics between Patient Health Questionnaire-9 (PHQ-9) completers (at least 1 PHQ-9 completion within 5-9 weeks) and noncompleters.

Variables	Completers (n=167)	Noncompleters (n=61)	Comparison, *P* value (BH[a]-adjusted *P* value)
Age (years), mean (SD); median (IQR)	43.45 (12.98); 44.0 (33.5-53.0)	41.18 (12.45); 41 (31.0-50.0)	.23 (.55)
Female, n (%)	126 (75.4)	45 (73.8)	.93 (.93)
Baseline PHQ-9 score, mean (SD)	10.2 (3.76)	10.8 (3.70)[b]	.33 (.55)
Current psychotherapy, n (%)	96 (57.5)	41 (67.2)	.24 (.55)
Current antidepressants, n (%)	102 (61.1)	39 (63.9)	.81 (.93)

[a]BH: Benjamini-Hochberg.

[b]n=58.

The multiple regression analysis revealed no significant difference in symptom reduction between the iFD app and the iFD tool (Table 4). The predictors accounted for 25.8% (adjusted R^2=0.21) of the variance in delta PHQ-9. The baseline PHQ-9 score was the only significant predictor of change in delta PHQ-9 (*P*<.001; *b*=–0.61). For a comprehensive overview of the full model results, including all covariates prior to the stepwise regression, see Table S2 in Multimedia Appendix 1.

Discussion

Principal Findings

In this study, we compared adherence based on various use parameters between the app version and the browser-based version of an iCBT for the treatment of depression. Although the app version was expected to offer improved accessibility through enhanced smartphone usability and therefore an improved possibility of using the program everywhere and “on the go,” no significant differences in use parameters were observed. Watts et al [14] similarly reported no significant differences in the *number of sessions* between the app and browser versions. Although our study included a broader set of use parameters to gain a more comprehensive insight into user engagement and activity, we arrived at comparable findings. This study also found no significant differences in symptom reduction between the iFD app and the iFD tool, which is not surprising given the similar adherence. Although in a survey many participants stated that they value health apps on their smartphone because they provide a quick and efficient connection to a wealth of information “on the go” [6], this does not seem to contribute to their being used more actively and more frequently than browser-based programs. It is possible that the iFD tool was frequently accessed via a smartphone, which allowed the use of the program “on the go” too, despite the tool’s limited usability on smartphones compared with the iFD app. However, it is notable that in the RCT of the iFD tool, guidance was provided by the study assistants in a standardized manner. In the pilot study of the iFD app, guidance for participants was provided by their practitioners, and the extent of guidance varied considerably; the guidance often being

XSL•FO
RenderX

considerably lower than that for the browser-based version, as time is very limited due to a high volume of patients in routine care, a factor that could contribute to reduced adherence [27,28]. In the pilot study, participants reported spending an average of 13.8 minutes over 8 weeks discussing the app with their practitioner. In contrast, with the iFD tool, study assistants spent an average of 29.76 minutes speaking with the participants about the tool over the course of 6 weeks. Therefore, achieving a similar level of adherence nonetheless could still be an indicator of good usability of the iFD app.

Limitations

The results from this study should be interpreted with caution as they are based on convenience samples with differing recruitment strategies, and the sample size of the pilot study was limited. Additionally, several limitations should be considered. The amount of guidance was included as a control variable; however, in the iFD app study, it was only estimated by participants, whereas in the iFD tool study, it was objectively measured. This limits comparability but still allows for controlling for broad differences. Furthermore, the PHQ-9 instructions differed between the studies: the iFD app participants were asked to rate their symptoms for the past 2 weeks (standard instruction), while participants in the iFD tool study were asked to rate symptoms since their last PHQ-9 completion. In addition, the period between completion of the baseline PHQ-9 and the last PHQ-9 varied between weeks 5 and 9, as the last completed PHQ-9 was included in the analysis and the study duration differed between the studies (iFD app: 8 weeks; iFD tool: 6 weeks). This combination of different instructions and varying periods may limit the comparability of the PHQ-9 changes between the studies. Although no significant differences in symptom reduction were found, these methodological differences remain a limitation. In addition, the iFD tool offers the option of working with self-printed worksheets that could not be measured in the study, which means that the comparability of the *number of worksheets* could also be limited if this option was used frequently. Furthermore, it was not feasible to monitor whether the iFD tool was used on mobile phones—a possibility that exists but does not offer as good a usability experience compared with the iFD app. Additionally, the 2 studies were conducted 4 years apart (iFD tool: 2016 - 2018; iFD app: 2022 - 2023), during which digital health use and awareness increased [29]. Legislative changes (eg, the Digitale-Versorgungs-Gesetz in 2019, which enables practitioners to prescribe digital interventions as part of routine medical care [30]) and the COVID-19 pandemic (in-person appointments were often not possible) may have contributed to a greater acceptance and use of digital interventions during the period in which the pilot study was conducted.

Conclusions

This study provides initial evidence that adherence to iCBT content is comparable for browser- and app-based interventions and that symptom reduction is similar for both formats. Despite the limitations of this secondary analysis, it nonetheless offers a rare opportunity to directly compare the same intervention delivered via a mobile app and a browser-based format. The superiority of apps in terms of adherence seems plausible, but this could not be confirmed in this study. Future studies are needed to establish an evidence base for selecting the optimal format.

Acknowledgments

The authors would like to thank the European Alliance Against Depression (EAAD) for their support of the iFightDepression tool. Furthermore, they would like to express their gratitude to all the participants for taking part in the studies.

Funding

The randomized controlled trial in this secondary analysis was funded within the framework of cooperation between the German Foundation for Depression and Suicide Prevention and the Deutsche Bahn Stiftung GmbH. For the pilot study and the secondary analysis itself, no external funding or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this paper.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

KS, CA, and UH were involved in conceptualizing the secondary analysis. CA and KS contributed to data collection for the primary studies used in the secondary analysis. KS conducted the analyses and wrote the original draft under the close supervision of CA. Visualizations were created by KS. UH supervised the development of the original draft. Review and editing were carried out by KS under the supervision of UH and CA.

Conflicts of Interest

The iFightDepression tool was developed by the European Alliance Against Depression (EAAD), where UH is the chairman of the board. In Germany, the iFightDepression tool is operated, continuously developed, and evaluated by the German Foundation for Depression and Suicide Prevention, a member organization of the EAAD. KS and CA are employed by the German Foundation for Depression and Suicide Prevention. The German Foundation for Depression and Suicide Prevention is an independent nonprofit

XSL•FO

Abstract

Background: Problematic social media use has been linked to reduced well-being and impulse control difficulties. While digital self-control apps show potential for reducing general app usage, they often lack customization, leading to limited effectiveness and increased user resistance. Their impact on problematic social media use remains uncertain.

Objective: This study evaluates the effectiveness of the Wellspent app, a customizable mobile intervention app designed to promote self-regulated social media use by targeting user-defined problematic app use and offering tailored behavioral nudges.

Methods: In a 3-week randomized controlled trial, 70 iPhone users (mean age 26.2, SD 5.6 years; 47/70, 67% female), regularly using at least 1 social media app, were randomly assigned to an intervention (n=35) or control group (n=35). The intervention group received personalized full-screen reminders with the option to quit or continue social media app use whenever an app session exceeded a self-defined time limit. Participants completed weekly online surveys measuring problematic social media use, problematic smartphone use, self-efficacy, and daily screen time on their most problematic app. Linear mixed models tested intervention effects.

Results: While no significant reduction in problematic social media use or increase in self-efficacy was observed, the intervention group showed a significant reduction in daily screen time on their most problematic app by approximately 29 minutes (estimate=−29.35, SE 6.84, 95% CI −42.79 to –15.99; *P*<.001), and a significant decrease in perceived problematic smartphone use (estimate=−0.46, SE 0.18, 95% CI −0.80 to –0.11; *P*=.01).

Conclusions: The Wellspent app demonstrated short-term efficacy in reducing problematic smartphone use. By allowing users to tailor interventions to their personal goals, the app shows promise as a self-directed tool to support healthier digital habits. Further research should explore long-term effects and feature-specific impacts.

Introduction

Overview

In 2022, nearly 60% of the world's population spent an average of 2 hours and 27 minutes per day on social media platforms [1]. While these platforms offer various positive benefits, like providing a sense of closeness or inspiration [2], they also possess [1] features that can foster habitual engagement and contribute to cycles of instant gratification, thereby potentially impeding the pursuit of long-term goals [3].

XSL•FO
RenderX

This duality has spurred an expanding body of research examining the complex relationship between social media use and well-being, highlighting the importance of individual, contextual, and content-related factors in shaping its impact [4-9]. Although findings on the relationship between total time spent on social media and well-being remain inconsistent [7,10], problematic social media use, characterized by excessive, compulsive, or poorly regulated engagement that disrupts daily functioning, has been consistently associated with reduced well-being [7,11,12]. In particular, problematic social media use has been associated with adverse health outcomes, including reduced life satisfaction, increased symptoms of depression, loneliness, and stress [11], as well as lower levels of physical activity [9] and decreased productivity [13]. A meta-analysis by Cheng et al [14] further illustrates the global relevance of this issue, estimating that the prevalence of problematic social media use among adults and adolescents reaches up to 31% in the most affected countries.

Healthy and Problematic Social Media Use

A healthy balance between connection and disconnection is a key aspect of "digital well-being," which has been defined as an "optimal balance between the benefits and drawbacks obtained from mobile connectivity" that is achieved "when experiencing maximal controlled pleasure and functional support, together with minimal loss of control and functional impairment" [15]. Problematic social media use, on the other hand, is characterized by a compulsive pattern of social media use that interferes with daily functioning [16]. It displays elements of addictive behaviors, including cognitive salience, mood modification, tolerance, withdrawal, conflict, and relapse [17,18].

The Integrative Model of Mobile Media Use and Need Experiences (IM³UNE model) highlights self-control—the ability to override or inhibit immediate desires in favor of goal-directed behavior [19]—as an important factor in the relationship between mobile connectivity and digital well-being. High levels of self-control protect users from excessive or habitual social media use [20], while deficits in self-control are closely linked to problematic social media use [21].

To better understand self-control in both digital and nondigital environments, research has drawn on the dual-process model. This framework posits 2 modes of information processing: an automatic, impulsive, and unconscious process (System 1), and a reflective, deliberate, and conscious process (System 2) [22]. In the context of problematic social media use, System 1 reflects the habitual, cue-driven use of social media, which is frequently associated with adverse well-being outcomes [23,24].

Specific design features of social media platforms, often referred to as "dark patterns," are deliberately constructed to exploit System 1 processing and maximize user engagement [25]. For instance, infinite scrolling mechanisms create an illusion of endless content and contribute to compulsive engagement by removing natural stopping cues [26]. Once immersed in these apps, disengaging becomes increasingly difficult, as System 2, despite recognizing the negative consequences of such use, often fails to override automatic behavior. This interplay between automatic engagement and diminished self-regulation underscores the need for interventions that facilitate reflective, intentional technology use. As a result, digital self-control tools have emerged to help individuals regulate their social media use and regain control over their behavior [27].

Digital Self-Control Tools

Digital self-control tools aim to prompt System 2–driven behavior to support users in regaining self-control over their smartphone use. These tools, often informed by interventionist theories like nudge theory [28], guide users' choices and behaviors in the digital environment through behavioral interventions. Many digital self-control tools operate as self-nudges, enabling users to set up choice architectures that protect their goals from competing temptations [29]. Most of these interventions often use a "just-in-time" approach to intervene precisely when overuse is likely to occur [30].

Several apps have been proposed in recent years with varying techniques and degrees of enforcement [31-36]. For instance, the app MyTime offers real-time feedback on time spent across apps and prompts goal reflection, which led to reduced daily use and increased perceived self-regulation in a randomized trial with college students [31]. MindPhone, a smartphone app that interrupts habitual unlocking with intention prompts, was found to increase awareness and reduce habitual use over 14 days, especially among users with initially higher problematic smartphone use scores [36]. One Sec delays app access with a short breathing pause and prompt. A within-subject field study showed that this design significantly reduced Instagram use and increased perceived control without notable user frustration [35].

Despite promising developments, existing digital self-control tools continue to face critical limitations regarding long-term effectiveness and sustained user engagement [37-39]. Many tools rely on overly restrictive mechanisms, such as app blocking, which can undermine users' sense of autonomy and trigger psychological reactance—ultimately reducing continued use. Others adopt low-friction approaches, such as passive notifications, which are often ignored at the moment of temptation and fail to interrupt habitual use [37,40-42].

A further limitation lies in the lack of customization: most tools do not allow users to align the intervention with their personal goals, definitions of distraction, or preferred self-regulation strategies. A systematic review of 334 digital self-control tools found that few support the nuanced, user-defined boundaries essential for meaningful and sustainable behavior change [38].

Moreover, evidence on the effectiveness of many digital self-control tools remains limited, particularly with regard to addressing the underlying psychological mechanisms of problematic social media use, such as impulsivity, habitual behavior, and deficient self-control [30,39]. Although a wide variety of tools exists, few interventions integrate empirically grounded behavior change strategies with autonomy-supportive design principles. This presents a critical gap in the literature: the need for digital self-control tools that combine customization, user agency, and theory-based mechanisms of change. Studies indicate that users are more likely to engage with interventions that allow them to set individualized goals,

XSL•FO
RenderX

determine when and how reminders are delivered, and track their progress toward greater self-regulation [43,44].

This study addresses this gap by evaluating the Wellspent app, a customizable, autonomy-supportive intervention designed to promote self-regulated social media use. By combining evidence-based behavior change techniques (BCTs) [45] with flexible, user-driven customization, Wellspent aims to effectively support users in regaining control over their usage patterns while preserving users' sense of autonomy. Through a preregistered randomized controlled trial, this study offers one of the first rigorous evaluations of a digital self-control tool specifically designed to target problematic social media use in a personalized and theory-informed manner.

Aims and Research Questions

The increasing need for effective tools to support healthier and more intentional social media use has led to the development of the Wellspent app, a theory-informed digital self-control tool. The app represents a novel approach to digital self-regulation by combining evidence-based BCTs [45], such as goal setting, behavioral feedback, self-monitoring, and intention-based nudges, with a high degree of user autonomy and customization. Unlike many existing tools that rely on rigid blocking mechanisms or generic notifications [38], the Wellspent app allows users to define their own usage goals, select problematic apps, and personalize reminder timing, tone, and content.

A core differentiator of the Wellspent app lies in its autonomy-supportive design. Rather than enforcing restrictions, the app preserves users' freedom to choose whether to quit or continue using an app after each prompt. This design is grounded in the dual-process model of behavior regulation [22], aiming to interrupt automatic, habitual engagement (System 1) and foster more reflective, goal-directed decision-making (System 2). Prior research suggests that such personalized and autonomy-supportive interventions may enhance message resonance, reduce psychological reactance, and improve long-term adherence [46]. With its emphasis on autonomy, customization, and theory-driven behavior change, this study addresses a critical gap in the digital well-being literature and contributes to the development of more effective, user-centered self-regulation tools.

The significance of this study lies in its methodological rigor. To date, few interventions in the field of digital self-regulation have undergone a rigorous empirical evaluation using gold-standard methods [47,48]. This study presents a preregistered randomized controlled trial with 70 participants, comparing the effects of the Wellspent app with a no-treatment control group. The design ensures high internal validity and allows for causal inferences regarding the app's impact on behavior.

An earlier publication from the overarching study project on intervention effects examining separate outcomes found no significant effects on overall well-being, affect, or stress but observed reduced stress among users with initially high levels of problematic smartphone use in the intervention group [47].

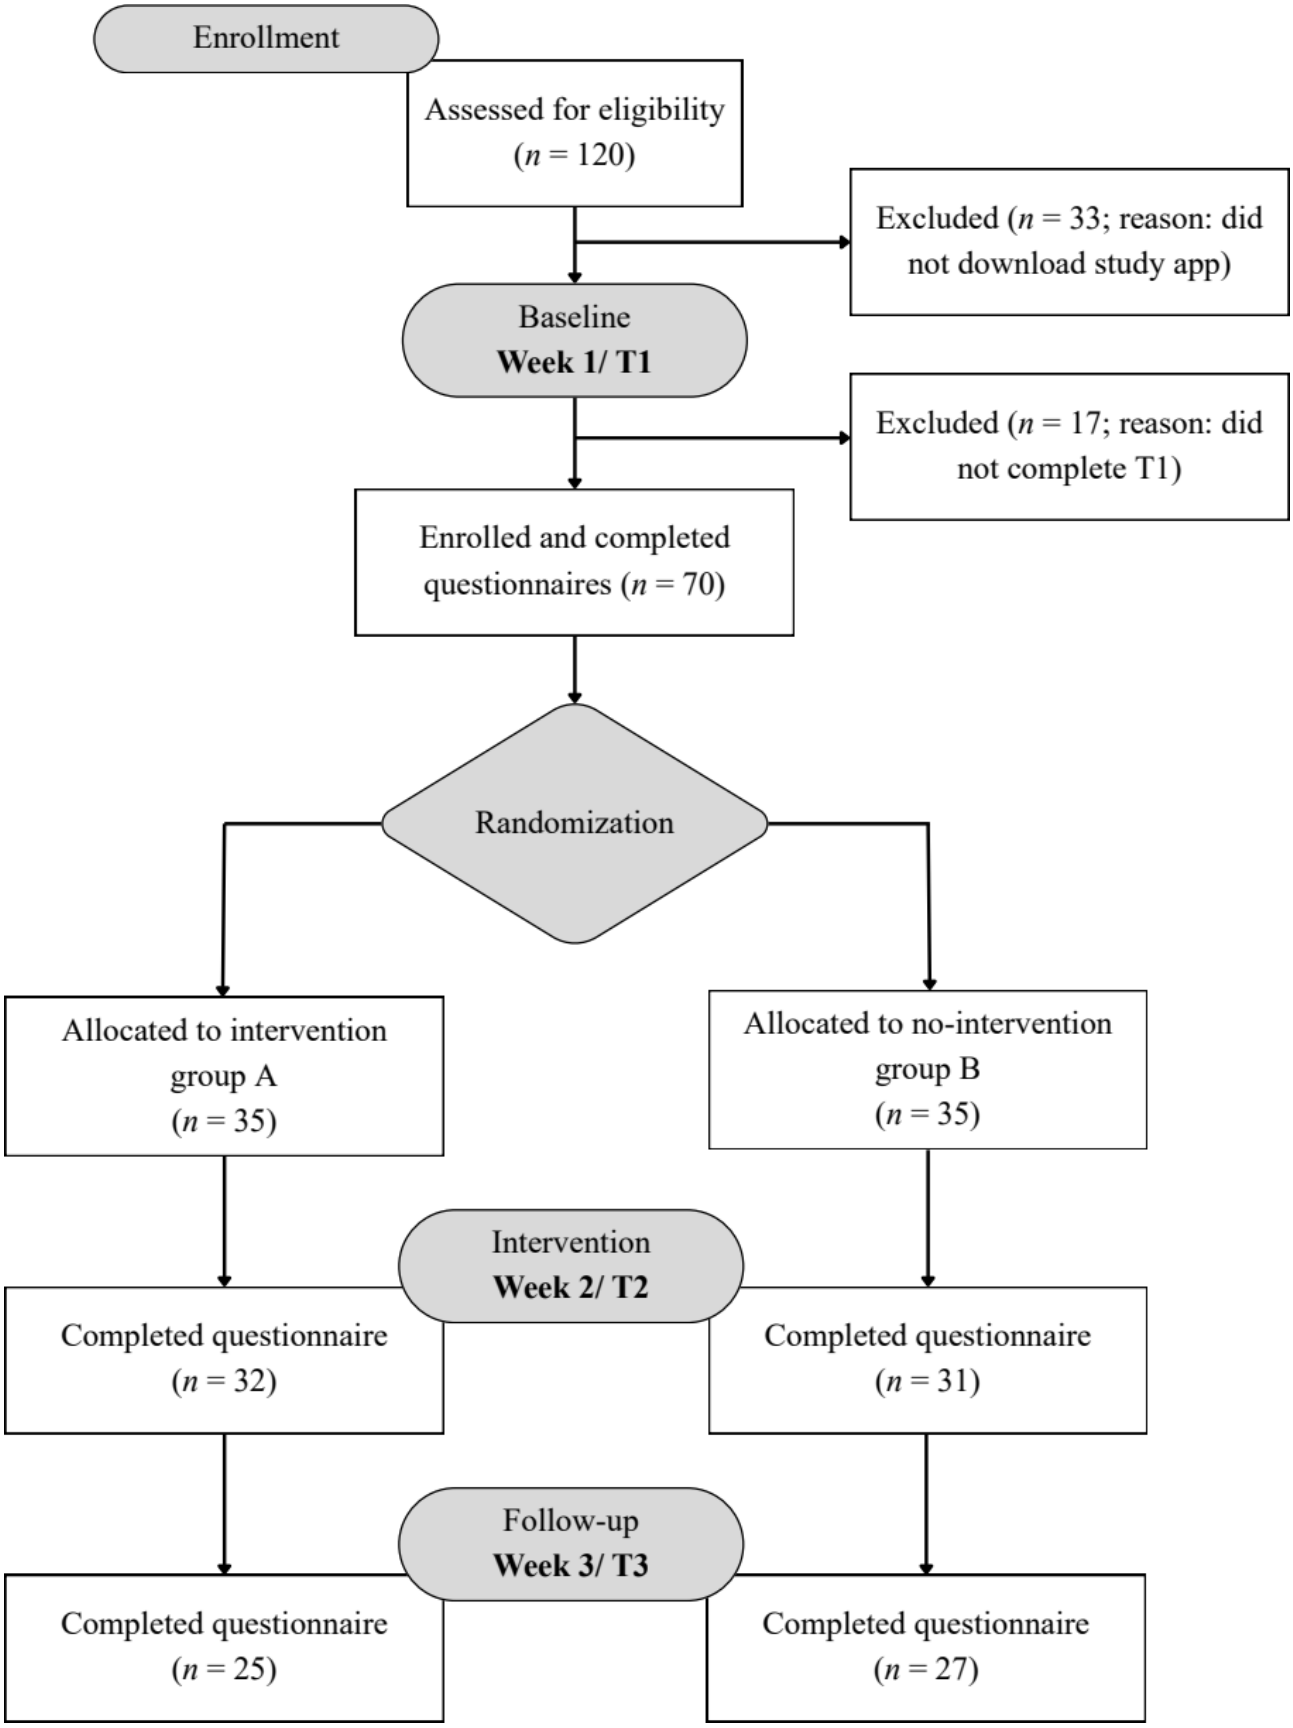
The primary objective of this study is to investigate whether participants in the intervention group receiving the Wellspent app, compared to a control group, demonstrate reductions in problematic social media use, problematic smartphone use, and time spent on the most problematic social media app, as well as an increase in self-efficacy for self-regulating social media app use.

Methods

Study Design and Participants

This study presents findings from a randomized controlled trial designed to evaluate the effectiveness of the Wellspent app, a digital self-control tool aimed at promoting self-regulated social media use on smartphones. The trial was preregistered at the German Clinical Trial Register (DRKS00031767) on May 8, 2023. The first participant was enrolled on May 22, 2023, and a sample size of 108 participants was targeted. The study was conducted between May and June 2023.

Participants were recruited via private social media channels (Facebook, LinkedIn, WhatsApp, and Instagram) and email lists for study opportunities at the Freie Universität Berlin, Germany. Prospective participants enrolled through an online registration page, where they received information regarding the study's purpose, data protection guidelines, and the voluntary nature of participation. Informed consent was obtained from all participants prior to their inclusion in the study.



Inclusion criteria required participants to be at least 18 years of age, proficient in English, own an iPhone with iOS 16 (as the Wellspent app was exclusively available for this operating system), and regularly use social media. Social media was broadly defined as platforms enabling users to engage with content, share updates, or interact with others online (eg, Instagram, Facebook, and TikTok).

The final study sample consisted of 70 participants (47/70, 67% female; mean age 26.2, SD 5.6 years), with 35 participants allocated to each group. The remaining 70 participants were randomly assigned (1:1) by the author team to either the intervention group (n=35) or the control group (n=35) using a simple randomization procedure via Research Randomizer [49]. No blocking or stratification was used. Formal blinding was not implemented, as participants were aware of their group assignment.

Participants assigned to the intervention group received the app's intervention features during week 2. The control group received no intervention and continued using their phones as usual. Use of the intervention app in week 3 was voluntary for the intervention group. Both groups completed follow-up assessments at the end of week 2 (T2) and week 3 (T3). At each time point, participants were prompted via email to complete the respective questionnaires, with follow-up reminders sent 24 hours later. Demographic data (including age, sex, level of education, and occupation) were collected at baseline (T1; Figure 1).

XSL•FO
RenderX

Figure 1. Flow diagram outlining participant allocation into the intervention or control group.

Ethical Considerations

This study was approved by the Ethics Committee of the Department of Education and Psychology at Freie Universität Berlin, Germany (proposal number 009.2023; approval date May 5, 2023). Prior to enrollment, all participants provided informed consent, having received detailed information about the study's purpose, data processing procedures, and their right

XSL•FO
RenderX

to withdraw at any time. To ensure privacy and confidentiality, all data were pseudonymized at the point of data collection, and no personally identifiable information was retained. All collected data were stored on secure servers in accordance with the General Data Protection Regulations regulations. Participants were compensated with academic course credits (when they were students) and received a 1-year premium account for the Wellspent app, provided by the app's developer; no other financial incentives were offered.

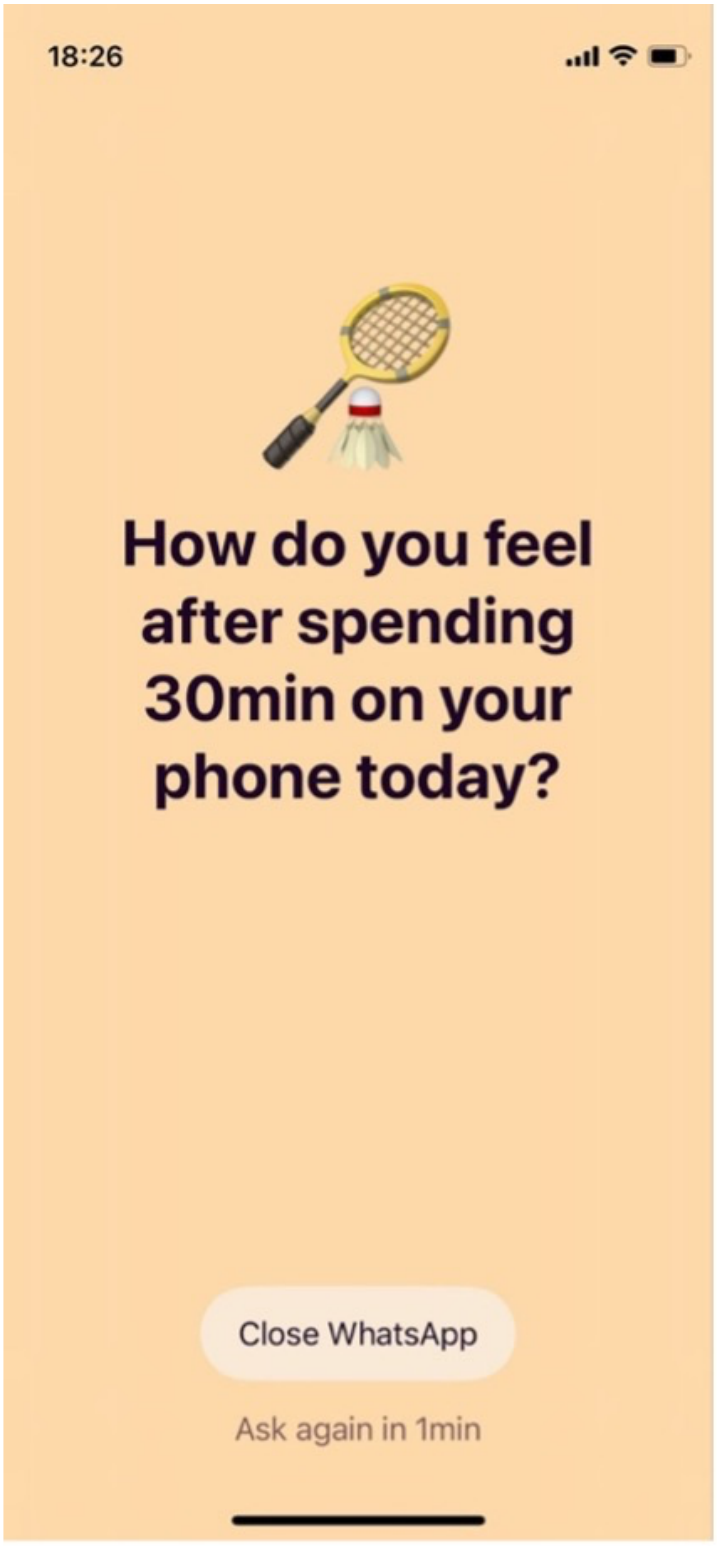
Intervention

The Wellspent app is a theory-informed, customizable mobile intervention developed to support self-regulated social media use. It targets user-identified problematic apps and delivers personalized behavioral nudges. The intervention draws on BCTs from the BCT Taxonomy v1 [45], addressing psychological mechanisms associated with problematic social media use [50]. Specifically, the intervention incorporates the following BCTs [51]:

1. Goal setting (behavior; Behavior Change Intervention Ontology [BCIO: 007004]): users define daily time limits for selected social media apps.
2. Prompts/cues (BCIO: 050578): full-screen reminders are displayed when usage exceeds a user-defined threshold.
3. Feedback on behavior (BCIO: 007022): real-time messages show time spent on selected apps.
4. Self-monitoring of behavior (BCIO: 007024): visual summaries allow users to track progress toward their individual goals.
5. Substitution of behavior (BCIO: 007095): users specify alternative behaviors to engage in when prompted to take a break from social media.

The intervention was designed according to self-nudging principles [29], enabling users to customize the app's behavior to align with their habits, goals, and preferences. This approach preserves autonomy and supports reflective (System 2) rather than habitual (System 1) decision-making [22]. Customization features and exemplary reminder nudges are detailed in Multimedia Appendix 1.

All users in the intervention group completed the same standardized setup process:



1. Installation and onboarding: participants installed the Wellspent app on their iPhones (iOS 16+).
2. Selection of problematic apps: participants identified one or more social media apps they personally considered problematic (eg, Instagram and TikTok).
3. Goal setting: for each selected app, participants defined a daily usage limit (eg, 45 min) and a nudge interval (eg, after 10 min of continuous use).
4. Customization of reminder prompts: participants tailored full-screen reminders to their preferences:

- Reminder frequency: how often reminders should appear once the nudge interval is exceeded (eg, every 3 min).
- Alternative activity: users selected an activity to engage in instead of scrolling (eg, reading and exercising).
- Tone of voice: participants chose the communicative style of the reminder (eg, motivational or reflective). See Figure 2 for an example.
- "Danger Zones" (optional): users could define vulnerable time windows (eg, before bed), during which reminders became more salient.

- Triggering of full-screen reminders: once the self-defined nudge interval was exceeded during app use, a full-screen reminder appeared. These reminders required active dismissal but did not block app access, allowing users to decide whether to continue or take a break.
- Timing within the study: the intervention began in week 2. In week 3, continued app use remained voluntary for participants in the intervention group.

XSL•FO
RenderX

Figure 2. A screenshot of an exemplary reminder message from the Wellspent app.

Measures

Weekly self-report measures were collected between baseline (T1) and follow-up (T3) to assess the following outcomes: problematic social media app use, problematic smartphone use, self-efficacy to self-regulate social media app use, and participants' screen time for their most problematic social media app.

Problematic Social Media App Use

The primary outcome, problematic social media app use, was measured using an adaptation of the Bergen Social Networking Addiction Scale (BSNAS) [52]. The BSNAS comprises 6 items, such as "How often during the last 7 days have you used social media so much that it has had a negative impact on your job/studies?" rated on a scale from 1 ("very rarely") to 5 ("very often"). The internal consistency of the baseline problematic

XSL•FO
RenderX

social media app use scale demonstrated acceptable reliability (α=.77).

Problematic Smartphone Use

Self-reported problematic smartphone use was included as an additional measure beyond preregistered outcomes to examine effects on overall smartphone use and its known correlation with various health outcomes [53]. Problematic smartphone use was measured with a single item: "How often during the 7 last days have you found your smartphone use problematic?" rated on a scale from 1 ("very rarely") to 5 ("very often"). Prior research indicates a high correlation between this 1-item measure and the established scale from Foerster et al [54] in an earlier study [48].

Self-Efficacy to Self-Regulate Social Media App Use

Three items adapted from Keller et al [48] measured self-efficacy to self-regulate social media app use. Participants responded to statements commencing with "During the last 7 days have you felt that you can..." (eg, "...use social media apps consciously even if I first have to find a way to integrate this into my daily routine."), rated on a scale from 1 ("not at all true") to 6 ("exactly true"). The internal consistency at baseline (T1) indicated acceptable reliability (α=.63).

Social Media App Use

Participants' daily minutes spent on their most problematic social media app were derived from objectively measured screen time app records. This data was input by participants in hours and minutes for their most problematic social media app when completing the questionnaires for the respective study weeks (week 1, week 2, and week 3). Weekly scores were calculated by averaging the daily minutes of social media app use over the past 7 days. Univariate outliers (z>3.29) were winsorized to 1 unit higher than the highest valid value, with z<3.29 in the distribution [55].

User Acceptance

User acceptance of the intervention was defined as the user refraining from dismissing a reminder (and thereby continuing their app use) within 1 minute of receiving the reminder nudge. The acceptance rate of the Wellspent app's reminders was computed by dividing the instances of accepted interventions by the total number of occurrences.

Qualitative Information

Qualitative data were collected through an online survey conducted via Qualtrics at the end of the intervention period. Participants in the intervention group answered a series of 10 open-ended questions aimed at exploring their experiences with the Wellspent app (Table S1 in Multimedia Appendix 2). These questions included prompts such as "How would you describe the Wellspent app to a friend?" and "What does the Wellspent app help you with?" The questions were designed to gather insights into users' perceptions of the app's functionality, usability, and effectiveness, as well as to identify potential areas for improvement. A thematic analysis approach was used informally to identify key themes from participants' responses [56].

Covariates

The list of covariates included participants' age, sex (women=1; male=0), education (1=university degree; 0=no university degree), positive affect, and screen time in minutes at baseline. Positive affect was measured with an adaptation of the Positive and Negative Affect Schedule with items such as "Please indicate the extent you have felt this way when thinking about your social media app use over the last 7 days" (1="very slightly or not at all"; 6="extremely") [47].

Data Preparation and Preliminary Analyses

Prior to hypothesis testing, data were screened and cleaned. Univariate outliers in screen time (z>3.29) were winsorized to 1 unit above the highest valid score with z<3.29, following recommendations by Tabachnick and Fidell [55]. To assess baseline comparability between the intervention and control groups, t tests and chi-square tests were conducted for key demographic and outcome variables. These tests also informed attrition analyses comparing retained and dropout participants.

Statistical Analysis

Power

A power analysis was conducted using G*Power (version 3.1.9.7; Heinrich-Heine-Universität Düsseldorf) [57] to determine the necessary sample size for a repeated measures ANOVA, for 2 groups across 2 measurement points in time (ie, from baseline to postintervention and baseline to follow-up) [58]. It indicated that a minimum of 54 participants (27 per group) were required to identify a significant group × time interaction effect. This calculation assumed a medium effect size of 0.25 (Cohen medium effect size) [35,48,58], with a significance level (α) of .05, and a power value of 1–β=0.95 [59]. Anticipating a 50% dropout rate, as observed in a similar intervention study by Keller and colleagues [48], our target recruitment was set at a minimum of 108 participants.

Main Analysis

Data analyses were conducted according to the intention-to-treat approach using both SPSS (version 29; IBM Corp) and RStudio (version 4.3.2; R Core Team) [60]. While SPSS was primarily used for data cleaning purposes, RStudio with its *lme4* package [61] was used for multilevel modeling. We acknowledge that this data analysis deviated from the ANOVA-based power analysis; however, multilevel modeling accounts for the nested data structure and the within-group and between-group variability. Group differences in problematic social media use, problematic smartphone use, self-efficacy, and screen time were assessed using linear mixed models. These models were structured with 3 time points (T1, T2, and T3; within level) nested within participants (between level), and to apply a restricted maximum likelihood procedure in order to account for missing data [61]. To determine intervention effects on the outcome measure, time (0=T1, 1=T2, and 2=T3) × experimental condition (0=control group and 1=intervention group) interactions were estimated as predictors. In subsequent sensitivity analyses, age, sex, positive affect, education level, and screen time in minutes were included as covariates in models 1 - 3. Model 4 included age, sex, positive affect, and education level as covariates. While we are unable to share

XSL•FO
RenderX

participant data due to privacy regulations, the R code for the data analyses is available in the project's Open Science Framework repository [62].

Results

Sample Characteristics, Randomization, and Attrition Check

Of the 120 persons screened for eligibility, 33 of them did not install the Wellspent app, and 17 persons did not complete the baseline questionnaire. The randomized sample consisted of 70 individuals (47 women and 23 men) with a mean age of 26.19 (SD 5.63; range 18 - 45) years. Figure 1 shows a CONSORT (Consolidated Standards of Reporting Trials) flow diagram outlining the study's design and participant allocation across the randomized controlled trial with 3 measurement points. Most participants were students or young professionals. Participants' most chosen problematic social media app was Instagram (29/35, 82%), followed by TikTok (4/35, 10%) and Twitter (1/35, 4%). Detailed demographic data are presented in Table 1, and descriptive statistics for all outcome measures across time and condition are provided in Table 2.

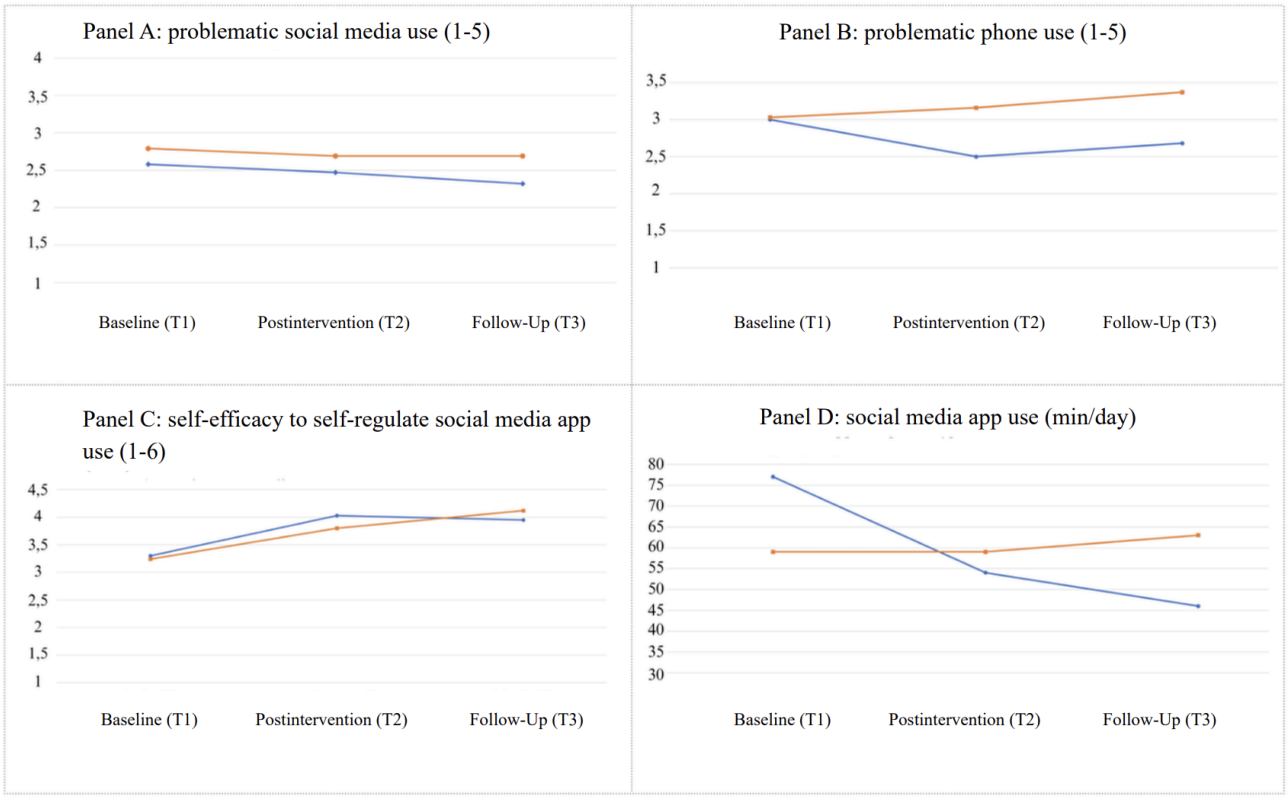
[a]T1: baseline.

[b]T2: postintervention.

[c]T3: follow-up.

Randomization confirmed no significant differences across baseline variables between groups. In the attrition analysis, we found that participants who dropped out from the study before T3 (n=18) showed higher levels of positive affect than participants retained in the longitudinal sample (n=52; nonretainers: mean 2.59, SD 0.53 vs retainers: mean 2.20, SD 0.67; *P*=.03). Among the total sample, a subsample of 52 participants (representing a dropout rate of 26%) completed the study by week 3, comprising 25 participants from the intervention group and 27 participants from the control group. These numbers are almost in accordance with the power analysis, which indicated a targeted longitudinal sample size of 27 persons per group. The attrition rate of the present study aligns with observations from other online-based studies [63]. Table 1 provides an overview of key demographic characteristics of the baseline sample.



Changes in Study Outcomes Over Time

Overview

Mean levels of problematic social media app use, problematic smartphone use, social media app use, and self-efficacy to self-regulate social media app use over time and across both conditions were examined and presented in Table 2 and visualized in Figure 3. Within the intervention group, 33% (6430/19,522) of reminder events in week 2 led to participants refraining from further app use within 1 minute after receiving the reminder. This rate increased slightly to 34% (5394/15,996) in week 3. Notably, within the intervention group, 25 (78%) participants voluntarily continued their use of the Wellspent app in week 3.

XSL•FO
RenderX

Figure 3. Mean levels over time of outcome variable in the intervention (blue) and control (orange) group. Only parts of the response scales are displayed in panels A, B, and C.

Primary Outcome: Problematic Social Media Use

For the primary outcome, problematic social media app use, the multilevel model revealed a nonsignificant time × group interaction effect (model 1: estimate [Est]=−0.27, SE 0.13, 95% CI −0.51 to –0.01; *P*=.05; intraclass correlation [ICC]=0.69).

Secondary Outcome: Problematic Smartphone Use

Problematic smartphone use showed a significant time × group interaction effect (model 2: Est=−0.46, SE 0.18, 95% CI –0.80 to –0.11; *P*=.01; ICC=0.52), indicating improvements in the intervention group when compared to the control group (Figure 3, Panel B).

Secondary Outcome: Self-Efficacy to Self-Regulate Social Media Use

Self-efficacy to self-regulate social media use showed a similar increase over time in both the intervention and control group (model 3; time effect: Est=0.57, SE 0.11, 95% CI 0.34-0.78; *P*<.001; ICC=0.34), but no significant time × group effect emerged (model 3: Est=−0.10, SE 0.17, 95% CI −0.44 to 0.22; *P*=.55).

Secondary Outcome: Social Media App Use

Regarding time of social media app use, a significant time × group effect was observed (model 4: Est=−29.35, SE 6.84, 95% CI −42.79 to −15.99; *P*<.001). This indicates that social media app use significantly decreased in the intervention group (vs the control group), with an average reduction of approximately 29 minutes per day from week 1 to week 3 (Figure 3, Panel D). The overall pattern of results remained consistent when covariates age, sex, positive affect, and education level were added in sensitivity analyses (reported in Table 3). For problematic social media use, the pattern differed, with the effect reaching statistical significance only in the adjusted model. This suggests that the finding may not represent a robust effect.

Qualitative Results

Qualitative feedback was explored informally by reviewing the open-ended responses from the intervention group, collected via Qualtrics at the end of the intervention period. Responses were grouped into recurring patterns based on the researcher's judgment, without following a formal coding or analysis protocol. Emerging themes included the following.

App Effectiveness and Positive Feedback

Participants provided positive feedback on the app's effectiveness in managing screen time, frequently praising its simplicity and user-friendly interface. One participant remarked, "It's a very easy-to-use and straightforward app that allows you to monitor your social media use through reminders sent during self-chosen time intervals." (P26). The app's reminders were particularly appreciated for interrupting mindless scrolling, serving as timely prompts about time spent on social media, and encouraging users to put their phones down. For instance,

XSL•FO
RenderX

a participant noted, “Great app that keeps you alarmed that there’s life outside of the social media apps.” (P32). The ability to set individual budgets for different apps was also considered valuable for promoting conscious social media use: “The budgets are very useful because different apps need different kinds of monitoring.” (P26).

Concerns and Areas for Improvement

The main concerns raised by the intervention group primarily revolved around technical bugs, such as repeated reminders after dismissal, inaccuracies in screen time tracking, and restrictions on selected apps. These issues were seen as areas for improvement, as they impacted the overall user experience.

Integration Into Daily Life and User Acceptance

Participants expressed varying views on integrating the Wellspent app into their daily social media use. Some highlighted the app’s value in enhancing awareness and reducing usage time, describing it as “helpful but not intrusive” (P21). Others underscored its assistance in enabling alternative activities: “It helps me to do other things instead.” (P10). However, instances emerged where user acceptance was hindered, particularly when the app’s reminders interrupted enjoyable social media experiences: “It can be annoying when you are enjoying being on social media, and have done so in moderation, to get constant notifications. I ended up moving the nudge interval when I wanted to use social media for longer periods of time.” (P3).

Overall, while participants generally acknowledged the app’s efficacy in monitoring screen time, some expressed a need for improvements in certain features to fully embrace its integration into daily life. Suggested enhancements included additional statistics tracking (eg, weekly screen time reduction), enhanced friction when exceeding limits (eg, app lock with a code), different modes (eg, study, work, or intentional scrolling mode), and adaptive nudge intervals (eg, prolonged nudge intervals after extended periods of nonuse).

Discussion

Principal Results

This randomized controlled trial investigated the effectiveness of the customizable intervention app Wellspent in supporting self-regulated social media use. The intervention produced significant reductions in daily time spent on the most problematic app (approximately 29 minutes) and reduced perceived problematic smartphone use. In contrast, no significant effects were found for problematic social media use or self-efficacy to self-regulate social media use. These findings suggest that behavioral change, in the form of reduced usage time, can occur relatively quickly through moderate, autonomy-supportive interventions, whereas cognitive and self-perception outcomes may require longer, more reflective processes.

Effects on Problematic Social Media Use

The intervention did not significantly decrease problematic social media use. This aligns with research showing that problematic use arises from deeper, multifaceted patterns, such as emotional health [16], habit strength [64], and personality characteristics [65], making it difficult to change quickly. The intervention app may not have supplied the sustained cognitive scaffolding needed to alter participants’ perceived problematic use within 2 weeks.

Effects on Problematic Smartphone Use

The intervention group reported lower levels of problematic smartphone use compared to the control group. This suggests that behavioral reductions may have translated into a more general feeling of control over one’s device. Notably, perceived problematic smartphone use may be easier to shift in the short term than problematic social media use because it reflects global awareness (“I use my phone too much”) rather than app-specific patterns linked to social, emotional, or identity-related motives.

Effects on Self-Efficacy to Self-Regulate Social Media App Use

Self-efficacy significantly increased in both groups, but participants from the intervention group did not exceed those from the control group. Self-efficacy typically grows through repeated mastery experiences and feedback on successful behavior regulation [66]. As the intervention app focused on in-the-moment friction rather than visible progress tracking, participants may have lacked the experience of sustained success and explicit feedback loops. Similar interventions have also failed to find strong between-group intervention effects on self-efficacy [19], pointing to the need for longer interventions, richer in feedback and reflection.

Effects on Social Media App Use

The intervention produced a reduction in time spent using social media apps of approximately 29 minutes per day. This finding aligns with prior research highlighting the potential of digital self-control tools to reduce usage time when users are nudged at critical moments [35,40]. Compared to digital self-control tools with generic interventions or one-size-fits-all designs [38], Wellspent offered a tailored and user-centric alternative. The full-screen reminder appearing after a personally defined nudge interval (eg, 10 min on Instagram) created a structured moment of pause, allowing users to shift from automatic to deliberate decision-making [22]. Previous literature emphasizes that user autonomy and personalization increase intervention acceptance and long-term engagement [46]. Our results support this perspective, particularly the positive user feedback from intervention participants regarding flexibility and customization. By integrating customizable, goal-aligned nudges into real-time usage patterns, the app sets a precedent for user-centered intervention strategies in digital self-control.

Limitations and Future Research

Together, the findings support emerging evidence that autonomy-preserving tools can meaningfully influence digital behavior within short periods. These findings highlight three key considerations for practitioners and designers of digital self-control tools:

1. Moderate enforcement can be effective: interventions do not need to be coercive to reduce screen time. Full-screen reminders that offer users a choice, rather than restricting

XSL•FO
RenderX

access, can facilitate reflective engagement without triggering reactance.
2. Customization enhances acceptance: giving users the ability to select their target apps, usage limits, and reminder style appears to foster a sense of ownership and autonomy, which in turn increases voluntary engagement and retention. Future digital self-control tools should prioritize configurability to accommodate individual usage patterns and values.
3. Behavioral change may require more than just friction: while nudging can reduce immediate app use, deeper cognitive outcomes such as self-efficacy or problematic social media use may require additional components, for example, reflective journaling, feedback on progress, or social accountability mechanisms.

This study has several limitations. First, the sample size was relatively small, and self-report measures may be subject to bias, particularly regarding subjective app usage and problematic use. The target sample size of 54 participants, as determined by the power analysis, was not reached. The final analysis sample for the multilevel models on the primary outcome consisted of 46 participants, which may have limited the statistical power to detect medium effects. Second, the short intervention duration may have limited the app's impact on self-efficacy and habitual behavior. Third, although self-efficacy to self-regulate social media use was assessed, a direct measure of self-regulation (eg, action control) was not included in the study. This omission may limit the ability to fully capture the psychological mechanisms underlying digital behavior change. Future studies should incorporate validated measures of self-regulation to provide a more comprehensive understanding of intervention effects. Fourth, the study was limited to iOS users, excluding other relevant target groups.

Future research should explore the long-term effects of customizable digital self-control tools and investigate how additional features, such as social comparison, adaptive feedback, or intention tracking, could enhance both behavioral and psychological outcomes. Mixed method designs integrating behavioral data, qualitative feedback, and longitudinal tracking could provide deeper insights into how users engage with interventions over time.

Conclusions

This study provides initial evidence for the effectiveness of a customizable, moderately enforced digital self-control tool in reducing social media screen time and perceived problematic smartphone use. By allowing users to define when, where, and how interventions occur, the Wellspent app demonstrates a user-centered approach to digital self-regulation. These findings support the growing consensus that flexible and autonomy-supportive digital self-control tools offer a promising path toward sustainable behavior change in digital environments.

Acknowledgments

The authors are thankful for the contributions of Marius Rackwitz (development of the study app).

All authors declared that they had insufficient funding to support open access publication of this manuscript, including from affiliated organizations or institutions, funding agencies, or other organizations. JMIR Publications provided article processing fee (APF) support for the publication of this article.

Funding

The authors declared no financial support was received for this work.

Authors' Contributions

LM developed the study concept and conducted the data collection under JK's supervision. LCB conducted the data analysis. LM drafted the initial manuscript, and LCB, CR, TD, TR, and JK collaboratively provided feedback. The final manuscript was approved by all authors for submission.

Conflicts of Interest

LM was employed as a working student at Wellspent GmbH during the time of the intervention period. CR is a cofounder of Wellspent GmbH. All other authors declare no conflicts of interest.

Abstract

Background: Sedentary employees face increased chronic health risks due to physical inactivity, immobility, and unhealthy eating behavior. Although mobile health (mHealth) interventions show promise in improving lifestyle behaviors, their effectiveness in occupational settings remains underexplored. Building on previous workplace interventions, this study developed and evaluated a mobile-enabled web app, SIMPLE HEALTH, developed with Din-J Design Co, Ltd, integrating activity tracking, healthy eating, and behavioral support for sedentary employees.

Objective: This study evaluated the short-term effects of a 12-week mHealth intervention on physical activity, sedentary behavior, dietary habits, and cardiometabolic health indicators among sedentary employees in Taiwan.

Methods: A 2-arm quasi-experimental study was conducted at 2 aerospace industrial workplaces. A total of 101 sedentary employees (mean age 46.9, SD 12.2 years; 52/101, 51.5% female) were enrolled from 2 worksites that were assigned by coin toss to either the intervention condition (n=50) or the control condition (n=51). The intervention group participated in the SIMPLE HEALTH program, an mHealth intervention grounded in Social Cognitive Theory and the Ecological Model, consisting of 8 components: activity tracking, goal setting, behavior logging, reminders, personalized advice, educational and motivational electronic booklets, and individual and team challenges. The control group received 6 print educational booklets. Cardiometabolic biomarkers, objectively measured physical activity (Fitbit Charge 3; Fitbit Inc), occupational sitting (occupational sitting and physical activity questionnaire), and dietary behavior (3-day photographic food records and the healthy eating behavior inventory) were assessed at baseline and 12 weeks. Data were analyzed using generalized estimating equations following the intention-to-treat principle.

Results: At 12 weeks, the intervention group showed a significant increase in step counts (adjusted mean difference, MD 1227.13, 95% CI 2.90-2451.36; *P*=.049), a more favorable between-group change in moderate physical activity (adjusted MD 0.17, 95% CI 0.01-0.33; *P*=.04), and favorable dietary behaviors, including reduced intake of calories (adjusted MD −144.59, 95% CI −276.57 to −12.60; *P*=.03), carbohydrates (adjusted MD −19.88, 95% CI −37.99 to −1.78; *P*=.03), fats (adjusted MD −6.99, 95% CI −13.69 to −0.29; *P*=.04), and grains (adjusted MD −1.46, 95% CI −2.43 to −0.50; *P*=.003), and increased vegetable intake (adjusted MD 0.47, 95% CI 0.06-0.88; *P*=.02), compared to the control group. Favorable trends were noted in diastolic blood pressure (adjusted MD −2.38, 95% CI −4.99 to 0.22; *P*=.07) and soft lean mass (adjusted MD 0.34, 95% CI −0.06 to 0.75; *P*=.10). Both groups showed significant within-group improvements in low-density lipoprotein cholesterol (intervention: *P*=.01; control: *P*=.03), body fat percentage (intervention: *P*<.001; control: *P*=.01), waist circumference (intervention: *P*=.001; control: *P*=.002), and occupational sitting (intervention: *P*<.001; control: *P*=.03), and occupational walking (intervention: *P*=.01; control: *P*=.046), but between-group differences were nonsignificant.

Conclusions: The 12-week mHealth intervention improved physical activity and dietary behaviors and showed favorable trends in cardiometabolic indicators among sedentary employees. These findings support integrating mHealth programs into employee

XSL•FO
RenderX

wellness initiatives to promote healthy behaviors, mitigate productivity loss, and reduce chronic disease burden. Further research should assess long-term sustainability, scalability, and cost-effectiveness in diverse occupational settings.

Trial Registration: ClinicalTrials.gov NCT04347096; https://clinicaltrials.gov/study/NCT04347096

KEYWORDS

sedentary work; physical activity; healthy diet; mobile health intervention; cardiometabolic health; employee

Introduction

Sedentary employees face an elevated risk of developing chronic health conditions due to physical inactivity, prolonged sitting, and poor dietary habits. In modern economies, the demand for physical labor has declined, resulting in more desk-based occupations that require employees to remain seated for extended periods. This occupational shift, compounded by the pervasive use of digital technologies, has contributed to widespread sedentary behavior in the workplace [1,2].

Furthermore, sedentary habits often extend beyond work hours, with employees spending their leisure time engaging in passive activities such as watching television, browsing social media, or using computers [3]. Globally, approximately 27.5% of adults fail to meet the World Health Organization (WHO) recommendations for physical activity [2]. In Taiwan, this issue is more pronounced—43.3% of adults do not achieve the recommended levels of physical activity [4], and 34.6% of workers report not engaging in any exercise in the past month [5]. Without effective intervention, it is projected that nearly 500 million new cases of preventable noncommunicable diseases will occur between 2020 and 2030, resulting in an annual global health care cost of approximately US $27 billion [2].

Unhealthy dietary patterns further exacerbate these risks. Office environments often promote overconsumption of calorie-dense and nutrient-poor foods, such as snacks and meals high in fat, sugar, and sodium [6,7]. In Taiwan, only 16% and 15.5% of adults meet daily vegetable and fruit intake recommendations, respectively, while average salt intake—9 g for men and 7.2 g for women—exceeds the WHO's recommended limit of less than 5 g per day [4]. Inadequate fruit and vegetable intake is estimated to contribute to 19% of gastrointestinal cancers, 31% of ischemic heart disease cases, and 11% of strokes, with diet-related cardiovascular diseases and cancers comprising approximately 85% and 15% of the total disease burden, respectively [8]. Moreover, global analyses attribute 2.4 million deaths annually to insufficient fruit and vegetable consumption and 1.8 million deaths to excess sodium intake [9].

Considering these challenges, the adoption of healthy lifestyles is crucial in preventing chronic diseases, premature death, and mitigating social and economic burdens. A large prospective cohort study [10] in Iran with more than 50,000 participants has demonstrated that combining healthy eating with physical activity significantly reduced the risk of mortality from all causes and cardiovascular diseases. Meta-analyses have also shown that a prudent or healthy diet is linked to reduced all-cause and cardiovascular disease mortality and a lower prevalence of metabolic syndrome [11,12]. A high-quality diet could lower the risk of atherothrombotic ischemic stroke, regardless of physical activity levels [13]. Dietary fiber intake is associated with a lower risk of metabolic syndrome [14], while high carbohydrate intake is linked to a higher risk [15].

Workplace interventions promoting good nutrition and physical activity have been shown to improve work-related and health-related outcomes. Grimani et al [16] conducted a review of 14 studies on nutrition and physical activity interventions in the workplace, revealing significant improvements in absenteeism, workability, work performance, and productivity. These benefits were particularly evident when interventions were designed to target the physical work environment and organizational structure. Similarly, Glympi et al [17] explored workplace dietary interventions among office workers, categorizing them into 4 main types: web-based, food-based, information-based, and multicomponent interventions. Among these, information- and web-based interventions emerged as the most prevalent, attributed to their cost-effectiveness. In this study, interventions refer to structured, evidence-based behavioral programs designed to improve health outcomes, while approaches refer to the delivery frameworks—such as eHealth and mobile health (mHealth)—used to implement them.

The growing availability of mobile devices and smartphones has made mHealth interventions increasingly attractive for promoting healthy behaviors in workplace settings. These interventions, which may include mobile apps, web-based platforms, text messaging, wearable devices, or sensor-assisted feedback, have demonstrated effectiveness in improving physical activity, diet quality, and health outcomes in various populations [18-20]. However, relatively few have been specifically designed for or tested among sedentary workers, who face unique environmental and behavioral challenges.

Building on our previous research [21,22], we aimed to extend traditional workplace interventions to a mobile platform. Our earlier "Sit Less, Walk More" studies demonstrated that modifying the physical environment and providing printed educational materials could increase physical activity, reduce sitting time, and improve cardiometabolic health and work productivity among office employees [21,22]. Nevertheless, postintervention feedback suggested that participants sought more flexibility, personalization, and accessibility—particularly outside the workplace. These findings guided the development of an evidence-based mHealth intervention, SIMPLE HEALTH, designed to integrate physical activity, sedentary behavior reduction, and healthy eating through a mobile-enabled web app.

The SIMPLE HEALTH program builds directly upon the theoretical and practical foundation established by our prior

XSL•FO
RenderX

work. It applies Social Cognitive Theory [23], Ecological Model [24], and incorporates evidence-based behavior change techniques, such as self-monitoring, goal setting, feedback, and social support. Unlike our previous environmental interventions, which relied on printed materials and workplace modifications, SIMPLE HEALTH was delivered digitally through a web app—a platform optimized for smartphones but accessible through any internet browser. The term mHealth intervention here denotes the broader behavioral program delivered via mobile technology, whereas the web app refers to the digital interface through which users accessed the program. Although a web app can technically be opened on a desktop, SIMPLE HEALTH was specifically designed for smartphone use, allowing real-time interaction, behavior tracking, and personalized reminders through LINE (LINE Corporation), a widely used instant messaging app in Asia.

While long-term behavior change is the ultimate goal of health promotion, evaluating short-term effects is a necessary first step to assess the initial efficacy, feasibility, and user engagement of newly developed digital interventions. Consistent with the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) framework, short-term evaluations provide critical feedback to refine program design and optimize future long-term trials. Therefore, this study focuses on the 12-week short-term outcomes of the SIMPLE HEALTH mHealth intervention, assessing its effects on physical activity, sedentary behavior, dietary habits, and cardiometabolic health among sedentary employees. We hypothesized that, compared with a control group receiving only print educational booklets, participants in the 12-week mHealth intervention would demonstrate significant improvements in physical activity, reductions in sitting time, healthier dietary behaviors, and favorable changes in cardiometabolic biomarkers.

Methods

Study Design and Setting

This study used a 2-arm, parallel, quasi-experimental design to examine the short-term effects of a mHealth intervention on healthy behaviors and cardiometabolic indicators among sedentary employees. The quasi-experimental design was selected to minimize contamination between groups while preserving the integrity of intervention delivery [25]. Recruitment and baseline assessments were conducted between April and May 2020 in 2 aerospace industrial workplaces in Taiwan.

Participants

Inclusion criteria were full-time employment in sedentary roles (sitting ≥6 hours per workday), age ≥20 years, absence of physical limitations restricting physical activity, and access to a smartphone with the LINE messaging app and an internet connection. Exclusion criteria were part-time employment, anticipated absence from work >2 weeks, relocation within 3 months, or pregnancy or planned pregnancy during the study period. A priori power analysis [26] (effect size=0.5; power=80%; correlation=0.5) indicated 48 participants per group were needed, accounting for a 20% dropout rate as suggested by prior work [21].

Recruitment and Allocation

Approval to conduct the study was obtained from workplace senior management. Study invitations were disseminated via company websites, email, word-of-mouth, and on-site information sessions. Occupational health nurses introduced the study at both sites, and the nurse at the intervention site was trained as a research liaison using a standardized handbook.

Participants were enrolled by occupational health nurses after obtaining site-level consent from senior management. Worksite allocation to the intervention or control condition was determined by a coin toss conducted by an independent research assistant. Group assignments were concealed until completion of baseline assessments to minimize bias. Although the quasi-experimental design limited full allocation concealment, procedures were implemented postbaseline to reduce selection bias.

Participants and the site nurse were not blinded due to the nature of the mHealth intervention. However, all data collectors (except for 1 trained research assistant) and the dietitian analyzing dietary records were blinded. Statistical analyses were conducted on deidentified data to ensure analytical blinding.

A total of 101 employees were enrolled and assigned to the intervention group (n=50) or the control group (n=51). Intervention participants also received a Mi Smart Band 4 (Anhui Huami Information Technology Co) for daily activity tracking and a participant handbook.

Procedures

Assessments were performed at baseline and 12 weeks during paid work hours. At the control site, an occupational health nurse distributed monthly educational booklets. At the intervention site, participants engaged with the SIMPLE HEALTH web app for 12 weeks. Both groups received comparable educational content, though the delivery format differed (print vs digital).

Intervention

The mHealth intervention, SIMPLE HEALTH, was grounded in Social Cognitive Theory [23] and the Ecological Model [24], emphasizing self-regulation, self-efficacy, and multilevel behavioral influences. Program design was guided by dietary and physical activity guidelines [27-29], expert consultation, and prior participant feedback [21]. To facilitate sustainable behavior change, evidence-based behavior change techniques were systematically incorporated [30].

SIMPLE HEALTH was a smartphone-optimized web app developed through iterative testing. It included eight interactive components: (1) activity tracking, (2) goal setting, (3) behavior logging, (4) reminders, (5) personalized advice, (6) electronic educational booklets, (7) electronic motivational booklets, and (8) individual and team challenges. A summary of the intervention components is presented in Multimedia Appendix 1, with screenshots in Multimedia Appendix 2 and detailed development and usability findings reported elsewhere [31].

XSL•FO
RenderX

Intervention participants accessed educational content equivalent to that of the control group but in a digital format. They were instructed to wear the activity tracker daily, set biweekly goals, log diet and activity behaviors, and use app-based reminders. Notifications were delivered through LINE. For data security, participants created personal login credentials and linked their accounts to the study's LINE Official Account using encrypted connections.

Comparator

Control participants received 6 colorful print booklets over 3 months covering 2 themes—"sit less, move more" and "healthy eating." These materials aimed to enhance knowledge, awareness, and practical skills for healthier behaviors. Control participants did not receive access to the app or activity trackers.

Measures

To assess the short-term effects of the intervention, we measured biomarkers of glucose metabolism, lipid metabolism, blood pressure, body composition, and physical activity and dietary behavior at baseline and 12 weeks. Data collection included an on-site assessment, activity monitoring, and a self-administered questionnaire.

Cardiometabolic Biomarkers

Morning on-site assessments involved collecting fasting blood samples (≥8 hours) by a trained medical technologist and a nurse. Samples were analyzed at an accredited medical laboratory for glucose, insulin, triglycerides, total cholesterol, high-density lipoprotein (HDL) cholesterol, and low-density lipoprotein (LDL) cholesterol. Blood pressure was measured twice using an automated sphygmomanometer (OMRON HEM-7320; Omron Healthcare) on the right arm, following a 3 - 5 minute rest. If readings differed by >10 mm Hg for systolic or >6 mm Hg for diastolic pressure, a third measurement was taken. The average of the 2 closest readings was used for analysis. Weight, BMI, waist circumference, percent body fat, and soft lean mass were measured using a body composition analyzer (model: ioi 353; JAWON MEDICAL). This device is certified by MDD/CE (93/42/EEC) CE 0197, meeting EN ISO 13485 standards for manufacture and quality. We adhered to guidelines to ensure accuracy and participant safety.

Physical activity was objectively measured using a triaxial accelerometer (Fitbit Charge 3; Fitbit Inc). Fitbit devices have been shown in systematic reviews to provide accurate step counts in free-living conditions [32,33]. Participants in both study groups were instructed to wear the Fitbit on the nondominant wrist during all waking hours, except while bathing or swimming, for 5 consecutive days (3 workdays and 2 nonworkdays).

Activity intensity was categorized into 5 levels based on established cut points derived from metabolic equivalents (METs) [34]: (1) sedentary behavior: <1.5 METs (eg, sitting, reclining, or lying down). (2) Light physical activity (lightly active): 1.5 to <3.0 METs (eg, slow walking and household chores). (3) Moderate physical activity (fairly active): 3.0 to <6.0 METs (eg, brisk walking). (4) Vigorous physical activity (very active): ≥6.0 METs (eg, running and aerobic exercise). (5) Moderate-to-vigorous physical activity: combined time spent in moderate and vigorous activities.

The Fitbit algorithm automatically recorded time in each intensity category, total steps, and daily energy expenditure. To complement device data, participants maintained a daily activity log to document their wake and sleep times, work hours, and any instances of device removal >15 minutes. They also recorded non-primary workplace work times.

Occupational sitting time was assessed by a reliable and valid instrument, the Chinese version of the Occupational Sitting and Physical Activity Questionnaire (OSPAQ) [22,35]. Participants estimated the proportion of time spent sitting, standing, walking, and performing physically demanding tasks during a typical workday in the past 7 days. They also reported the number of hours worked and days worked in the last 7 days. Time spent in each activity (min/d) was calculated by multiplying the percent time by hours worked per day.

Dietary behavior was objectively measured using food photography. Participants in both groups were asked to take pictures of their meals for 3 consecutive days (including 2 workdays and 1 nonworkday). They uploaded the images and descriptions of their meals to LINE, where a trained research assistant collected the data. A dietitian then analyzed each meal to determine calorie content, macronutrients (carbohydrates, protein, and fat), and daily food group intakes (grains, protein foods, vegetables, and fruits). Healthy eating behavior was assessed using the 12-item Healthy Eating Behavior Inventory (HEBI) [36], which was translated into Mandarin Chinese for this study. The HEBI-C demonstrated good reliability with a Cronbach α coefficient of 0.85. Each item was rated on a 5-point Likert scale (1=never, 5=very often), with higher scores indicating healthier eating behavior.

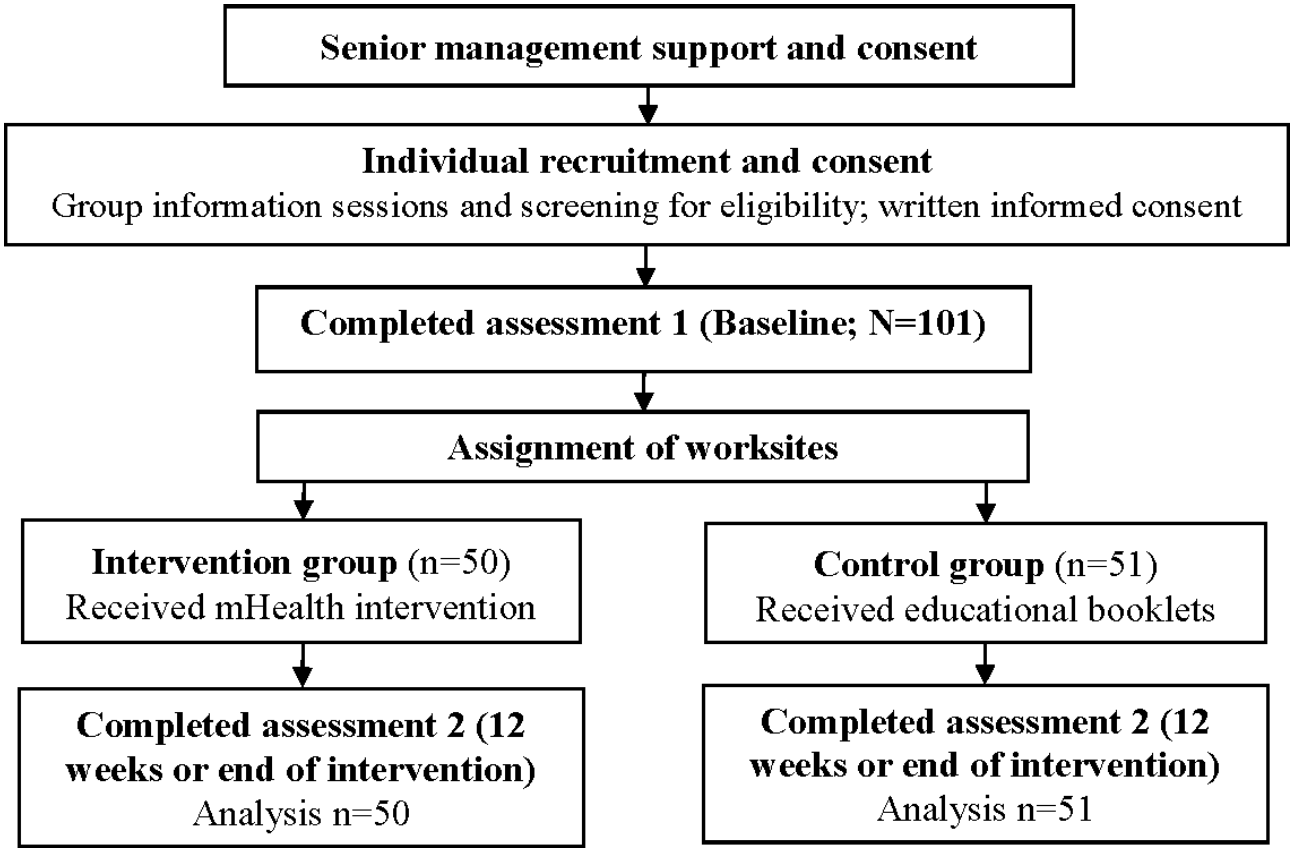
Demographic characteristics were assessed using single-item questions covering age, sex, education, marital status, working hours, and perceived health status. Perceived health status was measured with a question from the general health domain of the 36-Item Short Form Health Survey (SF-36) Questionnaire in Mandarin Chinese: "In general, would you say your health is excellent, very good, good, fair, or poor?" [37]. Additionally, participants were asked about their history of 18 common health conditions with the question, "Have you been diagnosed by a physician with any health conditions? (Response options: no, had in the past, currently have, or under medication control)." Smoking status was assessed with two questions: (1) "How would you describe your smoking habit? (Response options: never smoked, used to smoke, or currently smoke)" and (2) "If you currently smoke, how many cigarettes do you smoke on an average day? "

Statistical Analysis

The intention-to-treat principle was followed, where all participants were analyzed in the groups to which they were initially assigned, regardless of whether they completed the intervention or adhered to the protocol. This approach helps to minimize bias and provides a more realistic estimate of the intervention's effect by reflecting real-world scenarios where not all participants fully comply with the study procedures [38].

XSL•FO
RenderX

Descriptive statistics summarized the characteristics of the participants. The equivalence of the 2 groups was assessed using chi-square tests for categorical variables and *t* tests for interval and continuous variables. To examine the effects of the mHealth intervention on healthy behaviors and cardiometabolic health indicators, a generalized estimating equation (GEE) model was used. GEE was chosen because it accounts for intracorrelation between repeated measurements and provides unbiased estimates despite missing data [39]. GEE models with robust estimators and unstructured correlation structures were used, adjusting for baseline potentially confounding variables. For consistency across the text and tables, the group × time interaction effect from the GEE model is reported as the adjusted mean difference (adjusted MD), representing the between-group difference in change from baseline to 12 weeks. A 2-tailed significance level was set at .05. All data analyses were conducted using SPSS version 26.0 (IBM Corp).



Ethical Considerations

The study protocol was approved by the China Medical University and Hospital Research Ethics Center (CRREC-109 - 017). Written informed consent was obtained from all participants before enrollment, detailing study objectives, procedures, potential risks and benefits, confidentiality, and voluntary participation rights. All data were anonymized using coded identifiers and stored on encrypted servers. Participants received gift vouchers valued at NT $100 (approximately US $3) after each assessment as recognition of their time. The trial was registered at ClinicalTrials.gov (NCT04347096; registered April 13, 2020).

Results

The study flow, including baseline and 12-week assessment participant numbers, is detailed in Figure 1. Demographic characteristics of the 2 groups are presented in Table 1. Both groups were similar at baseline, except for differences in age and marital status. The participants were predominantly middle-aged (mean age 46.9, SD 12.2 years), with a slight majority of females (52/101, 51.5%). Most participants were married or living together (69/101, 68.3%), had experienced common health conditions (79/101, 78.2%), had completed college or university education (47/101, 46.5%), perceived their health as fair or good (77/101, 76.2%), and were nonsmokers (88/101, 87.1%). The average weekly working hours were 46.0 (SD 2.16), and the average BMI was 24.5 (SD 4.07) kg/m².

[b]Presence of at least 1 of 18 common health problems.

Table 2 summarizes the intervention effects on physical activity, sitting, and dietary behavior outcomes. The intervention group showed a significant increase in steps (adjusted MD 1227.13, 95% CI 2.90-2451.36; *P*=.049), a more favorable between-group change in moderate physical activity (adjusted MD 0.17, 95% CI 0.01-0.33; *P*=.04), and intake of calories (adjusted MD −144.59, 95% CI −276.57 to −12.60; *P*=.03), carbohydrates (adjusted MD −19.88, 95% CI −37.99 to −1.78; *P*=.03), fats (adjusted MD −6.99, 95% CI −13.69 to −0.29; *P*=.04), grains (adjusted MD −1.46, 95% CI −2.43 to −0.50; *P*=.003), and vegetables (adjusted MD 0.47, 95% CI 0.06-0.88; *P*=.02) compared to the control group (all *P*<.05). Although no treatment effects were seen for occupational sitting (intervention: baseline mean 7.90, SD 0.81 vs 12-week mean 7.32, SD 0.96; control: baseline mean 7.30, SD 1.23 vs 12-week mean 6.89, SD 1.36; mean difference −0.58, 95% CI −0.81 to −0.35; *P*<.001 vs mean difference −0.41, 95% CI −0.77 to −0.05; *P*=.03) and occupational walking (intervention: baseline mean 0.73, SD 0.66 vs 12-week mean 1.05, SD 0.76; control: baseline mean 0.86, SD 0.49 vs 12-week mean 1.07, SD 0.79; mean difference 0.32, 95% CI 0.08-0.57; *P*=.01 vs mean difference 0.21, 95% CI 0.004-0.415; *P*=.046), significant within-group improvements were observed in both groups.

Table 3 summarizes the effects of the intervention on cardiometabolic biomarkers. The direction of the effects for diastolic blood pressure (adjusted MD −2.38, 95% CI −4.99 to 0.22; *P*=.07) and soft lean mass (adjusted MD 0.34, 95% CI −0.06 to 0.75; *P*=.10) favored the intervention. However, unfavorable changes were observed in high-density lipoprotein cholesterol (adjusted MD −3.99, 95% CI −5.94 to −2.06; *P*<.001) and triglyceride (adjusted MD 15.66, 95% CI 0.87-30.46; *P*=.04) levels. Within-group analysis showed that the intervention group experienced a favorable change in fasting glucose at 12 weeks (baseline mean 96.24, SD 13.66 vs mean 93.82, SD 8.70; mean difference −2.42, 95% CI −4.89 to 0.05; *P*=.06). While no treatment effects were seen for low-density lipoprotein cholesterol (intervention: baseline mean 118.76, SD 34.11 vs mean 112.97, SD 32.07; control: baseline mean 111.73, SD 24.97 vs mean 107.63, SD 22.45; mean difference −5.79, 95% CI −10.14 to −1.45; *P*<.01 vs mean difference −4.10, 95% CI −7.88 to −0.32; *P*=.03), body fat percentage (intervention: baseline mean 26.27, SD 6.03 vs mean 25.59, SD 6.00; control: baseline mean 26.02, SD 5.33 vs mean 25.55, SD 5.19; mean difference −0.68, 95% CI −1.04 to −0.33; *P*<.001 vs mean difference −0.47, 95% CI −0.85 to −0.10; *P*=.01), and waist circumference (intervention: baseline mean 80.32, SD 7.00 vs mean 79.62, SD 6.95; control: baseline mean 85.25, SD 13.77

Discussion

Principal Results

This study evaluated the short-term effects of an mHealth program on physical activity, sitting time, dietary behavior, and cardiometabolic biomarker outcomes among sedentary employees. The intervention led to significant improvements in steps, moderate physical activity, and intake of calories, carbohydrates, fats, grains, and vegetables. Both the intervention and control groups demonstrated significant improvements in LDL cholesterol, body fat percentage, waist circumference, and occupational sitting and walking. However, the intervention group experienced unfavorable changes in triglyceride levels and HDL cholesterol. These findings contribute to the limited evidence on the benefits of mHealth programs targeting physical activity, sedentary behavior, and dietary habits, suggesting that such interventions may offer some cardiometabolic health benefits for sedentary employees.

Comparison With Prior Work

The significant improvements in physical activity (steps and moderate physical activity) and dietary behavior (intake of calories, carbohydrates, fats, grains, and vegetables) observed in our study align with previous research on mHealth interventions and web-based health promotion programs targeting multiple health behaviors, including physical activity and diet [40-43]. Cook et al [40] evaluated the effectiveness of a web-based multimedia health promotion program aimed at improving dietary practices, increasing physical activity, and reducing stress in employees of a human resources company. The intervention group showed significant improvement in attitudes toward a healthy diet and dietary stage of change. Another study by Cook et al [41] examined the effectiveness of a web-based health promotion program, HealthyPast50, on diet, physical activity, stress, and tobacco use in older employees of an information technology company. The intervention group significantly improved diet behavior change self-efficacy, planning healthy eating, and mild exercise, but not physical activity. Deitz et al [42] tested the effectiveness of a web-based cardiovascular health promotion program targeting physical activity, diet, stress, mood, and smoking in hospital employees. The intervention group significantly improved dietary attitudes, intentions, self-efficacy, exercise self-efficacy, and overall level of physical activities, particularly strenuous physical activity. Finally, Oftedal et al [43] examined the preliminary efficacy of a mHealth intervention targeting shift workers' physical activity, diet, and sleep quality. The intervention group significantly improved diet quality, though there were no significant changes in physical activity or sleep quality.

In this study, we observed inconsistent findings on the impact of increasing physical activity, reducing sitting time, and improving dietary behavior on cardiometabolic biomarkers, reflecting similar patterns found in previous research. Positive trends were noted in diastolic blood pressure, soft lean mass, and fasting glucose, though these were not statistically significant. In both intervention and control groups, there were significant improvements in LDL cholesterol, body fat percentage, and waist circumference. However, the intervention group showed unfavorable changes in triglycerides and HDL cholesterol.

The unfavorable changes in triglycerides and HDL cholesterol in the intervention group, despite promoting a low-carbohydrate diet that is high in healthy fats, may be due to several factors. Even small increases in carbohydrate intake can significantly impact lipid metabolism, potentially raising triglycerides and lowering HDL cholesterol, as the body's lipid response is highly sensitive to carbohydrate changes [44]. The type of carbohydrates and fats consumed also matters; diets high in refined carbs or low-quality fats can negatively affect lipid profiles, even with balanced macronutrient ratios [45]. Additionally, individual metabolic responses and genetic factors can lead to varied lipid responses, further complicating outcomes [44]. In brief, these unfavorable changes likely result from subtle shifts in macronutrient intake and the types of foods consumed, underscoring the complexity of dietary impacts on lipid metabolism.

Previous research on the impact of mHealth interventions on cardiometabolic biomarkers has yielded mixed results. For example, Deitz et al [42] found no significant effects of a web-based program on waist circumference and blood pressure. In contrast, Fukuoka et al [46] evaluated a diabetes prevention intervention that combined a mobile phone app and a pedometer targeting physical activity and dietary intake in overweight adults at risk for type 2 diabetes. This intervention group showed significant reductions in hip circumference and blood pressure but no significant effects on fasting lipid levels (triglycerides, total cholesterol, LDL, and HDL) or glucose levels (hemoglobin A_{1c} and glucose).

A recent review by Jung et al [47] provided a comprehensive analysis of the effectiveness of mHealth interventions in promoting physical activity and weight loss among workers. While the mHealth intervention group significantly improved physical activity, they did not show a significant difference in weight loss. Another review by Buckingham et al [48] assessed the effectiveness of mHealth technology, including wearable activity monitors and smartphone apps, for promoting physical activity and reducing sedentary behavior in workplace settings. The review found that 69% of studies reported significant impacts on reductions in weight, systolic blood pressure, and total cholesterol.

These mixed findings highlight the complexity of mHealth interventions and their varied effects on cardiometabolic health indicators. While some studies demonstrate significant benefits in specific biomarkers, others show limited or no impact. This underscores the need for further research to identify the most effective components and contexts for mHealth interventions. This includes examining the specific features that contribute to behavioral changes and improvements in health indicators. Understanding how these interventions influence behavior and health at a physiological level can help in designing more targeted and effective programs. Furthermore, it is crucial to conduct longer-term studies to assess the sustainability of behavior changes and the long-term impact on cardiometabolic health.

Of particular interest was the finding that both the intervention and control groups showed significant improvements in LDL cholesterol, body fat percentage, waist circumference, and occupational sitting and walking from baseline to 12 weeks after the intervention. This suggests either (1) both interventions effectively improved healthy behaviors and cardiometabolic health indicators or (2) most participants in both groups were highly motivated to improve their health, contributing to the observed changes. Initially, we hypothesized that the mHealth intervention group would be more effective than the control group with print educational booklets. Since this study did not have a no-treatment control group, a cautious interpretation of the intervention effect is needed. The improvements could be attributed to assessment effects for both groups. For example, after the baseline assessment, both groups received feedback on biomarkers related to glucose metabolism, lipid metabolism, blood pressure, and body composition, as well as dietary assessment along with recommendations for calorie intake and portion sizes for the 4 food groups (whole grains, protein, vegetables, and fruits). This feedback likely served as a motivating factor and benefited the control group in addressing their health and behavioral issues. Thus, this study's lack of a no-treatment control group limits our ability to definitively attribute the improvements to the interventions rather than other motivating factors or external influences. Future research should consider including a no-treatment control group to isolate the interventions' effects better.

Although the control group receiving colorful print educational booklets was originally intended as a control, the scope and quality of these materials likely played a significant role in promoting behavioral regulation and self-efficacy. As a result, the print materials effectively functioned as interventions, posing a substantial rival to the mHealth program. The effectiveness of print materials in changing health behaviors and outcomes is well-supported by research [40].

Compared to the print materials, participants in the mHealth program received electronic versions of the 6 educational booklets and additional intervention components. However, the print materials offered distinct advantages: users had all the material in hand from the start without needing to access a web app and could read the booklets easily. This is particularly advantageous for middle-aged people with presbyopia, who may prefer print materials over smartphones due to the small screen size. The apparent efficacy of the print materials suggests that providing them to the mHealth intervention group could further enhance the program's effectiveness. This finding highlights the importance of considering the format and accessibility of educational materials in health interventions, especially for populations that may have preferences or limitations related to technology use.

Implications for Occupational Health Practice

Integrating mHealth interventions into worksite health promotion programs can benefit employee well-being and productivity. The findings from this study suggest several practical implications for occupational health practitioners:

1. mHealth technologies can potentially enhance employee engagement in health promotion activities. The convenience and accessibility of web- and smartphone-based interventions can encourage more consistent participation than traditional methods. Additionally, mHealth technologies provide real-time monitoring and feedback, helping employees set their personal goals to achieve, track their progress, and stay motivated. Personalized feedback mechanisms are essential to maximize their impact.
2. Creating a supportive environment that promotes healthy behaviors is crucial for enhancing the effectiveness of health interventions. This includes providing access to mHealth tools and resources and fostering a workplace culture that values and encourages physical activity, healthy eating, and regular health monitoring.
3. Developing educational programs that leverage both digital and print materials can cater to different employee preferences. Our study showed that print materials were effective and could complement digital interventions, particularly for employees who prefer nondigital formats.

XSL•FO
RenderX

Offering a variety of educational materials ensures broader engagement.

4. Adopting a holistic approach to occupational health is essential to address multiple health behaviors simultaneously. mHealth interventions can target physical activity, sedentary behavior, diet, and other relevant health behaviors, offering a comprehensive solution for improving overall health. This approach ensures that various aspects of health are addressed together, leading to better outcomes.
5. Advocating for the integration of mHealth interventions into workplace health policies and practices is essential. Employers should be encouraged to invest in these technologies as part of their health promotion and disease prevention strategies. Integrating mHealth into the workplace can potentially sustain health improvements and cost savings in the long term.

Strengths and Limitations

This study has several notable strengths. First, it is the first mHealth intervention study to target physical activity, sedentary behavior, and dietary behaviors in a workplace context. This comprehensive approach provides valuable insights into how these interventions can be integrated into employee wellness programs. Second, the study achieved good participant retention, enhancing the reliability of the findings. Third, using objective measures to assess most outcomes, including cardiometabolic biomarkers, physical activity, and dietary behavior, adds robustness to the results.

However, the study also has limitations. First, the relatively short duration of the intervention may not capture the long-term effects on cardiometabolic health. To mitigate this, we recommend future studies with extended follow-up periods to understand the observed improvements' sustainability better. Second, the self-reported nature of the healthy eating behavior index and occupational sitting and physical activity questionnaire may introduce recall or social desirability bias. As we also included objective measures, the concern is minimal. Third, participant allocation was determined using a coin toss, which, although simple and transparent, is not an entirely unbiased method. Prior research has demonstrated that coin toss outcomes can be subtly manipulated or deviate from a true 50:50 probability due to human control or physical factors of the coin [49]. This limitation may have introduced a small but possible allocation bias, and future studies should use computer-generated randomization to minimize this risk. Finally, the generalizability of the results is limited as the study involved only 2 workplaces, and participants were not randomly selected. To enhance external validity, more studies with larger samples from diverse occupational settings and randomized sampling methods are recommended.

Conclusions

The mHealth intervention effectively improved physical activity, dietary behaviors, and certain cardiometabolic health indicators among sedentary employees. These findings suggest that integrating mHealth tools into workplace wellness programs can be beneficial. Future studies should explore long-term effects and broader applications across diverse occupational settings to confirm and extend these results.

Acknowledgments

We sincerely thank all participants and the collaborating workplaces for their invaluable contributions to this research. YPL acknowledges the financial support from the National Science and Technology Council (MOST108-2314-B-039 - 058-MY2) and China Medical University (CMU108-MF-36 and CMU109-MF-72), which made this study possible. We thank Dr. Jack Chen from ESTAT Statistical Consulting Co. Ltd. for his expert statistical support.

Abstract

Among 30,000 new wearable device users (11.6 million person-days), self-reported alcohol consumption significantly declined over 72 weeks, with the daily probability of drinking decreasing by 5.8 percentage points (P<.001) and reductions across age and biological sex.

Introduction

Alcohol use is a major contributor to global morbidity and mortality [1], and even low levels of consumption confer measurable health risk [2]. Despite growing awareness of this risk, alcohol remains among the most widely used drugs worldwide [3]. Although behavioral interventions can reduce intake, effects are often modest and short-lived [4], highlighting the need for scalable strategies supporting sustained, population-level reductions in alcohol use.

Wearable devices have become increasingly popular for continuous health monitoring, enabling real-time feedback on physiology and behavior. However, evidence linking wearable use to alcohol-related behaviors remains limited. A recent randomized controlled trial found that a wearable-supported behavioral program was associated with clinically meaningful reductions in alcohol use over 12 weeks [5]. To evaluate whether similar patterns emerge at scale and persist over longer durations, we examined longitudinal trajectories of self-reported alcohol consumption during the first 72 weeks of wearable membership in a large, real-world cohort.

Methods

Study Population

We studied 30,000 international adults (50.0% females) aged 18 - 79 years who joined the WHOOP platform (WHOOP, Inc.) in 2023. Participants enrolled throughout the year and contributed up to 72 weeks of data, structured into consecutive seven-day weeks anchored to each participant's join date. Quarters (Q1−Q6) were defined as consecutive 12-week intervals. Eligibility required at least 18 seven-day weeks with complete alcohol use reporting (≥25% of the observation window) [6], with additional weeks containing ≥3 entries also retained (Multimedia Appendix 1). Stratified random sampling by sex ensured balanced representation.

Self-Reported Alcohol Use

Daily alcohol use was self-reported through the WHOOP smartphone application via a customizable morning journal prompt asking users to confirm behaviors from the prior day (Figure S1 in Multimedia Appendix 1). Users indicated whether alcohol was consumed and could optionally report the number of drinks. Alcohol logging was not required for device use. Only days marked explicitly as "yes" or "no" were analyzed.

Members could also set personalized alcohol-related goals within the application, which could range from abstaining entirely to limiting drinking on specific days. Due to

XSL•FO
RenderX

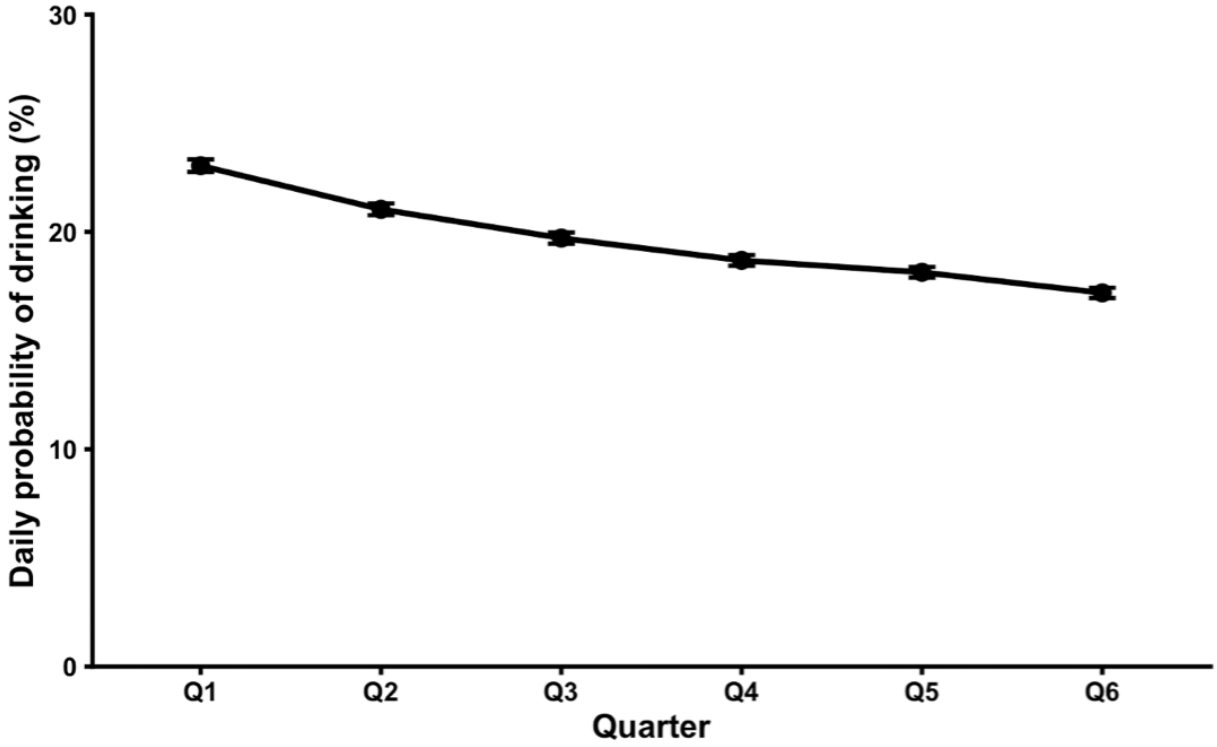
heterogeneity in goal types, goal setting was analyzed as a binary indicator (any goal vs none).

Statistical Analysis

Drinking frequency was modeled as the daily probability of alcohol use within each week using generalized linear mixed-effects models (binomial, logit link) with fixed effects for quarter, age, sex, season, total weeks contributed, and weekend proportion, with participant-level random intercepts. Estimated marginal means were computed by quarter and compared with Q1 using Dunnett-adjusted contrasts. Sensitivity analyses and modeling details are described in the Multimedia Appendix 1. All analyses were performed in R (version 4.2.2; R Foundation for Statistical Computing) with statistical significance set at α=.05.

Ethical Considerations

Participants consented to their anonymized data being used for research purposes. The study protocol was approved by an independent institutional review board (Salus IRB #251121, Austin, TX). Participants did not receive compensation for their participation in this study.



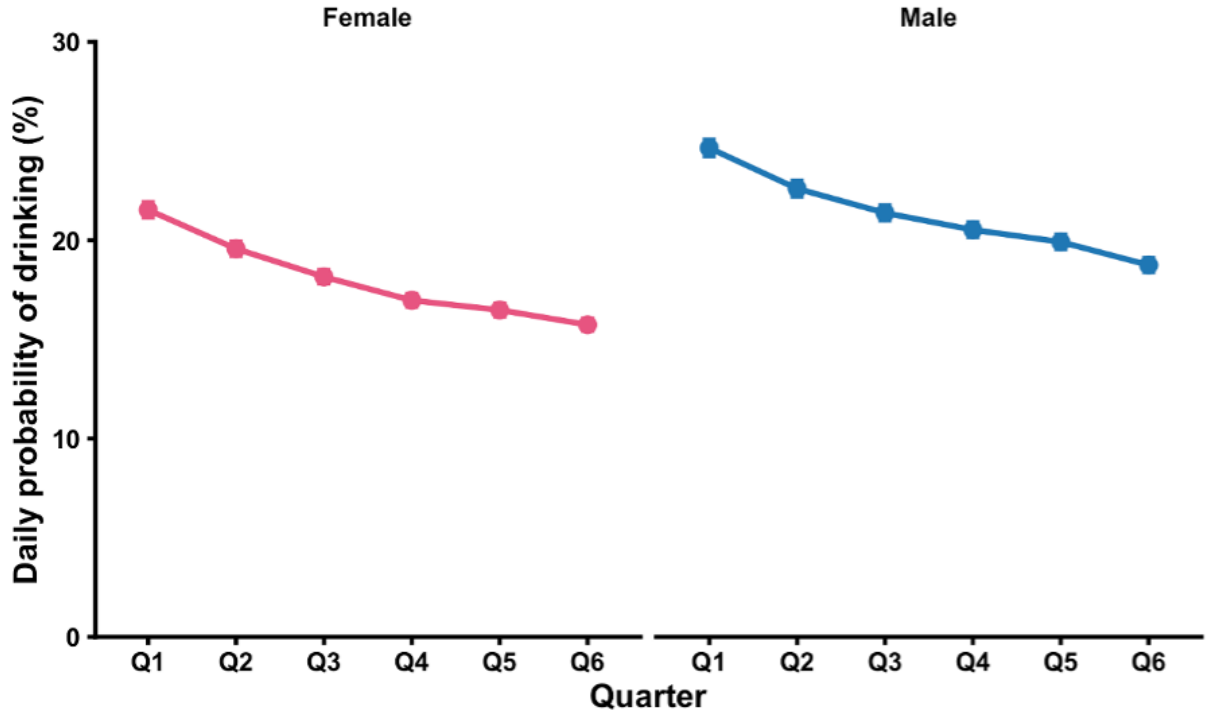
Results

The final dataset included 11,651,827 person-days (1,776,673 person-wk). Mean age was 34.4 (SD 10.5) yrs, BMI was 25.1 (SD 4.0) kg/m^2, and participants contributed a mean of 59.2 (SD 13.5) weeks (median 65 wk, IQR 18 - 72 weeks), with an average of 6.6 (SD 0.9) alcohol entries per week (Table S1 in Multimedia Appendix 1).

The daily probability of alcohol use declined over time (Figure 1), from 23.0% (95% CI 22.7 to 23.3) in Q1 to 17.2% (95% CI 16.9 to 17.4) in Q6, an absolute reduction of 5.8 percentage points (95% CI −6.0 to −5.7). Results were robust in sensitivity analyses, including restriction to complete seven-day drink number reporting, where drinking volume decreased by 1.11 drinks per week (95% CI −1.15 to −1.07; Figure S2 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 1. Adjusted daily probability of alcohol use during the first 72 weeks of membership. Marginal estimates from a binomial generalized linear mixed-effects model are shown for six sequential 12-week quarters (Q1–Q6). Points represent model-based predicted probabilities that a logged day was a drinking day, and error bars indicate 95% CIs. Absolute changes versus Q1 (percentage points) and corresponding Dunnett-adjusted *P* values are derived from model-based contrasts. The model included fixed effects for quarter, age, biological sex, season, total number of weeks contributed, and the proportion of days in each user-week that fell on a weekend, with a random intercept for participant.



Quarter	Daily Probability (%) (95% CI)	Absolute Change vs Q1 (pp, 95% CI)	*P*-value
Q1	23.0 (22.7–23.3)	—	—
Q2	21.0 (20.7–21.3)	−2.0 (−2.1 to −1.9)	<.001
Q3	19.7 (19.4–20.0)	−3.3 (−3.4 to −3.2)	<.001
Q4	18.7 (18.4–18.9)	−4.3 (−4.5 to −4.2)	<.001
Q5	18.1 (17.9–18.4)	−4.9 (−5.0 to −4.8)	<.001
Q6	17.2 (16.9–17.4)	−5.8 (−6.0 to −5.7)	<.001

The baseline daily drinking probability was higher among males than females (*P*<.001), but the relative decline from Q1 to Q6 was greater in females (*P*<.001; Figure 2). Baseline daily drinking probability differed across age groups (*P*s <.001). Progressively larger relative and absolute declines in drinking were observed with increasing age (*P*s <.001; Figure 3).

Q3	17.2 (16.9–17.5)	−2.9 (−3.0 to −2.7)	<.001	26.5 (25.8–27.1)	−4.3 (−4.6 to −4.1)	<.001	33.8 (31.5–36.2)	−6.6 (−7.5 to −5.6)	<.001
Q4	16.4 (16.1–16.7)	−3.7 (−3.8 to −3.5)	<.001	24.9 (24.3–25.5)	−5.9 (−6.1 to −5.6)	<.001	31.0 (28.9–33.3)	−9.3 (−10.3 to −8.3)	<.001
Q5	16.0 (15.8–16.3)	−4.0 (−4.2 to −3.9)	<.001	23.8 (23.3–24.4)	−6.9 (−7.3 to −6.7)	<.001	30.5 (28.3–32.7)	−9.9 (−11.0 to −8.9)	<.001
Q6	15.2 (14.9–15.4)	−4.9 (−5.0 to −4.7)	<.001	22.7 (22.2–23.3)	−8.1 (−8.3 to −7.7)	<.001	28.5 (26.4–30.7)	−11.9 (−13.0 to −10.8)	<.001

Both goal setters (n=13,298; Table S2 in Multimedia Appendix 1) and nongoal setters showed significant declines, though the relative decline was greater among non-goal setters (*P*<.001; Figure S5 in Multimedia Appendix 1).

Discussion

In this large real-world cohort of 30,000 WHOOP members, self-reported alcohol use declined over the first 72 weeks of membership, with both drinking frequency and volume decreasing across age and sex. These findings extend recent experimental results [5] by describing sustained reductions in alcohol use over 72 weeks in a large real-world cohort.

The observed declines may reflect increased awareness of health behaviors, heightened sensitivity to physiological feedback, or broader lifestyle changes after wearable enrollment [7]. Importantly, participants engaged in active self-monitoring through journal entries, a behavior shown to promote reductions in drinking [8]. Additionally, large-scale wearable-based analyses demonstrate that even moderate alcohol consumption disrupts cardiac autonomic regulation, sleep, and next-day physical activity [9]. Awareness of these consequences may reinforce behavior change. Notably, declines in drinking frequency were accompanied by reductions in volume, suggesting decreased frequency was not offset by increased intake on drinking occasions. Although causal effects cannot be inferred, the persistence of these changes over more than one year highlights the potential for digital health platforms to support sustained alcohol-related behavior change at scale.

Several limitations should be considered. Alcohol use was self-reported without standardized drink definitions, and participants were subscription-based wearable users who may be more health-conscious than the general population. The requirement for sustained reporting engagement (≥18 wk) may further limit generalizability. Although reporting frequency remained relatively high across quarters and sensitivity analyses restricted to complete reporting weeks and members with full 72-week follow-up yielded nearly identical results, informative missingness cannot be excluded. Without a control group, observed changes cannot be causally attributed to wearable enrollment or distinguished from secular trends [10]. Although statistically significant, absolute changes were modest, and clinical significance at the individual level cannot be determined. However, dose-response evidence indicates that alcohol-related

XSL•FO
RenderX

health risks increase continuously with consumption [11], with no established safe threshold [12], suggesting even modest population-level reductions may carry public health relevance, particularly when sustained over time and observed across demographic subgroups. Longer follow-up is needed to evaluate persistence beyond the study window. Despite these limitations, this study provides one of the largest longitudinal assessments of self-reported alcohol use to date, describing long-term trajectories of drinking frequency and volume over 72 weeks among new WHOOP members.

Acknowledgments

The authors wish to acknowledge the technical assistance of the WHOOP Data Science and Data Engineering teams for their contributions to feature development and data infrastructure. Abstract

Background: Being overweight and obese are major health concerns worldwide, contributing to lifestyle-related diseases such as hypertension, dyslipidemia, type 2 diabetes, and cardiovascular disease. Increasing physical activity is an effective strategy for weight management. However, earlier step count studies have remained limited to small populations, short-term measurements of 1 - 2 weeks, and mainly cross-sectional comparisons of average step counts. The effects of long-term step count changes on weight loss remain unclear.

Objective: This study was conducted to assess the effects of long-term patterns of step counts on weight loss using data from the “Asmile” mobile health app in Japan. We hypothesized that participants with continuously increasing step counts over time would have a higher likelihood of significant weight reduction than participants who show steady or fluctuating patterns, even if their average step counts were similar.

Methods: We analyzed data of 2778 Asmile users aged 40 - 74 years with BMI ≥25 kg/m² who underwent a specific health checkup during fiscal years 2019 - 2023 and who had valid step count records for 10 - 14 months. Step count trajectories, reflecting long-term trends in physical activity, were classified using a latent class mixed model into four patterns: *UP* (increasing), *FLAT* (steady), *DOWN* (decreasing), and *UP/DOWN* (increasing then decreasing). Logistic regression was applied to estimate odds ratios for achieving ≥3% weight loss, with step trajectory as the explanatory variable and weight loss as the outcome.

Results: Among participants, 1601 (57.6%) were men and 1177 (42.4%) were women, with respective mean ages of 65.8 (SD 7.9) and 64 (SD 8.2) years. Step count trajectories were distributed as 28.5% *UP*, 36.2% *FLAT*, 20.1% *DOWN*, and 15.2% *UP/DOWN*. Compared with the *FLAT* group, participants in the *UP* group had a significantly higher likelihood of achieving ≥3% weight loss (adjusted odds ratio 2.45, 95% CI 1.78 - 3.38).

Conclusions: Long-term tracking of step counts using the Asmile app revealed distinct activity patterns. Continuous increases in step counts were associated with the greatest likelihood of weight loss, emphasizing the importance of sustained physical activity. These findings support the use of long-term step monitoring to guide interventions for obesity and lifestyle-related disease prevention.

Introduction

Being overweight and obese have come to pose medical and social problems in economically advanced countries, including Japan, and in some low- and middle-income countries [1-4]. According to the World Health Organization, which provides widely accepted global guidelines, people with a BMI of 25 kg/m² or greater are classified as overweight, whereas those with a BMI of 30 kg/m² or greater are classified as obese [4]. Obesity is associated with lifestyle-related diseases such as hypertension [5], dyslipidemia [6], type 2 diabetes [7], and arteriosclerotic cardiovascular disease (CVD) [8]. In Japan, the Japan Society for the Study of Obesity in 2000 defined obesity as having a BMI greater than 25 kg/m^2 [9]. To avoid confusion caused by different definitions among countries, we designate both being overweight and being obese as "obesity" throughout this paper. For 3480 Japanese people with obesity or metabolic syndrome, Muramoto et al [10] reported that achievement of 3% weight loss improves risk factors associated with obesity. In obese populations, promoting weight loss is useful and important to reduce the risks of developing lifestyle-related diseases. Therefore, weight loss is often necessary to maintain health.

Walking is a daily physical activity that promotes weight loss and improves lifestyle-related diseases. Pedometers have been used for objective measurement of an individual's per-day step count. Earlier cross-sectional studies comparing BMI and average daily step counts have shown that individuals with higher step counts tend to have lower body weight than those with fewer steps [11-13]. A negative correlation was found between short-term physical activity and physical status [14]. However, earlier studies using pedometers have been burdened by several limitations: small sample sizes and short-term monitoring periods, typically 1 - 2 weeks. Moreover, although a negative correlation has been found, those results derive only from cross-sectional analyses. They do not reflect changes in step counts and weight loss induced by these changes. Therefore, relations between long-term and longitudinal step count changes and weight loss remain unclear.

For this study, we applied trajectory analysis to assess long-term changes in step counts. Latent class mixed models (LCMMs), a trajectory analysis approach, can cluster heterogeneous populations into latent and more homogeneous trajectories [15]. They are then classifiable by group, reflecting different long-term changes. Such models have been applied to the identification of long-term clinical phenotypic changes and elucidation of their group characteristics because skin-thickening trajectories are associated with organ involvement and survival [16]. The trajectories of systemic lupus erythematosus support the feasibility of performing adaptive trial designs [17]. Therefore, by analyzing the trajectories as variables reflecting homogeneous changes over a long period, one can better understand the near-causal effects on outcomes from those trajectories [18].

Therefore, this study was conducted to elucidate the effects of long-term fluctuations in step counts on weight reduction. From this observational study, we obtained approximately 1 year of step count data from 2778 users of the "Asmile" mobile health care (mHealth) app. Users were classified based on their step count trajectories inferred using LCMM. We hypothesized that, rather than simply comparing average step counts, long-term walking patterns would influence subsequent weight loss: specifically, participants with a continuous increase in step counts, rather than a temporary increase, would be more likely to achieve significant weight reduction.

Methods

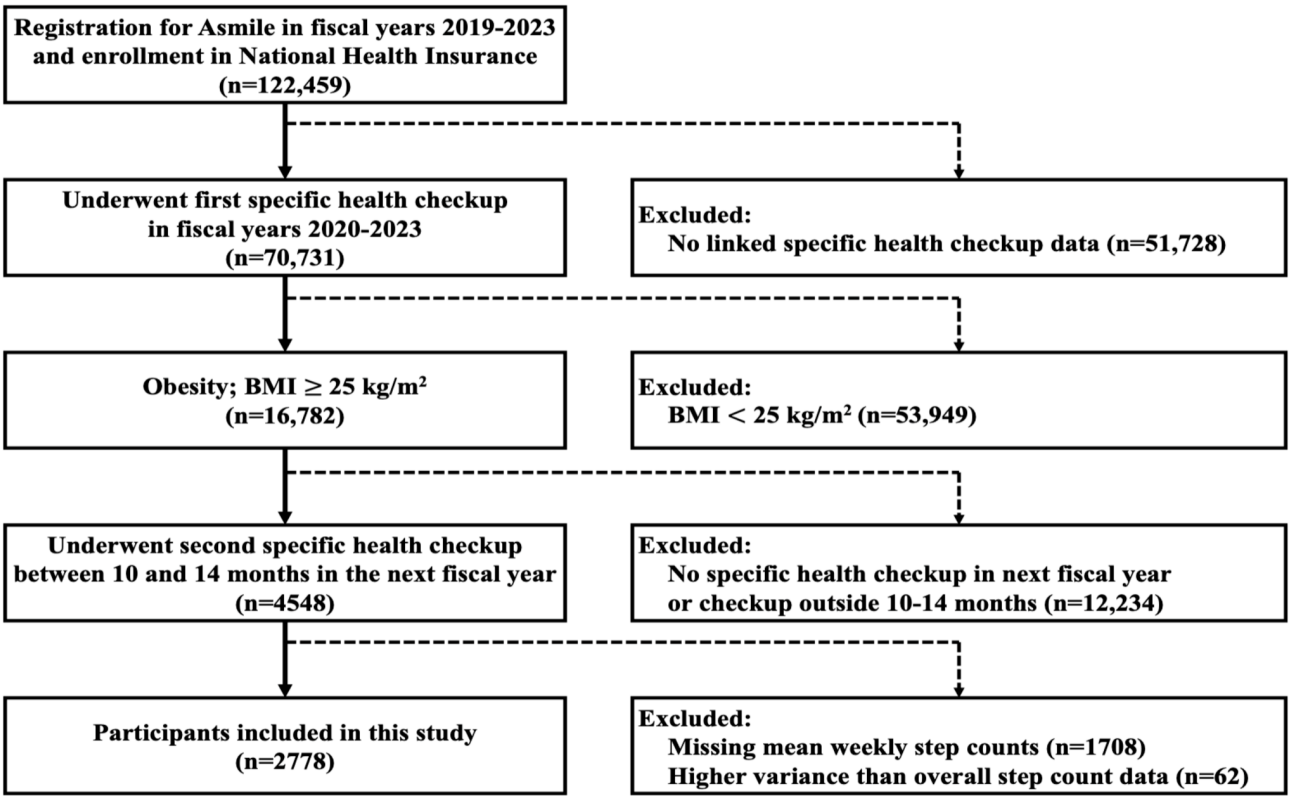
Mobile Health Care App "Asmile"

The Asmile mHealth app, available on iOS and Android, was released in 2019. It is provided by the Osaka Prefectural Government [19]. As of May 2025, more than 450,000 Asmile users have adopted this app to promote their health by recording daily activities and facilitating self-monitoring. One Asmile feature allows a user to record the walking step count automatically as a daily activity by integration with standard smartphone health care apps. Furthermore, daily user information (weight, body temperature, etc) and lifestyle habits (sleeping hours, breakfast intake, tooth brushing, etc) can be recorded manually in the Asmile app. Users with healthy lifestyles, such as those who walk a lot, are awarded points, which they can use to enter drawings for prizes such as electronic money. The granting of such digital incentives encourages more walking [20,21].

Another feature is that results of specific health checkups (SHCs) for National Health Insurance subscribers can be synchronized automatically with the Asmile app. This SHC is aimed at primary prevention and early detection of obesity and lifestyle-related diseases for all insured persons aged 40 - 74 years [22-24]. SHC data such as height, weight, BMI, blood test data, and urinalysis data are recorded. Therefore, the Asmile app allows users to check daily activity records over the long term and to check their health status by fiscal year. Using the Asmile app promotes healthy daily activities and increases awareness of one's health, which is expected to prevent lifestyle-related diseases.

Furthermore, recent usage of the Asmile app has revealed effects of the declaration of a state of emergency for COVID-19 on smoking behavior and the relation between oral frailty and falls [25,26], in addition to a causal effect on increased step counts [27]. Utilization promotes healthy daily activities and increases awareness of one's health, both of which are expected to prevent lifestyle-related diseases.

Participants



This study included participants who registered for the Asmile app during fiscal years 2019 - 2023 and who underwent their first SHC after registration and before the end of fiscal year 2023. We excluded participants with a BMI of less than 25 kg/m². In addition, because this study specifically addressed changes in step count and weight over a period of approximately 1 year, we excluded users who did not undergo a second SHC 10 - 14 months after the first SHC. For participants with more than one eligible SHC pair, we selected the SHC pair for which

XSL•FO
RenderX

the interval between the first and second SHC was closest to 12 months.

In total, data from 122,459 users enrolled in the National Health Insurance and newly registered for the Asmile app were screened. Among those users, 70,731 underwent the first SHC during the 2019 - 2023 fiscal years. After application of the exclusion criteria, 2778 participants with complete step count records and SHC links were included in the analysis (Figure 1).

Figure 1. Flowchart of the included participants' selection for analysis in this study.

Step Count Data

Step count data were recorded in the Asmile app by automatic integration with standard smartphone health care apps. To provide additional detail, the daily step count for the last 42 days was transferred each time the user opened the Asmile app. Considering misplaced or forgotten smartphone or system inadequacies, inappropriate step count data of fewer than 200 steps and greater than 50,000 steps per day were excluded. Those cutoff values were inferred based on the step count distribution of Asmile users [27]. We used step count data with larger steps in a day, for which the data were recorded using both iOS and Android.

When preprocessing the step count data, we first excluded participants without step count data for at least 1 day per week, and those with a higher variance than all step count data. Then, we calculated the weekly average step count for each week from the first SHC until the second SHC. In all, 2778 participants were included in the analysis, with no missing values.

Latent Class Mixed Models

For this study, we used an LCMM [15] to identify long-term step trajectories of Asmile users. This approach, assuming that there are *G* latent classes in a heterogeneous population, can classify them into *G* trajectories. This method accommodates the identification of long-term changes in physical activity from longitudinal step count data.

Letting *N* represent the number of individuals i∈1,…,N, with step count observations Y_{ij} at occasion *j*, we aim to classify these individuals into latent classes g∈1,…,G, each representing characteristic patterns such as increasing, decreasing, flat, or non-monotonic trajectories over time. The step count model is

(1)Yij|g=β0g+β1gtij+β2gtij2+uig+ ij

In the above equation, t_{ij} stands for the elapsed weeks at occasion *j*, β represents the fixed effects of latent class *g*, and u_{ig} denotes the random effects for participant *i* of latent class *g* that is independent of time. In addition, measurement error ij follows a Gaussian distribution of mean 0 and variance σ 2. The LCMM approach estimates model parameters by maximizing the marginal log-likelihood [28] as

(2)l(θ)=∑i=1Nlog (∑g=1GπgLg(Yi|ti, θ))

In the equation, θ denotes the set of parameters to be estimated; πg represents the prior probability of latent class *g* as

(3)πg=eγg∑l=1Geγl

where γg is a class-specific intercept-like parameter. Because the step counts are typically approximately 5000, we assume a multivariate normal distribution for the likelihood function LgYiti,θ. The posterior probability that individual *i* belongs to class *g* is given as

(4)π^ig=πg Lg (yi ∣ ti,θ)∑l=1Gπl Ll (yi ∣ ti,θ)

XSL•FO
RenderX

In practice, the log-likelihood is then maximized iteratively using a modified Marquardt iterative algorithm and the Newton-Raphson method. Each individual is assigned to the latent class *g* for which the posterior probability π^ig is the highest.

Next, as one condition for determining the number of latent classes, we obtained π-g: the mean of the posterior probabilities of belonging to the latent class among the participants. We determined *G* (the number of latent classes) under the following three conditions. First, a participant *i* belongs to latent class *g* that has the largest π^ig. At this point, we ensured that the number of participants belonging to each latent class constituted at least 5% of the total number of participants analyzed. Second, the average posterior probability π−g in each latent class was set as approximately 90% or higher. Third, we selected the optimal *G* (number of latent classes) with the minimum Bayesian information criterion under conditions 1 and 2.

We used the lcmm package [29] with R software to identify step trajectories. Earlier reports [15,30] provide additional details related to the LCMM algorithm.

Statistical Analysis

Categorical variables were expressed as numbers and proportions, whereas continuous variables were expressed as the mean (SD). The means of step counts were calculated for three periods: from undergoing the first SHC to undergoing the second SHC, from undergoing the first SHC to 28 elapsed weeks, and from 28 elapsed weeks to undergoing the second SHC (maximum 56 elapsed weeks). Differences in these periods' associated variables were analyzed using *t* tests for men and women, analysis of variance between latent classes, and the chi-square test for categorical variables.

Long-term step counts of Asmile users were classified as step trajectories using LCMM. All Asmile users belonged to one of the *g* latent classes. We performed logistic regression using the *g* latent classes classified by LCMM as explanatory variables. The response variable was the presence or absence of weight loss of 3% or more at the second SHC, around one year after the start of step count recording, because achievement of 3% weight loss improves risk factors associated with obesity [10]. Adjustment variables included age, sex, mean step counts, smoking status, and the presence or absence of drug history. Here, drug history refers to whether a participant reported, at the time of the health checkup, taking medication for one or more of the following: diabetes, hypertension, or dyslipidemia. Specific drug names or classes, such as GLP-1 RAs or SGLT2 inhibitors, were not available. The odds ratios for each step trajectory were estimated. For sensitivity analysis, odds ratios were estimated for 1006 Asmile users who were not taking medication, to exclude the possibility of hospital attendance. The *P* values of the estimated partial regression coefficients are based on the Wald statistic.

Here, $P<.05$ was inferred as significant. All statistical analyses were conducted using R (version 4.3.1) with the lcmm package (version 2.1.0). This study is reported in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines.

Ethical Considerations

The study protocol was approved by the ethics committee of the Health and Counseling Center of The University of Osaka (institutional review board approval number 8 in 2024). All procedures involving human participants were conducted according to the 1964 Declaration of Helsinki and its later amendments or comparable ethical standards. At the time of app registration, the Asmile users consented to the use of nonidentifiable information in accordance with the terms of service related to the privacy policy. Informed consent to this study from the participants was waived because all data were anonymized according to the Japanese Ethical Guidelines for Medical and Health Research Involving Human Subjects enacted by Japan's Ministry of Health, Labour and Welfare. Anonymized data were provided by the Osaka Prefectural Government. No compensation was provided to participants.

Results

Characteristics

Table 1 presents baseline characteristics of the 2778 users. For weight and BMI, the first SHC was defined as preweight and pre-BMI. The second SHC was defined as postweight and post-BMI. Of the participants, 1601 (57.6%) were men and 1177 (42.4%) were women, with respective mean ages of 65.8 (SD 7.9) and 64 (SD 8.2) years. The mean step counts were significantly different between men and women, with men averaging 6461 (SD 3481) steps/day and women averaging 4953 (SD 2483) steps/day ($P<.001$). In addition, men and women had different weights ($P<.001$). Nevertheless, no difference was found for either BMI (pre-BMI: $P=.18$; post-BMI: $P=.84$) or weight difference after about 1 year ($P=.41$).

Classification of Step Count Trajectory

Figure 2 shows each trajectory of the 2778 participants and notable heterogeneity among participants. Models with 1 - 5 latent classes were built sequentially. Under conditions in which at least 5% of 2778 participants belonged to each latent class with at least a 90% probability, the 4-class model had the lowest Bayesian information criterion (Multimedia Appendices 1-3). That finding confirmed that assuming 4 classes provided the best explanatory power. Actually, the 4 classified step trajectories reflected walking styles over the long term. We labeled these trajectories as *UP*, *DOWN*, *UP/DOWN*, and *FLAT*.

Figure 2. Results of step trajectories. Horizontal axis: number of weeks elapsed from undergoing the first SHC to the second SHC. Vertical axis: average steps per day at each elapsed week. (A) All individual trajectories and the average trend using B-splines. Gray solid line: step trajectories for each of the 2778 individuals. Black dotted line: average step trajectory of 2778 participants. (B) Results of the latent 4 classes as step trajectories classified by the step count model using latent class mixed models. SHC: specific health checkup.

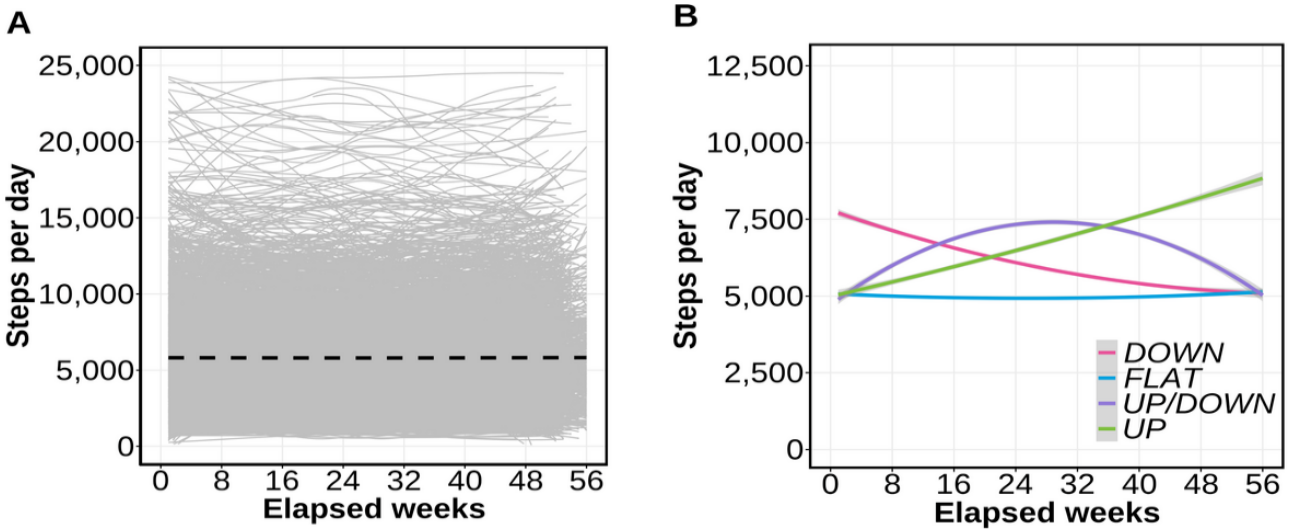

Table 2 presents characteristics of the 4 latent classes (*UP*, *DOWN*, *UP/DOWN*, and *FLAT*). Among the classes, age (*P*=.82) and the duration until undergoing the next checkup (*P*=.07) were found to have no significant difference. In addition, no significant difference was found for any class in pre-BMI (*P*=.39), but a reduction in BMI for the *UP* class was found in comparison to the other classes for post-BMI (*P*=.01). The average step count of the *FLAT* class was low compared to the

XSL•FO
RenderX

other classes (*P*<.001). More notably, irrespective of the long-term step count data, the average physical activities of the *UP*, *DOWN*, and *UP/DOWN* classes were almost identical when compared simply: 7592 (SD 3302) steps/day, 7223 (SD 3852) steps/day, and 7541 (SD 3282) steps/day.

Table . Characteristics of the 4 classes as step trajectories.

[a]Preweight and pre-BMI were defined as the measurements obtained at the first specific health checkup (SHC). Postweight and post-BMI were defined as those obtained at the second SHC.

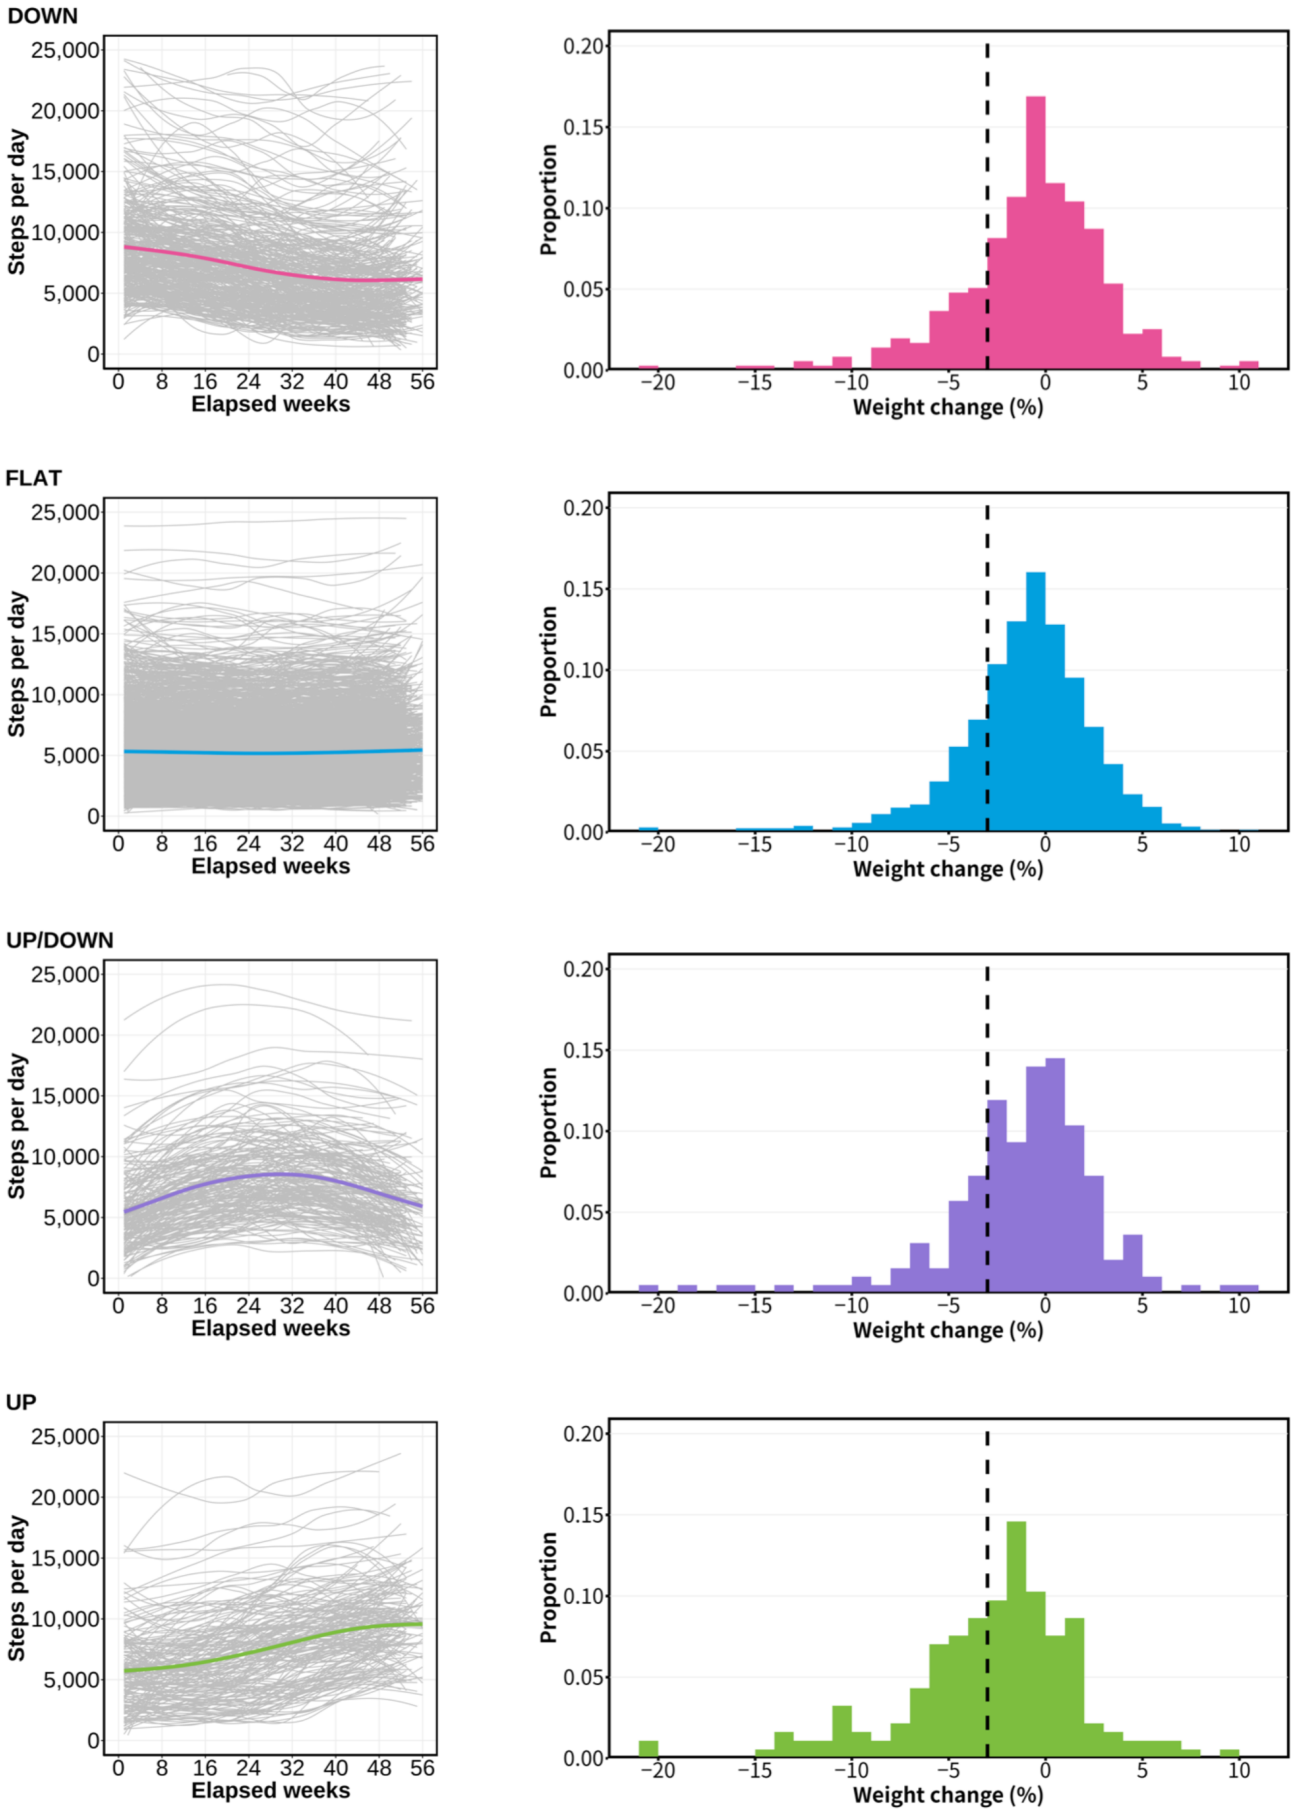
Figure 3 shows trajectories of the 4 latent classes (*UP*, *DOWN*, *UP/DOWN*, and *FLAT*) and the weight changes in the respective classes. *UP*, *DOWN*, *UP/DOWN*, and *FLAT* exhibited long-term step changes with the respective trends of increasing, decreasing, increasing and decreasing, and steady. It is noteworthy that the *UP* class included the most cases of more than 3% weight loss. The distribution of weight change was symmetrical in *FLAT*. In *DOWN*, compared to *FLAT*, the proportion with weight loss of around 3% was lower, whereas the proportion with weight gain of 5% or more was higher. The distribution in the *UP*/*DOWN* class was polarized. Among all classes, the *UP* class

XSL•FO
RenderX

showed the highest proportion of users with weight loss of 3% or more.

The *UP* class was characterized by a long-term increase in step counts: the mean of step counts for 1 - 28 elapsed weeks was 6469 (SD 3309) steps/day, but after 29 elapsed weeks, it was 8894 (SD 3381) steps/day. This class included 185 participants, 76 (41.1%) of whom were found to have greater than 3% weight loss. The absolute weight change was −2.1 (SD 3.4) kg. The relative weight change was −2.8% (SD 4.7%). These were the greatest negative values among all classes.

The *DOWN* class was characterized by a long-term decrease in step counts: the mean step count for 1 - 28 elapsed weeks was 8024 (SD 3952) steps/day; that after 29 elapsed weeks was 6287 (SD 3802) steps/day. This class included 355 participants, 75 (21.1%) of whom achieved greater than 3% weight loss. The preweight and postweight differences and weight loss were, respectively, −0.5 (SD 2.7) kg and −0.7% (SD 3.8%): the largest values among all classes.



The *UP/DOWN* class was characterized by a long-term increase and decrease in step counts: the mean step count for 1 - 28 elapsed weeks was 7347 (SD 3304) steps/day; after 29 elapsed weeks, it was 7763 (SD 3345) steps/day. This class included 193 participants whose mean step counts of 7541 (SD 3282) steps/day were higher than the overall mean step counts of 5822 (SD 3186) steps/day and the *FLAT* group's mean step counts of 5257 (SD 2829) steps/day.

The *FLAT* class was characterized by long-term stay-in step counts: the mean step count for 1 - 28 elapsed weeks was 5243 (SD 2828) steps/day; that after 29 elapsed weeks was 5270 (SD 2864) steps/day. This class, which included 2045 participants, had mean step counts of 5257 (SD 2829) steps/day, which were closest to the overall mean step counts of 5822 (SD 3186) steps/day.

Step Count Trajectory Effects on Weight Loss

Figure 4 presents the estimated odds ratios of each trajectory for 3% weight loss. Performing multivariable logistic regression analysis with 4 latent classes (*UP*, *DOWN*, *UP/DOWN*, and *FLAT*), we assessed effects on weight loss from *UP*, *DOWN*, and *UP/DOWN* compared with *FLAT* (reference). The adjusted odds ratios of *UP*, *DOWN*, and *UP/DOWN* were, respectively, 2.45 (95% CI 1.78 - 3.38), 0.92 (95% CI 0.69 - 1.22), and 1.12 (95% CI 0.79 - 1.59). Among these, a significant association was found only for the *UP* class. By contrast, no significant difference was found for any *DOWN* or *UP/DOWN* class relative to the *FLAT* class.

Figure 4. Forest plot of odds ratios of the respective trajectories for weight loss.

Sensitivity Analysis

The effects of those step trajectories on weight loss were estimated as odds ratios for 1006 Asmile users who were taking no medication. These adjusted odds ratios of *UP*, *DOWN*, and *UP/DOWN* were, respectively, 2.42 (95% CI 1.41 - 4.13), 1.07 (95% CI 0.71 - 1.63), and 1.30 (95% CI 0.77 - 2.19). Sensitivity analysis estimated the effects on weight loss for those who did not take medications. Results demonstrated that the effects of clusters of step counts on weight loss remained (Multimedia Appendix 4).

Discussion

Principal Results

This trajectory analysis of 2778 Asmile members linked to SHC confirmed the usefulness of classification into 4 latent classes of *UP*, *DOWN*, *UP/DOWN*, and *FLAT*, which respectively represented increased, decreased, increased/decreased, and unchanged step counts for 10 - 14 months. Logistic regression analysis with these 4 latent classes suggested an association of a long-term increase in step counts with achieving greater than 3% weight loss, whereas a decrease in step counts was not associated significantly with weight loss about 1 year later.

Results indicated that subgroups, as latent classes, exist within the long-term step trajectory (Figure 2). We also characterized those subgroups (Table 2). These subgroups were classified as 4 heterogeneities of *UP*, *DOWN*, *UP/DOWN*, and *FLAT*, respectively, defined as described above (Figure 3).

For *UP*, the highest weight loss and the lowest post-BMI were observed. In earlier studies, a correlation between physical activity and BMI was proposed. Particularly, Krumm et al [11] and Thompson et al [12] reported that women with levels of activity such as approximately 10,000 steps/day typically have a BMI of less than 25 kg/m^2. Dwyer et al [31] reported that, for people with low daily energy expenditure, such as <10,000 steps/day, increasing daily step counts contributes to the reduction of obesity. These results are cross-sectional analyses, particularly addressing average steps, but they reveal a negative correlation between the average steps and BMI. In contrast, our results are longitudinal analyses, particularly addressing long-term step changes. In addition, the *UP* results support their association because the increased step counts show the greatest weight loss over the long term. It is noteworthy that the results indicate long-term increased physical activity as one factor affecting weight loss.

For *DOWN*, we observed the lowest weight loss, along with higher post-BMI than *UP*. Wyatt et al [13] reported that people with a BMI greater than or equal to 30 kg/m² take 2400 steps/day fewer than those with a BMI of less than 25 kg/m². They report a negative correlation between the average steps and BMI in cross-sectional analyses, particularly addressing average steps. Additionally, for some patients with advanced cancer undergoing chemotherapy, Manz et al [32] reported that a 1000-step/day decrease is associated with a 16% higher risk of hospitalization or death. Their results revealed risks attributable to a decrease in daily steps. The *DOWN* results can support their finding of negative correlation because intermittent decreased step counts over a long term show higher post-BMI than *UP*. In fact, for almost identical average step counts reported for *UP* and *DOWN*, findings indicate that decreased physical activity over the long term might achieve only insufficient weight loss. Therefore, to reduce risks associated with the decrease in step counts, a person should strive to increase and maintain step counts over a long period.

For *UP/DOWN*, we observed higher mean step counts than for *FLAT*, indicating greater weight loss than for *FLAT*. In addition, even though the mean step counts for *UP/DOWN* were closer to those of *UP* and *DOWN*, they showed less weight loss than that achieved by *UP* and greater weight loss than that achieved by *DOWN*. This finding, which was not obtained from a simple

XSL•FO
RenderX

comparison of mean step counts, suggests that increased intensity of physical activity over the long term is strongly reflected in weight loss.

For *FLAT*, which included the most Asmile users, baseline characteristics including age, sex, mean step counts, and BMI were similar to those of the overall population. Because *FLAT* reflects the distribution of the overall population in this study, we used *FLAT* as a reference when estimating weight loss effects.

To estimate the odds ratios of step trajectories for greater than 3% weight loss, we performed logistic regression analysis using the 4 latent classes: *UP*, *DOWN*, *UP/DOWN*, and *FLAT*. Actually, *UP* showed a higher adjusted odds ratio of 2.45 when using *FLAT* as a reference, including significantly more cases of weight loss greater than 3%. The results estimated a significant effect of increased step counts, reflecting long-term fluctuations of weight loss, because explanatory variables classified long-term fluctuations into several step trajectories as a latent class with LCMM. It is noteworthy that the average amounts of physical activity were similar for *UP*, *DOWN*, and *UP/DOWN*, but the *UP* group, which reflected increased and maintained step counts over the long term, was more likely to achieve weight loss than either the *DOWN* or *UP/DOWN* class.

Furthermore, most earlier studies using step counts have compared mean step counts. They have not considered long-term fluctuations in step counts, particularly capturing a decrease or a pattern of increase and decrease. From this study, *DOWN* and *UP/DOWN* were found to have no significant weight loss for *FLAT* as a reference, with respective odds ratios of 0.92 and 1.12, which are close to 1. As a notable finding, results suggest that a sustained walking style was associated more strongly with achievement of significant weight loss because the odds ratio for the overall mean step count was 1.01 per 1000-step increase, suggesting a possible, though nonsignificant, association between daily step count and weight loss. However, a higher odds ratio was observed for *UP*, which reflects a long-term walking style (Multimedia Appendix 5). These findings suggest that long-term increase and maintenance of physical activity such as walking, rather than temporary increases in physical activity, more strongly affect weight loss. In turn, this will engender a reduction in the risk of developing diseases caused by obesity.

Comparison With Earlier Work

Several earlier studies have evaluated mHealth app effects on physical activity, but most have had limited sample sizes and comparisons of simple step counts. In their meta-analysis, Flores Mateo et al [33] and Islam et al [34] reported that interventions using the mHealth app showed greater weight loss than the control. However, no significant difference in physical activity was found. Moreover, an important limitation is that these physical activities were recorded and assessed using a questionnaire and self-reporting. The data were not recorded automatically. In a randomized controlled trial of a mobile app intervention during a longer-term 32 weeks, Yoshimura et al [35] recorded and assessed physical activities using a step-count-specific app during weight loss. The intervention group was also instructed to use the app to check their daily step counts and ranks. Particularly, they revealed effective step increases on weekends. Nevertheless, no effect on weight loss was observed. They suggested the need to develop specialized tools to enhance weight loss effects. Their study represents an excellent analysis of the long-term effects of physical activity using a step count-specific app, but it falls short as an evaluation of weight loss when considering long-term step changes.

Painter et al [36] reported self-monitoring, such as weight, step counts, and food, as significant predictors of weight loss during a 6-month intervention. Their analysis showed that the weight loss ≥10%, 5% - 10%, and <5% groups had 6-month mean step counts, respectively, of 8078, 6657, and 5277 steps/day. A significant difference was also found among those means of step counts. Their study simply compared mean step counts and weight loss, confirming their mutual relation. By contrast, our observational study revealed a relation between long-term step-count changes and weight loss. Mean step counts were nearly equivalent among the *UP*, *DOWN*, and *UP/DOWN* classes, but significant weight loss was observed only for *UP*. These results clarify the relation between step count and weight loss from different perspectives. Therefore, considering that the *UP* class, the group with increased step counts, is more likely to achieve weight loss, the results reported by Painter et al [36] are supported: groups with greater weight loss had higher mean step counts. The findings reported herein further suggest that walking style is important for achieving long-term weight loss and suggest that increasing and maintaining physical activity levels is crucially important.

Benefits of Increasing and Maintaining Step Counts Long-Term

Oyama et al [27] reported a causal effect of using Asmile on increased step counts by approximately 400 steps/day and approximately 10,000 steps during 4 weeks in a large observational study of 80,689 Asmile users in Osaka prefecture.

The benefits of increased step counts for aiding weight loss and reducing CVD risk have been reported. In a randomized controlled trial including young adults, Rogers et al [37] analyzed step count effects on postprandial metabolism and showed that CVD risk was reduced by 10,000 steps/day, which significantly reduced postprandial lipemia, an independent predictor of CVD, compared with 2000 steps/day activity. Therefore, considering the *UP* effects of weight loss found from our study, continuous health promotion in mHealth, including Asmile, supports improved health status and prevention of lifestyle-related diseases.

Limitations

This study has several strengths, such as its large sample size linked to continuous daily activity (long-term step counts) and health status (medical checkup for each year), the classification of individuals' heterogeneous step count trajectories into latent classes, and the odds ratio estimation as identifying effects of long-term step count trajectories on weight loss.

However, the study also has some limitations. First, we were able to track the medication use of Asmile users (ie, whether they reported taking medications for diabetes, hypertension, or dyslipidemia), but their actual hospital attendance was unknown.

XSL•FO
RenderX

These are fundamentally important unobserved confounders because they might influence physical activity and weight change. To address potential confounding by medication use, we conducted a sensitivity analysis including only participants who were not taking any medication. The results were consistent with those of the main analysis.

Second, the Asmile users' occupational characteristics are not considered. Changes in physical activities might occur because of occupational changes; for example, white-collar workers spend more time sitting than blue-collar workers during daily life [38]. Whereas step counts provided detailed information related to daily movement, participants with 1 or more weeks in which step count data were missing completely were excluded from the analysis. In the Asmile app, daily step counts for the last 42 days are transferred each time the user opens the app. Therefore, missing data generally occur because of participants' app usage behavior rather than because of random loss. For that reason, excluding these participants might introduce selection bias. Nevertheless, we regarded this approach as appropriate for a more conservative analysis because it allowed us to examine high-quality longitudinal step count data specifically and address an important knowledge gap related to the effects of physical activity over time on weight change.

Third, Asmile users are likely to be more health conscious than people who are not using the mHealth app, including Asmile. Therefore, caution must be exercised when roughly generalizing and interpreting the results of this analysis. Moreover, because the study population consisted mainly of active individuals with a BMI ≥25 kg/m² who participated in the app-based program voluntarily, the findings might not be generalizable to individuals with obesity or less-active populations.

In addition, dietary habits were not available in this dataset, although they are important determinants of weight loss and maintenance [39,40]. Many other factors, such as metabolic-related variables, general health conditions, and genetic predisposition, can also influence weight changes [41-43]. Comorbidities common in older adults, such as cancer, dementia, or other chronic conditions, were not available in the dataset, but they might also influence physical activity levels and weight change [44,45].

Finally, step count data capture the amount of movement but might not fully reflect the intensity or type of physical activity (eg, step-based measures might underestimate energy expenditure under certain stride frequencies or fail to encompass nonwalking activities such as cycling, running, or standing) [46-49]. Therefore, physical activity effects on weight might be underestimated in this study.

Maximizing ecological validity by linking and considering additional user characteristics, including dietary, metabolic, genetic, comorbidity, and physical activity intensity data, will be necessary for future studies.

Conclusions

This study revealed effects on weight loss of the trajectories of long-term step counts, as monitored using the "Asmile" mHealth app. Particularly, the long-term trajectory of increased step counts significantly affected 3% weight loss. These findings suggest that sustained engagement in physical activity might play an important role in long-term health management.

Acknowledgments

The authors are grateful to R Sasaki, Y Yamazaki, and all members of the National Health Insurance Division, Department of Public Health and Medical Affairs, Osaka Prefectural Government, for providing Asmile data. Generative artificial intelligence tools, including ChatGPT (OpenAI), were used to assist in improving the language and clarity of the manuscript under the supervision of the authors. All intellectual content and interpretations are the authors' own.

Funding

This work was partly supported by the Japan Society for the Promotion of Science (JSPS) KAKENHI grants (24K10918, 23K17228, and 22H05108) and by the Japan Science and Technology Agency (JST) ERATO grant (JPMJER2102).

Data Availability

Data cannot be shared publicly because local governments own medical checkup data. Data are available from the Health and Counseling Center, The University of Osaka (contact via campuslifekenkou-syomu@office.osaka-u.ac.jp) for researchers who meet the criteria for access to confidential data.

Abstract

Background: Problematic smartphone use among adolescents is a growing public health concern closely associated with psychological distress and loneliness. Effective, culturally grounded, school-based interventions are needed.

Objective: The aim of this study was to assess the effects of a 12-week program combining traditional social sports games and mental exercises on smartphone addiction, nomophobia, psychological distress, and loneliness in adolescents.

Methods: In this randomized controlled trial, 69 school-recruited Tunisian adolescents (aged 14-16 years) with clinically elevated smartphone addiction scores were assigned to an experimental group (n=36, 52.2%) or a control group (n=33, 47.8%). The experimental group received a 12-week intervention comprising 4 weekly sessions integrating traditional social sports games with mental exercises, whereas the control group continued standard physical education. Outcomes (smartphone addiction, nomophobia, psychological distress, and loneliness) were assessed at baseline and after the intervention using scales validated in Arabic.

Results: Linear mixed-effects models adjusted for age, sex, and BMI revealed significant group × time interactions of moderate magnitude across all outcomes (P<.05 in all cases) favoring the experimental group. Adjusted postintervention comparisons confirmed significantly lower scores in the experimental group for smartphone addiction, nomophobia, psychological distress, and loneliness (P<.05 in all cases; partial η_p^2=0.08 - 0.12). Mediation analysis indicated that reductions in loneliness accounted for 34.4% of the intervention's effect on smartphone addiction, consistent with partial mediation.

Conclusions: A culturally adapted, school-based intervention combining traditional social sports games and mental exercises significantly reduced problematic smartphone use and improved psychological well-being. The partial mediation through reduced loneliness highlights the critical role of social connectedness in adolescent digital health interventions.

Introduction

Adolescence constitutes a critical period of neurobiological, emotional, and social development marked by heightened sensitivity to reward processing, peer feedback, and affective stimuli. Ongoing maturation of prefrontal-limbic circuits during this stage increases impulsivity and emotional reactivity, rendering adolescents particularly vulnerable to maladaptive behavioral patterns in technology-saturated environments [1].

In Tunisia, these developmental vulnerabilities intersect with rapid digital expansion that has outpaced public health policy and digital literacy initiatives. As a result, smartphones have become central tools for managing academic demands, emotional regulation, and social relationships among adolescents [2-4]. While digital access offers clear benefits, excessive reliance on digital devices has contributed to the growing prevalence of problematic smartphone use (PSU).

PSU is characterized by compulsive, excessive smartphone engagement that results in functional impairment across academic, emotional, and social domains [5]. Among its core manifestations, nomophobia, the fear of being without one's smartphone, has emerged as a prominent indicator of psychological dependence and psychological distress [6,7]. Empirical evidence consistently links PSU and nomophobia to emotional dysregulation; reduced academic performance; and elevated symptoms of anxiety, depression, and stress [8].

Loneliness is a key psychosocial mechanism underlying PSU. Adolescents often engage in smartphone use to compensate for perceived social disconnection, yet digitally mediated interactions frequently fail to satisfy deeper relational needs. This mismatch can create a self-reinforcing cycle where increased smartphone use exacerbates loneliness, further driving compensatory digital engagement [9,10]. Therefore, interventions that disrupt this cycle by directly enhancing social connectedness are critical. Meta-analytic evidence indicates that physical activity (PA) interventions, particularly those that are group based and sustained (≥12 weeks), effectively reduce smartphone addiction [11], with loneliness established as a mediator of this effect [12,13]. This process aligns with self-determination theory (SDT) as socially engaging PA can satisfy core psychological needs such as relatedness, thereby reducing reliance on smartphones for compensatory fulfillment [14].

SDT further explicates this mechanism, positing that psychological well-being depends on the satisfaction of 3 basic psychological needs: autonomy, competence, and relatedness [15]. From this perspective, PSU may represent a maladaptive coping strategy that emerges when the need for relatedness remains unmet. Thus, loneliness functions both as an indicator of need frustration and as a mechanistic pathway sustaining compulsive smartphone use.

Building on this rationale, PA interventions, particularly structured, group-based programs, have demonstrated efficacy in reducing PSU and improving psychological well-being among adolescents [16,17]. There is further evidence suggesting that PA-based interventions are more effective when combined with psychological strategies such as mental skill training, which strengthens emotional regulation, stress tolerance, and self-regulation capacities [11].

Cultural adaptation represents a critical determinant of engagement and sustainability. In the Tunisian context, traditional social sports games (eg, seated ball game and dodgeball) constitute culturally resonant, rule-based PAs that promote face-to-face interaction, cooperation, and prosocial behavior. These activities foster peer bonding and shared enjoyment, directly targeting the SDT need for relatedness while counteracting the isolating effects of excessive screen use [18,19].

Despite this strong theoretical and empirical rationale, important gaps remain. Few controlled studies have evaluated multi-component, culturally grounded interventions that integrate structured PA with psychological skill development using a randomized controlled design in a school setting. Moreover, no study has empirically tested whether reductions in loneliness mediate the effects of such interventions on PSU despite the central role of relatedness within SDT.

To address these gaps, we developed and evaluated a 12-week school-based intervention integrating traditional social sports games with mental exercises (TSSG-ME) among Tunisian adolescents. We hypothesized that participants in the TSSG-ME group would demonstrate significantly greater reductions in smartphone addiction and psychological distress than a control group (CG). Grounded in SDT, we further hypothesized that reductions in loneliness would mediate the intervention's effect on smartphone addiction, reflecting enhanced satisfaction of the need for relatedness.

Methods

Study Design and Setting

This study was a 2-arm, parallel-group randomized controlled trial. The trial was retrospectively registered with the Pan African Clinical Trials Registry under the identification number PACTR202601838702413 on January 30, 2026. The registration was conducted retrospectively due to an administrative oversight during the initial recruitment phase as the research team prioritized data collection commencement following funding approval. This study was conducted between October 2024 and February 2025 across 3 public middle schools in the Sfax region of Tunisia during routine health screenings.

Participants

A total of 960 adolescents (aged 14-16 years) were initially recruited during routine health screenings across 3 public middle schools in the Sfax region. A total of 151 students with PSU were identified. The inclusion criteria were (1) meeting the clinical cutoff for smartphone addiction and (2) reporting structured PA not exceeding 3000 metabolic equivalent of task minutes per week as assessed using the Arabic-language International Physical Activity Questionnaire [20]. The exclusion criteria were (1) BMI below the 3rd or above the 97th percentile [21] and (2) habitual sleep duration outside the range of 6 to 10 hours per night [22]. This resulted in the exclusion

XSL•FO
RenderX

of 76 students (n=37, 48.7% due to excessive activity; n=39, 51.3% due to the BMI and sleep criteria).

Eligible participants (n=75) were randomly assigned to the experimental group (EG; n=36) or the CG (n=33) using stratified block randomization. Randomization was stratified by sex (male and female), with a combination of random block sizes of 4, 6, and 8 to ensure balanced allocation across groups throughout the recruitment period. The allocation sequence was obtained using computer-generated random numbers by an independent researcher who was not involved in participant recruitment, intervention delivery, or outcome assessment.

Allocation concealment was ensured using sequentially numbered opaque, sealed envelopes prepared by the independent researcher and opened only after completion of baseline assessments and confirmation of eligibility. Participants were enrolled by the lead author, and group assignment was implemented by a research assistant not involved in outcome assessment.

Due to the nature of the behavioral intervention, participants and intervention providers could not be blinded. However, outcome assessors and data analysts were blinded to group allocation throughout the trial.

During the trial, 8% (6/75) of the participants were excluded due to extended absences (>1 week), incomplete assessments, or newly emerging clinical conditions (EG: n=4; CG: n=2), resulting in a final analytic sample of 69 participants (EG: n=36, 52.2%; CG: n=33, 47.8%). The Little test was nonsignificant (χ^2_{18}=12.5; *P*=.82), supporting the assumption that data were missing completely at random. Given the low rate of missingness and the missing completely at random assumption, we conducted complete-case analyses without multiple imputation. Baseline comparisons confirmed equivalence between groups on all demographic and outcome variables (*P*>.05 in all cases). A detailed flowchart of participant screening, randomization, allocation, and follow-up is presented in Figure 1.

Intervention

Overview

Grounded in SDT, the intervention was designed to target basic psychological needs. The traditional social sports game component primarily addressed the need for relatedness through cooperative and socially structured play, whereas the mental exercise component targeted competence and autonomy through structured skill building and self-regulation practices. The intervention began within 1 week following randomization for both groups.

Experimental Group

The EG participated in a structured 12-week intervention consisting of four 60-minute sessions per week. Three sessions were conducted during regular school hours, and 1 extracurricular session was held on Friday afternoons [23]. Each session was divided into 2 core modules: traditional social sports games (45 minutes) and mental exercises (15 minutes). The sports module used 4 culturally embedded Tunisian games (seated ball game, dodgeball, sbeïla [a traditional chasing game], and korra teyara [a traditional target throwing game]) implemented with an emphasis on teamwork, communication, and strategic decision-making [18]. Game complexity increased over time: weeks 1 to 3 focused on rule acquisition and teamwork, whereas weeks 4 to 12 introduced dynamic variations and collaborative problem-solving strategies [24,25].

The mental exercise module followed a standardized 5-phase sequence to facilitate cognitive and physical recovery [26,27]. This sequence began with a 2-minute prerelaxation phase for session orientation followed by a 3-minute induction to calmness using diaphragmatic breathing and guided imagery. The main relaxation phase (5 minutes) incorporated Jacobson's progressive muscle relaxation, autogenic training, and mindfulness-based techniques. The session concluded with a 2-minute recovery period of light stretching and a 3-minute reflective closure involving verbal discussion or a short written reflection.

Control Group

The CG followed the standard, time-matched physical education curriculum mandated by the Tunisian Ministry of Education, consisting of 2 weekly sessions (one 2-hour and one 1-hour session) [23]. Sessions included conventional individual activities and team sports. The CG did not receive the novel social games or mental exercises, serving as a treatment-as-usual control. This design allowed for a pragmatic comparison with standard school practices but did not control for nonspecific intervention effects such as increased attention, novelty, or social interaction.

Instruction and Fidelity

Sessions were delivered by a team of 3 instructors, each with over 10 years of experience working with youth. The team comprised 2 physical education specialists with master's degrees in adapted physical activity and sport pedagogy and 1 certified mental preparation coach with a professional certificate in mental skill training for adolescents. To ensure treatment fidelity, all instructors received comprehensive training on the research protocol and adhered to a standardized intervention manual. For each session, participants were organized into 3 subgroups, enhancing peer interaction and enabling close instructor supervision. Attendance was monitored via session registers, with the EG maintaining an average attendance rate of 97.7% (SD 2.4%).

Data Collection

Procedures

The primary outcome of this study was smartphone addiction, measured using the SAS-SV. Secondary outcomes included nomophobia (Nomophobia Questionnaire; NMP-Q), psychological distress (Depression, Anxiety, and Stress Scale–21 [DASS-21] subscales), and loneliness (University of California, Los Angeles, Loneliness Scale). Trained assessors administered all instruments in Arabic during face-to-face sessions, with data collected electronically via Google Forms on digital tablets to minimize entry errors [28]. All assessments were conducted at 2 time points: baseline and immediately after the intervention.

XSL•FO
RenderX

Investigation Tools

Smartphone Addiction

Smartphone addiction was assessed using the SAS-SV, a self-report instrument designed to evaluate the severity of PSU and originally validated by Kwon et al [29]. The SAS-SV is a 10-item instrument rated on a 6-point scale (1="strongly disagree"; 6="strongly agree"), capturing dimensions such as daily life disturbance, withdrawal, cyberspace-oriented relationships, overuse, and tolerance. Sex-specific cutoff scores were used to classify participants as smartphone addicted (≥33 for girls and ≥31 for boys). Total scores range from 10 to 60, with higher scores indicating greater levels of PSU. An Arabic-adapted version of the SAS-SV**,** validated by Sfendla et al [30], was used to ensure linguistic and cultural appropriateness. In this sample, the scale demonstrated good internal consistency (Cronbach α=0.84).

Nomophobia

Nomophobia was assessed using the Arabic version of the NMP-Q, validated by Farchakh et al [31]. The 20-item instrument evaluates fear of being without a smartphone across four domains: (1) inability to communicate, (2) losing connectedness, (3) inability to access information, and (4) giving up convenience. Participants rated each item on a 7-point Likert scale (1="totally disagree"; 7="totally agree"). Total scores range from 20 to 140, with severity levels classified as absent (20), mild (21-59), moderate (60-99), and severe (100-140). The Arabic NMP-Q showed excellent internal consistency (Cronbach α=0.948) in this sample.

Depression, Anxiety, and Stress

Emotional distress was measured using the Arabic version of the DASS-21 validated by Ali et al [32]. The DASS-21 includes three 7-item subscales that independently measure depression, anxiety, and stress. Items are rated on a 4-point Likert scale (0="did not apply to me at all"; 3="applied to me very much/most of the time"). Severity was classified per subscale (eg, depression: 0‐9=normal; ≥28=extremely severe). The tool showed strong internal consistency for this age group (Cronbach α≥0.83).

Loneliness

Loneliness was assessed using the Arabic-adapted University of California, Los Angeles, Loneliness Scale–Short Form, validated by Alateeq et al [33]. This 8-item self-report tool evaluates perceived social isolation through statements such as "I don't have a friend." Responses are rated on a 4-point Likert scale (1="never"; 4="always"), with total scores ranging from 8 to 32. Higher scores indicate greater loneliness. Internal reliability was acceptable (Cronbach α=0.777), confirming suitability for adolescents in Tunisia.

Sample Size

An a priori power analysis was conducted using G*Power (version 3.1) [34] for a repeated-measure ANOVA with a within-between interaction. To detect a medium effect size (η_p^2=0.06, equivalent to *f*=0.25) for the primary group × time interaction, with α of .05 and 1 − β of 0.80, a total of 64 participants were required; the final sample comprised 69 adolescents. The choice of a medium effect size is consistent with prior intervention research on adolescent digital addiction and related school-based programs, which reports moderate intervention effects on problematic digital technology use outcomes [35].

Data Analysis

Data were analyzed using SPSS Statistics (version 28.0; IBM Corp). Baseline group differences were examined using independent 2-tailed *t* tests for continuous variables and chi-square tests for categorical variables. Primary intervention effects were evaluated using linear mixed-effects models, which included group, time, and the group × time interaction as fixed effects, with participants as a random effect. These models were adjusted for the covariates of age, sex, and BMI and tested for each outcome. Exploratory within-group pretest-posttest changes were assessed using paired *t* tests, and between-group differences at the posttest time point were examined using independent *t* tests. Analyses of covariance were conducted to compare adjusted postintervention outcomes between groups controlling for baseline scores as well as age, sex, and BMI. Effect sizes were calculated using η_p^2 and interpreted according to conventional benchmarks [36]. Mediation analyses were performed using bootstrapping procedures with 5000 resamples to estimate indirect effects and 95% CIs [37]. Statistical significance was set at an α value of .05 (2 tailed).

Ethical Considerations

This study received ethics approval from the local Committee for the Protection of Persons at the Faculty of Medicine of University of Sfax, Tunisia (approval 0554/2023). The research was conducted in full compliance with the ethical standards outlined in the Declaration of Helsinki (2013). Written informed consent was obtained from participants' legal guardians, and verbal assent was obtained from each adolescent prior to participation. All data, including smartphone use records, questionnaire responses, and behavioral observations, were anonymized. Any potentially identifiable information was stored separately on a password-protected server accessible only to the principal investigator. No financial or material compensation was provided to participants.

Results

Baseline Characteristics

A detailed flowchart of participant screening, randomization, allocation, and follow-up is presented in Figure 1. At baseline, no statistically significant differences were observed between the EG (n=36) and CG (n=33) across demographic, anthropometric, or psychological variables (Table 1). The groups were comparable in age, sex distribution, BMI, smartphone addiction, nomophobia, psychological distress (global and subscale scores), and loneliness (*P*>.05 in all cases). Effect size estimates were negligible, indicating satisfactory baseline equivalence prior to the intervention.

Primary Intervention Effects (Group × Time Interaction)

Linear mixed model analyses revealed statistically significant group × time interaction effects across all primary outcomes (Table 2), consistently favoring the EG. Interaction effects were of moderate magnitude, including smartphone addiction (η_p^2=0.12; *P*=.004), nomophobia (η_p^2=0.10; *P*=.007), and global psychological distress (η_p^2=0.10; *P*=.009). Similar moderate interaction effects were observed for depression (η_p^2=0.09), anxiety (η_p^2=0.08), stress (η_p^2=0.08), and loneliness (η_p^2=0.08), indicating a consistent intervention-related improvement across behavioral and psychosocial domains.

Table . Linear mixed model results for intervention effects (group × time interaction) adjusted for age, sex, and BMI[a].

Outcome	*F* test (*df*)	*P* value	η_p^2
SAS-SV[b]	8.9 (1, 67)	.004	0.12
NMP-Q[c]	7.8 (1, 67)	.007	0.10
DASS-21[d] global	7.3 (1, 67)	.009	0.10
DASS-21 subscales			
Depression	6.9 (1, 67)	.01	0.09
Anxiety	6.2 (1, 67)	.02	0.08
Stress	5.9 (1, 67)	.02	0.08
ULS-8[e]	5.5 (1, 67)	.02	0.08

[a]*F* statistic represents fixed group × time interaction effects from linear mixed models with random intercepts for participants. Models were adjusted for age, sex, and BMI. Effect size (η_p^2) benchmarks: 0.01=small; 0.06=moderate; 0.14=large.

Pretest-Posttest Changes and Between-Group Differences

Figure 2 illustrates the distribution of pre- and postintervention scores across outcome measures for the EG and CG. Visual inspection indicates clear reductions from before to after the intervention in the EG across smartphone addiction, nomophobia, loneliness, and psychological distress (global score and subscales), whereas score distributions in the CG remained largely stable over time. Exploratory within-group comparisons showed statistically significant pretest-posttest reductions in the EG across all outcomes (*P*<.05 in all cases), whereas no significant changes were observed in the CG (*P*>.05 in all cases). Between-group comparisons at the posttest time point favored the EG across all measures (*P*≤.02).

XSL•FO
RenderX

Figure 2. Effects of the 12-week intervention on smartphone addiction and psychological outcomes. Data are presented for (A) smartphone addiction (Smartphone Addiction Scale–Short Version; SAS-SV), (B) nomophobia (Nomophobia Questionnaire; NMP-Q), (C) loneliness (University of California, Los Angeles, Loneliness Scale; ULS-8), and (D) psychological distress (Depression, Anxiety, and Stress Scale–21; DASS-21) across the experimental and control groups. Violin plots show score distributions; yellow circles indicate means, and black bars indicate means and SDs. Whiskers represent the 1st to 99th percentiles. *Significant within-group change (paired *t* test) at *P*<.05. $Significant between-group difference at the posttest time point (independent *t* test) at *P*<.05.

Adjusted Postintervention Outcomes

After controlling for baseline scores, analyses of covariance confirmed significant postintervention group differences across all outcomes (Table 3). The EG demonstrated significantly lower adjusted posttest scores than the CG for smartphone addiction (η_p^2=0.12; *P*=.004), nomophobia (η_p^2=0.11; *P*=.006), global psychological distress (η_p^2=0.12; *P*=.005), depression (η_p^2=0.10; *P*=.008), anxiety (η_p^2=0.09; *P*=.01), stress (η_p^2=0.09; *P*=.02), and loneliness (η_p^2=0.09; *P*=.01). All effects were in the moderate range, supporting the robustness of the intervention after adjustment for baseline variability.

XSL•FO
RenderX

Table . Analysis of covariance (ANCOVA) results for posttest scores adjusted for baseline scores, age, sex, and BMI[a].

Outcome	EG[b], adjusted mean (SE)	CG[c], adjusted mean (SE)	*F* test (*df*)	*P* value	η_p^2
SAS-SV[d]	34.6 (0.5)	37.8 (0.5)	9.1 (1, 66)	.004	0.12
NMP-Q[e]	95.2 (1.6)	101.7 (1.7)	8.2 (1, 66)	.006	0.11
DASS-21[f] global	58.1 (1.7)	66.4 (1.8)	8.7 (1, 66)	.005	0.12

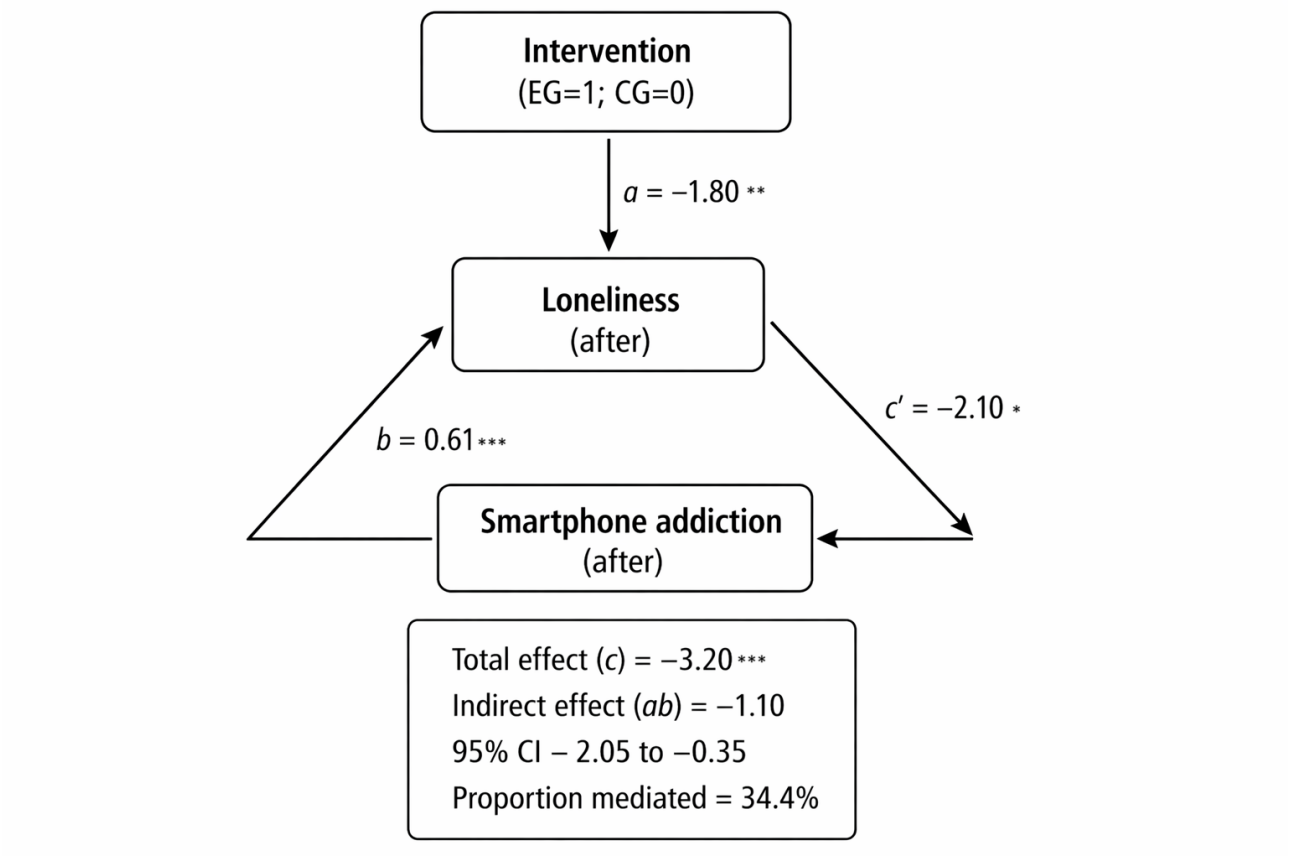
Mediation by Loneliness Reduction

Mediation analysis showed that reductions in loneliness partially mediated the effect of the intervention on postintervention smartphone addiction (Table 4 and Figure 3). The indirect effect was statistically significant (*ab*=−1.10, 95% CI −2.05 to −0.35), accounting for 34.4% of the total effect. The intervention significantly reduced loneliness (*a*=−1.80; *P*=.002), and higher loneliness was associated with greater smartphone addiction (*b*=0.61; *P*<.001). The direct effect of the intervention remained significant after accounting for loneliness, indicating partial mediation. No adverse events or unintended effects were reported in either group during the trial period.

Table . Simple mediation analysis (PROCESS Model 4) adjusted for baseline scores, age, sex, and BMI[a].

Path and effect	Unstandardized coefficient (SE; 95% CI)	*t* test (*df*)	*P* value
Total effect (*c*)			
[b]Effect of group on SAS-SV[b] (after)	−3.20 (0.85; −4.89 to −1.51)	−3.76 (67)	<.001
Direct effect (*c′*)			
Effect of group on SAS-SV (after)	−2.10 (0.90; −3.89 to −0.31)	−2.33 (66)	.02
Indirect effect (combined; *ab*)	−1.10 (0.45; −2.05 to −0.35)	—[c]	—
Indirect effect (path specific)			
Effect of group on loneliness (*a*)	−1.80 (0.55; −2.88 to –0.72)	−3.27 (67)	.002
Effect of loneliness on SAS-SV (*b*)	0.61 (0.11; 0.39 to 0.83)	5.55 (66)	<.001



[a]Indirect effect 95% CIs were derived from 5000 bootstrap samples. The model was adjusted for age, sex, BMI, and baseline scores (Smartphone Addiction Scale–Short Version and University of California, Los Angeles, Loneliness Scale). Path *a*=intervention→loneliness; path *b*=loneliness→Smartphone Addiction Scale–Short Version. The proportion mediated was 34.4%.

[b]SAS-SV: Smartphone Addiction Scale–Short Version.

[c]Not applicable. The indirect effect (ab) is estimated using bootstrap procedures and therefore does not have a corresponding *t* value, df, or *P* value.

Figure 3. Loneliness (University of California, Los Angeles, Loneliness Scale) as a mediator of the intervention effect on smartphone addiction (Smartphone Addiction Scale–Short Version; SAS-SV)—simple mediation model (PROCESS Model 4) with 5000 bootstrap samples. The model was adjusted for age, sex, BMI, and baseline scores. The values shown are unstandardized coefficients. Path *a*=intervention→loneliness; path *b*=loneliness→SAS-SV. The indirect effect was significant (95% CI did not include 0), with 34.4% of the total effect mediated by loneliness. **P*<.05; ***P*<.01; ****P*<.001; CG: control group; EG: experimental group.

Discussion

Summary of Main Findings

This randomized controlled trial evaluated a 12-week, school-based intervention integrating traditional social sports games with mental exercises for Tunisian adolescents with elevated smartphone addiction. Linear mixed model analyses revealed significant group × time interaction effects of moderate magnitude (η_p^2=0.08-0.12), consistently favoring the EG over the CG. Participants receiving the TSSG-ME intervention demonstrated statistically significantly greater reductions in smartphone addiction, nomophobia, psychological distress (global and subscale scores), and loneliness. After adjusting for baseline scores, between-group differences at the posttest time point remained significant with moderate effect sizes. Furthermore, mediation analysis indicated that reductions in loneliness accounted for approximately 34.4% of the intervention's total effect on smartphone addiction, supporting a partial mediation model.

Interpretation and Comparison With the Literature

Reductions in smartphone addiction were among the most robust outcomes. These findings are consistent with those of prior studies showing that structured physical engagement and psychological support can reduce behavioral dependence on mobile technologies [38]. This aligns with meta-analytic findings that combined interventions integrating PA with psychological skill building produce more consistent reductions in smartphone addiction than single-component approaches [11,14]. This study contributes by demonstrating the efficacy of a culturally grounded program in a Tunisian context.

The term "traditional social sports games" denotes structured, rule-based PAs with inherent social organization and deep cultural resonance, distinguishing them from generic physical exercise [18,19]. The mental exercise component refers to a standardized protocol of evidence-based techniques adapted from sports psychology designed to build self-regulation and stress tolerance beyond simple relaxation [26,27]. The observed moderate effect sizes were clinically meaningful and consistent with those reported in other behavioral intervention trials targeting PSU [39]. They reflect a realistic and attainable impact, particularly given that our sample comprised adolescents with clinically elevated baseline symptoms who may have had greater room for improvement.

The reduction in nomophobia underscores the intervention's potential to alleviate the anxiety associated with smartphone separation. By fostering rewarding, in-person social experiences and peer validation, the traditional games likely diminished the perceived indispensability of constant digital connectivity [6]. Concurrently, the mental exercise component equipped participants with concrete skills for managing emotional arousal,

XSL•FO
RenderX

offering a healthier alternative to digital coping mechanisms [40].

Critically, our findings provide empirical support for the psychological mechanism proposed by SDT [15]. Reductions in loneliness mediated 34.4% of the intervention's total effect on smartphone addiction, highlighting a key pathway. This suggests that the TSSG-ME program enhanced the basic psychological need for relatedness through prosocial, face-to-face interaction in traditional games, reducing perceived social isolation. Consequently, adolescents' compensatory reliance on smartphones for social fulfillment likely decreased, alleviating addiction symptoms. This mechanism aligns with research identifying loneliness as a critical link between unmet social needs and PSU [41,42] and supports evidence that loneliness mediates the relationship between health-promoting behaviors and reduced maladaptive digital use [13,43]. Using culturally embedded games to foster relatedness also aligns with literature emphasizing their effectiveness in promoting sociability [44]. A key limitation is that mediation was tested with concurrent postintervention measures; temporal precedence cannot be fully established, so causal interpretation should be made cautiously.

The dual-component design posits complementary pathways: the traditional social sports games primarily targeted relatedness through social engagement and shared PA, whereas the mental exercise component targeted competence and autonomy through enhanced self-regulation [45]. Their integration likely addressed the multifaceted social-motivational and emotional-cognitive vulnerabilities underpinning smartphone addiction more comprehensively than either component alone [46]. Future research using factorial designs is necessary to disentangle their independent and synergistic contributions.

Limitations

Several limitations should be acknowledged. First, the study relied on self-reported measures, which may be subject to response bias; future research should incorporate objective metrics such as device-based screen time tracking. Second, the culturally specific sample, while emphasizing the importance of contextual adaptation, may limit the generalizability of the findings to broader populations. Third, the absence of long-term follow-up assessments precludes conclusions regarding the sustainability of the intervention effects. Fourth, the use of a passive CG (standard physical education) rather than an active, time-matched comparator (eg, generic group sports or relaxation program) restricts the ability to attribute observed outcomes specifically to the traditional social games and mental training components as opposed to nonspecific factors such as increased social engagement or novelty. Finally, although effect sizes were statistically significant and clinically meaningful, they were moderate, highlighting the complex, multifactorial nature of PSU and suggesting the need for further optimization of the intervention.

Conclusions

This study provides evidence that a culturally adapted, school-based intervention combining traditional social sports games and mental training can yield significant, moderate improvements in smartphone addiction, nomophobia, psychological distress, and loneliness among adolescents. The mediation of the treatment effect through reduced loneliness highlights the importance of enhancing real-world social connectedness, supporting a key mechanism derived from SDT. By providing alternative, healthier avenues for satisfying psychological needs for relatedness and competence, programs such as TSSG-ME may reduce reliance on maladaptive smartphone use.

Beyond individual outcomes, these findings suggest that integrating culturally relevant social activities into school-based programs may serve as a scalable strategy to support adolescent mental health in increasingly digital contexts. Policymakers and educators could leverage such approaches to mitigate the negative consequences of excessive smartphone use. Future research should use longitudinal designs, active CGs, and diverse populations to confirm causal pathways and assess long-term efficacy. However, given that mediation was examined cross-sectionally, causal interpretations should be made cautiously.

Editorial Notice

This randomized study was retrospectively registered. The authors noted that the registration was conducted retrospectively due to an administrative oversight during the initial phase of the study, although the protocol was approved by the Committee for the Protection of Persons prior to participant recruitment. The editor granted an exception from International Committee of Medical Journal Editors rules mandating prospective registration of randomized trials because the risk of bias appeared low and the study information registered with the authors' ethics committee matched the trial reporting. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness as retrospective registration does not prevent authors from changing their outcome measures retrospectively.

Abstract

Background: As digital health solutions gain traction, there is an urgent need for effective, person-centered stress management tools for employees. Advances in wearable stress monitoring and machine learning now enable the collection of high-resolution, real-time data and the delivery of personalized interventions with respect to both timing and content. Despite this technological progress, there remains a notable paucity of mobile health (mHealth) interventions that capitalize on these capabilities to implement just-in-time adaptive interventions (JITAIs).

Objective: This pilot study aimed to examine the preliminary effects of the RELAX mHealth app, which uses a JITAI framework to reduce occupational stress, with a particular focus on initial indications of stress reduction, the influence of the app's degree of personalization on these effects, and overall user experience.

Methods: A 2-arm randomized trial was conducted with 46 employees across two phases of 3 weeks each. Participants used the RELAX mHealth app, which adapts intervention timing based on real-time stress data and tailors content according to users' preferences. Stress was assessed via multiple heart rate variability (HRV) parameters measured with wearable sensors, alongside subjective questionnaires and ecological momentary assessment (EMA) questionnaires. Usability and user satisfaction were also evaluated. In the second phase, a group randomization was implemented, with two groups of different degrees of in-app personalization.

Results: The findings were mixed. While selected subjective stress indicators decreased from baseline to the end of the study, one physiological measure increased. Retrospective chronic stress (P=.048) and arousal related to the most recent stress event prior to EMA entry (P=.02) were reduced; however, the low frequency (LF)-to-high frequency (HF) ratio of HRV increased (P=.03). Other stress variables, such as work-related stress, valence of daily experiences, and momentary arousal, showed no change over the course of the study. No between-group differences were observed with respect to the assigned degree of personalization. Additionally, usability increased (P<.001), whereas satisfaction decreased at a trend level (P=.05).

Conclusions: Although the results provide selective preliminary indications of stress reduction with app use, the variability of outcomes raises concerns about its current practical utility. The effects are also discussed with regard to the specific design of the prototype and the study setup. Technical issues and user discomfort were noted despite increasing usability over the study period, indicating areas for improvement in the developed prototype. Given the absence of a control group and the use of interventional arms only, no definitive conclusions about effects can be drawn. Nevertheless, this study highlights both the potential and the challenges of a personalized mHealth approach to occupational stress management. Further refinement of the app and more comprehensive evaluations are needed to fully understand the impact and functional usability of this JITAI-based approach in real-world settings.

Introduction

Mobile Health and Individual Occupational Stress

Digital health solutions, including mobile health (mHealth), hold considerable promise as a means of delivering cost-effective, low-threshold interventions to individuals via their personal smartphones [1]. This form of health care has experienced substantial growth in recent years [2], and digital solutions have the potential to deliver effective stress management, particularly for employees [3]. The habitual use of smartphones during working hours [4] presents a significant opportunity for mHealth apps to be used in close proximity to stress-inducing factors, both in terms of temporal and local proximity. However, the precise conditions of occupational stress of the individual employee can vary considerably [5], thus hindering approaches that follow a one-size-fits-all concept. If not fully addressed, individual stress can have a detrimental effect on health and well-being over time [6]. Depending on the individual situation, the consequences range from loss of performance and mental and physical issues [7-9] to economic consequences for the company [10]. It can be concluded that there is a significant need for interventions that optimally address the individual circumstances of employees to prevent the adverse consequences.

Numerous mHealth approaches for occupational stress have been developed across both the unevaluated commercial sector and those with scientifically proven effectiveness [11-13]. The one-size-fits-all approach is predominantly adopted, with a single or limited number of interventions from cognitive behavioral therapy (CBT) being offered in the form of a smartphone app [11-13]. These apps include specific interventions, such as relaxation techniques, psychoeducation, and cognitive methods, with the objective of providing users with generalized low-threshold support in managing occupational stress. The suitability of these apps for specific stress situations is determined by the user, as these apps operate in a passive manner. This highlights the limitations of such apps in providing any depth and personalized approach of traditional psychological counseling or therapy by a qualified professional. The incorporation of individual needs and situational factors, recognized as essential elements in the efficacy of psychological interventions [14], is a crucial aspect that remains beyond the capabilities of these apps.

Just-in-Time Adaptive Intervention Concept in mHealth

Technical advances in mHealth can replicate traditional face-to-face counseling if they adhere to the just-in-time adaptive intervention (JITAI) concept. JITAI refers to interventions that are delivered at opportune moments and adapt their content to the needs and conditions of the user at those moments [15]. Such an approach requires continuous transmission of real-time personal data to best adapt to prevailing circumstances [16]. This rapidly generates a substantial volume of data, necessitating the incorporation of advanced artificial intelligence (AI) techniques [17]. Algorithms and learning agents, operating discreetly in the background of the app, process the incoming data to ensure optimal personalization [18]. Therefore, the advanced capabilities of mobile devices and the promising concept of JITAIs are mutually beneficial. This approach could multiply personalization by leveraging smartphone technology to provide constant support, potentially surpassing the limitations of conventional, practitioner-based meetings.

In the context of occupational stress, JITAIs have been regarded as a particularly promising medium for providing personalized stress management assistance via smartphones, irrespective of the presence of stress during the workday [19,20]. Design methodologies incorporating personal demographic data to customize the frequency of app interventions are already in practice [21,22]. Nonetheless, these methodologies signify a rudimentary approach to the potential personalization of mobile app use. The development of advanced diagnostic methods for personal stress, such as additional self-report tools and passive sensors, has the potential to enable the app to better understand users' needs and to adapt in real time for JITAI foundations [23,24]. The use of this multimodal approach in the context of occupational stress is already underway [11,23]. The use of "wearables" is particularly advantageous in this context, as they can be worn during work and thus provide a continuous input of personal stress data for the app without needing much attention [25]. In this respect, heart rate variability (HRV) [26,27] is the stress parameter that is most commonly used and validated.

Recent Developments and Research

Developments of JITAIs for mHealth are in their infancy, primarily due to the current lack of practical implementations. In general stress management, unobtrusive wearables and app interventions can be effectively combined [28,29], with a few personalized work-stress mHealth offerings identified [23,30]. These approaches often target physical rather than mental stress [31], and most methods limit themselves to monitoring without integrating the data into interventions [24]. This results in the development of personalized apps, but not personalized interventions, thereby not aligning with the JITAI concept. Furthermore, current approaches use either the app or the wearable for measurements and interventions, exhibiting a lack of comprehensive, dynamic integration of multimodal measurement options and data for personalized interventions [23]. mHealth biofeedback apps enable interactive, tailored strategies for occupational stress by integrating real-time sensor data [32]. They provide immediate stress feedback, and when combined with breathing exercises, users can modulate heart rate (HR) through guided breathing, influencing physiological stress [19,33,34]. This interaction supports personalized data analysis and adaptive mHealth interventions. Nevertheless, the time-dependent parameter of the adaptive concept is absent in this instance, thus preventing full compliance with the JITAI concept, leaving users to manage the task of applying the interventions at the optimal time. Moreover, the selection of a singular intervention method restricts the capacity to thoroughly address the user's unique stress circumstances and individual needs.

While there is one approach that integrates several additional CBT interventions alongside biofeedback for workplace stress,

XSL•FO
RenderX

it does not leverage sensor data [19], indicating that the full benefits of ongoing stress monitoring are not fully used. At present, the application to personalize interventions using individual sensor data to tailor the full spectrum of possible interventional conditions, such as content, modules, and presentation timing of the intervention, in line with the JITAI framework, is primarily only conceptualized as such [35,36]. To the best of our knowledge, only one study has formally implemented the concept of automatically selecting CBT interventions based on prior stress indicators measured with a wearable device [37], thereby aligning with the criteria established by JITAI. However, further personalization through long-term learning of individual user preferences, a potential of learning agents, has not been addressed here.

RELAX Prototype and Research Hypotheses

A prototype based on the JITAI concept was developed and extended with a learning agent to enable longer-term adaptation of interventions within the RELAX project. The prototype is equipped with a smartphone app that gathers both direct and indirect subjective stress data. Concurrently, a wearable wristband sensor is combined to monitor cardiovascular stress indicators. The information gathered from the sensor provides objective measurements of stress levels via HRV. The AI, trained on both personal and stress-related datasets, is responsible for determining the optimal timing for app-based interventions tailored to each user. Additionally, it selects the most appropriate intervention by content for the user at that specific moment, ensuring a personalized approach to stress management. This personalized selection of interventions was preceded by an intensive training phase in which users should evaluate guided access interventions from a pool of a plethora of interventions and thus express their needs and preferences to the AI. At the evaluation time, the training phase was ongoing, but the prototype had achieved the basic JITAI criteria: interventions were triggered by real-time stress, and content could be adaptively selected. More information of the architecture of the app and the personalization process of interventions is described in the study protocol of this study [38].

This study is an analysis of the prototype's developmental status. It was conducted as a pilot study to test the potential for stress reduction through the app and its feasibility in the everyday work situations of employees. The following research hypotheses were formulated for this purpose:

- Hypothesis 1: A decrease in stress levels in comparison to the participant's baseline can be observed following the initiation of app use. It is expected that the developed prototype will join the existing effective mHealth applications for stress management. With its structured interventions and diagnostic wearable, it combines proven features [23] and extends them with a JITAI component. The JITAI approach is anticipated to further influence stress by delivering more targeted interventions than prior methods.
- Hypothesis 2: A greater degree of personalization of the app is associated with a greater observed reduction in stress. The benefits of personalization have already been described in previous research on stress management solutions [39], as well as on digital health solutions in general [40], or on behavior change apps in general [41]. Personalization, as the core of the JITAI concept, can have different degrees, thereby giving rise to the question of which nuances are decisive for effectiveness gains. There is evidence of a consistent positive correlation between the degree of personalization and the desired effect [42,43]. However, the exact influence of different forms of personalization is still largely unknown [44].

In addition to the two hypotheses on preliminary app effects, this study assesses the usability of the system. User experience is crucial for mHealth effectiveness [45]. App efficacy hinges on users' willingness to use it as intended. User concerns, particularly in the domain of health monitoring, encompass a range of issues, including data protection [46], digital stress [47], accessibility, and user control [48]. Prior mHealth work has shown mixed usability: some reported satisfaction [37] and continued use [49], while others faced technical challenges that impaired the user experience [19]. Given these concerns, the study addresses usability and includes supplementary analyses for a broader understanding.

Methods

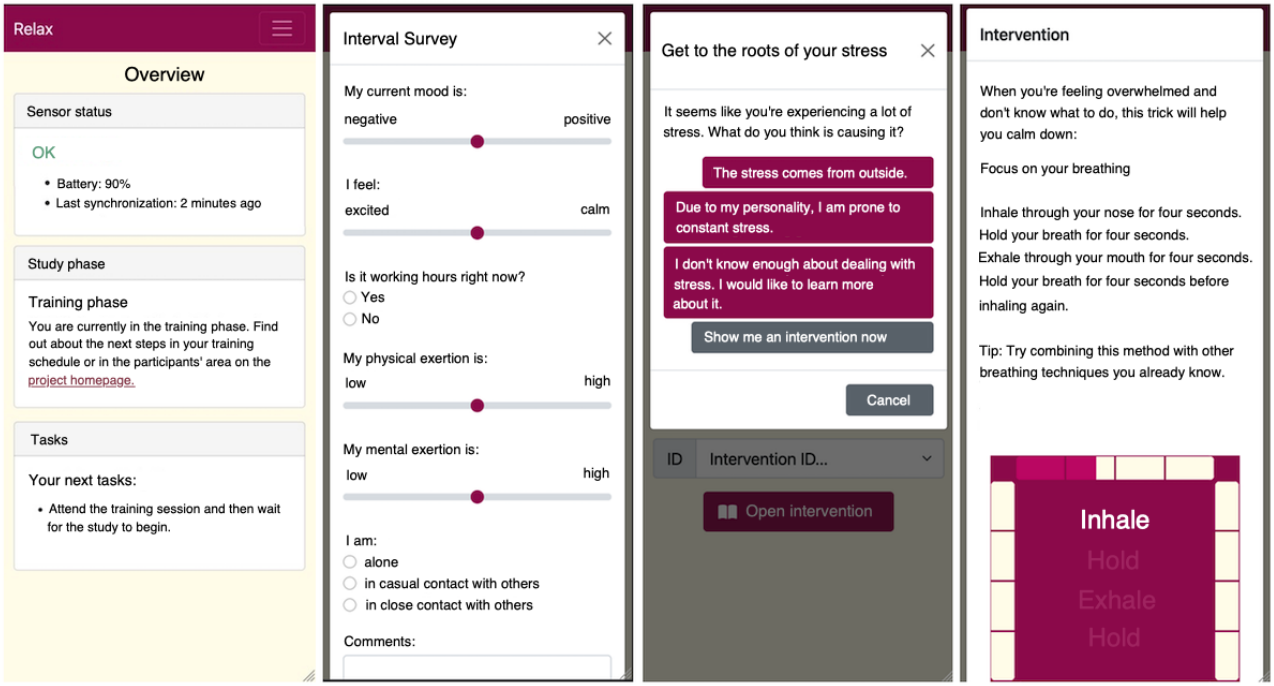
Study Design

The design of this study is described in detail in the corresponding study protocol [38]. The experimental design entailed a 2-arm trial comprising two randomly assigned experimental groups. Participants were required to use the RELAX project app in their naturalistic working environment. The study comprised two phases of 3 weeks each (phase 1 and phase 2). In phase 2, participants were randomly assigned to two distinct levels of personalization of the app (*high* vs *low*). Time series or continuous measurements were obtained via the app and the sensor in the study phases as well as in study-related surveys before the study (T1), between the study phases (T2), and after the study (T3). During the study phases, the participants had access to personalized interventions in the app.

Recruitment was carried out as described in a study by Kunas et al [38]. The ad hoc sample was recruited through previously committed companies and by social media and public flyers. Employees who met the inclusion criteria were given access to the study infrastructure. Adherence during the study was supported by regular reminders via email, the study website, and messages on the app dashboard. Randomization to the experimental groups from phase 2 onward was blinded, as was the evaluation. The allocation of participants and the evaluation process were conducted by different parts of the study team. The participants were randomly assigned to the groups using a pseudo-random function implemented with the NumPy package in the Python programming language. Following the conclusion of the study, participants were given access to the alternative version of personalization.

Ethical Considerations

The study was ethically approved (EK-GZ 25/2023) and preregistered prior to data analysis [50]. Registration was



XSL•FO
RenderX

completed after data collection because modifications to the study design and the prototype were anticipated as the study progressed. The final protocol provides a detailed account of the study design and the prototype architecture and documents all changes, including, for example, the app update implemented in the second week to resolve technical issues identified during the first week. Participants gave their informed consent and were informed that they could opt out of participation at any time without facing any negative consequences. Their consent covered data analyses, especially after anonymization, including secondary analyses. The collected data were pseudonymized with a code for the duration of the study for the purpose of facilitating the identification of the individual participant in the event of technical issues and for the purpose of determining the compensation. Following the completion of the study, all data were anonymized. Upon completion of the study, participants were remunerated with a financial incentive of €80 (US $93.7). Additionally, they were permitted to retain the study sensor at their discretion.

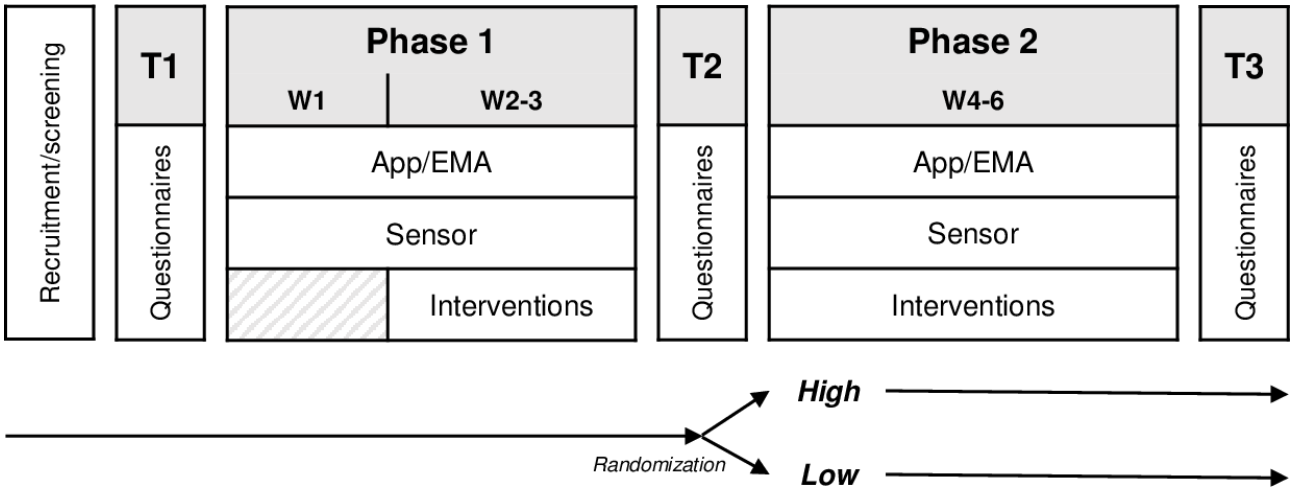
Intervention

The intervention involved the use of the RELAX app in conjunction with the associated sensor. Further details of the app are described in the study protocol [38]. Figure 1 illustrates the user interface of the app in the English translation; the German original of the screen texts is available in the online supplementary materials in Multimedia Appendix 1.

Figure 1. User interface of the RELAX app in English translation, from left to right: dashboard, ecological momentary assessment questionnaire, first level of decision tree, and guided breathing intervention.

Participants were able to select the self-report questionnaires via the app. The questionnaires had to be completed on a daily basis in the morning and evening in both study phases, as well as several times during the day. The data from the questionnaires served as a measurement tool for the outcomes of the study and as input for the learning agent in the background of the app. In instances where the learning agent identified elevated levels of stress, automated access to a decision tree was initiated, culminating in the provision of suitable microinterventions. In the context of the physiological stress event, personalized current threshold value was calculated for the user (top 25% of values for the quotient of low frequency (LF) vs high frequency (HF), but at least 1.2; bottom 25% of values for the square root of squared mean value of the sum of the differences of successive R-R intervals, but maximum 50 ms; see [38] for detailed description of how the learning agent operated). In the event that both values exceeded or fell below the threshold values in two consecutive 5-minute windows, a stress event was annotated. The subjective triggers remained unaffected by personalization, and the threshold was on the valence scales only, with the mood being ≤3 on the Likert scale (1=negative and 7=positive).

For each branch of the decision tree, the app could recommend several microinterventions from a pool of 179 possible microinterventions for stress reduction. As described in the study protocol [38], the areas of microinterventions included several subareas of CBT, such as psychoeducation, training, or relaxation, which varied in the presentation format. Preset weightings indicated a probability of which microintervention would be triggered in an individual case (see [38] for the distribution of initial weightings). These weightings could be influenced by the user giving feedback ratings after completing the microintervention, which allowed the overall app experience to be personalized over the period of use.



In phase 2, the versions of the app in both experimental groups differed in terms of the extent to which feedback ratings for the microinterventions received were incorporated. The version with *high* personalization modified the weighting of the probabilities for the occurrence of the individual

XSL•FO
RenderX

microintervention according to the individual ratings. In contrast, the version with *low* personalization was influenced by the aggregate ratings of the entire group of participants, indicating that no personalization per se was facilitated by the individual user. In phase 1, all participants received the same form of personalization according to the *low* group.

The sensor used in this study was the Polar Verity Sense, a wristband that uses photoplethysmography to measure various HRV parameters. Participants were required to wear the sensor continuously throughout the two study phases, with the exception of a 1-hour break each day. The passive nature of the recording process needed minimal involvement on the part of the participants, who were only required to ensure that the sensor was correctly connected to the app. The sequence of events in the study is presented in Figure 2, with the six study weeks abbreviated as W1-6.

Figure 2. Timeline of the study. EMA: ecological momentary assessment.

Outcomes

The demographic data were collected at the stage of screening for recruitment prior to the initiation of the study. The main outcomes evaluated in this study are derived from the primary outcomes of the corresponding study protocol (see Kunas et al [38] for measurement times and instruments). The collection of outcome data was facilitated by the use of standardized questionnaires and items developed by the study group via the app and online surveys for subjective data and the sensor for physiological data.

First, stress was measured in chronic form using the items of the daily ecological momentary assessment (EMA), which was created by the study team, as well as in work-related form using the standardized Valencia Eustress-Distress Appraisal Scale (VEDAS) [51] before the start of the study, between the study phases, and after the end of the study. A distinction was made between work-related distress and eustress. Stress was also measured using HRV parameters. These included the SD of R-R intervals, square root of squared mean value of the sum of the differences of successive R-R intervals, and LF/HF, which were measured continuously via the sensor. Further subjective variables encompassed the emotional states of arousal and valence, recorded at the time of entry and regarding the most recent stress event via EMA. Finally, satisfaction with the user experience and the usability of the system were measured using the standardized self-assessment Customer Satisfaction Score [52] and the System Usability Scale [53].

Statistical Analysis

The data were preprocessed according to the study protocol [38], including generating weekly data for the time series stress data. Datasets with more than 75% missing values were excluded from the analysis, and the procedure was therefore stricter than initially anticipated [38]. To measure the effect of the intervention on stress reduction, pre-post analyses were conducted in a within-subject design with the stress-related and emotional outcomes. Usability and satisfaction were compared separately between T2 and T3. For the between-subject analysis, the *high* versus *low* groups were included in all analyses. The System Usability Scale scores were converted to the standard 0 to 100 scale.

Corresponding linear mixed models (LMMs) were calculated for the analyses, with measurement times and groups as fixed factors and stress levels and usability variables, as measured by the different instruments or indicators, as dependent variables. Post hoc tests with Bonferroni correction were included for the detailed differentiation between measurement times. An α of .05 was used as the significance level, and partial eta-squared (η^2_p) indicated the effect size for the LMMs. To control for the false discovery rate, the Benjamini-Hochberg correction was applied. Only the adjusted *P* values are reported.

Results

Sample Characteristics

A total of 46 employees participated in the study after four people dropped out in the first 2 weeks of the study. The sample size exceeded the target of 31 participants, as determined by the a priori power analysis for feasibility estimation [38]. The sample consisted of 25 women (54%), 20 men (44%), and 1 diverse person (2%), with an average age of 40 (SD 9.71, range 24-62) years. The majority of the participants were Austrians (n=36, 78%), and the rest were Germans (n=10, 22%). In terms of occupation, the service sector was most strongly represented

XSL•FO
RenderX

in the sample with 17 employees (37%), followed by society, sport, or cultural sectors with 8 employees (17%) and the industrial sector with 6 employees (13%). In terms of educational level, the majority of respondents (n=20, 44%) had a postgraduate degree, followed by a university degree (20%) and a high school degree with 9 people each (20%).

On average, participants received 10.24 interventions (SD 7.41). There was no difference in the number of interventions in phase 2 between the groups ($t_{44}=-1.24$; $P=.22$). The sample sizes of the individual LMM analyses varied due to missing values, a consequence of the quality criterion on the collected data. This resulted in sample sizes ranging from 22 to 46 in the analyses. The proportion of data from the subjective questionnaires relative to the total possible data varied, on average, between 85% and 100%, depending on the study phase and parameters, and between 45% and 60% for the sensor data. Figure 3 shows the study's flow diagram, and Table 1 displays the means and SDs of the analyzed outcomes, arranged by time point or study group.

Stress Reduction (H_1)

The overall picture reveals only isolated significant results. There was a decrease in daily chronic stress over the course of the study ($F_{5,165}$=2.89; P=.048; η^2_p=0.081). Post hoc analyses revealed no significant differences between weeks; however, there was a tendency between W1 and W5 (P=.06). Furthermore, there was a decline in the self-reported arousal of the most recent stress event, as reported from the time of app entry, that was identified over the course of the study period ($F_{5,150}$=4.52; P=.02; η^2_p=0.131). Post hoc tests revealed several effects between the weeks: Specifically, these included comparisons between W1 and W5 (P=.02), W1 and W6 (P=.02), W2 and W5 (P=.04), and W2 and W6 (P=.03). However, no significant effects were observed in other subjective parameters, such as work-related stress experience or valence.

The sensor data revealed that only one parameter exhibited significant effects during the study period, with LF/HF increasing over the weeks ($F_{5,109.01}$=3.91; P=.03; η^2_p=0.152). According to the definition of the parameter, this can be interpreted as an increase in sympathetic activity, which indicates increased physiological stress. However, none of the other HRV parameters exhibited a similar pattern. The results of the LMMs are displayed in Table 2.

Group Differences (H_2)

No significant group effects were identified.

Usability and Satisfaction Explorations

With regard to the usability, an increase in positive feedback from the participants was observed between the middle and the end of the study ($F_{1,45}$=24.80; P<.001; η^2_p=0.355). A tendency of an effect also emerged in the satisfaction data, which, however, showed a significant decrease between the two measurement points ($F_{1,45}$=7.12; P=.05; η^2_p=0.137). Technical issues occurred during the study, which inevitably disrupted measurements, particularly with regard to the sensor data. These disruptions primarily affected the connection between the sensor and the app in the initial weeks of the study. Furthermore, there have also been reports of discomfort caused by the daily demands of using the app and the sensor. Regarding the latter, the battery life was criticized.

Discussion

Principal Findings

This pilot study on the mobile app for occupational stress management developed in the RELAX project, according to the JITAI concept, has taken on the first evaluation of this app. The study aimed to determine the preliminary effectiveness of the app in terms of stress reduction during the study period and whether the degree of personalization of the stress interventions modifies the influence of the app. In addition to the indications of impact, the study also sought to examine the usability of the app in order to assess its transfer to a real-world context. The study's findings, overall, were rather mixed in all respects.

Evidence of Stress Reduction

Hypothesis 1, which predicted a reduction in stress levels by the end of the study compared to the baseline, could only be proven for certain stress indicators. Specifically, the subjective chronic stress measured daily and the subjective arousal of the

XSL•FO
RenderX

most recent stress event in the daily EMA entries demonstrated a reduction in stress between given previous weeks and subsequent weeks. The substantial reduction in these stress variables occurred in the fifth and sixth week after the study began. These partial results align with prior research on stress management through mHealth [11,23] and offer preliminary indications of the app architecture's effectiveness for the pilot study.

The absence of effects on other subjective measures of stress may be explained by the nature of the variables collected. The stress markers collected at untriggered, that is, self-selected measurement points of EMA entries, could contain a bias, where participants deliberately choose the EMA time points when they are not stressed. In the recommended EMA paradigm, the temporal parameters of measurement are typically prespecified by the researcher [54]. However, in this study, the subjects were permitted to select the temporal parameters of their observations autonomously, thereby allowing for the bias. Conversely, the question regarding the intensity of the most recent stress event in these EMA surveys specifically asks about stress situations, thereby ensuring that similar negative moments are recorded in this category for direct comparison. In contrast, the actual momentary experiences at EMA entry time could offer a much wider range of possible experiences in the moment, which might not provide clear direction when aggregated.

As indicated by prior studies [55], the manner in which stress is assessed using EMA has been found to influence the frequency with which subjects disclose their stress levels. Consequently, using explicit items regarding the most recent stressful event has been shown to yield more dependable data concerning stress compared to momentary inputs that are not based on events. The same rationale can be applied to the valence measurements. At the time of EMA entry, the valence may have been without clear direction in the spectrum of potential valences. It is noteworthy that the negative valence of the most recent stress event has remained constant, despite a decline in arousal levels during the most recent stress moment. According to the findings of research conducted on mood, the arousal level is more volatile and susceptible to interventions than the valence level [56]. However, empirical studies on stress management with just-in-time interventions show that the valence of an affect can be influenced after only a few weeks [57,58], so this aspect requires further consideration.

The absence of change in work-related stress prior to and following the study necessitates an alternative explanation for the self-reports. One possibility is that the instrument used to assess these constructs, the VEDAS [51], was predominantly influenced by the content of specific work-related factors. The items in the questionnaire address specific scenarios that have been identified as potential triggers for stress, such as the pressure to take work home or to extend one's working hours. These factors might not have been adequately addressed by the interventions within the short time frame of this study. Despite the high degree of personalization of the interventions, it is possible that there was an absence of an appropriate intervention for every possible scenario. For instance, interventions involving broadband techniques, such as different types of relaxation or skills training, may not be immediately effective for a person in a highly specific scenario. A preponderance of extant literature already recommends that factors such as the individual, the context, and the content must be considered equally in a potential intervention if that intervention is to be truly effective [59]. The decision tree, with predefined structures for individual, context, and content factors, restricts this aspect. In this context, the validity of an instrument such as the VEDAS should be reconsidered, as the person-centered approach to interventions and the situation-based approach to this instrument may not be sufficiently aligned.

The physiological indicators demonstrated a contrary effect to the expected subjective stress reduction. In this case, the only observed effect in the change of stress levels was manifested as an increase in the HRV parameter of the LF/HF. In the context of the relationship between subjective and physiological stress markers, it is essential to consider the complex interplay between these two parameter classes. A recent review of the correspondence between daily stress parameters at different levels demonstrated that only approximately half of the studies examined exhibited an association between the two indicator classes [60]. It is also conceivable that the duration of the study was insufficient to elicit a discernible effect on the markers of HRV, which are generally regarded as being relatively stable. Chronic stress, as has been previously discussed in analogous studies, may not have exerted a perceptible influence due to its inherent stability [19].

The validity of the LF/HF ratio as a stress marker is also debated in the literature [61]. When derived from real-life conditions in long-term measurements, such as from everyday wearables, it appears to be an unreliable indicator [62]. In this study, LF/HF was the only HRV parameter to show a significant change, despite expectations of corresponding changes across the multiple HRV indices [63]. Taken together, these observations suggest that the physiological recordings in this study should be interpreted with caution and that their interpretive value may be limited. In addition, the shortcomings of sensor measurement, which in some cases miss up to 75% of the possible data due to limited compliance or technical challenges, must be addressed. Comparable studies in the health care sector have shown adherence rates of more than 50% for the majority of subjects, with a maximum of 95% of data achieved relative to the total possible data in the study periods [64].

Although there were promising changes in selected subjective stress markers that could indicate an accumulated intervention-related effect in the later weeks of the study, the possibility must also be considered that, given the lack of significant changes in other parameters, the overall finding is negligible, and the app was not able to reduce stress as intended. The only two stress indicators that demonstrated a reduction during the study period had to be assessed retrospectively on a daily basis. The arousal of the most recent stress event included the query of a period of several hours before the entry, and the daily subjective chronic stress required the assessment of the entire past day with regard to various stress dimensions. Consequently, despite the implementation of the EMA method, recall bias could affect the validity of the results, as the experience in question could not be measured precisely in real time [65]. As Shiffman [54] previously demonstrated, recall

XSL•FO
RenderX

bias includes the tendency to handle negative and positive experiences differently. Therefore, there may have been a tendency to recall prompted negative experiences in a biased manner, resulting in systematic results that may not reflect reality.

Analysis of Personalization and Usability

In consideration of the degree of personalization according to H_2, it was observed that both levels of personalization provided by the algorithm, high and low, contributed equally to the changes in stress levels or the absence of such changes. It is important to note again that the duration of the experiment may have been too short to fully manifest the potential of the high degree version of personalization. The necessity for the algorithm to undergo further training following the splitting into two groups may indicate that the difference in user experience was not yet substantial enough to be reflected in differences in the stress scores. The necessity of navigating the decision tree for each intervention, which serves to narrow down potentially suitable interventions on an individual basis, underscores the fact that the user had still a considerable degree of influence on the system at this particular stage of development. Consequently, the automatic selection of interventions by the app may have been marginalized. As an alternative possibility, the extensive personalization options provided by a selection of nearly 200 interventions, which may have already exceeded the threshold for a discernible effect, could have resulted in a ceiling effect, thereby preventing a potential group effect. Comparable research, which focused on an expanded range of potential interventions, has previously discussed the simplification of the app again, a discussion that occurred subsequent to their analysis of the degree of personalization and the corresponding results [19].

Comparable research so far shows that multilevel approaches to stress management, in which several levels of data are considered dynamically, show a high variability in effectiveness [23]. In this context, the persuasiveness of an intervention must always be considered [66] because this study does not show whether the participants performed the interventions at all and, if so, correctly, because they were unguided. Given the early stage of the research, it is to be expected that the desired effects cannot yet be clearly identified. At this stage of development, not only the effectiveness factors may not be fully developed, but the usability factors are also only explored and optimized in several iterations of evaluation studies. In the present case, this was an initial evaluation, which means that it will remain unclear what proportion of the pattern of results is actually attributable to effectiveness factors and what proportion to usability factors.

An increase in usability was observed over the course of the study, as shown by the self-report data between the study phases and at the end of the study. The adaptation of the app during the study period, particularly subsequent to the initial phase, in alignment with the expressed preferences of users, can be regarded as a notable improvement. Concurrently, there were indications of a decline in satisfaction at the trend level. This finding suggests a contradictory interpretation: while users initially perceived the system as more usable, their preference for it decreased over time. During the course of the study, personalization mechanisms were integrated into the background of the app to tailor interventions to individual stress levels. This was anticipated to improve the user experience and satisfaction. The potential for the daily use of the app to induce exhaustion or discomfort could offer an alternative explanation for the observed outcomes. The technical modifications implemented in the application may have promoted its use; nevertheless, the intrinsic characteristics of its daily use may have resulted in an escalation in discomfort over time. In the context of mHealth for stress management, the consideration of digital stress is imperative, as it can readily engender an effect that is contrary to the intended objective [47].

The adherence rates indicate an overall rather low level of engagement in the daily study activities. Conversely, the relatively high incidence of subjective data indicated the general willingness of the participants, suggesting that the low sensor rates are most likely attributable to technical barriers. Consequently, there is an ongoing need for technical enhancements to ensure a seamless user experience and optimize functioning. The absence of seamless functionality in a digital system can significantly compromise user experience, potentially impeding the system's intended functionality [45]. Consequently, this study sought to illustrate the potential of the JITAI concept through the use of the developed app on a system yet to be optimized.

Strengths and Limitations

The present evaluation of the RELAX app demonstrates the initial results of a mHealth approach to the practical implementation of the JITAI concept in the domain of occupational stress management. The application's objective is to deliver interventions that are not only time efficient but also content focused, with the aim of optimally addressing the individual's situation and needs. This approach builds on earlier methods that either limited themselves to the compilation of diagnostic data or offered generic, one-size-fits-all interventions [11-13]. A notable aspect of the study is the remarkably low rate of attrition, with only 4 participants (8% of the total sample) dropping out, which is particularly noteworthy given the intensive nature of the repeated daily EMAs and the wearable monitoring process that included nocturnal recordings. Dropout rates from other mHealth studies on chronic diseases exhibited comparatively higher percentages, ranging from 40% to 49% [67]. Despite the presence of incomplete data recordings, adherence remained consistent, underscoring the necessity for such interventions in employees' daily lives.

The assessment of multiple levels of stress markers made it possible to compare them, whereas previous studies of comparable approaches have focused on only a few parameters [13,23]. This approach allowed for the identification of variability in the effects across dimensions, which, although not in the expected manner, may provide valuable insights from alternative perspectives. It is acknowledged that stress markers do not always align, particularly between physiological and subjective parameters [68]. The findings from this study lay the foundation for future research to dive deeper into this divergence

XSL•FO
RenderX

and potentially link it to underlying factors within the specific mHealth context.

This study fulfills the quality requirements of a pilot study. However, it must therefore also be evaluated with the limited significance of such a study. The absence of a control group without intervention, as previously identified as a limitation in the study protocol [38], prevents clear attribution of all changes in stress parameters due to the intervention. The study design used here does not provide the internal validity required for statements on the effectiveness of the intervention. At this juncture, the outcomes of this study can only be interpreted as effects that occurred during the study period, which may provide an indication of effectiveness that must be validated with a controlled follow-up study.

Furthermore, as previously stated in the discussion, the study period was relatively brief, thereby limiting the opportunities for user intervention. The small sample size precluded the ability to draw definitive conclusions; thus, the findings should be considered exploratory in nature. This is particularly evident in the group randomization, where the sample sizes were further diminished. Following the implementation of technical stabilization updates to the application and the completion of its development phase, which will enable fully automated intervention selection, the evaluation should be expanded to include a more substantial sample size and an extended study duration.

Moreover, the employees' daily experiences in their highly individual roles and in different industries are likely to have generated such a variable set of situations that the stress events within and between individuals call into question the comparability of the EMA data. The app's capacity to adapt to each unique situation and individual user could be considered overly ambitious for the current stage of development, particularly in light of the absence of complete automation in intervention selection at the time of evaluation. Consequently, users retained a substantial degree of active involvement and control over the app's functionality. To enhance the validity and generalizability of the findings, it is recommended that future evaluations use more mature app systems that prioritize the comparability of the sample and incorporate control groups.

Conclusions

In summary, the study preliminarily examined the impact of an mHealth app developed in accordance with the JITAI concept. The findings were inconsistent, with only two subjective stress markers demonstrating the hypothesized stress reduction, while one physiological parameter exhibited a debatable increase. The validity of the attribution of the observed effects to the performance of the app is not without question. It is conceivable that these effects are, in fact, an artifact of a system that has not yet been fully developed, if the effects are at all attributable to the system. These findings give rise to questions concerning the extent of the app's limited usability in its present developmental stage, such as the ease of use of the app system, as well as the integration of generally consistent daily mHealth use in the work context. Nevertheless, the study identified several promising starting points for the future development of a functional and effective app that can address occupational mental stress in an adaptive manner in terms of time and content.

Acknowledgments

We would like to thank all participants for their contribution to the research and University Prof Dr Frank Wilhelm for his valuable input in the analysis of the data. The translation into English was supported by DeepL. Generative artificial intelligence was not used.

Funding

The study received funding from the Austrian Research Promotion Agency. This open access publication was supported by the Publication Fund of Paris Lodron University of Salzburg.

Data Availability

The datasets generated and analyzed during the study are available from the corresponding author on reasonable request.

Abstract

Background: Parental oral health education is critical for preventing early childhood caries. However, few interventions are theoretically grounded or use digital approaches.

Objective: The objective of this study was to evaluate the effects of a health belief model–based digital intervention on maternal oral health behaviors.

Methods: This quasi-experimental study enrolled 648 mother-child dyads from 19 community health care centers (CHCs) in Beijing, China. CHCs were allocated to intervention or control groups depending on their voluntary adoption of the dental referral system. Ten CHCs (n=332, 52.6%) were assigned to the intervention group, where mothers received oral health education materials and had access to a dental referral system. The remaining 9 CHCs (n=316, 47.4%) served as the control group, in which mothers continued to receive standard child health care services. The primary outcome was parent-assisted toothbrushing, and the secondary outcome included other oral health behaviors, including night feeding practices, sugar intake, and dental visits. To evaluate the intervention effects on behavioral outcomes, generalized linear mixed models were used, accounting for repeated measures and potential confounding factors.

Results: Compared with the control group, the intervention group demonstrated a significant increase in parent-assisted toothbrushing, with an absolute difference of 10.3 (95% CI 3.0 to 17.6; *P*=.006) percentage points at 6 months and 1.5 (95% CI −7.2 to 10.1; *P*=.74) percentage points at 12 months. Additionally, dental visit rates were significantly higher in the intervention group at 12 months (odds ratio 4.65, 95% CI 1.30 to 16.70; *P*=.02). However, no statistically significant differences were observed between groups in nighttime feeding cessation or sugar intake control at either the 6- or 12-month follow-ups.

Conclusions: The health belief model–based digital intervention was effective in the short term for enhancing parent-assisted toothbrushing in young children, but its long-term effectiveness remains unproven. Future research should therefore prioritize exploring sustainability strategies.

digital intervention; health belief model; oral health; young children; quasi-experimental study

Introduction

Background

Early childhood caries (ECC) is one of the most prevalent chronic conditions affecting children worldwide [1]. The Global Burden of Disease Study (2017) estimated approximately 532 million cases of untreated caries in primary teeth [2], and the epidemiological data from 193 countries (2007 - 2017) revealed that 57.3% of children aged 3 to 6 years were affected by dental caries [3]. In China, the situation appears even more concerning, with the national oral health survey (2015) reporting that 71.9% of children aged 5 years were affected by ECC [4]. Beyond its immediate detrimental effects on young children's quality of life, ECC significantly elevates the risk of caries in permanent dentition, resulting in long-term oral health consequences [5,6].

XSL•FO
RenderX

Parents play an important role in their young children's oral health care. Key recommended practices for infants' and toddlers' oral care include parent-assisted toothbrushing, limiting dietary sugar intake, avoiding prolonged nighttime feeding, and scheduling regular dental visits [7]. Despite the importance of these practices, most parents fail to adhere to the recommended oral health behaviors [8,9].

Although numerous oral health education programs have been designed for parents, their efficacy across different studies remains mixed [10]. A critical issue is that most interventions lacked theoretical frameworks, limiting their ability to explain intervention outcomes [10]. Moreover, existing programs predominantly emphasize home-based oral care behaviors while neglecting the persistently low rates of dental visits among young children [11,12]. This oversight is problematic because early dental visits enable oral health professionals to deliver personalized oral health education and help families adopt optimal oral health practices [13]. Nevertheless, strategies to effectively promote dental visit adherence remain poorly investigated.

Interventions grounded in theoretical frameworks tend to be more effective, underscoring the value of theory-driven approaches in health behavior change [14]. The health belief model (HBM) is a well-validated social psychological framework for health behavior modification [15]. The model's core constructs, including perceived susceptibility, perceived severity, perceived benefits, perceived barriers, and self-efficacy, offer a comprehensive theoretical framework for intervention design. A previous review has demonstrated its efficacy in improving oral health behaviors among adolescent and adult populations [16], yet its application in parental oral health education programs remains unexplored. To date, only one relevant study protocol has been published [17]. That study delivered HBM-based SMS text messaging interventions to parents of children aged 18 to 30 months, but it focused only on toothbrushing and sugar intake, without addressing early dental visits. Moreover, an existing intervention used caries prevalence and complication statistics to increase parents' awareness of ECC susceptibility and severity, but it did not address other important factors, such as perceived benefits and barriers to performing recommended oral health behaviors [18]. Therefore, the effectiveness of comprehensive HBM-based interventions in promoting early childhood oral health behaviors remains to be investigated.

Aims

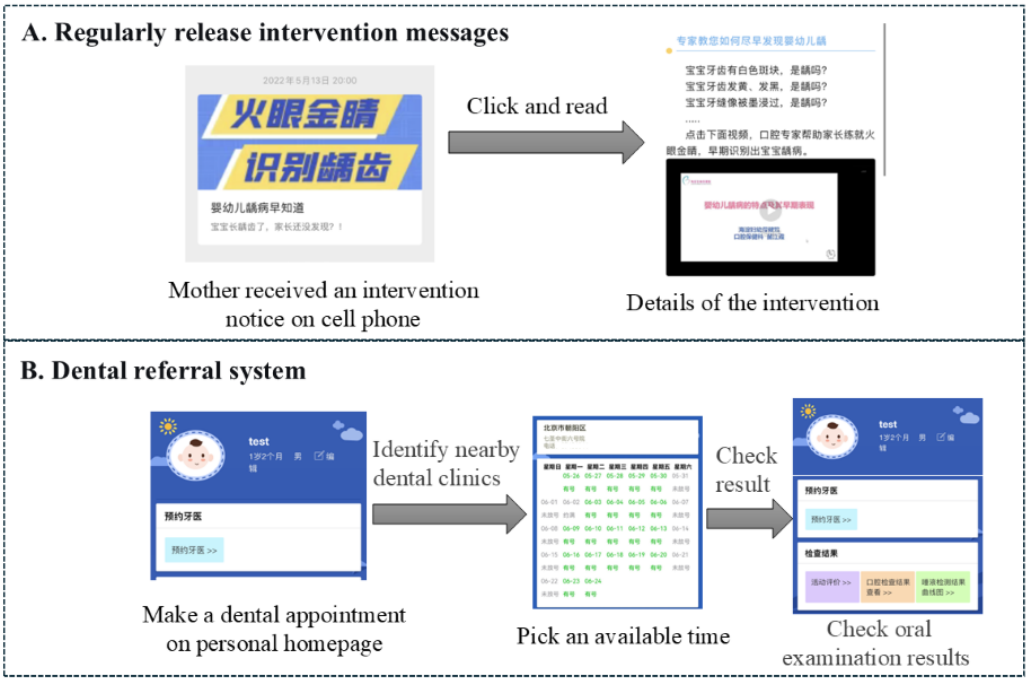
To address this gap, we developed a novel digital intervention grounded in the HBM. To improve the low rate of dental visits among young children, the intervention integrated a dental referral system to facilitate access to dental care by helping parents locate nearby clinics and book appointments directly. The primary objective of this study was to evaluate the effects of this HBM-based digital intervention on improving maternal oral health behaviors for young children.

Methods

Design, Participants, and Recruitment

A parallel, quasi-experimental design was used to evaluate the effects of the HBM-based digital intervention on maternal oral health behaviors for young children aged 11 to 14 months. Participants were eligible if they met the following criteria: (1) aged 11 to 14 months, (2) at least one tooth has erupted, and (3) no cleft lip or palate. Children diagnosed by a physician with a chronic disease were excluded. The potential participants were recruited from 19 community health care centers (CHCs) in Beijing, China, between September and November 2020. Mothers of infants aged 11 to 12 months were approached during routine visits to community vaccination clinics, while those with children aged 13 to 14 months were contacted via telephone based on vaccination registry records and were invited to participate in this study. Mothers who agreed to participate were then asked to review and sign the informed consent form at the CHC.

CHCs were assigned to the intervention or control group based on their voluntary decision to implement the dental referral system with an allocation ratio of 1:1. Of the 19 CHCs, 10 (52.6%) that opted to implement the system formed the intervention group, while the remaining 9 (47.4%) served as the control group. To mitigate potential selection bias between treatment groups, we implemented controls for a set of family- and child-related factors known to be associated with young children's oral health in the literature [19-21] (refer to the Control Variables section).



Intervention and Control Group

Mothers in the intervention group received the intervention through a WeChat (Tencent Holdings Limited) public account, via which we disseminated the intervention materials and hosted the dental referral system (Figure 1). The intervention lasted for 6 months, divided into two phases: (1) an intensive phase (first 2 months) with weekly intervention material deliveries, followed by (2) a maintenance phase (remaining 4 months) with biweekly material distribution. Throughout the intervention period, participants could use the online dental referral system to book dental appointments for their children. Guided by HBM, the intervention materials targeted the following constructs: (1) perceived susceptibility—presented Chinese epidemiological data on high prevalence of ECC [4]; (2) perceived severity—emphasized the adverse developmental consequences of untreated ECC; (3) perceived benefits—outlined advantages of oral health behaviors, including impacts on children's dental health, speech development, and long-term oral health outcomes [22,23]; (4) perceived barriers—provided practical strategies to address common obstacles (eg, managing child resistance during toothbrushing) [24]; and (5) self-efficacy—built confidence through the sharing of peer maternal experiences and success stories [25]. All content was reviewed and approved by a panel of 8 experts (including 3 oral health professionals, 2 pediatricians, and 2 health promotion specialists) to ensure scientific accuracy and appropriateness. Furthermore, the digital platform's usability and accessibility were evaluated in a 2-phase process: an initial assessment by the research team, followed

XSL•FO
RenderX

by a test with 8 mothers for user-friendliness and clarity. Feedback from these processes was incorporated prior to the final release. The detailed intervention materials, including the topic, key contents, corresponding theoretical constructs, and engagement metrics (eg, views) for each session, are provided in Multimedia Appendix 1.

Figure 1. Key elements of the intervention program. (A) Regular intervention message to parents; (B): dental referral system for appointment booking.

Mothers in the control group received standard child health care as stipulated by the national health management service for children aged 0 to 6 years [26], which for 1- to 2-year-olds includes biannual general physical examinations and feeding guidance. We did not provide any additional interventions to the control group.

Outcomes and Measurements

Due to COVID-19 pandemic–related restrictions, this study modified its primary outcome from oral health assessments to parent-assisted toothbrushing behaviors. This adaptation was made for two reasons: (1) standardized caries detection became impossible during the epidemic and (2) as a key ECC-preventive behavior [27], toothbrushing demands daily practice, reflecting ongoing parental commitment to their child's oral care. Other oral health behaviors, including nighttime feeding cessation, dental visits, and sugar intake control, served as secondary outcomes in this study. Consistent with our theoretical framework, the intervention aimed to improve maternal oral health behaviors by knowledge enhancement and psychosocial modification, with these factors concurrently assessed as secondary outcome measures.

All data were obtained using structured questionnaires at CHCs. Parent-assisted toothbrushing was operationally defined as the daily toothbrushing performed by caregivers before bedtime. Accordingly, the frequency of toothbrushing and whether it occurred before bedtime were recorded. The use of fluoridated toothpaste was also documented. Following biannual dental visit recommendations for young children, we assessed whether they had received dental visits in the preceding 6 months. Regarding nighttime feeding practices, mothers were asked whether they had discontinued nighttime feeding for their young children; responses indicating "yes" were categorized as nighttime feeding cessation. Additionally, data on the frequency of sugar intake, including candies, sugar-sweetened beverages, and bakery products, were collected.

Maternal oral health knowledge was evaluated using a 9-item questionnaire, which was developed according to Chinese infants' and toddlers' oral health guidelines (Multimedia Appendix 2) [23]. Each item offered 3 response options: "true," "false," and "don't know." Correct answers received 1 point, while incorrect or "don't know" responses scored 0.

This study also assessed HBM components, including perceived susceptibility to ECC, perceived severity of ECC, perceived benefits and barriers of oral health behaviors, and self-efficacy. All components were measured using 5-point Likert scale items (1=strongly disagree to 5=strongly agree), with cumulative scores calculated for each domain. A pilot study was conducted with 187 mothers (excluded from the main study) to assess the scales' readability and internal consistency. These scales demonstrated acceptable internal consistency, with Cronbach α coefficients ranging from 0.67 to 0.93. The items for each HBM component are presented in Multimedia Appendix 3.

Blinding

Blinding of participants was not possible due to the nature of this quasi-experimental study. Furthermore, as the primary outcome was self-reported, blinding of the outcome assessors was not applicable.

XSL•FO
RenderX

Sample Size

On the basis of our previous survey in Beijing, the rate of parent-assisted toothbrushing among 2-year-old children was 22.6%. This rate served as the reference for the control group, while the expected rate in the intervention group was set at 33% (ie, the prevention fraction of 50% based on a previous study [28]). The minimum necessary sample size was 258 participants for each arm based on a 2-sided test at the .05 level of significance and 80% power. Assuming a 20% loss of participants to follow-up, 310 participants were needed in each arm.

Control Variables

This study included 7 covariates encompassing both child and maternal characteristics. Child-related covariates included sex (male vs female), baseline age (categorized as 11 - 12 months vs 13 - 14 months), order of birth (first child vs nonfirst child) and primary caregiver status (mother vs others). Maternal characteristics included infant feeding practices, educational attainment, and household income. Infant feeding practices (0 - 6 months) were categorized into 3 groups: exclusive breastfeeding, mixed feeding, or exclusive formula feeding. Educational attainment was classified into 3 levels: college and below, bachelor's degree, or graduate degree. Based on participants' self-ranking of their family income relative to others in the local area, household income was classified into 3 tiers, including high (top 40%), middle (60% - 80%), or low (bottom 40%). The selection of birth order and infant feeding practices as covariates is supported by previous evidence linking them to children's oral health outcomes [19,20].

Follow-Up

Consistent with World Health Organization recommendations for evaluating novel digital health interventions, this study incorporated medium- and long-term impact assessments through 3-wave data collection [29]. Thus, data collection occurred at 3 time points in this study: outcome variables were assessed at baseline, 6 months (immediately after the intervention), and 12 months (6 months after the postintervention assessment). Maternal oral health knowledge and psychosocial variables were measured at baseline and 12 months, and control variables were obtained at baseline.

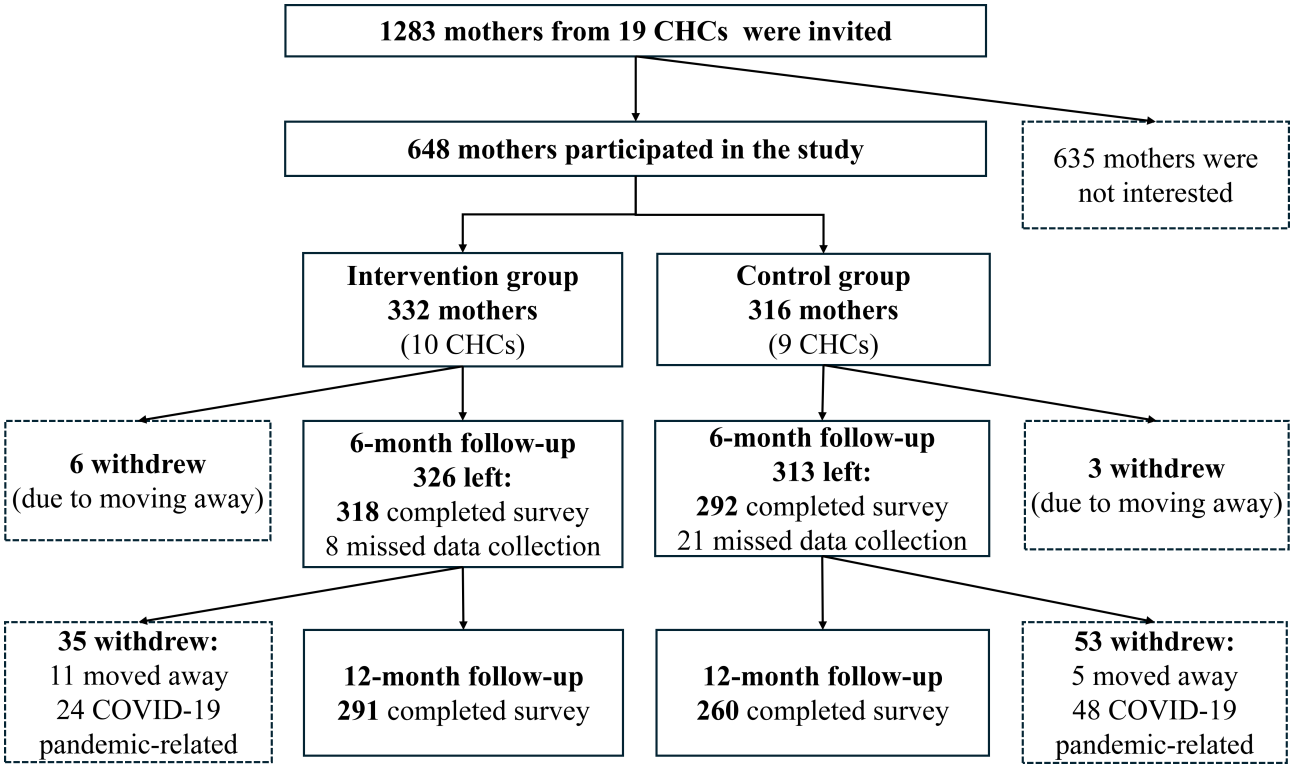
Statistical Analysis

Behavioral outcomes and control variables were reported as frequencies (proportions) and analyzed by chi-square test or Fisher exact test, as appropriate. Maternal oral health knowledge and psychosocial variables were described as mean (SD) and compared using 2-tailed independent *t* tests. Logistic regression generalized linear mixed models were used to assess behavioral outcome effects, and linear mixed models were applied to assess the psychosocial outcome effects. Fixed effects included time, treatment group, and their interaction (time×treatment). Random effects included community, accounting for within-cluster correlations. A statistically significant interaction indicates that the treatment effect varied over time.

Data analysis followed the intention-to-treat principles. Participants who had at least one follow-up visit were included in the primary analysis. Missing data were accounted for by a mixed-effects model using the full information maximum likelihood estimation method [30]. Sensitivity analyses were conducted to evaluate the robustness of the primary results. First, a complete-case analysis was performed. Second, given the continuous nature of the behavior, the last observation carried forward (LOCF) approach was applied under the assumption that the behavior would remain unchanged after the last measurement. Analyses were conducted using R software (version 4.4; R Foundation for Statistical Computing).

Ethical Considerations

Ethics approval (IRB00001052-19136) was obtained from the institutional review board of Peking University Health Science Center. This study was performed in accordance with the 1964 Declaration of Helsinki and its later amendments or comparable ethical standards. Informed consent was obtained from all mothers. All data were anonymized prior to analysis. No personally identifiable information was included in the analysis or the reporting of findings. Participants received a pack of baby wipes (valued at RMB 50 [US $7.30]) on each visit. No additional financial compensation was offered for participation.



Results

Baseline Characteristics

This study enrolled 648 mother-child dyads. Of the children, 331 (51.1%) were male, and 546 (84.3%) were aged 11 to 12 months. Maternal education levels were distributed as follows (Table 1): 508 (78.4%) held at least a bachelor's degree, 103 (15.9%) had a college degree, and 37 (5.7%) completed high school or less. The baseline characteristics of participants were well matched between the intervention and control groups. Follow-up rates were 94.1% (n=610) at 6 months and 85% (n=551) at 12 months, meeting prespecified expectations (Figure 2).

Table . Baseline characteristics of participants.

Characteristics	Total (n=648), n (%)	Intervention group (n=332), n (%)	Control group (n=316), n (%)	*P* value
Child sex				.80
Male	331 (51.1)	168 (50.6)	163 (51.6)	
Female	317 (48.9)	164 (49.4)	153 (48.4)	
Child age group (months)				.63
11 - 12	546 (84.3)	282 (84.9)	264 (83.5)	
13 - 14	102 (15.7)	50 (15.1)	52 (16.5)	
Birth order				.36
First child	462 (71.3)	242 (72.9)	220 (69.6)	
Non–first child	186 (28.7)	90 (27.1)	96 (30.4)	
Primary caregiver				.80
Mother	294 (45.4)	149 (44.9)	145 (45.9)	
Others	354 (54.6)	183 (55.1)	171 (54.1)	
Infant feeding practice				.76
Exclusive breastfeeding	339 (52.3)	175 (52.7)	164 (51.9)	
Mixed feeding	224 (34.6)	111 (33.4)	113 (35.8)	
Exclusive formula feeding	85 (13.1)	46 (13.9)	39 (12.3)	
Maternal education				.15
High school or below	37 (5.7)	16 (4.8)	21 (6.6)	
College (2 - 3 y)	103 (15.9)	61 (18.4)	42 (13.3)	
Bachelor's degree or higher	508 (78.4)	255 (76.8)	253 (80.1)	
Household income				.30
High	157 (24.2)	75 (22.6)	82 (25.9)	
Middle	459 (70.8)	237 (71.4)	222 (70.3)	
Low	32 (5)	20 (6)	12 (3.8)	

Of the initial sample, 38 (5.9%) participants did not complete the 6-month follow-up. Compared with completers, noncompleters had significantly higher baseline self-efficacy scores (*P*=.03) and a higher prevalence of dental visits (*P*=.003) at baseline (Multimedia Appendix 4).

Behavioral Outcome

The intervention demonstrated significant short-term effects on parent-assisted toothbrushing behavior. Compared with controls, mothers in the intervention group showed a 10.3 percentage point increase (95% CI 3.0-17.6) in toothbrushing behavior, corresponding to an adjusted odds ratio (OR) of 2.43 (95% CI 1.24-4.74). The observed improvement was consistent in sensitivity analyses using complete-case analysis (adjusted OR 2.19, 95% CI 1.06-4.53; Multimedia Appendix 5) and the LOCF approach to handle missing data (adjusted OR 2.88, 95% CI 1.43-5.78; Multimedia Appendix 6). However, this improvement was not sustained at the 12-month assessment (Table 2), with an adjusted OR of 1.20 (95% CI 0.61-2.36). No statistically significant effect was found for toothbrushing with fluoridated toothpaste at this follow-up as well (Multimedia Appendix 7), with an adjusted OR of 2.12 (95% CI 0.78-5.75).

12-month follow-up	118/291 (40.5)	104/260 (40)	1.5 (−7.2 to 10.1)	.74	1.20 (0.61 to 2.36)	.59
Nighttime feeding cessation						
Baseline	104/332 (31.3)	79/316 (25)	1.0 (−4.5 to 6.5)	.73	1.00	—
6-month follow-up	225/318 (70.8)	214/292 (73.3)	−0.6 (−3.3 to 2.0)	.64	0.53 (0.16 to 1.73)	.29
12-month follow-up	253/291 (86.9)	222/260 (85.4)	0.0 (−0.1 to 0.2)	.67	1.21 (0.23 to 6.32)	.82
Sugar intake control						
Baseline	259/332 (78)	241/316 (76.3)	2.4 (−4.8 to 9.8)	.51	1.00	—
6-month follow-up	220/318 (69.2)	212/292 (72.6)	−3.5 (−12.2 to 9.2)	.43	0.73 (0.41 to 1.28)	.27
12-month follow-up	190/291 (65.3)	172/260 (66.2)	0.1 (−9.8 to 10.0)	.99	0.87 (0.49 to 1.53)	.62
Dental visit in past 6 months						
Baseline	9/332 (2.7)	9/316 (2.8)	−0.1 (−0.7 to 0.5)	.65	1.00	—
6-month follow-up	33/318 (10.4)	15/292 (5.1)	1.5 (−0.1 to 3.6)	.15	3.29 (0.98 to 11.05)	.05
12-month follow-up	30/291 (10.3)	13/260 (5)	2.0 (–0.5 to 4.4)	.12	4.65 (1.30 to 16.70)	.02

[a]Odds ratio value of 1.00 indicates the reference group in the model.

[b]Not applicable.

Additionally, the intervention showed a limited effect on dental visits. Mothers in the intervention group had a higher likelihood of taking their children for dental visits compared with controls, with adjusted ORs of 3.29 (95% CI 0.98 - 11.05) at 6 months and 4.65 (95% CI 1.30 - 16.70) at 12 months. However, the low incidence of dental visits led to wide CIs in both the primary and sensitivity analyses. The sensitivity analyses yielded ORs of 1.81 (95% CI 0.29-11.38) for the complete-case analysis (Multimedia Appendix 5) and 3.85 (95% CI 0.82-17.95) for the LOCF approach at 12-month follow-up (Multimedia Appendix 6). No statistically significant effects of the intervention were observed on either nighttime feeding cessation or sugar intake reduction at the 6- or 12-month follow-ups (*P*>.05).

Maternal Knowledge and Psychosocial Outcomes

We further assessed changes in maternal knowledge and psychosocial variables over the 12-month study period. The intervention significantly improved maternal oral health knowledge scores (mean difference 0.31 points; 95% CI 0.01-0.60), whereas no statistically significant changes were observed in other psychosocial components (Table 3).

[a]ECC: early childhood caries.

Discussion

Main Findings

In this quasi-experimental study, the HBM-based digital intervention achieved a 10.3 percentage point improvement in parent-assisted toothbrushing behavior at the 6-month follow-up, but this improvement did not persist to the 12-month follow-up. Additionally, slight improvements were observed in dental visit adherence and maternal oral health knowledge at the 12-month follow-up.

Comparison With Prior Work

Previous interventions targeting mothers of young children (aged 0-3 years) primarily focused on oral health knowledge and skills without solid theoretical foundation [18,31,32]. Among the few theory-guided interventions, one used the theory of planned behavior (TPB). While this intervention improved maternal attitudes and perceived behavioral control, it did not yield significant changes in behavioral intention or toothbrushing behavior at the 3-month follow-up [28]. This limited efficacy may be attributed to 2 key conceptual omissions in TPB. First, TPB does not incorporate self-efficacy, which is crucial for sustaining parental involvement in children's oral hygiene [33]. Second, it overlooks the perceived threat, a construct whose enhancement has been linked to reduced caries incidence in children [18]. HBM integrates these essential components. Consequently, it was selected as the theoretical framework for this study.

Guided by HBM, our study achieved short-term improvements in toothbrushing behavior, likely mediated by increased maternal oral health knowledge [34], as our results indicated that maternal oral health knowledge scores increased 0.31 points from baseline. However, the intervention effects diminished by the 12-month follow-up, possibly due to persistent perceived barriers or inadequate self-efficacy reinforcement [24,35]. To facilitate lasting behavioral modifications, future research should explore the efficacy of hybrid interventions that integrate initial education with booster sessions (eg, regular reminders) to address behavioral relapses. Future practice should embed oral health promotion into routine child health services (eg, during vaccination visits), thereby creating systematic opportunities for timely problem-solving to overcome barriers and for skill-refreshing to enhance self-efficacy.

Previous interventions focused on home-based oral behaviors and largely overlooked the importance of dental visits [10,36]. To our knowledge, this study is the first to implement an online dental referral system designed to facilitate parental scheduling of dental appointments for children. However, the intervention yielded only a modest effect, with a mere 2.0 percentage point increase in dental visit rates at the 12-month follow-up. This limited effect is likely multifactorial. First, the COVID-19 pandemic created a universal barrier, during which families avoided nonessential pediatric dental care [37]. More fundamentally, our digital dental referral system primarily addressed the barriers of finding and scheduling an appointment, but it could not overcome other critical obstacles, such as financial constraints [38], and parental attitudes regarding dental

XSL•FO
RenderX

visits. If mothers primarily view dental visits as therapeutic rather than a preventive service, they are unlikely to take their children to oral health professionals in the absence of symptoms [39,40]. This suggests that future interventions need to address not only service access but also cost barriers and underlying beliefs about dental visits.

It should be noted that this study was likely underpowered to detect a significant effect on dental visits, with the low incidence of this behavior resulting in wide CIs. This limits the robustness of our findings and calls for cautious interpretation of the results. Therefore, future studies with larger sample sizes are required to evaluate the intervention's effect.

However, our intervention showed no significant effect on nighttime feeding cessation. Further analysis revealed that the mean cessation age was similar between groups (intervention: mean 13.48, SD 4.18 months vs control: mean 13.41, SD 3.86 months; *P*=.79). This overall cessation timing closely aligned with the baseline age of participants (11 - 14 months), which could partially explain the limited intervention effect.

Strengths and Limitations

This theory-based digital intervention evaluated both oral health behavior changes and shifts in maternal psychosocial factors, offering explanatory insights into the mechanisms behind behavioral improvements. However, the study had several limitations. First, randomization was not feasible due to COVID-19 pandemic–related constraints that prevented comprehensive implementation of the referral intervention across participating CHCs. The lack of randomization limited our ability to fully account for potential confounders [41]. To mitigate this, we used a parallel group comparison and adjusted for child- and maternal-related confounding variables, strengthening causal inference. Second, the COVID-19 pandemic prevented clinical assessments of oral health outcomes (eg, caries incidence), restricting our analysis to rely on self-reported behaviors, which might introduce reporting bias. Future studies can more comprehensively assess the effect of theory-based digital interventions on children's oral health.

Conclusions

The HBM-based digital intervention was effective in the short term for enhancing parent-assisted toothbrushing in young children, but its long-term effectiveness remains unproven. Future research should therefore prioritize exploring sustainability strategies.

Acknowledgments

The authors thank the children and their mothers for their involvement. No generative artificial intelligence tools were used to generate or ideate the text or visual materials included in this manuscript.

Funding

This study was supported by the National Natural Science Foundation of China (grant 82504423).

Data Availability

The dataset used and analyzed during this study will be available from the corresponding author upon reasonable request.

Authors' Contributions

ML, CC, and QY designed the study. MZ, SW, and QY drafted the manuscript. MZ and XZ recruited participants. CC and QY were responsible for the intervention preparation. MZ, XZ, and QY collected the data, and SW and QY analyzed the data. All authors revised the manuscript and approved the final version for submission.

Abstract

Background: Goal personalization features integrated into mobile health apps have the potential to enhance physical activity, as some evidence shows that the personalized goals generated by algorithms are more effective than default or fixed goals. However, it remains unclear whether goals set by users are more effective than fixed goals and which personalization strategy is more effective for different user segments.

Objective: This field study aimed to evaluate (1) the efficacy of 2 step goal personalization strategies—personalized-by-you and personalized-by-the-algorithm—and (2) which strategy is more effective among users with different activity levels.

Methods: All users of SamenGezond, a Dutch mobile health app, have a default goal of 2000 steps per day, 5 days a week. For this study, 2 random groups were selected, totaling 5800 users. Subsequently, an email was sent to 3800 users in group 1, asking whether they were satisfied with their current goal. Those who were not satisfied were offered 2 personalization options: to set a goal themselves or to have the algorithm integrated in the app set goals for them. In total, 1399 users responded: 230 chose to set their own goals (personalized-by-you group), 236 opted for setting the goal by the algorithm (personalized-by-the-algorithm group), and 933 chose to keep the default goal (not-changed group). The algorithm used a moving-window percentile rank method based on step data from the previous 4 weeks. Users who did not personalize retained the default goal. The remaining 2000 users in group 2 did not receive the email and also retained the default goal. To evaluate the effectiveness of step goal personalization strategies, we used propensity score matching and difference-in-difference analysis.

Results: Users in the personalized-by-you group increased weekly step count by 3793 a week, while those in the personalized-by-the-algorithm group increased by 4315 steps a week, compared with the not-changed group (users with default goals). The 2 strategies appear to have a similar effect. Interestingly, users in the not-changed group also increased their weekly steps by 1759. Furthermore, the effectiveness of each strategy varied by baseline activity level. The personalized-by-you strategy was effective for medium- (increase of 5842 steps) and high-active users (increase of 4266 steps) but not for low-active users (increase of 384 steps; P=.82). Conversely, the personalized-by-the-algorithm strategy was effective for low- (increase of 5095 steps) and medium-active users (increase of 5278 steps) but not for high-active users (increase of 1446 steps; P=.51).

Conclusions: Step goal personalization demonstrates short-term effectiveness. However, their impact varies by users' baseline activity levels, indicating the need for a tailored approach for different user segments. Future studies should examine the long-term effects of such interventions to design sustainable health behavior change strategies.

Introduction

Background

Despite the compelling evidence of its benefits, many barriers (eg, inconvenience, lack of time, and motivation) hinder individuals from regularly exercising. According to the World Health Organization, 1 in 4 people worldwide is physically inactive [1]. Overcoming these obstacles requires stronger motivation and self-regulation. Mobile health (mHealth) technologies offer significant potential as a solution to physical inactivity [2-4]. mHealth refers to the integration of mobile computing, medical sensors, and communication technologies,

XSL•FO
RenderX

designed to deliver health care services [5]. These tools allow individuals to manage goals, track physical activity, and receive personalized feedback—making exercise more accessible and convenient. However, measurement capabilities and personalized feedback alone may not be sufficient to sustain motivation. In some cases, they can even backfire, leading to demotivation if users feel pressured or coerced [6-8].

Goal Management and Goal Setting

This study focuses on goal management, a central feature in most mHealth apps, as goals are fundamental drivers of motivation and self-regulation [9]. Goal setting is one of the most frequently used and effective strategies for behavioral change [10,11]. Despite its demonstrated importance, an essential question remains: what kind of goals should be set to effectively motivate behavioral change?

This question sparked abundant research and theories on goal setting. For instance, one line of research recommends setting achievable and realistic goals as formalized in the SMART (specific, measurable, achievable, realistic, time-bound) framework [12,13]. Other research emphasizes the motivational benefits of challenging goals [14,15]. Despite that both approaches have merits, the majority of research on goal setting agrees that challenging goals may be discouraging if perceived as unattainable, while easy goals may fail to motivate people [11,14]. The effectiveness of goal setting thus depends critically on aligning goals with users' abilities, needs, and contexts [11]. This raises an essential question: how can such goals be designed and calibrated effectively?

Goal Personalization

To achieve this alignment, many mHealth apps have introduced goal personalization features. These features allow users to modify the default goal, uniform across all users, offering options to personalize the goal to better align with individual circumstances. The process of goal personalization can typically take two forms: (1) personalized-by-you (also known as "customization"), where users set their own goals, and (2) personalized-by-the-algorithm, where the app generates goals based on users' previous exercise data with an integrated algorithm [16].

Goal personalization is expected to increase physical activity compared to no personalization (with default goals) for a few reasons. First, from a goal-setting theory perspective, personalized goals—whether self-set or algorithm-generated—might be more effective than default goals because they accommodate individual abilities and situational context. In addition, from the self-regulation perspective, goal personalization may have the potential to increase physical activity compared to default goals, since the process of personalization encourages active user engagement. This may further foster a greater sense of control and autonomy [17] and reinforce users' perception of themselves as the originators of their goals [18-20]. As a result, users may experience less depletion of self-control resources and feel more energized and maintain greater commitment to achieving their goals [21]. Previous research has partly demonstrated the efficacy of step goal personalization. For example, a study found that a personalized-by-the-algorithm strategy led users to take more steps than a static and default goal (eg, 10,000 steps) [22]. Similarly, 2 more studies reported that the personalized goals generated by the algorithm led to a slower decline in step counts over time compared to nonpersonalized, static goals [23,24].

Despite these promising findings, existing research faces several limitations. First, most studies compare the effectiveness of goals personalized by the algorithm with high, fixed goals (eg, 10,000 steps), which may be challenging for most users [22-24]. It remains unclear whether personalization is still effective when compared to low default goals (eg, 2000 steps). Moreover, much of the prior research on the effect of personalized-by-the-algorithm relies on small-scale randomized controlled trials, often involving fewer than 50 participants per condition, limiting the generalizability of findings [22-24]. For example, one study stated in its limitation section a low sample size of 64 staff workers from a certain university with a dominant proportion of female participants (83%). The results may not generalize to the general public [23]. Second, as far as we know, no previous research has examined the effectiveness of the personalized-by-you approach, relative to existing default goals, in promoting physical activity, underscoring the need for further research. Third, and more importantly, no evidence exists on which personalization strategy is more effective for different types of users. The goal-setting literature offers mixed insights: some studies suggest that self-set goals may be less effective than the assigned goals due to the sustained effort required from users [23,25,26], while others argue that self-set goals promote greater autonomy and may thus be more motivating [27,28]. It is possible that the effectiveness of goal-setting approaches is moderated by other factors, such as individuals' locus of control [29] or their levels of ability [11]. Thus, it is important to investigate which goal personalization strategy is more effective across different types of users.

Collectively, these limitations underscore the need to examine the effects of both goal personalization strategies and investigate which goal personalization strategy works best for different types of users.

Objectives

To address these gaps, this study investigates whether goal personalization increases health behavior and how the different routes of setting the personalized goal affect health behavior. Specifically, this study investigates the effect of goal personalization on physical activity by examining whether 2 personalization strategies (personalized-by-you and personalized-by-the-algorithm) outperform no personalization (with uniform default goals). Additionally, it also examines which strategy is more effective among users with different baseline activity levels (ie, high-, medium-, and low-active users), providing a more comprehensive understanding of how goal personalization operates in real-world settings.

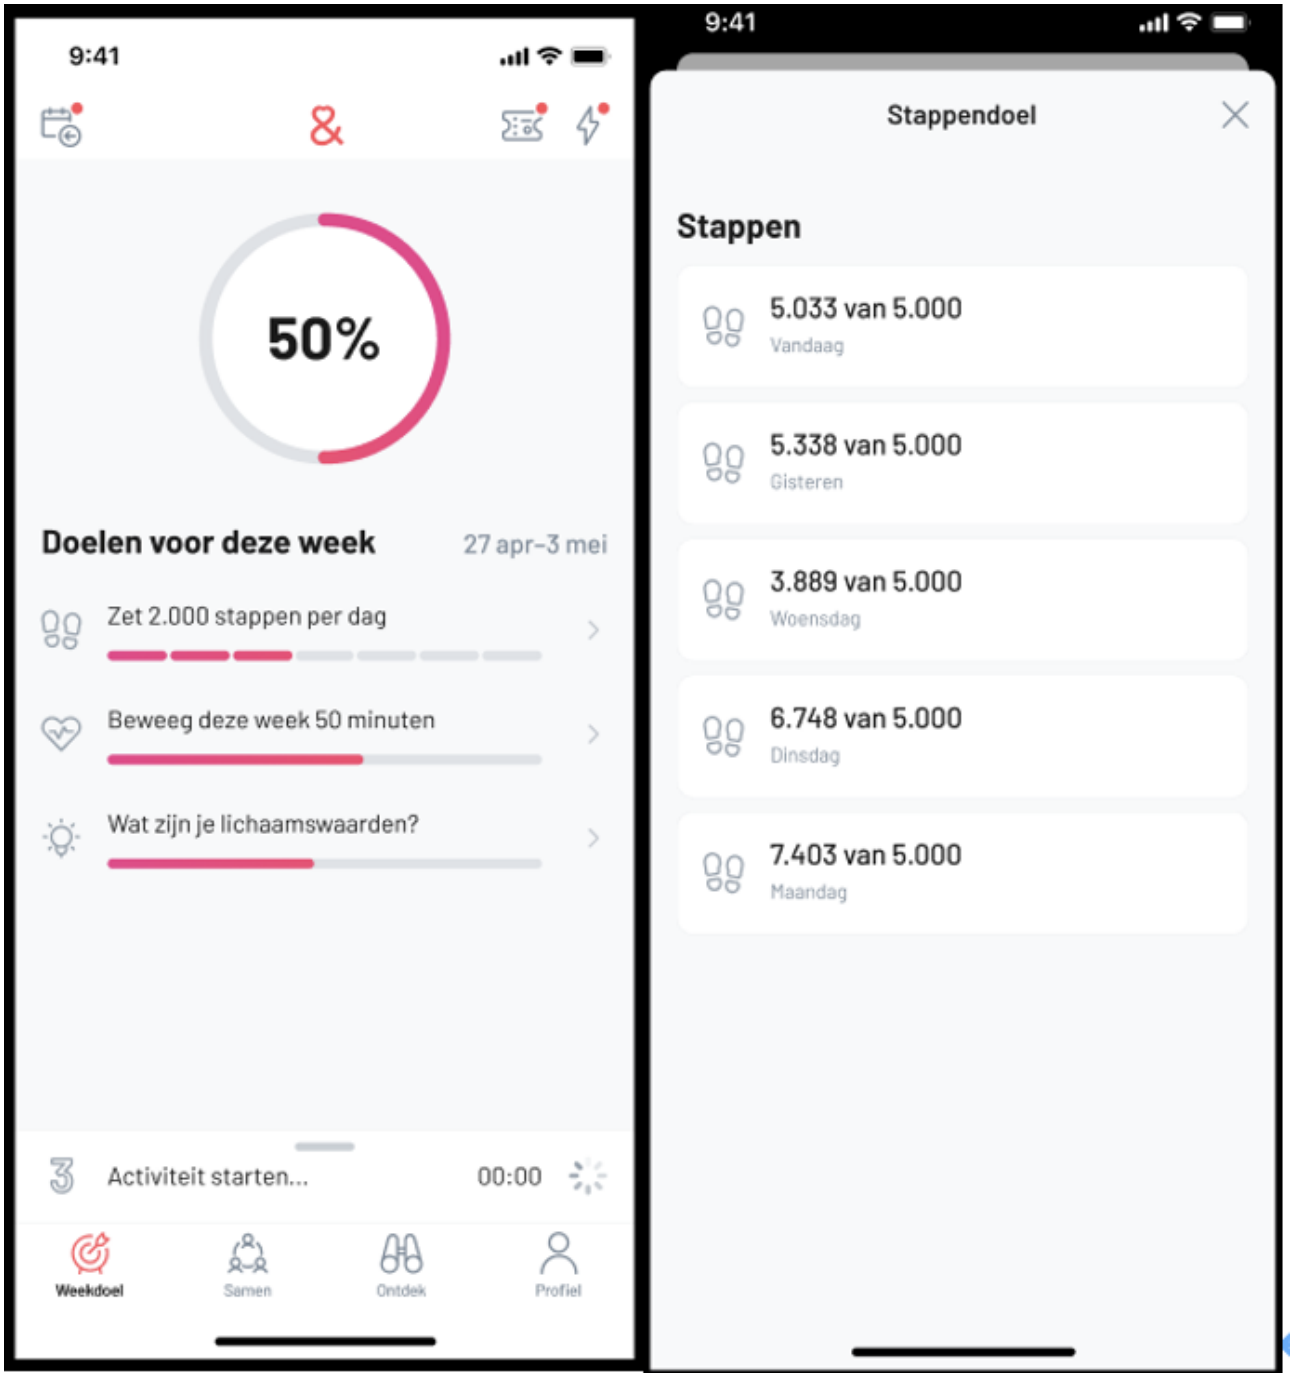
Methods

Ethical Considerations

This study utilized data from an experiment implemented by SamenGezond, which was designed to optimize the effectiveness

XSL•FO
RenderX

of the SamenGezond program. Specifically, this research involved a secondary analysis of the data from adult users of the SamenGezond, an mHealth app, collected by SamenGezond in accordance with its terms of use and privacy policy. The policy states that SamenGezond measures and stores user activities and analyzes them (1) to provide feedback and advice and (2) to test and optimize the effectiveness of SamenGezond. By agreeing to the privacy policy, users consented to the use of their data for analytical purposes. All data used in this research were fully deidentified and aggregated. The use of these data was approved by the institutional research board of the Faculty of Economics and Business of the University of Groningen (approval number FEB-20250424 - 01512).



Study Design

SamenGezond (which translates to "healthy together") is a health app based in the Netherlands, launched in October 2017. Similar to other mHealth apps, it aims to enhance users' health through features such as goal management, GPS-enabled physical activity tracking, and personalized feedback. In addition, the app offers access to health-related papers, expert advice, support from a web-based coach, and opportunities to join exercise communities. Each user is initially assigned a default step goal of 2000 steps per day, 5 days a week. As shown in Figure 1, the app's main page (left panel) displays a circular progress indicator representing the percentage of the user's weekly goal achieved. The circle is color-coded according to the completion level. Below this indicator, the user's step goal is shown, translated as "Take 2000 steps per day," followed by a progress bar indicating weekly performance. Users can also view their total number of steps for each day and the step goal for the week on a separate interface (right panel of Figure 1).

To obtain a valid sample for the study, we used 3 criteria to filter the users in the database. The criteria were, first, that the user had to be a member of the app for at least 4 weeks to ensure some experience with the app; otherwise, the participants would not be able to answer questions on their experience with the step goal. Second, the user must have used this app in the last year because historical exercise data are required to generate a new step goal for users. Third, the users must have subscribed to email communication to ensure the survey can be sent. After applying these criteria, we used the R package dplyr to randomly choose users in the database, ensuring that each user had an equal probability of being included in the sample. Specifically, we used the sample_frac function to select 10% of the users for group 1 and the sample_n function to select users for group 2. As a result, 3800 users were chosen for group 1 and 2000 users were chosen for group 2.

XSL•FO
RenderX

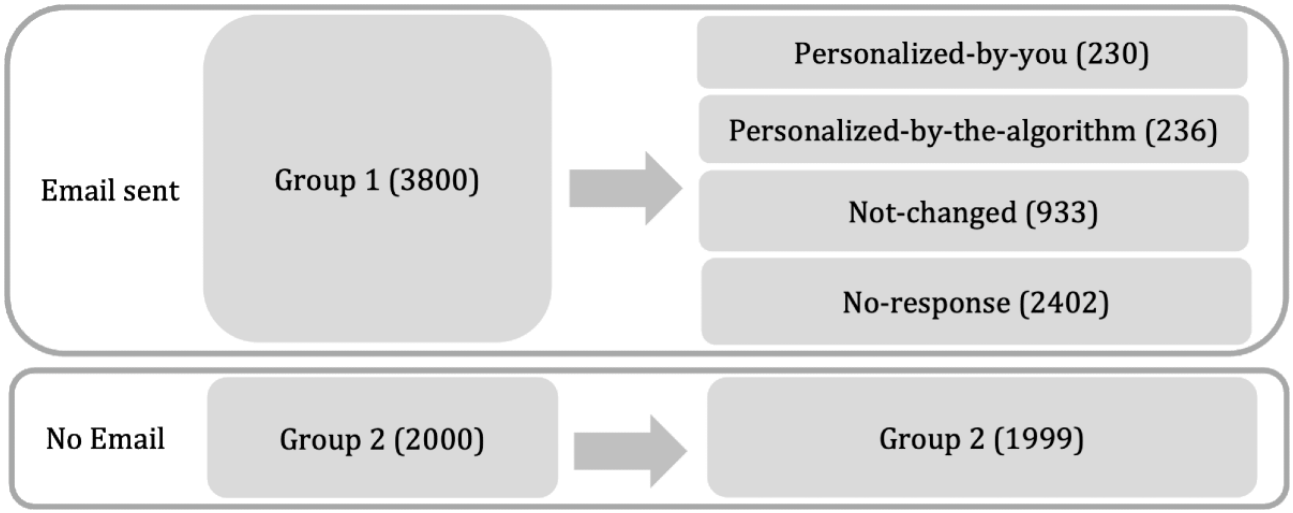


Figure 1. Screenshots of the (Dutch language) mobile health app.

The field study was conducted from week 8 to week 11 in 2023 (February 20 to March 19). A total of 5800 users who met our criteria were randomly chosen from the database by their user ID. In total, 3800 users were selected for group 1 and 2000 users for group 2. At the end of week 7, users in group 1 received an email containing a survey that asked whether they were satisfied with their current step goal. Users who were not satisfied, indicating the goal is "Too high" or "Too low," could choose to personalize their goal either by themselves or through the app (see part A of Multimedia Appendix 1 for detailed information on the survey). A total of 1399 users responded, resulting in 3 subgroups: 230 users personalized their goals themselves (personalized-by-you group), 236 users had their goals personalized by the app (personalized-by-the-algorithm group), and 933 users were satisfied with their current goal and thought their current step goal was "All right" and chose to retain the default goal (not-changed group), resulting in 3 treatment groups. The remaining 2402 users did not respond to the survey (no-response group). Users in group 2 did not receive this email. The procedure is illustrated in Figure 2. Note that when scrutinizing the data, we found that 1 participant from group 2 received and completed the survey due to a technical error. Since they chose to keep the default goal, they were classified into the not-changed group, resulting in 1999 users in the no-intervention group and 933 users in the not-changed group.

XSL•FO
RenderX

Figure 2. Experimental procedure.

In the personalized-by-you group, users set their goals within a reference range of 1000 steps to 20,000 steps. In the personalized-by-the-algorithm group, step goals were generated based on each participant's daily step count over the 4 weeks preceding the study. Not all participants have 28 observations. For example, if users only use the app for 3 days during the previous 4 weeks before the experiment, then they only have 3 observations. As the mean steps per day do not necessarily represent a "normal day" due to outliers, we adopted a moving-window percentile rank algorithm [22,24]. Specifically, step counts were sorted in ascending order for each participant, and the observation just below the median was selected as the new step goal. For example, for a participant with 10 observations, the fourth in rank was selected, and for a participant with 7 observations, the third in rank was selected. Then, we rounded the chosen step counts to the nearest hundred as users' step goals. We set limits on the new goal generated through this procedure. The users had to have at least 7 daily observations to generate a new goal based on their historical exercise. For those users, the algorithm constrains the goals from 2000 to 8000 steps. For example, for a user with 28 observations, if the 13th observation is over 8000, then the goal would be set as 8000. For participants with fewer than 7 observations, the goals were assigned to them based on the following rule: those who indicated that the default goal of 2000 steps was too high received a goal of 1500 steps, while those who felt it was too low were assigned 3500 steps, each for 5 days a week.

Statistical Analysis

For all of the users in our study (N=5800), we have their data on anonymous ID, group information, step goal, age, gender, app usage duration (measured as the total number of days they have registered as a member of this app), total steps between weeks 6 and 11, and the number of days the goal was achieved during that period. To prepare the dataset for analysis, we imputed missing age values using group means, categorized missing gender as "unknown," and replaced extreme outliers in total steps (eg, over 20 million steps per week) with the group mean for the respective week. The extreme outliers were caused by system error. An adult can only walk up to 560,000 steps a week if they walk 10 hours for 7 days based on the average walking speed. A total of 560,000 steps is far lower than 20 million steps.

A major challenge in identifying the causal effect of goal personalization on physical activity lies in the self-selection of users into different groups. The decision to personalize goals might be influenced by factors such as prior physical activity levels, app usage duration, and other individual characteristics. For instance, more active users may be more likely to engage in goal personalization. To address this issue, we utilize the propensity score matching (PSM) technique together with the difference-in-difference (DID) model, following previous research [30,31]. PSM was used to construct 3 matched control groups corresponding to the personalized-by-you, personalized-by-the-algorithm, and not-changed groups. The DID method then compares the pre- and posttreatment differences between each treatment group and its matched control group [32]. This approach helps to control the impact of exogenous and time-varying factors, such as weather, that may affect all users [32].

To ensure a sufficiently large matching pool for PSM, we combined the no-response group and group 2 (Figure 2), a total of 4401 users, as the matching group. Propensity scores were estimated using a logistic regression model based on users' age, gender, app usage duration, total steps in weeks 6 and 7, and the number of days the step goal was achieved in those weeks. We then applied 1:1 nearest neighbor matching to construct comparable control groups for each of the 3 groups. To evaluate the quality of PSM, we checked whether the variables were balanced between each treatment group and its matched control group. The mean values of the covariates, such as the mean age and gender proportion, are closely aligned across the matched pairs, confirming the success of the PSM procedure.

To estimate the effect of goal personalization on physical activity, as measured by total steps walked per week, our DID model specification is as follows:

$$(1)\text{Stepsit}=\beta 0+\beta 1\text{Personalizationit}+\theta i+\lambda t+\varepsilon it$$

In equation 1, Steps_{it} denotes the weekly total number of steps taken by user i in week t, and $\text{Personalization}_{it}$ is a binary variable indicating whether the users i personalized their goal

XSL•FO
RenderX

in week *t*. We also included individual fixed effects (θ_i) to control for unobserved heterogeneity across users and time fixed effects (λ_t) to account for exogenous influence (eg, weather). We estimated the DID model 3 times, each time comparing 1 of the 3 groups with its corresponding matched control group.

The identification of the goal personalization effect using a DID model relies on the common trend assumption. To test whether the common trend assumption is met, we split the personalization effect into different weeks by including the interactions of personalization and week. The findings indicate that there is no significant difference between week 6 and week 7 across all 3 groups, supporting the common trend assumption (shown in part B of Multimedia Appendix 1).

Results

User Statistics

The overall mean age of the 5800 users was 54.86 years (SD 10.42), with 60% (n=5800) being women. The average app usage duration was 813.77 days (SD 536.42). Tables 1-3 present detailed characteristics of users across the personalized-by-you, personalized-by-the-algorithm, and not-changed groups and their matched control groups.

Main Results

The results in Table 4 show a significant increase in physical activity among users in all 3 groups compared to their respective matched control groups. On average, users in the personalized-by-you group increased their weekly steps by 3793 (P<.001) from week 8 to week 11 after the personalization, compared to 2 weeks prior to the personalization. This corresponds to an average increase of 542 steps per day. Those in the personalized-by-the-algorithm group showed an increase of 4315 (P<.001) weekly steps (616 steps per day). These results demonstrate that both personalization strategies are effective in increasing physical activity levels. There is no significant difference between the overall effects of the 2 personalization strategies (t=0.354, P=.72). Users in the not-changed group, who did not alter their goals, also demonstrated an increase of 1759 (P<.001) per week (251 steps per day).

[b]*P*<.001.

Heterogeneity by Prior Activity Levels

To assess the potential heterogeneity in the goal personalization effect by prior activity, we estimate specification (equation 1) on subsamples classified according to total steps walked in week 6 and week 7. Specifically, the users in each of the 2 personalization groups were further divided into 3 groups: the first quartile (low-active users), the second and third quartiles (medium-active users), and the fourth quartile (high-active users), based on their step counts prior to the study.

The results reveal significant differences in the effects of the personalized-by-you and personalized-by-the-algorithm strategies across activity levels. Among low-active users, the personalized-by-you strategy showed no significant effect (*P*=.82, see Table 5, column 1), whereas the personalized-by-the-algorithm strategy demonstrated significant effectiveness, increasing weekly total steps by 5094 from week 8 to week 11 after the personalization, compared to 2 weeks prior to the personalization (*P*=.003; see Table 5, column 4). For medium-active users, both strategies are similarly effective: personalized-by-you increased weekly steps by 5841 (*P*<.001) and personalized-by-the-algorithm by 5278 (*P*<.001) over a 4-week period after the personalization (see Table 5, columns 2 and 5). In contrast, for high-active users, personalized-by-the-algorithm was not effective (*P*=.51, see Table 5, column 6), while personalized-by-you proved to be marginally effective (*P*=.09; see Table 5, column 3).

Table . Heterogeneous effects of personalization by prior activity[a].

	Personalized-by-you, steps			Personalized-by-the-algorithm, steps		
	Low-active users	Medium-active users	High-active users	Low-active users	Medium-active users	High-active users
Personalization	383.641 (–1694.72)	5841.661[b] (–1476.70)	4266.063[c] (–2598.36)	5093.521[d] (–1766.61)	5278.006[b] (–1476.70)	1446.37 (–2194.72)

Robustness Check

As robustness checks, we used different matching samples for PSM. In our main study, we combined both users in the no-response group and users from group 2 as the matching sample. For robustness checks, we treated these 2 groups separately as distinct matching samples. We then reestimated the same DID models. The results remain robust, with all 3 groups (personalized-by-you, personalized-by-the-algorithm, and not-changed groups) showing significant effects (shown in parts C and D in Multimedia Appendix 1).

Discussion

Principal Results

Given the potential benefits of goal personalization on physical activity and the lack of solid evidence in previous literature, a large-scale field study was conducted to examine the potential of personalization in prompting health behavior. Our findings demonstrate that goal personalization effectively increased physical activity, resulting in an average increase of over 500 daily steps over a 4-week period. This increase is meaningful at the individual level, as prior meta-analytic evidence based on over 200,000 participants indicates that an additional 500

XSL•FO
RenderX

steps per day is associated with a 7% reduction in cardiovascular-related mortality [33]. Our findings also demonstrate that even participants who only completed the survey but did not change their goal increased their weekly steps by 1759 over a 4-week period. The increase may be attributed to a reminder effect from receiving the email and completing the survey [34,35]. However, post hoc analyses reveal that users in both goal personalization groups take significantly more steps than those in the not-changed groups. This suggests that the observed increase in steps is not solely due to the reminder effect. Specifically, compared with the unchanged group, the users in the personalized-by-you group showed a marginally significant increase (P=.09), while the users in the personalized-by-the-algorithm group showed a significant increase (P=.02).

Moreover, this study also compared the effectiveness of 2 personalization strategies. While the overall effects of these 2 strategies are similar, heterogeneity tests based on prior activity levels indicate varying effectiveness across distinct groups. The personalized-by-you strategy proves effective for medium and high-active users, whereas the personalized-by-the-algorithm significantly boosts total steps for low-active and medium-active users.

We argue the potential reason why personalized-by-the-algorithm is effective for low-active users, while personalized-by-you is not, is as follows. Low-active users may overestimate their physical abilities when personalizing the goal by themselves, leading to goals that are less realistic and motivating. In contrast, goals generated by the algorithm are based on users' previous exercise data, likely aligning better with their capabilities. This alignment enhances individuals' self-accountability and competence and drives better health outcomes [36]. A post hoc analysis shows that low-active users in the personalized-by-you group set higher goals than those in the personalized-by-the-algorithm group—3730 steps versus 2844 steps—a difference that is marginally significant (P=.07). This finding underscores the importance of personalized-by-the-algorithm in setting realistic and motivating goals for low-active users.

The reason why personalized-by-you is effective for highly active users, while personalized-by-the-algorithm is not, is as follows. High-active users, being more experienced with exercise, may be capable of setting goals that better align with their ability, situation, and standard than the algorithm. Further analysis supports this, showing that high-active users in the personalized-by-you group set lower, more realistic goals (5700 steps on average) compared to those in the personalized-by-the-algorithm group (7061 steps on average; P=.002). The higher goals set by the algorithm might be too challenging and therefore demotivating these users.

These findings advance goal-setting theory in 3 ways. First, prior research provides mixed guidance on goal type: while the SMART framework emphasizes specific and attainable goals [12,13], other work stresses specific and challenging goals [14,15]. Both approaches have limitations: too-easy goals may fail to motivate meaningful health behavior. This study indeed shows that the default 2000-step goal was less motivating than the average 4747-step goal set in the personalized groups. Conversely, difficult goals can discourage users [11,14], as this study shows that the average 7061-step goals for high-active users in the personalized-by-the-algorithm group only had a similar effect as the 2000-step goal. Our study highlights the value of personalized goals that align with individuals' abilities, characteristics, and contexts. Second, beyond goal type, the study contributes to how to best set the goals by identifying 2 distinct goal personalization strategies. Third, the study examines the moderating role of prior activity level, offering theoretical insights into the conditions under which different personalization strategies are most effective. In sum, the findings extend goal-setting theory by clarifying what types of goals should be set, how goals can be personalized (methods), and when different personalization strategies are most effective (boundary conditions).

As for practical contribution, given the findings, mHealth technology companies should prioritize algorithmic personalization or, at the very least, frame the choices of personalization in a manner that encourages low-active users to opt for algorithm-based personalization. However, for high-active users, it is important to give them the opportunity to personalize their goals by themselves, as they are more motivated by self-control, autonomy, and self-accountability and are better equipped to set goals that align with their abilities.

Limitations

This research has limitations that warrant consideration. First, the participants were not randomly assigned to different treatment groups but made the decision by themselves, which could introduce potential biases. Although we employ PSM and DID to address the issue, only a randomized field experiment can fully mitigate such biases. Second, the lack of postexperiment data prevents us from assessing the long-term sustainability of the goal personalization effect. Third, we do not have data to test whether the goal personalization effect extends to other health-related activities, such as gym attendance or weight management, which limits the generalizability of our findings. Fourth, this study compares personalized goals to a fixed 2000-step goal, without considering other types of goals (eg, 5000-step goal), which may constrain the scope of the comparison. Finally, there are other goal personalization algorithms, such as machine learning approaches that predict step goals using previous step data and goal histories [23], or simple goal adjustment approaches based on goal achievement [37,38]. Future studies can investigate the comparative effectiveness of these goal personalization methods. Furthermore, more intelligent algorithms that incorporate contextual factors—such as users' moods and weather conditions—should be developed and empirically tested in future research to examine whether they can generate more motivating personalized goals and encourage users to be more physically active.

Conclusions

This study investigated the effects of 2 goal personalization strategies on increasing users' physical activity levels through an open-access mHealth app. The results show that both strategies significantly promote physical activity—by over 500

XSL•FO
RenderX

additional steps per day—with improvements that are meaningful at the individual level, particularly in reducing health risks. Moreover, the study identified the applicability of each personalization strategy: the personalized-by-you approach is more effective for medium- and high-active users, while the personalized-by-the-algorithm strategy works better for low- and medium-active users. These insights can inform the design of the goal management features in mHealth apps to enhance the effectiveness of health interventions.

Abstract

Background: Adolescents from underserved communities, particularly Black and Hispanic youth, engage in lower levels of physical activity (PA), increasing their risk for chronic disease. Conventional interventions often face barriers such as limited access to safe environments. Wearable mobile health technologies offer scalable and context-sensitive solutions; however, predictors of sustained adherence in school-based settings among high-risk populations remain underexplored.

Objective: This study aims to examine the behavioral and contextual predictors of adherence to a consumer-grade wearable PA tracker among underserved high school students.

Methods: In this school-based observational study, 63 students (mean age 14.8, SD 1.17 years) enrolled in physical education received Fitbit devices. Adherence was defined as ≥21 valid days of step count data. Measures included self-reported PA behaviors, neighborhood perceptions, physical fitness (including anthropometrics), and device adherence. Group comparisons were conducted using *t* tests and chi-square tests. Logistic regression was used to identify predictors of adherence.

Results: Overall, 73% (46/63) of participants met the adherence threshold. Adherent students reported fewer days of moderate-to-vigorous PA (2 vs 4 days/week; *P*=.004), lower team sports participation (21/46, 46% vs 12/17, 71%; *P*=.004), and higher perceived neighborhood safety (*P*=.02). In adjusted models, lower PA frequency, greater perceived safety, and neighborhood walkability significantly predicted adherence (χ^2_6=16.23*; P*=.01, Nagelkerke R^2=0.61).

Conclusions: Wearable mobile health technologies show promise for engaging underserved adolescents in PA, particularly those with lower baseline activity and limited access to structured sports. Key predictors of adherence included perceived neighborhood walkability, team sports participation, and prior PA behavior. School-based deployment of wearable devices should emphasize personalized goals and autonomy-supportive strategies to foster sustained engagement and promote PA among high-risk youth.

Introduction

With national and international guidelines recommending at least 60 minutes of moderate-to-vigorous physical activity (MVPA) daily for children and adolescents, physical inactivity remains a pressing public health concern [1,2]. Regular physical activity (PA) is associated with numerous health benefits, including lower resting heart rate (HR), a key indicator of cardiovascular health [3,4], improved functional fitness [5], and enhanced long-term physical and mental well-being [6]. Despite these benefits, only 22% of adolescents meet the recommended PA guidelines [7], with participation rates significantly lower among Black, Hispanic, and immigrant youth [8]. Many children and adolescents in racially diverse and low-resource neighborhoods lack access to consistent and supportive PA opportunities outside school [9]. Furthermore, the growing financial and time demands placed on parents for youth sports participation [10] have made consistent PA opportunities

XSL•FO
RenderX

increasingly inaccessible for many adolescents, particularly those from underserved communities.

Consumer-grade wearable mobile health (mHealth) technologies may offer a scalable, user-friendly means to assess and promote PA engagement [11]. Awareness and use of step-based metrics from wearables can provide an opportunity for self-monitoring, goal setting, and motivation to increase PA behavior and improve health and fitness. For example, typically step-based metrics ranging from 7000 to 11,700 steps per day are associated with meeting Centers for Disease Control and Prevention (CDC)-recommended PA levels [12-14] and with reducing cardiovascular and mortality risks [15]. Conversely, taking fewer than 7000 steps per day may indicate insufficient PA behavior [14]. Wearables can help adolescents become more aware of their PA levels and facilitate tracking of these metrics [16]. There is growing evidence supporting the role of mHealth technologies, including smartphones, apps, and wearables, in promoting positive health behaviors and some improvement in weight status among youth [17]. These devices incorporate behavioral change techniques, such as goal setting, self-monitoring, and feedback [18], and may be particularly useful in school-based programs where environmental constraints can be addressed.

Traditional PA opportunities often rely on structured sports or clinic programs outside of school, which may be inaccessible due to socioeconomic and parental involvement time constraints, limited transportation, and neighborhood safety concerns for underserved youth [19]. Additionally, limited access to safe recreational environments and health-promoting infrastructure further compounds these risks, reinforcing poor PA engagement and long-term health outcomes [20,21]. These limited access to PA opportunities disproportionately affect adolescents from underserved communities, who are at increased risk for deficiencies in motor proficiency, strength, cardiovascular endurance, and overall PA levels, factors closely linked to obesity and poor fitness [22]. Over time, these disparities contribute to the early onset of chronic health conditions such as cardiovascular disease and type 2 diabetes [23]. In contrast, wearable mHealth technologies offer a scalable, low-cost alternative that can be integrated into adolescents' daily routines, making them particularly promising for populations with limited access to conventional resources.

School-based physical education (PE) programs are a critical platform to provide accessible PA interventions [24]. Wearables integrated into school-based programs can promote autonomy and engagement even in constrained environments. Importantly, low levels of teacher burden have previously been associated with favorable perceptions of feasibility, further supporting the scalability of wearable devices (WD) applicability in school settings [25]. Prior studies suggest that wearables may positively influence PA levels by enhancing self-efficacy and behavioral regulation among adults [26]. Additionally, accuracy and behavioral impact of WD in general have mostly been examined in the adult population [26,27]. Despite the growing popularity of consumer wearables, little is known about long-term adherence to wearable technologies among high school age adolescents from underserved racial and ethnic minority groups [11,28]. There is a significant gap in understanding adherence behavioral patterns among adolescents facing environmental barriers, such as unsafe neighborhoods, low PA engagement, and limited access to recreational spaces.

Recent shifts in PA research emphasize the importance of broader contextual factors, both environmental (ie, social environments, physical settings, and access to resources) and personal (ie, enjoyment, autonomy, and perceived competence), in shaping PA behavior [29]. For example, previous studies found that wearables may be less accessible or sustainable for adults in underserved settings owing to socioeconomic barriers, limited internet access, and concerns about privacy and crime safety [30]. Additionally, research on long-term adherence remains limited, particularly among marginalized youth [31,32]. These contextual challenges may influence how adolescents engage with digital health tools, and the findings from broader populations may not be generalizable to these groups.

Bandura's Social Cognitive Theory (SCT) provides a behavioral foundation for understanding adherence to WD use, emphasizing how personal factors (self-efficacy and motivation), behavioral patterns (consistent device use), and environmental influences (social support and accessibility) interact to influence health behaviors [33]. The International Classification of Functioning, Disability, and Health (adherence) complements this perspective by situating these behaviors within a biopsychosocial framework, capturing how an individual's body functions and structures, activities and participation, and contextual factors (personal and environmental) collectively shape overall functioning and engagement in daily life [34]. Together, SCT and the International Classification of Functioning and Disability (ICF) informed the selection of study variables, including self-efficacy, readiness for change, perceived neighborhood safety, and physical fitness and function, allowing for a nuanced exploration of WD adherence and PA engagement among underserved adolescents.

To address the gap in understanding the influence of contextual factors on WD adherence, this study investigated associations among contextual factors, including sociodemographic characteristics, environmental conditions, PA behavior, and adherence to WD, among a racially and socioeconomically diverse cohort of high school students enrolled in a school-based PE program. Guided by the ICF framework, we included predictors, such as self-efficacy, readiness for change, perceived neighborhood safety, and physical fitness, each representing key domains within the ICF [34]. These factors have been validated in prior studies and are particularly relevant to understanding adolescent engagement in PA as they reflect the complex interplay between individual capabilities, motivation, and contextual influences [35]. Specifically, we examine the following: 1. whether demographic, personal, and environmental factors influenced WD adherence; and 2. Whether WD adherence was associated with differences in self-reported PA, fitness, and functional performance outcomes. Our findings aim to inform the design of future school-based wearable interventions that effectively engage adolescents from historically marginalized populations and promote PA through sustained behavioral changes.

RenderX

Methods

Overview

This prospective cohort study was conducted in collaboration with local nonprofit organizations and public-school administrators. Participants were recruited using a purposive sampling strategy designed to ensure the representation of racially and socioeconomically diverse adolescents in an underserved community. School-based physical therapists and PE teachers facilitated recruitment through in-class announcements and take-home informational flyers distributed during sessions of state-mandated Health Opportunities Through Physical Education (HOPE) courses. This course emphasizes lifelong fitness, healthy behavior, and personal responsibility [36]. All students enrolled in the HOPE were invited to participate, minimizing selection bias by including students regardless of their prior PA engagement or academic standing. To reduce sampling bias and ensure equitable participation, parent consent and student assent materials emphasized the voluntary nature of the study, clarified that participation would not affect academic standing, and explained the privacy protections in place. Materials were designed to be culturally appropriate and accessible, with bilingual staff available to address questions for parents or guardians. These steps were taken to minimize the likelihood that guardians would restrict participation based on personal beliefs, misconceptions about wearable technology, or concerns about data privacy.

Although the school served as the central hub for recruitment and data collection, participants wore WD during and outside school hours, enabling continuous monitoring of PA across multiple contexts, including home and community settings. Predictors of adherence, such as neighborhood safety, team sports participation, and self-reported PA behaviors, reflect influences beyond the school setting. Nevertheless, the school played a pivotal role in supporting this study through structured integration of the PE curriculum, device distribution, and ongoing student engagement.

Study Timeline

Data collection spanned the entire academic year, with baseline assessments conducted in the first quarter and follow-up assessments conducted in the final quarter. This extended duration enabled evaluation of adherence to WD use throughout the academic year.

Procedures

Baseline assessments were conducted over 2 PE class sessions. Day 1 included demographic and PA surveys, and day 2 involved physical performance testing. In collaboration with PE instructors and school-based physical therapists, students received individualized step-count goals, starting with a 10% weekly increase from their baseline average. PE teachers provided weekly reminders to wear and synchronize their Fitbit devices. Measures such as self-efficacy and readiness for change were selected based on their established predictive value in adolescent PA engagement, as supported by Bandura's SCT [33] and integration into the WHO-ICF framework. Environmental variables were included to reflect contextual influences consistent with ICF's socio-ecological approach. Table 1 provides a summary of variables assessed and associated theoretical construct.

[d]SCT: Social Cognitive Theory.

WD Adherence

Participants received a Fitbit Flex activity tracker and information on device use, care, and data synchronization from school-based physical therapists. These devices contain accelerometers and have demonstrated moderate to excellent validity compared to research-grade accelerometers in youth [39,40]. The Fitbit data were uploaded to Fitabase, a research platform for remote device monitoring. The weekly averages of daily steps were captured using Fitbit Flex devices [54]. Adherence days were defined as days with at least 10 hours of HR monitoring data [55], and Adherence week was defined as a week with at least 3 valid days of WD use [41]. A 21-day period of WD use stratified participants as adherent or nonadherent WD users. This threshold was chosen based on prior studies that defined high adherence to WD use as achieving at least 70% of the recommended daily use over a 30 day period [56] and systematic review benchmarks of 10 hours per day criteria for high adherence to daily use [41]. These timeframes were selected to balance early feasibility with theoretical relevance, particularly in adolescent populations, where motivation and environmental influences may fluctuate.

PA and Psychosocial Measures

PA behavior and psychosocial constructs were assessed using a patient-centered assessment and counseling for exercise and

XSL•FO
RenderX

nutrition (Pollution Abatement Costs and Expenditures) survey. This validated instrument includes items on decisional balance, self-efficacy, enjoyment, and social support [37,38]. It has demonstrated acceptable reliability (ICC=0.60 - 0.82) and moderate validity with accelerometer-derived MVPA (r=0.27 - 0.40) [41]. Additionally, the Pollution Abatement Costs and Expenditures Survey assessed all participants on: days per week of 60 minutes of MVPA, readiness for change, and perceived peer or family support [42-44]. Lastly, team sports participation was measured using the 2013 Youth Risk Behavior Survey, which has shown substantial reliability (κ=0.61 - 0.91) [45].

Neighborhood Walkability

Perceived neighborhood environment was assessed using the Neighborhood Environment Walkability Scale for Youth (NEWS-Y) [46]. The subscales measure safety from crime, traffic hazards, and access to land. Items were rated on a 4-point Likert scale, with higher scores indicating lower walkability. The NEWS-Y has demonstrated good test-retest reliability (ICC=0.56 - 0.87) and validity, as evidenced by associations with walking behaviors among youth [46].

Clinical Assessments

To evaluate physical fitness and functional performance, a series of standardized assessments was administered during PE class sessions by trained physical therapists. These measures were selected based on their reliability, validity, and relevance to the adolescent population.

Anthropometrics and Vital Signs

Height, weight, and waist circumference data were collected using standardized procedures [47]. BMI was calculated using CDC growth charts. The waist-to-height ratio (WtHR) was calculated; a ratio ≥0.5 indicated elevated central adiposity [48]. Resting HR and blood pressure were measured using standard clinical procedures and equipment [49].

Functional Fitness Assessments

Cardiovascular endurance was assessed using the 6-minute walk test, a submaximal exercise test that measures the distance an individual can walk in 6 minutes. The 6-minute walk test is widely used in pediatric populations and has demonstrated excellent reliability (ICC=0.94) and strong validity for estimating aerobic capacity [50,51].

Functional mobility was assessed using the timed up and go test, which evaluates lower-extremity strength, coordination, and mobility. Participants were timed as they ascended and descended stairs. The timed up and down stairs test has shown excellent reliability (ICC=0.978 - 0.999) and correlates well with other mobility and balance measures [57].

Balance was assessed using the timed single-leg stance test, in which participants stood on one leg for as long as possible without support. This test provides insight into postural control and neuromuscular stability and demonstrates acceptable reliability in youth populations [52].

Upper-body strength and endurance were assessed using 90° push-ups, in which participants performed push-ups until exhaustion with proper form. This test is a reliable indicator of muscular endurance (ICC=0.93) and has demonstrated moderate validity when compared to bench press performance (r=0.64; males and r=0.28; females) [53].

Data Analysis

Statistical analyses were performed using SPSS v28. Descriptive statistics were used to characterize the participants. Chi-square and independent t tests were used to compare the adherence groups in terms of demographic and outcome variables. Pearson correlation coefficient was used to assess the association between PA behaviors and psychosocial variables. Relationships were classified by effect size: 0.00 - 0.25 (none), 0.25 - 0.50 (weak), 0.50 - 0.75 (moderate), and >0.75 (strong) [58]. Binomial logistic regression was used to examine the associations between WD adherence and demographic, behavioral, and environmental predictors, including PA level, obesity status, perceived neighborhood safety, and nativity. A priori power analysis using G*Power (v3.1.9.6) determined a minimum sample size of 57 to detect medium effect sizes (Cohen d=0.5, f^2=0.30) with α=.05 and 80% power.

Ethical Considerations

This study was approved by the Western Institutional Review Board and the Research Ethics Committee of the County School Board. Informed consent was obtained from all the participants and their guardians. The eligibility criteria were high school adolescents aged 14 - 18 years who were enrolled in a HOPE course. Baseline assessments were conducted in the first academic quarter, and follow-up assessments were conducted in the final quarter. Surveys and physical fitness tests were conducted during the PE class. Race, ethnicity, and nativity (US or foreign-born) were self-reported. All collected data were stored on secure, password-protected servers; identifiable information was removed prior to analysis to ensure participant privacy and confidentiality. No financial or academic compensation was provided, and participation had no effect on course grades.

Results

Cohort Characteristics

Participant characteristics by WD adherence (N=63) are presented in Table 2. Of the total sample, 73% (46/63) met the WD adherence criteria. The average age was 14.8 (SD 1.17) years, with the majority in ninth grade (51/63, 81%). More than half of the participants were female (35/63, 56%), and 73% (46/63) received free or reduced lunch. Most were Black or African Americans (40/63, 72%), followed by Hispanics (16/63, 42%). Sixteen percent (10/63) were foreign-born, and 37% (23/63) reported maternal nativity outside the United States. The average BMI and WtHR for the sample were 23.06 (SD 4.62) kg/m² and 0.45 (SD 0.07), respectively.

Anthropometric Characteristics

As detailed in Table 3, 19% of participants were classified as overweight (12/63) and 15.9% were classified as obese (10/63). Also, 21% (13/63) had a WtHR >0.5, indicating elevated cardiometabolic risk. Significant differences between the WD adherence groups were found in resting HR (76.4 vs 67.4 bpm; *P*=.009) and single-leg stance duration (57 vs 59 s; *P*=.03). No statistically significant differences were found in BMI, WtHR, blood pressure, 6 MWT, timed up and down stairs, push-ups, or sit-to-stand performance.

[g]SLS: single-leg stance.

PA and Environmental Perceptions

Table 4 summarizes the psychosocial and environmental characteristics based on WD adherence. On average, participants reported engaging in ≥60 minutes of MVPA at 2.86 (SD 2.17) days per week. Only 13% (8/63) participants met the daily MVPA guidelines, with males being more likely than females to do so (7/28, 25% vs 2/35, 5.7%; *P*=.06). Notably, 24% (15/63) of the participants reported no MVPA during the week, with inactivity being more prevalent among female adolescents (13/35, 36% vs 3/28, 12%). Participation in team sports was positively associated with MVPA; among the 33 adolescents who participated in sports, only 3 reported no MVPA. However, WD-adherent participants reported fewer days of MVPA (2 d vs 4 d; *P*=.004), fewer days of muscle-strengthening activities (3 vs 4.8 d; *P*=.004), and lower team sports participation (21/46, 46% vs 12/17, 71%; *P*=.004) compared to their nonadherent peers. No significant differences were found in psychosocial measures such as self-efficacy, family or friend support, or decisional balance. Interestingly, adherent participants perceived their neighborhoods as safer, with lower scores for crime (1.7

XSL•FO
RenderX

vs 2.4; *P*= .02), traffic concerns (2.1 vs 2.4; *P*=.04), and reported greater access to land-use features (3.1 vs 2.9; *P*=.04).

Predictors of Wearable Adherence

The results of the binomial logistic regression analysis in Table 5 indicate that the model was significant (χ^2_6=16.23; *P*=.01), explaining 61% of the variance (Nagelkerke R^2). Overall, 2 significant predictors emerged: perceived neighborhood crime safety and MVPA frequency. Adolescents engaging in <3 days per week of MVPA had significantly higher odds of WD adherence (OR 6.1, 95% CI 1.5-24) than those who met or exceeded the 3-day threshold. These findings suggest that lower levels of PA and perceptions of neighborhood safety may influence engagement with WD.

Table . Logistic regression predicting the likelihood of wearable device adherence.

Variables	β	SE	Wald (*df*)	Sig.	Exp (β)	95% CI for Exp (β)

[a]HR: heart rate.

[b]PA: physical activity.

[c]Not applicable.

Despite the early engagement, adherence to Fitbit monitoring declined sharply over time. Of the 63 students who initiated device use, 42 (67%) maintained adherence for at least 2 months. By month 3, retention dropped to 29 students (46%), and by month 4, only 21 students (33%) remained. Long-term adherence was minimal: 9 students (14%) persisted through month 5 and only 3 (5%) continued through month 7. This trajectory reflects a steep early decline followed by a gradual taper, underscoring the challenge of sustaining engagement beyond the initial months.

Discussion

Principal Findings

This study offers novel insights into WD adherence among underserved adolescents in a school-based setting, thus addressing a critical gap in the literature. While prior research has emphasized the role of personal and environmental factors in shaping PA behaviors, primarily focused on homogenous or higher-resource populations [27], few studies have explored how these influences interact with technology engagement in diverse, resource-limited populations. Notably, our findings revealed that adolescents with lower baseline PA, defined as engaging in MVPA fewer than 3 days per week and those least involved in team sports were more likely to adhere to WD use, precisely the group most in need of sustained support. Furthermore, 90% (9/10) of participants with obesity adhered to WD use, underscoring the potential of wearables to engage adolescents at elevated risk for chronic health conditions. Although counterintuitive, this pattern may reflect an opportunity to drive behavior change, wherein previously inactive youth leveraged technology as a catalyst to initiate and sustain PA. These findings align with prior research, such as the RAW-PA study [25], which demonstrated the high acceptability of wearable interventions among adolescents attending socioeconomically disadvantaged schools. To further

XSL•FO
RenderX

explore the impact of WD adherence on PA behavior, we conducted a post hoc analysis of step-count trends over the academic year. WD-adherent participants with lower baseline PA demonstrated modest but consistent increases in average daily steps, suggesting a potential behavioral change. Although further research is recommended, these results support the potential for wearables to facilitate engagement and promote sustained improvements in PA levels among adolescents, who are most in need of interventions.

Furthermore, adherence to WD use is often undefined or underreported in adolescent cohorts [59], particularly in resource-limited community-based settings. Our study addressed this gap by defining adherence and examining longitudinal patterns in a population disproportionately affected by obesity and related chronic conditions, thereby distinguishing it from short-term pilot studies. WD adherence was defined as having WD HR data for more than 10 hours per day for at least 3 days of the week for a minimum of 3 weeks, which aligns with benchmarks established in the wearable adherence literature [55,56] and indicates meaningful engagement. Furthermore, the data collection spanned the academic year, providing a flexible timeline for teachers and students to initiate WD use as needed. Although the initial WD engagement was high (46/63, 73%) following deployment, adherence declined sharply after the first month, with only 14% persisting until month 5 and 5% through month 7. Our findings in this underserved population echo more recent systematic reviews reporting mixed results for long-term adherence and call for interventions that combine technology with behavioral support and environmental modifications [60,61]. These results underscore the challenge and opportunity of maintaining engagement beyond the initial novelty period and highlight the need for tailored strategies, such as non–peer-competitive gamification and personalized goal setting.

Our study also revealed a stronger than anticipated association between perceived neighborhood safety and WD adherence. Our findings support the role of baseline PA behavior and environmental perceptions in PA adherence in previous studies, while extending this knowledge to WD use among predominantly Black or African American and Hispanic high school adolescents. Moreover, schools can leverage wearable data to personalize interventions, monitor progress, and foster peer support, thereby enhancing engagement and safety. Integrating wearables into school-based programs that address environmental constraints may offer a promising strategy to promote equitable PA engagement and reduce chronic disease risk [62,63]. Collaborations between schools, policymakers, device developers, and health care professionals are essential to ensure equitable access to supportive technologies and environments [22,64,65]. Beyond behavioral approaches, environmental modifications, such as improving walkability, access to sidewalks, and expanding green spaces, can support sustained PA.

Future school-based studies should explore adaptive strategies with WD within PE and wellness classes. For example, dynamic goal adjustment and real-time feedback help maintain motivation throughout the academic year, ensuring consistent exposure and accountability [66]. Wearables may also complement these efforts by mitigating environmental barriers, enabling self-monitoring, goal setting, and engagement in safe, controlled environments such as homes or schools. To enhance long-term engagement, future interventions should prioritize personalized goal setting over gamified peer competition. Evidence suggests that normative comparisons, such as an arbitrary selection of 10,000 steps/day or competition with peers, may yield only short-term motivation and can negatively impact autonomy [67]. Supporting adolescents in setting individualized goals and encouraging self-referenced progress may foster more sustainable PA habits and better align with their personal values and contexts [67,68]. For adolescents not engaged in team sports, additional motivational strategies, including mentorship and small-group activities, may foster social connections and reduce perceived isolation [69].

Although inconclusive, our study also found higher WD adherence rates among female participants than among their male peers, further highlighting the potential influence of safety-related factors on engagement with wearable technologies and underscoring the need for future research to explore sex-specific motivators and barriers to adherence. Furthermore, our study provided insights into the unique needs of adolescents who are first- or second-generation immigrants navigating acculturation, a group that has been shown to experience sharp declines in PA over time in the United States [70]. Despite their medically underserved status, race, ethnicity, and foreign birth did not significantly influence WD adherence in this study. These findings suggest that WD technology can be a culturally neutral and accessible tool for promoting PA across diverse populations. Further research should disaggregate data by generational status and language proficiency to better support first-generation and non–English-speaking youths [71].

Limitations

This study offers valuable insights into WD adherence among underserved adolescents; however, it had several limitations that should be addressed. The unexpectedly strong influence of perceived neighborhood safety may reflect regional or demographic differences, including potential sampling bias, and suggests that environmental safety perceptions play a more prominent role in technology engagement than previously recognized. The reliance on self-report measures introduces potential recall and social desirability biases, and the cross-sectional design limits causal inferences. The relatively small sample size and concentration of participants within a single school year (51/63, 81% in ninth grade) further constrain generalizability. This age clustering may obscure developmental differences in PA behavior and technology engagement across adolescence. Additionally, variability in school schedules, seasonal factors, and academic demands may influence adherence patterns and should be considered in future studies. Future studies should aim for broader age representations and larger multisite samples to enhance external validity and capture developmental variability.

This study highlights the potential of wearable mHealth technologies to engage underserved adolescents in PA, particularly those with lower baseline activity levels and limited access to structured sports. Our findings suggest that WD

XSL•FO
RenderX

adherence is influenced not only by individual behaviors but also by contextual factors, such as perceived neighborhood safety, an often-overlooked determinant of technology engagement among youth. The counterintuitive finding that adolescents with lower baseline PA levels were more likely to adhere to WD use warrants further investigation. Future research should explore mHealth access, usability barriers, and motivational factors for sustained WD use to improve PA. Anecdotal reports from teachers indicated that some students faced challenges with WD use, including limited Wi-Fi connectivity at home or school, forgetfulness, and declining interest over time. These barriers merit further exploration to inform the design of more accessible and engaging mHealth interventions. Despite being at a critical developmental stage for establishing lifelong health behaviors, older adolescents (aged 14 y - 19 y) remain underrepresented in mHealth research. Multischool collaborations and standardized adherence metrics are essential for scaling wearable-based interventions and strengthening cross-study comparisons.

Conclusions

This study highlights the potential of wearable mHealth technologies to engage underserved adolescents in PA, particularly those with lower baseline activity levels and limited access to structured sports. Adherence to WD use was significantly associated with contextual factors, including perceived neighborhood walkability, team sports participation, and prior PA behavior. These findings underscore the importance of designing school-based WD deployment that prioritizes autonomy-supportive strategies, such as personalized goal-setting and self-referenced progress to initiate and sustain PA opportunities. Moving beyond normative comparisons and peer-based competition may enhance sustained engagement and promote equitable health outcomes among high-risk youth.

Abstract

Background: Approximately one-third of university students are overweight or obese, and a similar proportion experience anxiety or depression. Despite the interrelated nature of weight and mental health, interventions rarely address these issues simultaneously in young adults. Digital peer support interventions have the potential to promote healthy lifestyle and mental well-being. However, evidence is limited on whether a digital peer-driven approach can concurrently improve weight management and mental health in university populations with preobesity.

Objective: This randomized controlled trial (RCT) evaluated the efficacy of a digital peer support program in concurrently improving weight management and mental health outcomes among university students with preobesity.

Methods: In a single-blind parallel group RCT, 216 students with preobesity were allocated equally among three 6-month arms, which were a peer support intervention, an active wellness control, and a waitlist control. The peer support arm began with an interactive online workshop followed by moderated WeChat (Tencent) group discussions, daily micro tasks, biweekly group challenges, and digital badges to reinforce engagement. The active control group received the same schedule and formats but focused on general wellness topics. The waitlist group completed the same assessments without any intervention during the study period. The primary outcome measured the change in BMI from baseline to 6 months. Secondary outcomes included weekly physical activity measured in metabolic equivalent of task minutes, self-esteem, loneliness, anxiety, and depression assessed at 0, 2, 4, and 6 months. Analyses used linear mixed effects models.

Results: Retention exceeded 90%. At 6 months, the peer-support group achieved a greater BMI reduction than the active control by 0.47 (95% CI −0.89 to −0.04) kg/m² and waitlist by 0.54 (95% CI −0.85 to −0.01) kg/m². Weekly metabolic equivalent of task-minutes was 129.5 higher than active control (95% CI 53.3-205.6) and 152.9 higher than waitlist (95% CI 68.4-237.4). Self-esteem increased by 1.81 points versus active control (95% CI 0.22-3.39) and 1.99 points versus waitlist (95% CI 0.21-3.76). Loneliness scores fell by 3.79 points relative to active control (95% CI −7.03 to −0.56) and by 5.02 points relative to waitlist (95% CI −8.38 to −1.66). No significant differences emerged for anxiety or depression.

Conclusions: A comprehensive digital peer-support program delivered via WeChat produced modest but clinically meaningful improvements in weight management, physical activity, self-esteem, and social connectedness among undergraduates with preobesity compared with wellness control and no intervention. These findings suggest that integrating peer support into scalable digital platforms can simultaneously address physical and psychosocial health in at-risk university populations.

Introduction

Young adults with preobesity are defined by a BMI between 25 and 29.9 kg/m² [1]. This group represents a critical yet underaddressed population in the fight against obesity [2]. University students with preobesity have a high prevalence of excess weight, with studies reporting that roughly 20% - 30% of students fall into the overweight category, with an additional 5% - 10% already meeting obesity criteria [3,4]. Unlike individuals of normal weight, these students are already on the threshold of obesity, experiencing early weight gain–related health risks and often subtle metabolic changes [5]. Crucially, even at this preobese stage, individuals already experience adverse consequences, including heightened stress, increased depressive symptoms, and lower academic performance [6-8]. This underscores that focusing on students with preobesity is not merely a preventative measure but a response to an emerging health and psychosocial burden that distinctly affects this group.

Intervening during the preobese stage in emerging adulthood may offer a pivotal window to alter lifelong health trajectories [9]. The university years are a well-recognized turning point for weight gain and lifestyle habits, commonly known as the "freshman weight gain" phenomenon. Grounded in the socioecological model, first-year transitions expose students to interpersonal, organizational, and environmental cues that favor weight gain [10,11]. The prevention of further weight gain and the promotion of modest weight loss are widely viewed as more cost-effective and achievable than treating established obesity later on [12,13]. Overweight students generally have fewer entrenched behaviors and less severe physiological impairment than individuals with obesity, meaning early intervention can capitalize on the reversibility of risk [14]. From a public health perspective, preventing the progression from overweight to obesity avoids the need for intensive medical treatments and reduces long-term health care costs [12,15,16]. Focusing on college students with preobesity offers a critical window for high-impact preventive measures, potentially delaying cardiometabolic diseases and mental health decline before they become more difficult and expensive to manage [17,18].

Despite the clear rationale for early intervention, university students with preobesity face unique challenges that current interventions rarely address adequately [8,19]. This transitional life stage features new freedoms and psychosocial pressures. Academic stress, changing peer networks, and the shift from adolescence to adulthood can negatively affect eating, activity, and mental well-being [20]. Overweight students may struggle with body image concerns and social stigma while also encountering environments filled with unhealthy food options and sedentary habits [21]. These psychosocial stressors and environmental factors intertwine, often creating a vicious cycle where weight gain and mental health issues reinforce each other [22]. However, most existing health programs operate in isolation. Weight management initiatives in college settings tend to focus solely on diet and exercise [18], whereas campus mental health services rarely integrate lifestyle change for physical health [23]. There is a notable gap in interventions that treat physical and mental health as interconnected targets. In fact, a recent review highlighted that very few programs for university students have successfully improved both health behaviors, such as diet, physical activity, and weight-related outcomes, and mental health outcomes at the same time [8]. This lack of comprehensive approaches means students with preobesity at a crucial phase often do not receive support that addresses the full range of their needs, namely managing weight while concurrently bolstering psychological resilience and well-being. Moreover, no prior study has included both an attention-matched active control and a waitlist control arm to isolate specific peer-support benefits from general engagement effects.

Digital peer-support interventions, encompassing online group chats, moderated peer discussions, peer challenges, and digital badge systems, offer a promising and innovative solution to fill this gap for young adults with preobesity [24]. According to social cognitive theory, observing peers' successes and receiving encouragement enhances self-efficacy and outcome expectancies, thereby improving motivation, adherence, and outcomes in weight management [25]. In line with this theory, social support and positive peer influences operate through observational learning and modeling to normalize healthy behaviors and reduce the isolation or stigma an overweight student might feel, especially among university students who are highly receptive to peer influences [25,26]. By delivering such peer support via digital platforms, we can amplify its reach and convenience. Technology-based interventions are inherently adaptable, engaging students in real time, and digital platforms offer broad appeal and extensive reach across this population [27]. Through social media groups, mobile apps, or online forums, students can connect with "virtual" peers to share progress, setbacks, and encouragement [25]. Prior studies indicate that online peer communities can recreate the sense of camaraderie found in in-person support groups, providing accountability and empathy among participants with similar goals [25]. Moreover, digital peer support can be accessed on-demand and flexibly integrated into students' busy schedules, overcoming common barriers to participation such as time constraints or embarrassment in face-to-face settings [28]. Although this approach has been previously studied, existing trials seldom focus on the critical preobese life stage, compare multiple digital support modalities within the same randomized controlled trial (RCT), or include long-term follow-up and an expanded set of psychosocial outcomes.

In light of the above, this study aimed to evaluate the efficacy of a digital peer-support program on weight management and mental health in university students with preobesity. To test this, we conducted a single-blind, parallel-group, 3-arm RCT comparing a digital peer-support intervention, an attention-matched active control, and a waitlist control, with prespecified pairwise comparisons. We hypothesized that participants in the peer-support arm would demonstrate greater improvements in BMI and mental health measures than those in the active control arm, and that both intervention arms would outperform the waitlist control. By examining this novel intervention, our goal is to address an important gap in student health promotion and contribute evidence on the integration of digital peer support in weight management and mental health prevention efforts. Our intervention was grounded in social

XSL•FO
RenderX

cognitive theory and the socioecological model [29,30]. We anticipated that peer modeling within a supportive digital environment would enhance self-efficacy and motivation for healthy behaviors and provide a multilevel context for behavior change.

Methods

Study Design

We conducted a single-blind, parallel-group, superiority RCT entirely online over a 6-month intervention period to evaluate a brief digital peer-support intervention for weight management and mental health in university students with preobesity. The participants were drawn from 6 universities in Guangzhou, including Sun Yat-sen University, South China Normal University, Jinan University, South China Agricultural University, South China University of Technology, and Guangdong University of Foreign Studies. Participants were recruited between September 1 and October 31, 2024, and follow-up assessments were conducted at 2 months in November 2024, 4 months in January 2025, and at the study end on April 30, 2025. The study is reported in accordance with CONSORT (Consolidated Standards of Reporting Trials) guidelines and was registered prior to enrollment (ClinicalTrials.gov ID NCT06966661). Participants were recruited from university campuses via online advertisements, email bulletins, and social media postings. Interested individuals accessed a screening survey by clicking a link or QR code in the advertisement.

Participants and Recruitment

Eligible participants were currently enrolled university undergraduate students, aged 18 years or older, with preobese weight status (defined as BMI between 25.0 and 29.9 kg/m² based on self-reported height and weight at screening). Additional inclusion criteria were access to a stable internet connection and a device for video conferencing, to enable participation in the online program. Participants were excluded if they had a BMI in the obese range (≥30 kg/m^2) or normal range (<25 kg/m^2) at screening, had any diagnosed medical or psychiatric condition that would interfere with study participation or require alternate care (eg, uncontrolled diabetes, an eating disorder, psychosis, or acute suicidal ideation), or were already enrolled in a weight management program or receiving psychological counseling. To ensure safety, individuals with severe depression or high acute mental health risk were directed to clinical services and not enrolled. Pregnant students were also excluded due to potential weight changes unrelated to the intervention.

Randomization and Blinding

Eligible consenting participants were randomly assigned in a 1:1:1 ratio to 3 groups that were the digital peer support intervention group, the active control group receiving standard online wellness content, and the waitlist control group. Randomization was carried out using a computer-generated sequence. This sequence applied permuted blocks of varying sizes (6 and 9). The allocation list was prepared by an independent statistician who was not involved in participant recruitment or intervention delivery. To maintain allocation concealment, the randomization list was stored in a password-protected file on a secure server accessible only to the statistician. Study coordinators obtained the next assignment code via a secure messaging system only after participants completed baseline assessments and eligibility confirmation, which prevented recruiters from foreseeing upcoming assignments. Because the trial was conducted entirely online, sealed envelopes were not used. Instead, participants were assigned by the statistician through a secure web-based platform. The study used a single-blind design, and participants were informed that the trial compared 3 different online wellness programs but were not told which program was the primary intervention. Both the intervention and active control groups received online content and peer interaction for 6 months to control for expectation and exposure time; the waitlist control group did not receive any intervention activities during this period.

Facilitators and research staff who delivered the intervention could not be blinded due to the nature of the program. However, they were not involved in outcome assessments, and distinct facilitators managed each group without evaluative responsibilities. Follow-up data on BMI, self-esteem, loneliness, and other outcomes were collected via self-administered online surveys distributed by research assistants who were blind to group assignment and used anonymous study codes to track responses. These assistants did not have access to the randomization list. Data analysts remained blinded to group assignments until the primary analyses were completed.

Intervention Group

Participants in this arm began with a 15-minute live interactive workshop delivered synchronously via an online videoconferencing platform. All participants joined remotely from their own devices. A trained health educator used a shared digital whiteboard and chat functions to guide the group through evidence-based guidance on balanced eating, regular movement, stress management, and resilience building using real-time polls and interactive infographics to illustrate key points in a neutral, student-friendly language while participants added their own reflections and questions. Immediately afterward, teams of 4 to 6 students convened in a dedicated WeChat group for a 1-hour conversation combining text and voice interactions under the guidance of a trained moderator, with participants sharing brief reflections on personal challenges, exploring sustainable behavior change strategies, and agreeing on 1 or 2 small health goals for the coming week while the moderator used open-ended prompts to ensure inclusive and supportive dialogue. Over the 6-month follow-up, the WeChat group delivered daily micro tasks 7 days a week, such as minute-long nutrition quizzes, morning breathing exercises, and simple step count challenges. Each completed task earned participants a digital badge displayed in the group, and automated motivational messages reinforced progress and reminded students of their goals. Every 2 weeks, the moderator launched a friendly group challenge via the WeChat group, such as collectively walking 10,000 steps in a day to foster camaraderie and mutual accountability, and the WeChat group remained open for ongoing peer support with study staff overseeing the conversation to keep discussions respectful and on topic.

XSL•FO
RenderX

Active Control Group

Participants followed the same schedule and digital formats, including a 15-minute workshop, a 1-hour WeChat discussion, daily micro tasks, and 2-week challenges, but the content focused on general student wellness topics, such as effective study habits, time management, and healthy sleep. WeChat discussions addressed academic strategies, identification of barriers, and the setting of weekly improvement goals.

Waitlist Control Group

Participants in this arm completed all baseline and follow-up assessments on the same schedule as the other 2 groups but did not receive any workshop activity, WeChat discussions, or micro task prompts during the 6-month period. They were informed that they would gain access to the full peer-support program after the final data collection. Throughout the study, they continued their usual routines without additional contact beyond survey reminders and, at the conclusion of the follow-up, they were offered the opportunity to join the interactive workshop, the WeChat peer discussions, and to receive the series of daily micro tasks.

Procedures

After providing informed consent, each participant completed an online baseline survey capturing demographic information, self-reported height and weight, and all outcome measures. Participants were then randomized in equal proportions to 1 of the 3 arms and received secure instructions for scheduling their workshop and WeChat group times or confirmation of their waitlist status. Sessions were arranged to match participants' availability, and reminders were sent by email and text 1 to 2 days before each workshop or discussion session. Attendance and engagement were logged by facilitators, and all WeChat group activities were monitored by study staff to document participation. Completion of the daily micro-learning tasks and the awarding of digital badges were automatically recorded via backend logs in the WeChat mini-program. Each week, the data manager generated adherence reports to flag participants who completed fewer than half of the assigned tasks or who had not earned a badge in 7 consecutive days. These participants were contacted by study staff to encourage reengagement. No participants were excluded or reassigned on the basis of missed tasks. Adherence metrics were summarized descriptively and considered in exploratory analyses but did not influence eligibility or weighting in the primary available-case analyses. Follow-up assessments were delivered online at 2 months, 4 months, and 6 months after baseline using identical survey links to maintain blinding. Nonresponders received reminders at 5 and 12 days postinvitation and a final contact attempt by phone or messaging app if needed. Participants who completed each survey received a modest gift card honorarium and, after the final follow-up, the waitlist control group was provided access to the peer support program while the study was closed to further interventions.

Outcomes and Measures

The primary outcome was BMI, which was recorded from baseline to the 6-month assessment, with interim follow-up assessments at 2 months and at 4 months. Participants were instructed to weigh themselves in the morning before eating and to measure height against a flat wall, noting any deviations in the procedure.

Secondary outcomes encompassed changes in physical activity, anxiety, depression, mental well-being, perceived stress, general well-being, self-esteem, loneliness, and social connectedness. Physical activity was captured by the International Physical Activity Questionnaire, a 7-item measure recording the frequency and duration of walking, moderate-intensity, and vigorous activities over the previous 7 days [31]. Anxiety symptoms were assessed using the 7-item Generalized Anxiety Disorder (GAD) scale, which rates symptoms over the past 2 weeks from 0 (not at all) to 3 (nearly every day) for a total score of 0-21 [32]; the Chinese version demonstrates strong reliability, validity, and measurement invariance in university samples [33]. Depressive symptoms were measured by the 9-item Patient Health Questionnaire (PHQ), scored 0 - 3 per item for a total of 0-27 [34]; Chinese validation studies report high internal consistency and test-retest reliability [35]. Mental well-being was captured by the 14-item Warwick-Edinburgh Mental Well-being Scale (WEMWBS), with each item scored 1 - 5 for a total range of 14-70 [36]; the Chinese WEMWBS shows robust internal consistency and construct validity among nursing trainees and general students [37]. Perceived stress was assessed via the 10-item Perceived Stress Scale (PSS), rated 0 (never) to 4 (very often), yielding scores from 0 to 40 [38]; the Simplified Chinese version exhibits high reliability (α>.90) and a clear 2-factor structure [39]. General well-being was measured by the 5-item World Health Organization Well-Being Index (WHO-5), scored 0 (at no time) to 5 (all of the time) and converted to a 0 - 100 index [40]; the Chinese WHO-5 has demonstrated good internal consistency (α≈.85) and unidimensional fit in student and patient samples [41]. Self-esteem was measured by the 10-item Rosenberg Self-Esteem Scale on a 4-point agreement scale [42]; Chinese adaptations confirm robust factorial and criterion validity [43]. Loneliness was assessed by the 20-item University of California, Los Angeles (UCLA) Loneliness Scale Version 3, with items rated 1 (never) to 4 (often) [44]; recent validation of Chinese variants supports strong reliability and validity in adolescent and university populations [45]. Social connectedness was measured by the 8-item Social Connectedness Scale (SCS), scored 1 (strongly disagree) to 6 (strongly agree) [46]; the Chinese translation demonstrates satisfactory psychometric properties in student samples [47].

Statistical Analysis

Effect size assumptions (Cohen $d \approx 0.50$) were derived from published digital weight management trials [48]. A priori power analysis using G*Power (Heinrich-Heine-Universität Düsseldorf) for a 3-arm, 4 timepoint repeated measures design [49], with an assumed within-subject correlation of 0.5, 2-tailed α=.05, and 80% power, indicated a minimum sample of 159 participants (n=53 per arm). Allowing for up to 20% attrition, we therefore enrolled 216 participants (n=72 per arm), ensuring robust power to detect the expected effects.

Primary and secondary outcomes were measured at baseline and 2, 4, and 6 months. Analyses were performed on an

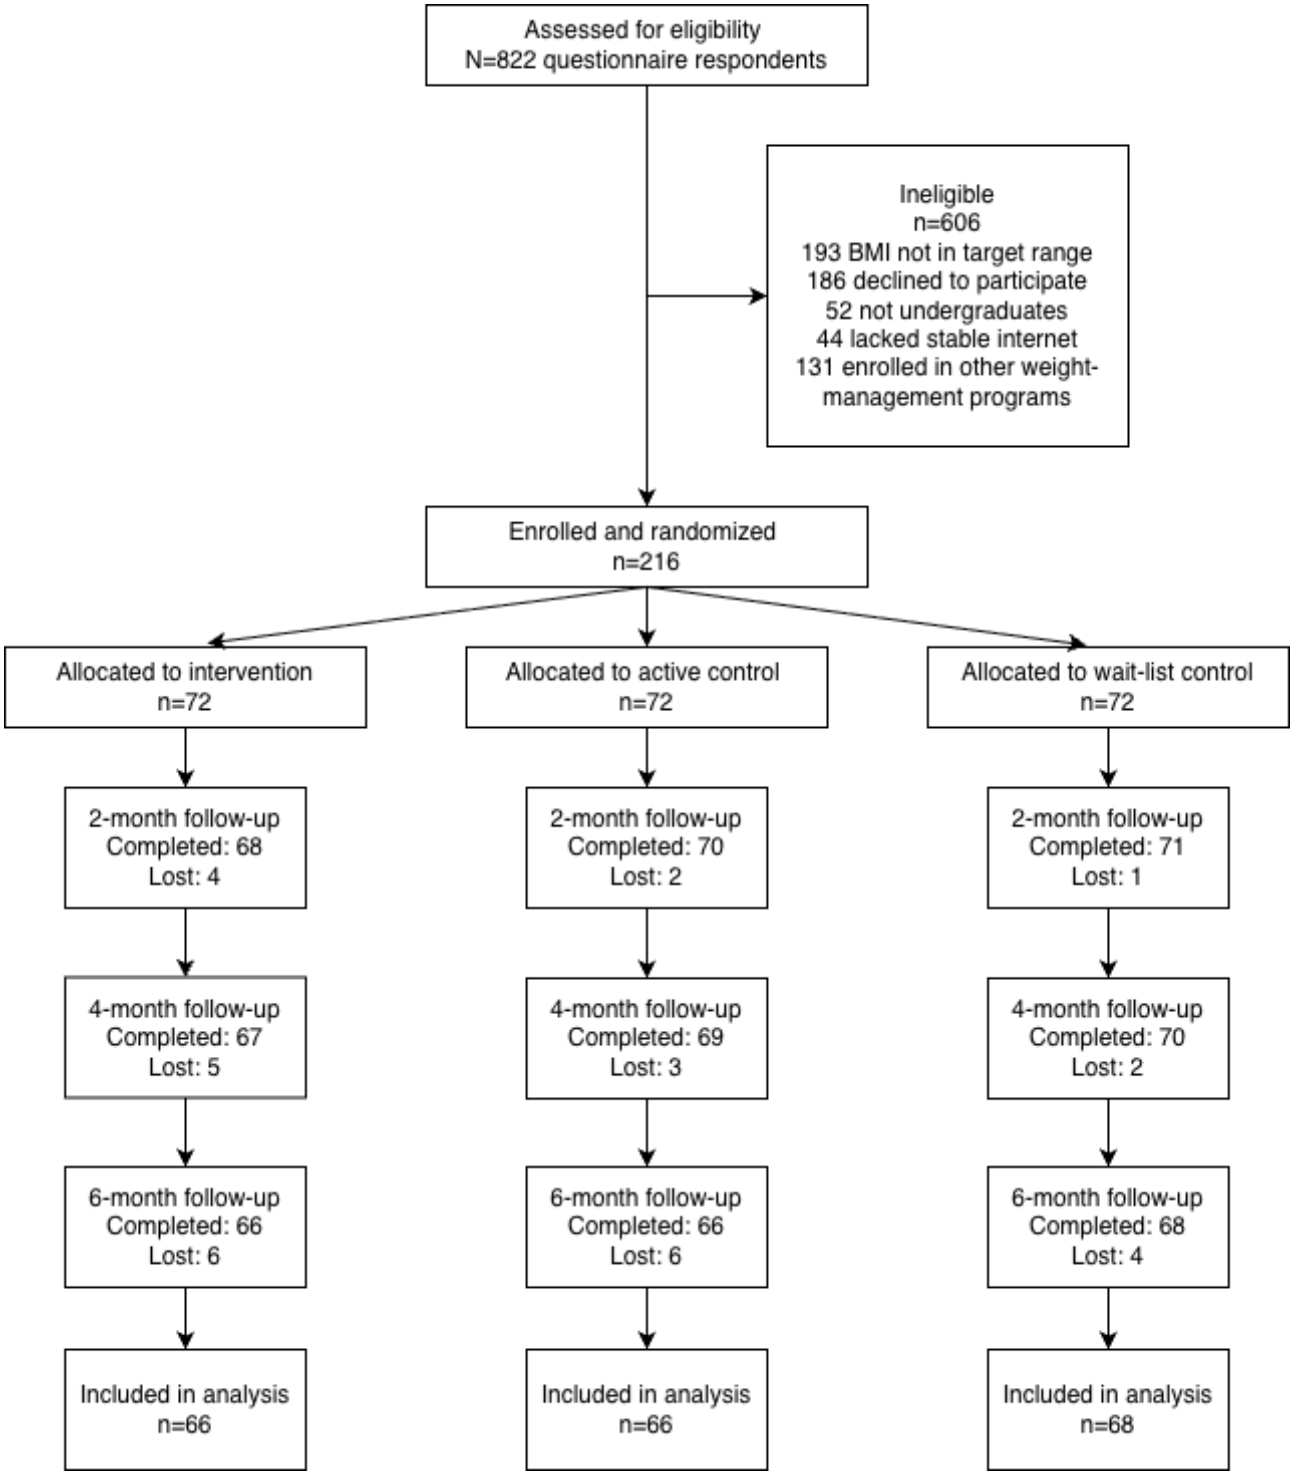
XSL•FO
RenderX

available-case basis. Participants who completed at least 1 follow-up assessment were included in the analysis. Missing data were less than 5% and under the missing at random assumption, linear mixed effects models estimated by maximum likelihood were used without additional imputation [50]. Each model specified fixed effects for study arm time and the study arm by time interaction and adjusted for the baseline value of the outcome. A random intercept for each participant accounted for within-subject correlation across repeated measures. The primary test of efficacy was the study arm by time interaction for BMI, and significance for this test was evaluated at 2-tailed P <.05. Secondary outcomes were analyzed in the same way, and false discovery rate–adjusted P values were reported to provide context for the full set of psychosocial measures. Model diagnostics included inspection of residuals for normal distribution and equal variance. All analyses were performed in R (version 4.2.2; R Foundation for Statistical Computing) with the *lme4* and *mice* packages, and results are presented alongside 95 % CIs [51].

Ethical Considerations

The study protocol was reviewed and approved by the Institutional Review Board of Guangzhou Sport University (approval number 2025LCLL-057), ensuring that the research adhered to institutional and national ethical guidelines for research involving human participants. All participants provided informed consent electronically after a one-on-one discussion with a research staff member about the study procedures and eligibility criteria. Participation was voluntary, and they were informed that they could withdraw from the study at any time without consequences. Data were collected via secure online surveys and stored on a password-protected server accessible only to the research team, and personal identifiers were removed before analysis so that only deidentified, aggregated data were used for publication to protect participant confidentiality. Participants did not receive monetary or material compensation, and digital badges and peer support interactions provided within the intervention were part of the program design and served as motivational tools rather than compensation.

Results



Of the 822 students assessed for eligibility, 216 met inclusion criteria and were randomized equally to the intervention (n=72), active control (n=72), and waitlist control (n=72) arms. Follow-up rates exceeded 90% at each of the 4 assessment points (Figure 1). Baseline demographic and clinical characteristics were well-balanced across groups: the overall mean age was 21.69 (SD 2.40) years, 48.15% (104/216) were female, and the mean BMI was 27.03 (SD 1.29) kg/m^2; no between-group differences reached statistical significance on any measure (Table 1).

Adherence to the program activities was high. Participants in the digital peer-support arm completed an average of 130.94 out of 181 of assigned daily micro tasks (72.34%, SD 12.38%) and attended a mean of 21.68 out of 24 scheduled WeChat group discussions (90.33%). In the active wellness control arm, participants completed a mean of 124.80 out of 181 daily tasks (68.94%, SD 13.11%) and attended 21.30 out of 24 group discussions (88.73%). These adherence estimates were obtained through daily check-ins conducted by research assistants within the WeChat groups, who recorded participant confirmations of task completion and discussion attendance in study logs rather than relying on automated device logs.

At 2 months, there were no significant group differences on any outcome. However, by 4 months (Table 2), the intervention arm had already achieved markedly higher weekly physical activity than both control groups: adjusted total metabolic equivalent of task (MET) - minutes were 124.10 MET greater than in the active control (95% CI 45.64-202.55; P<.001) and 147.32 MET greater than in the wait - list control (95% CI 62.51-232.13; P<.001). Self - esteem scores in the intervention arm exceeded those of the active control by 1.93 points (95% CI 0.35-3.52; P=.04) and those of the wait - list control by 2.08 points (95% CI 0.30-3.87; P=.04). Loneliness scores were also significantly lower among intervention participants, with scores 3.76 points below the active control (95% CI –6.93 to –.58; P=.03) and 5.09 points below the waitlist control (95% CI –8.40 to –1.78; P=.03), reflecting a greater reduction in perceived social isolation (Figure 2).

Outcomes and timepoint[a]	Intervention	Active control	Waitlist control	Int (LRT)[b], χ^2 (df)	Intervention versus AC[c], mean difference (95% CI)	Intervention versus WLC[d], mean difference (95% CI)
6 months	33.55 (9.94)	37.35 (9.69)	38.57 (10.45)	—	–3.79 (–7.03 to –0.56)	–5.02 (–8.38 to –1.66)

[a]Adjusted means (SE) are estimated from linear mixed‐effects models with a random intercept for each participant, including fixed effects for group (1 = intervention, active control, 3=waitlist control), time (baseline, 2 months, 4 months, 6 months), and their interaction. Interaction effects were tested via likelihood‐ratio tests (chi-square (df)); reported chi-square and degrees of freedom refer to the comparison between the full model (with group × time) and the reduced model (without the interaction). Pairwise contrasts (intervention vs active control; intervention vs waitlist control) give mean differences and 2‐sided 95% CIs. Positive values indicate higher scores in the intervention group.

[b]LRT: likelihood ratio test.

[c] AC: active control.

[d] WLC: waitlist control.

[e]Not applicable.

[f]MET: total weekly metabolic equivalent minutes.

[g]GAD: Generalized Anxiety Disorder‐7.

[h] PHQ: Patient Health Questionnaire‐9.

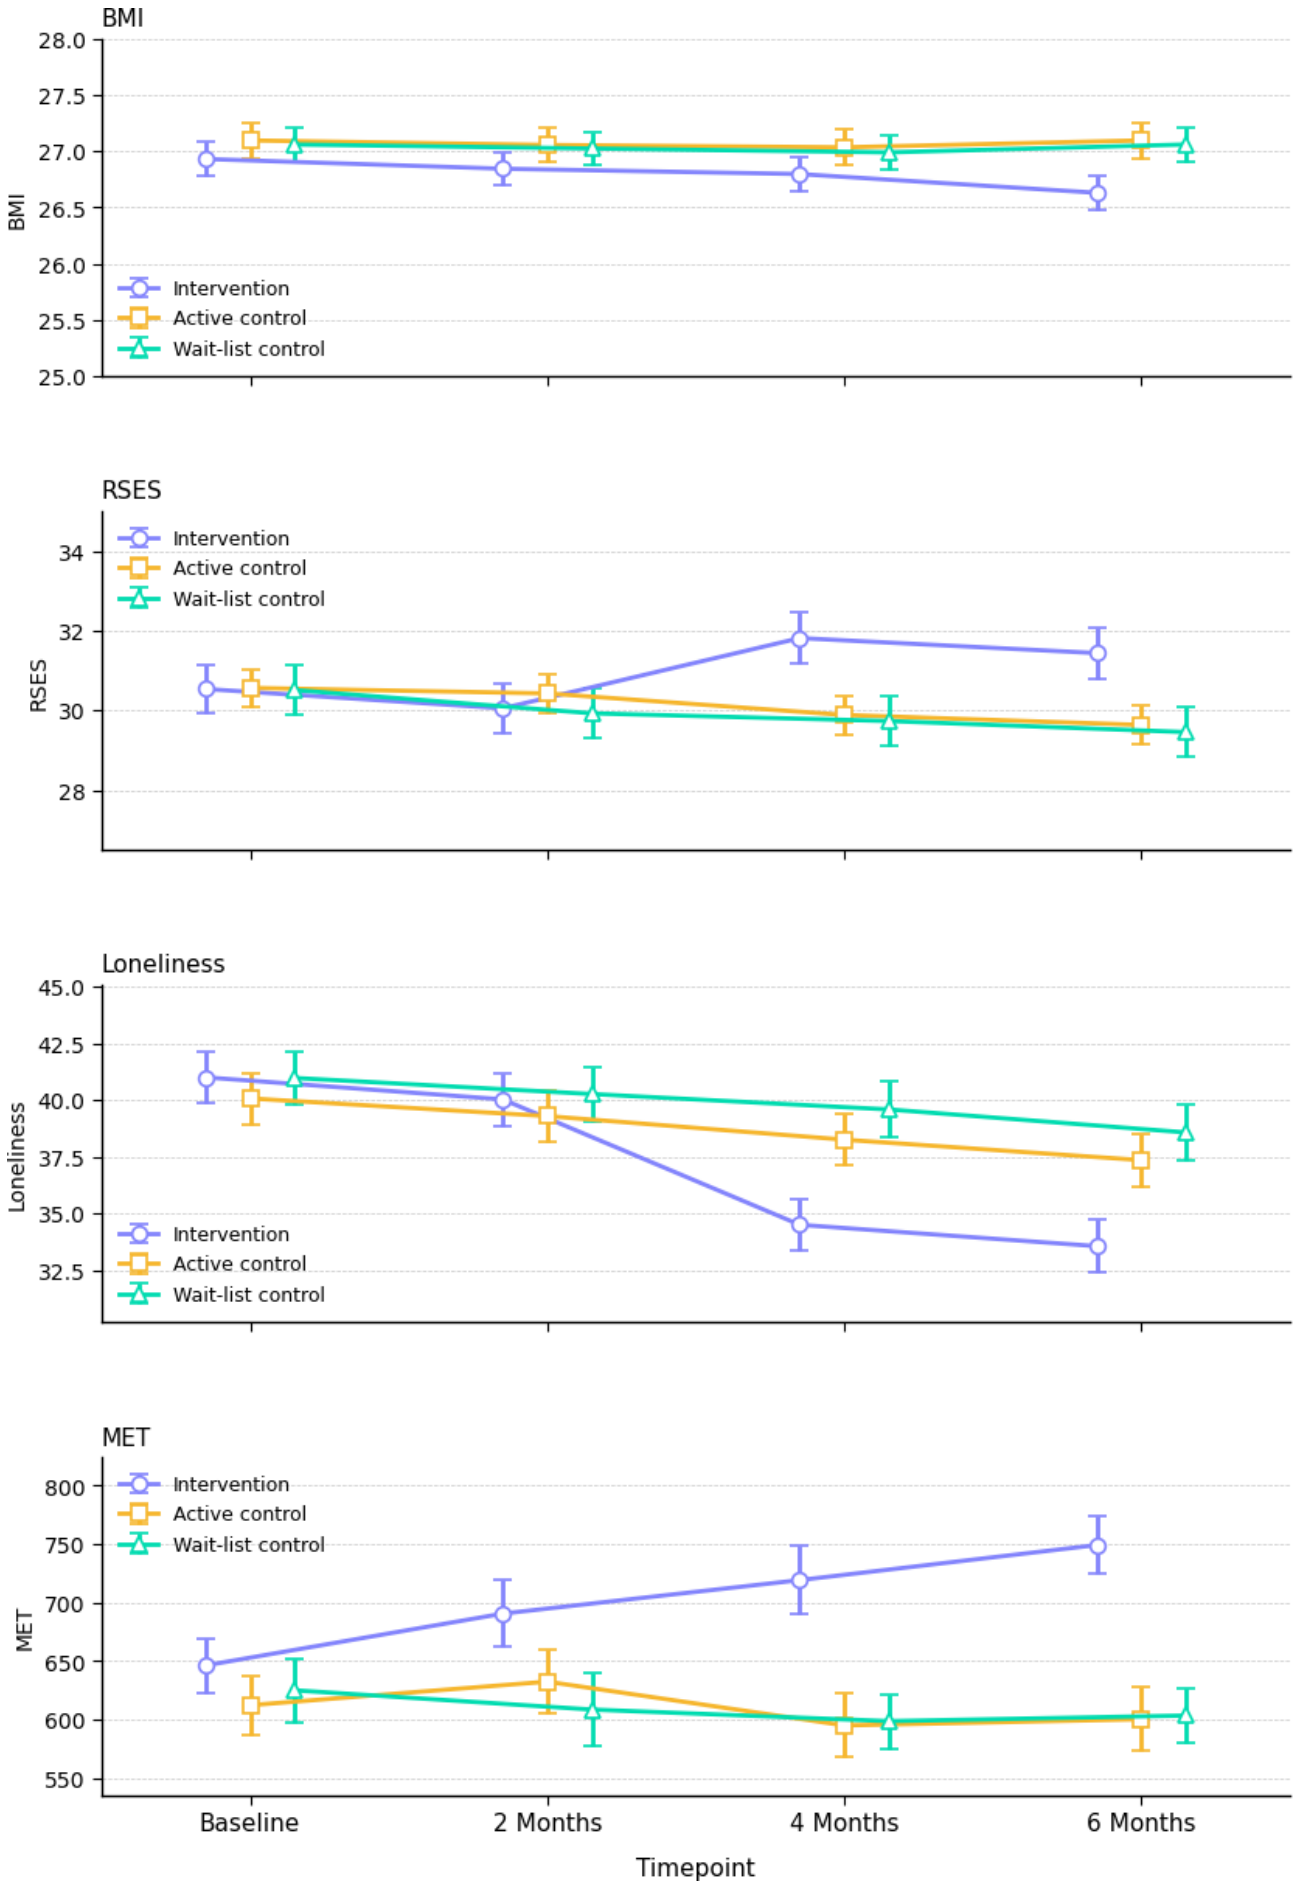
[i]WEMWBS: Warwick–Edinburgh Mental Well‐being Scale.

[j]PSS: Perceived Stress Scale.

[k]WHO‐5: 5-item World Health Organization Well‐Being Index.

[l]Self‐Esteem: Rosenberg Self‐Esteem Scale.

[m]Loneliness: UCLA Loneliness Scale.



At 6 months, these benefits not only persisted but, in the case of BMI, became statistically significant. Although BMI differences were nonsignificant at 4 months, by 6 months the intervention group's mean BMI was 0.47 kg/m² lower than that of the active control (95% CI –0.89 to –0.04; *P*=.04) and 0.54 kg/m² lower than that of the waitlist control (95% CI –0.85 to –0.01; *P*=.03). Weekly MET‐minutes remained elevated among intervention participants (129.45 MET-minutes greater than active control; 95% CI 53.28-205.61, *P*<.001; 152.87 MET greater than waitlist control; 95% CI 68.35-237.38, *P*<.001). Similarly, self‐esteem differences persisted: intervention scores were 1.81 points higher than active control (95% CI 0.22-3.39; *P*=.02) and 1.99 points higher than waitlist control (95% CI 0.21-3.76; *P*=.03). Loneliness remained lower in the intervention arm, with mean scores 3.79 points below active control (95% CI –7.03 to –0.56; *P*=.03) and 5.02 points below waitlist control (95% CI –8.38 to –1.66; *P*<.001; Figure 2; Table 2).

Besides these intervention effects, no differences in mental health, specifically depression, anxiety, and stress, were observed between conditions, and no adverse or unintended events occurred in any study arm. Participants' evaluations of intervention quality did not differ between the intervention and control conditions, and follow‐up evaluations indicated high overall satisfaction rates among study participants.

Discussion

Principal Findings

In this RCT, a digitally delivered peer-support intervention yielded significant improvements in both physical and psychological outcomes among university students with preobesity. Compared with participants in the active control and waitlist control groups, those receiving digital peer support experienced a greater reduction in BMI over 6 months, accompanied by marked increases in weekly physical activity. Notably, the intervention also promoted significant enhancements in self-esteem and produced a meaningful decrease in loneliness scores. These convergent improvements demonstrate that a well-structured digital peer-support program can effectively address weight-related metrics while simultaneously bolstering mental well-being in a high-risk young adult population.

Comparison with Prior Work

When contextualized within the broader literature, our results both corroborate and extend existing findings. Prior meta-analyses of peer-support interventions have reported modest reductions in weight and BMI, often limited to decreases on the order of 0.5 - 1.0 kg and 0.1 - 0.2 kg/m², respectively [48]. In contrast, the BMI improvement observed here exceeded those averages, suggesting that delivering peer support through a comprehensive digital platform may enhance engagement and efficacy. Similarly, earlier work by Yeo and colleagues found that digital peer-support programs led to higher levels of physical activity [24]. Our trial confirms that young adults can achieve and maintain substantial activity gains when supported by peers in a virtual setting. More striking is the contrast between our findings on psychosocial outcomes and those of many prior weight management trials. Whereas some research has found limited or no improvement in self-esteem or loneliness following peer support, often attributing these null effects to insufficient social cohesion or lack of personalized engagement [8], our intervention clearly produced robust psychological benefits. The structure of our digital program, which combined interactive workshops, ongoing peer dialogues, gamified challenges, and personalized goal-setting, likely fostered a sense of community and accountability that translated into higher self-esteem and reduced perceived social isolation.

Potential Mechanisms

Several features of our study design and implementation may underlie these positive outcomes. First, we targeted college students with “preobesity,” a population at a critical inflection point that is often overlooked by both obesity-prevention initiatives and mental health programs [2]. By focusing on individuals with BMI between 25 and 29.9 kg/m², our intervention capitalized on a phase when behavior change is particularly feasible, as these students are frequently less entrenched in unhealthy habits and experience fewer physiological impediments compared to individuals already in the obese range [52]. Second, the digital nature of our peer-support platform enabled consistent, real-time interaction and social reinforcement, meeting students in their preferred communication channels. Daily micro-tasks, biweekly group challenges, and digital badges created an environment in which healthy behaviors became normalized and visible, thereby leveraging social comparison and accountability to strengthen motivation. Third, the inclusion of both an attention-matched active control and a waitlist control increased the rigor of our design. By demonstrating that the intervention’s benefits exceeded those of an equally engaging, wellness-focused program, we confirmed that the peer-support component itself was responsible for the superior outcomes, rather than the generic effects of participation or attention.

Behavioral and psychosocial theories provide mechanistic explanations for the observed effects. According to social cognitive theory, observing peers’ successes and receiving encouragement enhances self-efficacy, which in turn promotes adoption and maintenance of healthy behaviors [53]. In our study, participants saw fellow group members achieving step-count goals, sharing healthy meal ideas, and offering positive feedback, all of which contributed to a collective sense of possibility. As self-efficacy increased, participants likely felt more capable of meeting weekly activity targets and monitoring their weight, resulting in the higher MET scores and lower BMI values observed at 4 and 6 months. Concurrently, the online peer-support format fostered social connectedness and reduced feelings of isolation, with participants reporting a growing sense of belonging as they exchanged challenges and celebrated accomplishments in a respectful, nonjudgmental space [54]. Improvements in self-esteem likely stemmed from personal achievements, such as meeting fitness goals and from external validation like peer praise, thereby reinforcing a more positive self-concept [55]. Moreover, reductions in loneliness may have mitigated stress and negative affect, both of which are known barriers to sustained lifestyle change [54]. By alleviating emotional distress and enhancing social support simultaneously, the intervention created a synergistic environment in which mental well-being and physical health could rise together [56].

Implications

Finally, the integration of physical, behavioral, and psychosocial measures in our outcome assessment underscores the value of holistic intervention approaches. In contrast to many programs that focus narrowly on either weight loss or mental health, our trial demonstrates that digital peer support can generate parallel benefits across multiple domains. This alignment is particularly important in the university setting, where academic pressures, social transitions, and evolving peer networks intersect to shape students’ health behaviors and psychological states. By addressing these factors in concert, providing evidence-based guidance on nutrition and exercise alongside structured opportunities for emotional support, the intervention enabled participants to tackle weight management without sacrificing mental health, and vice versa. Such a comprehensive strategy not only enhances immediate outcomes, such as lower BMI, higher activity levels, improved self-esteem, and reduced loneliness, but also establishes a foundation for sustained long-term well-being. Given the extensive reach and accessibility of digital platforms, our findings underscore the importance of integrating peer-supported programming as a foundational element of university health promotion strategies.

Limitations

This study has several limitations. First, the use of self-reported weight and physical activity data may have introduced measurement error, given the well-established divergence between self-reported and objectively measured values. Second, relying on BMI as the sole physical outcome may not adequately capture changes in body composition, as BMI does not differentiate between fat and lean mass. Third, the study sample consisted exclusively of digitally literate, university students with preobesity, which may limit the generalizability of the findings to other populations, including individuals in different age groups, weight categories, or with limited digital access or engagement. Fourth, we observed no significant changes in some secondary outcomes. This null finding may be attributable to the relatively short follow-up period and limited sensitivity of the self-report instruments. Long-term follow-up is needed to determine whether improvements in BMI, physical activity, and mental health are sustained beyond the intervention and to evaluate any delayed effects on the incidence of obesity and mental health disorders. Fifth, we could not directly verify completion of some self-guided micro tasks at the individual level; future trials should incorporate objective sensing or device-based validation to confirm task completion without increasing participant burden.

Conclusions

In this RCT among university students with preobesity, a digital peer-support intervention led to improvements in both physical and mental health outcomes compared to a control condition. Participants receiving the program attained a modest reduction in BMI and increased physical activity, while also reporting higher self-esteem and lower loneliness than controls. These findings highlight the promise of interventions that leverage peer support via digital platforms, an accessible and replicable approach to addressing emerging health risks in young adults. The intervention's digital, peer-driven design enables broad dissemination across campus settings and beyond, engaging at-risk students who may not use traditional health services. Notably, this trial is among the first to target the preobesity stage with a holistic approach that concurrently addresses weight management and mental health. By intervening early with an integrated program, this approach prevents progression to obesity while mitigating psychological distress, illustrating a novel paradigm for young adult health promotion.

Acknowledgments

The authors thank all the participants for their time and involvement in this study, research assistants for their hard work throughout the project, and all the faculty members who helped coordinate and support the study. The authors further confirm that no generative artificial intelligence tools were used in the drafting or editing of this manuscript.

Abstract

Background: Mobile health (mHealth) apps are increasingly being used to promote physical activity (PA) and can support exercise uptake and maintenance. Despite their potential, these tools face high dropout rates and inconsistent adherence, posing a significant challenge. Understanding how users engage with fitness apps is essential for improving user experience and health outcomes.

Objective: This study aims to analyze user behavior patterns in the Mammoth Hunters (MH) fitness app (Mammoth Hunters SL), focusing on retention (days from registration to user's last recorded training session), average weekly training frequency, and adherence (alignment between planned and actual training). We examined how these outcomes are influenced by sociodemographic, motivational, and other variables.

Methods: This cross-sectional study involved 2771 Mammoth Hunters app users. In a subsample (n=289), training data were complemented by motivational data acquired through online surveying via an ad-hoc scale (internal consistency >0.83) based on the self-determination theory (SDT). Descriptive statistics and nonparametric tests (Kruskal-Wallis, Dunn post-hoc, and Spearman correlation) were used to assess correlation between sociodemographic, motivation, and training behavior variables.

Results: Mean retention (days) was significantly higher among males than females (135 vs 109, respectively; $P<.01$), users in the subscription vs free plan (154 vs 81; $P<.001$), active or very active individuals vs inactive, midbuilt vs thin body types (132 vs 120; $P=.001$), and those with slightly lower BMI. Users pursuing antiaging or muscle gain goals showed longer retention than those aiming to lose weight (gain: 132, antiaging: 128, lose weight: 116; $P<.001$). Average weekly frequency (sessions per week) of training was statistically significantly different by sex (male: 1.9 vs female: 1.8; $P=.04$), body type (thin: 1.96 vs mid: 1.77; $P=.04$), activity level (very active: 2.05 vs inactive: 1.83; $P=.04$), and motivation type (extrinsic introjected motivation correlated positively: $r=0.17$; $P<.05$), but did not correlate with perceived difficulty or fitness goals. Adherence, defined as actual vs targeted training frequency, was only significantly different among body types, with thin users showing higher adherence than the midbuilt

XSL•FO
RenderX

group (57% vs 52.1%; *P*=.02). Intrinsic motivation showed a positive correlation with retention (*r*=0.19; *P*=.002), as did identified motivation (*r*=0.12; *P*<.05).

Conclusions: This study shows that retention is influenced by demographic factors, with males, subscribers, previously active, midbuilds, those aiming to gain muscle, and individuals with autonomous types (ie, intrinsic and identified) of motivation displaying greater long-term participation. These findings provide valuable preliminary insight into the complexities of exercise training behavior in apps. They suggest that training frequency, retention, and adherence do not respond to the same factors. App developers, researchers, and trainers should assess these variables separately and develop strategies accordingly.

fitness app; physical activity; exercise adherence; retention; motivation; mHealth

Introduction

Adherence to Physical Activity and Exercise

Physical activity (PA) and exercise are fundamental components of a healthy lifestyle, with well-established benefits for physical and mental well-being. PA, as defined by the World Health Organization (WHO), encompasses any bodily movement that results in energy expenditure, while exercise is considered a structured subset of PA, performed with the intent of improving or maintaining physical fitness [1]. Regular engagement in PA is crucial for reducing the risk of chronic diseases, yet adherence to recommended activity levels remains a global challenge [2]. Despite the widespread awareness of PA benefits, sustaining an active lifestyle is often hindered by behavioral, environmental, and psychological barriers [3]. Understanding factors that influence adherence is therefore critical for improving PA participation and ensuring long-term engagement.

Influence of mobile health on PA Behaviors

In recent years, mobile health (mHealth) apps have emerged as a potential solution to bridge the gap between PA recommendations and actual adherence. Fitness apps, a subset of mHealth, offer structured training programs, progress tracking, and personalized feedback, aiming to enhance motivation and user engagement. The widespread availability of smartphones has contributed to a surge in fitness app usage, with millions of users accessing digital exercise programs globally [4]. These apps incorporate behavior change techniques such as goal setting, social support, and gamification to facilitate sustained exercise habits [5]. However, despite their potential, high attrition rates and inconsistent long-term adherence pose significant challenges to their effectiveness [6]. Recent evidence reinforces that these barriers still persist across different populations and intervention designs. For example, several authors reported significant dropout rates even in gamified or socially incentivized fitness apps [7,8]. Similarly, previous studies highlighted continued adherence challenges in young individuals or older adults despite tailored mHealth interventions [6,7,9].

Adherence to exercise, particularly in digital interventions, remains a complex issue, often inconsistently defined across studies. Traditional adherence models typically assess exercise frequency, duration, and intensity, yet these criteria may not fully capture engagement in app-based fitness programs [3]. Furthermore, users may abandon apps due to technical difficulties, loss of motivation, or unrealistic expectations [10]. Consequently, understanding the determinants of fitness app adherence requires a multidimensional approach, integrating psychological, technological, and behavioral perspectives [11].

The challenges surrounding fitness app adherence are compounded by factors such as user characteristics, app usability, and the broader social and environmental contexts in which users engage with digital interventions. Studies have highlighted that individual attributes such as age, sex, health consciousness, and baseline PA levels may influence the likelihood of sustained engagement with fitness apps [12]. Additionally, app design elements, including intuitive navigation, feedback mechanisms, and interactive features, play a crucial role in user retention [13]. Social and motivational factors, such as competition, social support, and reinforcement strategies, have also been shown to impact adherence levels in digital exercise interventions [5]. Recent evidence highlights the importance of incorporating behavioral theories and enhancing usability and perceived value in reducing attrition and promoting sustained engagement with mHealth tools. For instance, recent findings emphasize the relevance of behavioral theories in crafting more effective mHealth interventions, showing how tailored features can reduce dropout and improve user retention [14]. Similarly, perceived value and usability have been identified as key drivers of long-term engagement with digital health tools [15]. Other studies suggest that personalization, motivational strategies, and social features are critical to increasing user commitment [12,16], overall highlighting the multifactorial nature of adherence and reinforcing the need for user-centered app design approaches.

Given the rising reliance on digital solutions for health and fitness, it is imperative to explore how different aspects of fitness apps contribute to sustained PA engagement. Previous research presents mixed findings on the long-term efficacy of fitness apps in promoting adherence, with some studies reporting positive behavior changes and others limited long-term impact [8,17].

Understanding real users' training behavior, beyond theoretical frameworks or self-reported intentions, is essential to identify how engagement translates into real-world usage. Analyzing app usage data provides evidence of behavior patterns, allowing researchers to identify which user profiles are more likely to sustain app use. This study establishes a theoretical and practical differentiation between adherence and retention, and how they

XSL•FO
RenderX

relate to user motivation to exercise. This is a critical matter, since sustained usage is key to ensuring the long-term impact of digital health interventions [18].

Study Goal

This study aims to explore the factors influencing the training behavior of users of a fitness app, focusing specifically on exercise adherence, retention, and motivation, and to explore how these outcomes are influenced by sociodemographic, motivational, and training-related factors. We hypothesize that sociodemographic characteristics, motivation types, and training behaviors significantly influence users' retention, adherence, and frequency of training. Understanding these factors is essential for optimizing fitness app design, improving intervention strategies, and ultimately promoting long-term participation in exercise.

Methods

Data Collection and Processing

Data were collected in collaboration with Mammoth Hunters (MH; Mammoth Hunters SL), a fitness app that focused on high-intensity interval exercises to improve strength, endurance, and mobility. MH delivered structured programs rooted in functional movement, making it an ideal platform for investigating digital fitness adherence, motivation, and retention. MH was launched in 2014 by a team of fitness experts and scientists from Barcelona, Spain. A free version with limited access to certain workouts and features was available upon registration, while the Pro version (per subscription) provided full access to personalized plans, a greater variety of workouts, and advanced tracking tools. MH ceased operations in September 2021, being one of the most widely used high-intensity training apps worldwide, having accumulated a total of 719,421 users. The company's shutdown, as well as its noninvolvement in any of the stages of study, ensured no conflict of interest.

The study used a cross-sectional design. Data in the MH app database included user registries ranging from November 21, 2020, to May 27, 2022. Motivation data were collected via online surveying on March 20, 2022. Data cleaning and descriptive analyses were conducted using the R programming language (version 4.3.1; R Core Team) in the R Studio environment software (version 2023.9.1.494; Posit, PBC).

The initial MH dataset contained 5858 entries, which corresponded to users who had granted informed consent to share their deidentified data for analysis. To ensure the accuracy and relevance of the data, several cleaning steps were executed, including a convenience selection of the most relevant variables and exclusion of registries with insufficient or missing data (see Table S1 in Multimedia Appendix 1 for more detail of the MH app's original variables).

Outliers were identified through data visualization and consultation of descriptive statistics. A decision was made to remove all outliers to avoid distortion in the analysis, based on two main reasons: (1) certain tests run by MH staff members had intentionally introduced outlier scores to facilitate their identification and removal, and (2) some outliers resulted from the arbitrary temporal cutoff applied to the dataset, specifically, some participants had only just begun training with the app shortly before the data extraction date, leading to unrealistic extreme values in some outcome variables (eg, extremely low retention or extremely high adherence). Therefore, all values exceeding Q3+1.5×IQR or falling below Q1–1.5×IQR were removed.

The motivation-related outcome variables were determined using the means of the composite scores from the observable items corresponding to each factor in the scale, allowing us to define the latent variables. Outcome variables retention, frequency, and adherence were derived from existing variables on the mobile app (eg, number of sessions executed, last training date, and user sign-up date) to enhance analytical depth. User retention was calculated as the number of days between a user's initial registration date within the fitness app and their last recorded training session. Weekly training frequency was calculated by dividing the total number of training sessions completed by a user by the total number of weeks from their first to their last executed session. Adherence was quantified as the percentage to which a user's actual average weekly training frequency aligned with their initial plan (self-declared upon registration). Additionally, data types were adjusted as required to ensure compatibility and accuracy.

Following the described data cleaning steps, the final dataset comprised 2771 user entries. See Table 1 for more details on study variables.

Table 1. Description of explanatory and outcome variables.

Explanatory variables	Type	Description
Sex	Categorical; sociodemographic	User biological sex, with 2 categories: female and male.
Body type	Categorical; sociodemographic	Self-reported body type selected by the user at registration, out of 3 available categories: thin, mid, and strong.
Activity level	Categorical; sociodemographic	User activity level at the time of registration in the fitness app, with 3 categories: inactive, active, and very active.
Fitness goal	Categorical; sociodemographic	The goal the user aims to achieve through app use (selected from 3 available categories: lose weight, gain muscle, and antiaging).
Pro version	Categorical; training	Indicative of app user being subscribed to a payment ("Pro") program or not. Two categories: yes and no.
Training schedule	Categorical; training	Time of day in which the user executes most (>50%) of their training sessions. Processed into 3 categories: morning (5:30-12:30 hours), afternoon (12:31-20 hours), and night (20-5:29 hours).
Age	Numerical; sociodemographic	User's reported age at registration.
BMI	Numerical; sociodemographic	User BMI calculated from their declared height and weight.
Subjective body fat	Numerical; sociodemographic	Users' self-reported body fat.
Difficulty	Numerical; training	Average perceived exertion reported at the end of the training session. 0 (lowest)-10 (highest).
Enjoyment	Numerical; training	Average user-reported enjoyment after each training session. 0 (lowest)-5 (highest).
SDT[a]-based variables		
Intrinsic motivation	Numerical; motivation	Average score of the intrinsic motivation items on the scale: a decimal number between 1 (lowest) and 5 (highest).
Identified extrinsic motivation	Numerical; motivation	Average score of the identified extrinsic motivation items on the scale: a decimal number between 1 (lowest) and 5 (highest).
Introjected extrinsic motivation	Numerical; motivation	Average score of the introjected extrinsic motivation items on the scale: a decimal number between 1 (lowest) and 5 (highest).
Outcome variables		
Retention	Numerical; training	Measured as the total number of days from the user registration date in the app to their last recorded training session.
Frequency, weekly average	Numerical; training	Calculated by dividing the total number of user sessions by the total number of weeks between their first and last recorded sessions.
Adherence	Percentage; training	Defined as the percentage alignment between the user's actual weekly training frequency and their predefined weekly training goal.

[a]SDT: self-determination theory.

Motivational data, which had been previously collected (March 20, 2022) by means of an ad-hoc scale (Table S2 in Multimedia Appendix 1), provided insight as to the motivational regulation of a subsample (n=753) of MH users. The scale was based on the self-determination theory (SDT) [19,20]. It showed good fit indices and a 3-factor structure as confirmed per exploratory and confirmatory factor analyses, with internal consistency indices >0.830 for the 3 subscales (intrinsic, identified extrinsic, and introjected extrinsic motivations). Data obtained through surveying (n=753) and data obtained from the MH fitness app (n=2771) were then merged, and a sample consisting of n=328, for which both training and motivational data were available, was obtained. Thirty-nine registries had to be disregarded due to missing data for the calculation of adherence and weekly training frequency outcome variables. A resulting total of 289 was complete for all explanatory and outcome study variables.

XSL•FO
RenderX

Descriptive Analysis for Sociodemographic, Training, and Motivation Variables

Following data cleaning, descriptive statistics were computed to summarize and describe the dataset's characteristics. Frequencies and percentages were calculated for categorical variables to provide an overview of their distribution and proportions within the sample. For numerical variables, measures of central tendency (mean and median) and measures of dispersion (minimum, maximum, and quartiles) were obtained to characterize data distribution and its variability.

Inferential Analysis of Explanatory Variables

Normality was assessed using the D'Agostino-Pearson test, along with skewness and kurtosis coefficients to quantify distributional properties. Additionally, histograms and quantile-quantile plots were inspected to visually evaluate deviations from normality. The results indicated significant departures from normality, and nonparametric tests were used for subsequent analyses. The Kruskal-Wallis test was conducted to evaluate differences among groups, followed by post-hoc analysis using the Bonferroni correction to adjust for multiple comparisons. The effect size was assessed using Dunn, which quantifies the magnitude of observed differences. To examine relationships between numeric variables, Spearman correlation tests were performed. The Holm correction was applied to control for multiple comparisons and to adjust the significance levels accordingly. For training behavior analysis, the categorical variables evaluated were sex, Pro version, self-declared level of previous PA, body type, fitness goal, and training schedule. Additionally, explanatory numerical variables included age, BMI, subjective body fat, perceived difficulty, and enjoyment. Intrinsic, identified extrinsic, and introjected extrinsic motivations were also considered (Table 1). The relationship of all these variables was analyzed with three outcome variables: adherence, frequency, and retention.

Inferential Analysis of Outcome Variables

Adherence was calculated as the percentage match between the target weekly frequency, as selected by the user upon sign-up, and the actual, executed weekly training frequency. The latter was averaged by dividing the total number of executed sessions by the total number of weeks from the sign-up date to the last executed session for the given user. Finally, retention was measured as the total number of days from the user sign-up date to the user's last recorded training session (Table 1). Outcome variables were analyzed through the same procedures as explanatory variables.

Ethical Considerations

Ethical approval for this study was obtained from the Research Ethics Committee of Universitat Ramon Llull in March 2020 (reference code 1920003P). All included users provided informed consent to use their data for research purposes, either through the app at registration or through the motivational survey. All data were anonymized before analysis, ensuring the privacy and confidentiality of participants in compliance with data protection regulations. No compensation was provided to participants, as the data were collected retrospectively and only for research purposes.

Results

Descriptive Results for Sociodemographic, Training, and Motivation Variables

Our sample consisted of 2771 MH users. Of them, a 64.8% majority identified as male, and 35.2% as female. Their age range spanned from 21 to 64 years, with a median age of 43 years and a mean age of 42.45 years. Users' fitness goals varied, with the largest segment (46.6%) aiming to "gain muscle" mass, followed by those wanting to "lose weight" at 32%. A smaller portion, 21.4%, pursued "antiaging" benefits. Table 2 provides full details on sample description and other results.

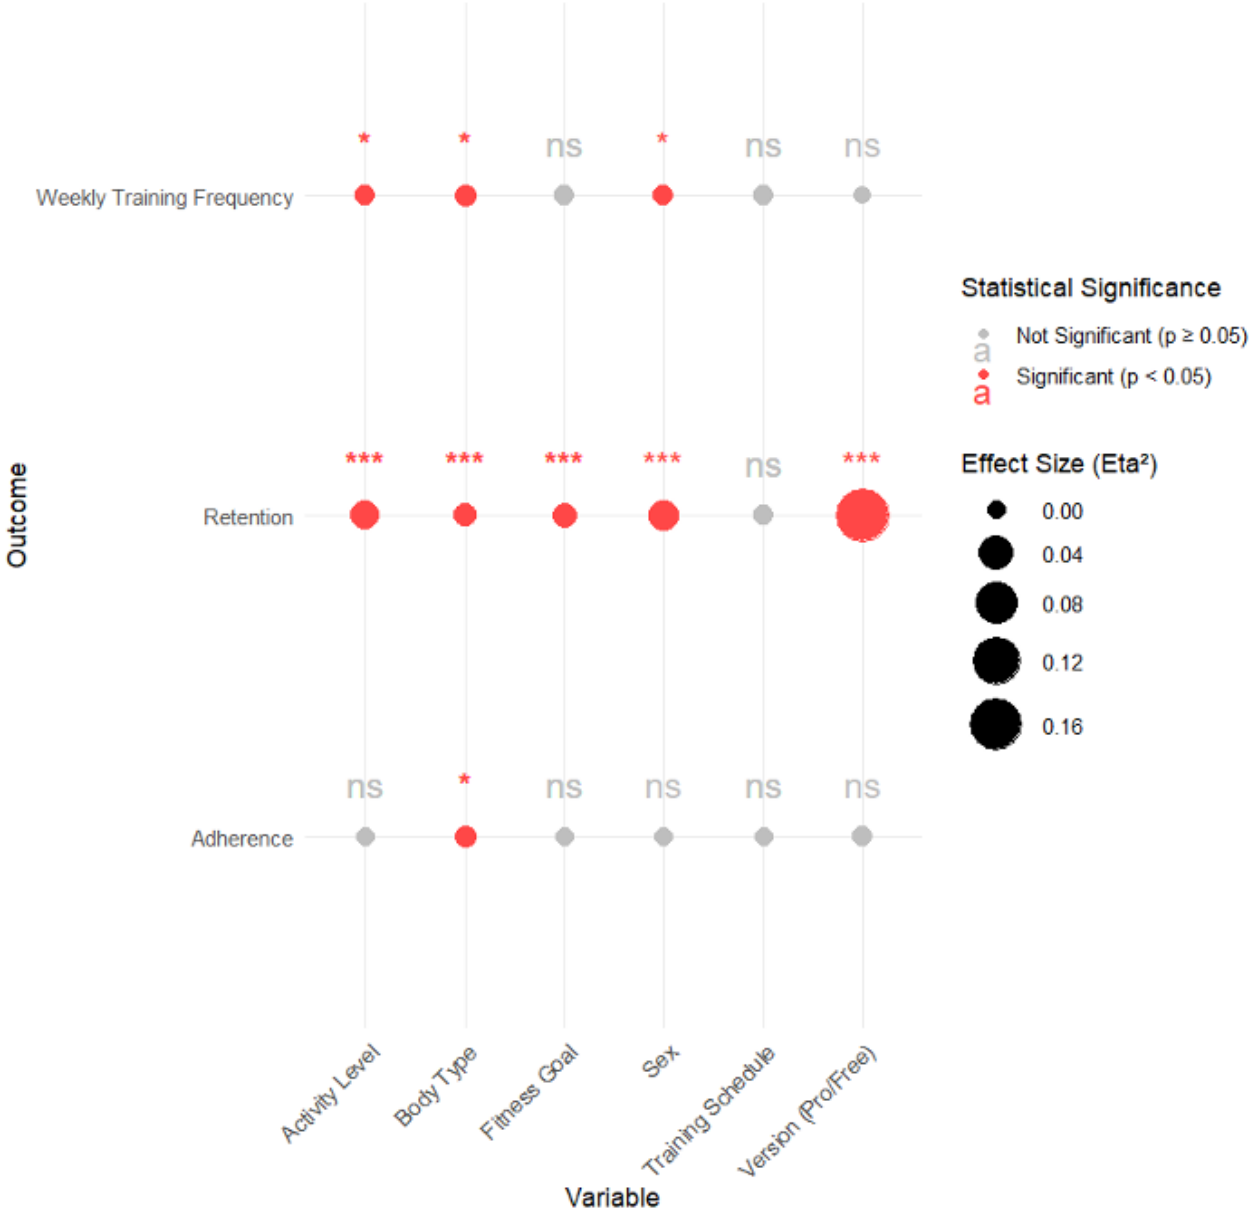
Range (minimum-maximum)	1.18-166.67

Figure 1 illustrates the number of training sessions completed each week, by the total number of users, over a 49-week span. At the beginning, there was a sharp peak in the number of training sessions, with 7469 sessions recorded in the first week after user registration, for a total of 2771 users. Following this peak, the number of sessions decreased rapidly over the next several weeks. It declined to 2295 by the end of the first month (a reduction of 69.3%), to 1678 by the end of the second month, and to 1448 (a reduction of 80.6%) by the end of the third. By around week 10, the decline began to stabilize, though a gradual downward trend persisted. By the 30th week, the number of sessions plateaued at a much lower level, approximately below 100 sessions in a week.

XSL•FO
RenderX

Figure 1. Total number of sessions in time (per training week) for all users (N=2771).

The time from user registration to their first training session ranged from 0 to 319.84 days, with a median delay of 7.98 days and a mean of 30 days. Most users initiated training within the first few days after registering, and the frequency declined steeply after 10 days. Delays beyond 50 days were rare, and only a very small proportion of users waited more than 100 days. A small subgroup of 31 users showed exceptionally long delays between 200 and 350 days.



Differences Between Training Outcome Variables

Retention Results

All categorical variables except for training schedule showed statistically significant differences to retention (Table 3). For the sex variable, retention values were statistically significantly (P<.001) higher in the “male” group when compared to the “female” group, though the effect size was small (Dunn r=0.14). For the Pro version variable, indicative of whether the user was or was not subscribed for service at the time of data download, retention values were statistically significant (P<.001) with a moderate-to-large effect size (Dunn r=0.41), higher in the “yes” group than in the “no” group.” In regard to activity level, retention values were statistically significant (P<.001, Dunn r=0.11; and P<.001, Dunn r=0.07, respectively) and were higher for the “active” and “very active” groups than for the “inactive” group. No statistically significant (P>.05, Dunn r=0.03) differences were found in retention values between the “active” and “very active” groups. Refer to Figure 2 for further details on the Kruskal-Wallis results for the outcome variables.

XSL•FO
RenderX

Figure 2. Summary of Kruskal-Wallis findings for each outcome variable.

[c]*P:* Kruskal-Wallis significance.

[d]*P*<.001.

[e]*P*<.01**.**

For the body type variable, the “mid” group retention values were statistically significantly higher (*P*<.002; Dunn *r* 0.07) than those in the “thin” group. No statistically significant differences were found in retention values between the “mid” and “strong” groups, nor between the “strong” and “thin” groups (*P*>.05; Dunn *r*=0.04 and *P*>.05; Dunn *r*=0.00, respectively). In the fitness goal variable, retention values were significantly lower for the “lose weight” group compared to the “antiaging” and “gain muscle” groups (*P*<.02; Dunn *r*=0.05 and *P*<.001; Dunn *r*=0.09, respectively) (Table 4).

[c]*P*<.01.

[d]*P*<.05.

Regarding explanatory numerical variables, all of them showed statistically significant correlations with retention. Age had a moderate positive correlation (r=0.21; P<.001) with retention, while subjective body fat and BMI showed a low negative correlation (r=–0.13; P<.001; r=–0.06; P<.01, respectively). Training difficulty had a moderate, positive correlation (r=0.24; P<.001), and enjoyment had a low, positive correlation (r=0.11; P<.001).

Of all motivation dimensions, intrinsic motivation had the highest positive correlation (r=0.19; P<.01) with retention. Identified extrinsic motivation had a small, statistically significant, positive correlation (r=0.12; P<.05). Introjected extrinsic motivation had a much lower, positive, and nonstatistically significant correlation (r=0.07; P>.05; Table 5).

[d]$P<.05$.

For the sex variable, figures in the "male" group were statistically significant ($P<.005$; Dunn $r=0.04$) and higher than those for the "female" group. In the activity level variable, the "very active" group values were significantly higher ($P<.05$; Dunn $r=0.05$) than those in the "inactive" group. Neither the "active" versus "inactive" groups nor the "active" versus "very active" groups showed any statistically significant differences in weekly training frequency values. For the body type variable, values in the "thin" group were statistically significantly ($P<.04$; Dunn $r=0.05$) higher than those of the "mid" group. No statistically significant differences were found between the "mid" and "strong" groups, nor between the "strong" and "thin" groups, for weekly training frequency values. For more detail on multivariate analyses of variance results for weekly training frequency, please refer to Table 7.

[a]U = standardized test statistic.

[b]P<.05.

After corrections for multiple comparisons, none of the explanatory numerical variables reflected statistically significant correlations with weekly training frequency.

Regarding types of motivation, only introjected extrinsic motivation correlated significantly with training frequency *(*r=0.17; P<.05), after corrections for multiple comparisons, with a moderate-low positive correlation. Intrinsic and identified extrinsic motivations showed close to no correlation with frequency (r=0.00 and P>.05 for both) (Table 5).

Adherence Results

Adherence was found to be associated with one of the categorical variables (Table 8). These differences were found in body type, which presented a highly statistically significant (P<.005; Dunn r=–0.06) difference between the groups “mid” and “thin”. In particular, the values for the “mid” group were statistically significantly lower than those for the “thin” group. No statistically significant differences were found between groups “mid” and “strong,” nor between “strong” and “thin,” in adherence to the training program.

Discussion

Summary of Key Findings

This study examined training behaviors among users of the MH fitness app and identified key factors associated with training behavior. Variables including adherence and retention were evaluated, with the latter having shown greater relevance in users long-term maintenance of training behavior. The main findings pointed at paid subscription and intrinsic motivation as being the most determinant factors to user retention. Other variables that correlated with retention included sex, body type, BMI, and fitness goal. In contrast, adherence was only linked to body type, while training frequency varied slightly by sex, activity level, motivation, and body type.

This piece of research involved 2771 individuals and is possibly one of the largest existing cohort studies of fitness app users to date. Previous large cohorts include the Konstanz Life Study with 1236 users of either fitness or nutrition apps [21]. Some systematic reviews have covered samples of 3555 participants from a total of 22 interventions (n=833 in the largest single study) [8] or 1622 total participants from 6 different studies [7]. Our work possibly also covers the longest time duration (18 months). Previous research has been 2-24 weeks [7], up to 5 months [22], or even 6 months in some cases [8].

Our sample figures fall within the "expected" ranges for a fitness app that offers high-intensity training, delivered electronically. Results are also in line with the systematic review by Stecher et al [8], which included participants between 10.6 and 61.5 years of age and found a mean of 39.6 (SD 6.5) years. Participants in this study presented some features worth noting, which were probably specific to our sample population. The majority (75.6%) of them were previously "active" or "very active." This was most likely due to the fact that all data registries were obtained from an app update (MH version 2.0) which, naturally, received many of its users from the previous version. This could also partially explain why 62% of our users were on the Pro version (paid subscription). MH always offered a free training program upon first registration, so the newest users would be expected to be on a free deal, while more experienced users would naturally progress to payment modes.

The studied sample primarily pursued "muscle gain" or "weight loss" fitness goals. A remarkably small (21.4%) percentage trained for "antiaging" purposes. We initially interpreted this finding as a sign that individuals were focusing mainly on "appearance," but this would have to be further investigated, as muscle gain [23,24], as well as weight loss [25], are also known markers of improved health [25] and consequently better aging.

Attrition Rates and Perceived Difficulty

It is well-established that attrition rates in mobile apps are extremely high. Meyerowitz-Katz et al [26], in their 2020 meta-analysis, stated that up to 98% of people only use apps for a short period of time. Our results fully align with this marked tendency, as we appreciated a remarkable drop in the number of training sessions within the first few weeks of enrollment. There was an observable decline of 69.3% by the end of the first month, a reduction of 77.5% by the end of month 2, and an 80.6% decline by the end of month 3. These figures strike even harder if we assume that many enrollments allegedly came from MH users who were transitioning from the old to the new version of the app. Participants in our study preferred "afternoon" (12:31-20:00 hours) training sessions and declared mean rates of session "difficulty" of 5.56, over a total of 10 points. The "difficulty" variable and its results need to be interpreted with caution. In our study, "difficulty" was an equivalent of perceived exertion, and it aimed to be indicative of how hard the session had felt to the user. However, this data were inquired once the user had not only finished the training but also finished the cool-down phase, and this could have led to respondents underrating the perceived exertion derived from the main block of training. Contrary to our expectations, difficulty in our sample showed a strong positive correlation to retention, which could be interpreted as a sign that challenge fosters engagement. Indeed, there is previous evidence that complex, vigorous, or hybrid activities correlate with intrinsic motivation [27], which commonly underlines activity retention. Regarding constructs of adherence, this finding could also reflect a self-selection bias, where more committed users are more likely to opt for challenging sessions, thus reinforcing their engagement over time.

Factors Influencing Training Frequency

Frequency of training seemed not to be related to factors such as age, BMI, declared enjoyment or perceived difficulty, subscription vs nonsubscription, declared fitness goal, or preferred training schedule. However, statistically significant differences were observed based on sex, previous activity level, motivation, and body type. Frequency of training was greater in the introjected motivation group, in males, in the very active vs inactive, and in the thin vs mid groups. One could argue that the controlled and external regulation of introjected motivation could explain the increased frequency observed in this group. This would partially align with previous research that points to the primacy of extrinsic motivation in exercise contexts [28]. The fact that introjected motivation seems to encourage higher training frequencies but no longer retention or higher adherence might be indicative of an enthusiasm that is not sustained over time. As to the user's previous activity level, while it seems logical that highly active individuals would train more often, this could be influenced by their prior engagement with the MH app or other forms of PA. If they were former MH users, their higher frequency could indicate loyalty, whereas if their activity stemmed from external sources, it is noteworthy that they also engaged frequently with the app. In contrast, inactive individuals may have felt overwhelmed by structured training. Previous research highlights differences in how beginners perceive social comparison and networking features in fitness apps, as well as how exercise proficiency affects adherence [29]. Additionally, attitudes toward PA significantly impact behavior, with Feng et al [30] showing that greater activity levels correspond to deeper integration and sustained engagement. Another possible explanation is that very active users may use more app features, enhancing their overall experience and leading to higher engagement [30]. Our results should, however, be interpreted with caution, since despite statistical significance, effect sizes

XSL•FO
RenderX

were small to very small, which is indicative of them having limited practical implications.

Reflections on Adherence to mHealth Training

In our study, adherence did not correlate with age, sex, previous level of activity, declared fitness goal, being on a free plan versus subscription mode, training schedule, perceived difficulty, or enjoyment in sessions.

Only one statistically significant difference was found for adherence, and it was for the "thin" group, which showed higher adherence than the "mid" group. Both frequency and adherence in this study were correlated with "thin" body type, but in both cases the effect size was small, so the association may not imply high practical impact. Notably, no motivation type proved to be more relevant for adherence, in spite of several authors having pointed to the more autonomous regulations of motivation leading to increased adherence and persistence [31]. Recent evidence confirms that maintaining physical activity remains challenging for healthy adults, with persistent individual-level barriers (ie, lack of motivation, attitudes, and concerns about physical changes) [32]. Adherence results in our study ranged from 1.2% to 166.7%, which was an impactfully wide range. It is important to note that intensity and duration data were not consistently available across users, which limited our ability to construct the adherence measure. Adherence in this study was based only on training frequency, a limitation that highlights the need for more standardized and comprehensive adherence metrics in future app-based exercise research. These results brought us to the following insights. Adherence is rather a measure of precise forecasting, as it basically depends on the ability to foresee future behavior. In that case, several personal characteristics may come into play, which have not been assessed in this study, such as the concept of self-efficacy, ambition, the ability to plan in advance, or the ability to pursue goals. Similarly, in healthy adults, psychological factors such as self-efficacy, enjoyment, and planning were significant predictors of long-term adherence to PA, emphasizing the relevance of individual motivational and behavioral traits in sustained engagement [33]. In addition, a study identified lack of time, motivation, and fatigue as frequent barriers to PA in healthy young adults, while enjoyment and social support emerged as consistent facilitators [34]. We found the lowest adherence rates for those who trained 6 times per week, while the highest adherence values were for those who trained twice per week. Based on our results, individuals with lower frequency expectations managed better to fulfill their target plan and were, consequently, more adherent. Again, we see a disadvantage in how different researchers seem to measure and define adherence, in addition to the fact that electronically delivered interventions often lack a detailed reporting of it [35]. We note that in our study, adherence was based on training frequency (% of targeted versus actual), which naturally correlates both variables. In contrast, retention and adherence operate on different parameters, especially when the exercise program is nonprescribed, lacks external obligation, and has no set duration.

Retention as a Key Variable, Distinct From Adherence

In this study, retention correlated significantly with most study variables. There was higher retention in the male group, in subscribers, in "active" and "very active," in "mid" body types versus "thin," and also higher retention when the fitness goal was "antiaging" or "gain muscle" versus "lose weight." "Pro version" users exhibited higher retention, aligning with previous research linking price to commitment [29,36,37], suggesting that subscription may indicate greater interest. The effect size for our finding was moderate-to-large, which points at subscription possibly being the most determinant factor in long-term training behavior. All other correlations had small to very small effect sizes. "Thin" body types, which had shown correlation with frequency and adherence, did not display higher retention, potentially reflecting an initial enthusiasm that wanes over time. The finding that "antiaging" goals led to higher retention than "lose weight" aligns with theories suggesting that health-oriented goals promote sustained engagement. However, the fact that "gain muscle" goals also outperformed "lose weight" in retention suggests that aesthetic-driven objectives may still play a role in long-term engagement, challenging this interpretation.

The study found that only intrinsic motivation had a statistically significant positive correlation with retention, while no such correlation was observed between intrinsic motivation and adherence. The distinction between retention and adherence is emphasized, as these concepts are considered distinct. In line with previous evidence [28,38-40], our study reflects that intrinsic and identified autonomously regulated motivations are the strongest correlated with retention. There is, however, previous evidence that points at extrinsic regulations of motivation as possibly the most important ones for exercise contexts [28,41]. We agree with Wilson's statement that future research with larger sample sizes is recommended, considering potential variations in extrinsic motivation types [28] and a revision of the commonly accepted theory that intrinsic motivation is the most desirable to engage in and sustain exercise activities.

To translate our findings into practical applications, we suggest that fitness app developers consider tailoring features to specific user subgroups (ie, providing targeted support or content adaptations for users with a "mid" body type). Moreover, including motivational aspects that support intrinsic regulation, such as goal-tracking tools, personalized feedback, and autonomy-enhancing design, may further increase retention and adherence.

Strengths and Limitations

The present study focused on analyzing user training behavior by means of a cross-sectional study conducted on 2771 MH app users over a period of 18 months. To the authors' knowledge, the largest study previously available was a cohort study conducted under the Konstanz Life Study, which followed a total of 1236 users of either fitness or nutrition apps [21]. Other revisions involved larger samples, such as that by Stecher et al [8], (with 3555 participants across 22 interventions) or He et al [7] (with 1622 participants from 6 studies). Previous studies followed participants for periods of 2 to 24 months [7,8,22].

XSL•FO
RenderX

Based on this evidence, our study could be the largest of its kind in sample size and follow-up period so far. Nonetheless, we acknowledge that broader meta-analyses may include larger cumulative samples and aggregated durations across multiple interventions and apps [26].

The use of real-world app data, combined with motivational surveys, provides valuable insights into user behavior, retention, and adherence patterns. Additionally, the study uses robust statistical analyses, including nonparametric tests and multiple correction methods, ensuring the reliability of the findings.

However, the research also has limitations. The cross-sectional design prevents establishing causal relationships between motivation, training behavior, and adherence. The dataset is limited to users of a single fitness app (MH), potentially restricting generalizability to other platforms with different features or user demographics. We obtained informed consent from 5858 users. Of those registries, 2771 were complete and eligible for analysis. This loss should be acknowledged as the fact that we only managed to merge motivation and training data for a total of 289 participants, which limits the statistical power of our motivation-related analyses. Finally, adherence was measured in terms of training frequency, which may not fully capture engagement in app-based fitness programs, highlighting the need for more nuanced adherence metrics in future research.

Conclusions

This study provides crucial insights into the exercise behavior and retention patterns of MH app users, highlighting key factors that influence user engagement. New insights are shared in regard to how motivation relates to training behavior with fitness apps. Clear differentiations are presented between adherence and retention, as conceptualized by the study authors. Fitness apps are a promising tool toward more active lifestyles, but we are yet lacking a sound understanding of related human behavior. Strategies such as gamification, goal-setting, or prompting are available to app developers to increase user engagement. However, longitudinal studies and mixed methods approaches are needed both to study causality and explore qualitative drivers to trainee behavior.

Acknowledgments

We would like to thank all users of MH app who consent to share their anonymized data for research purposes. All authors declared that they had insufficient funding to support open access publication of this manuscript, including from affiliated organizations or institutions, funding agencies, or other organizations. JMIR Publications provided article processing fee (APF) support for the publication of this article.

Funding

This study was supported with research funds provided by Aristos Campus Mundus projects (ACM2022_25 and ACM2023_19) and Fundació Naccari-Ravà 2022. The funding bodies had no role in study design, data collection, data analysis, or manuscript preparation.

Abstract

Background: Limited empirical evidence exists on the effectiveness of a hybrid approach to heart-healthy lifestyle interventions that integrates mobile health (mHealth) technology with face-to-face counseling. Moreover, its superiority over exclusive mHealth use in promoting heart-healthy behavioral outcomes within a community setting remains unclear.

Objective: This study aims to evaluate the effectiveness of a hybrid community-based approach to heart-healthy lifestyle intervention incorporating a mobile app and motivational interviewing among community-dwelling adults without a history of cardiovascular disease.

Methods: We conducted a 3-arm, parallel-group, randomized controlled trial with assessments at baseline and after 12 weeks. A total of 75 participants, each presenting at least 1 component of metabolic syndrome and no history of cardiovascular disease, were randomly assigned to 1 of 3 groups: hybrid (n=25), mobile (n=25), or control (n=25). Participants were recruited through an online platform. The hybrid group underwent a 12-week hybrid intervention combining a mobile app (ie, “My HeartHELP”) and face-to-face motivational interviewing led by a nursing researcher. The mobile group used only the mobile app, while the control group received written material on general heart health. The intervention was facilitated by 3 trained nursing researchers. The primary outcome was a composite score of “heart-healthy behaviors,” while secondary outcomes included scores for heart-healthy “information,” “self-efficacy,” “motivation,” and cardiovascular parameters. The trial was conducted in 2 rounds from October 2022 to May 2023. An intention-to-treat analysis was performed.

Results: Of the 75 participants, 72 (96%) completed this study. Compared with the control group, both the hybrid and mobile intervention groups demonstrated significantly greater improvements in behavioral outcomes, including composite heart-healthy behavior ($F_{2,69}$=7.25, P=.001), its theoretical predictors—heart-healthy motivation ($F_{2,69}$=8.54, P<.001) and self-efficacy for diet ($F_{2,69}$=4.87, P=.01) and exercise ($F_{2,69}$=5.48, P=.006)—as well as fasting glucose levels ($F_{2,69}$=3.90, P=.03) following the 12-week intervention. Particularly, the hybrid group—unlike the mobile group—showed significantly greater improvement in dietary behavior, a subscale of heart-healthy behavior, compared with the control group, and demonstrated significantly greater improvements in interest or enjoyment, a core subscale of intrinsic motivation, than the mobile and control groups.

Conclusions: The hybrid community-based heart-healthy lifestyle intervention—integrating a mobile app and motivational interviewing—demonstrated overall effectiveness comparable to the mobile app alone, while yielding greater improvements in dietary behavior and core intrinsic motivation. These findings highlight the potential of mHealth apps as practical, stand-alone tools to promote cardiovascular health, particularly in community settings with limited access to in-person professional support. However, incorporating motivational interviewing may further enhance internalized motivation and complex behavior changes over time. Health professionals can therefore adopt mHealth either independently or in combination with motivational interviewing.

XSL•FO

Future studies should optimize integration strategies to enhance effectiveness and evaluate the long-term sustainability of such hybrid approaches.

Introduction

Cardiovascular disease remains the leading cause of mortality worldwide [1]. To mitigate cardiovascular disease risk, the World Health Organization advocates for lifestyle modification interventions targeting smoking, poor dietary habits, physical inactivity, obesity, and alcohol consumption [2]. Evidence indicates that multiple unhealthy lifestyle behaviors significantly elevate cardiovascular disease risk [3], whereas adopting multiple healthy lifestyle behaviors can reduce all-cause mortality by up to 58%-66% [3,4]. Despite these findings, only a small proportion of individuals at risk of cardiovascular disease in the United States have achieved these recommended lifestyle changes [5]. Consequently, there is a pressing need for innovative, integrated strategies to effectively promote heart-healthy lifestyles in a comprehensive approach.

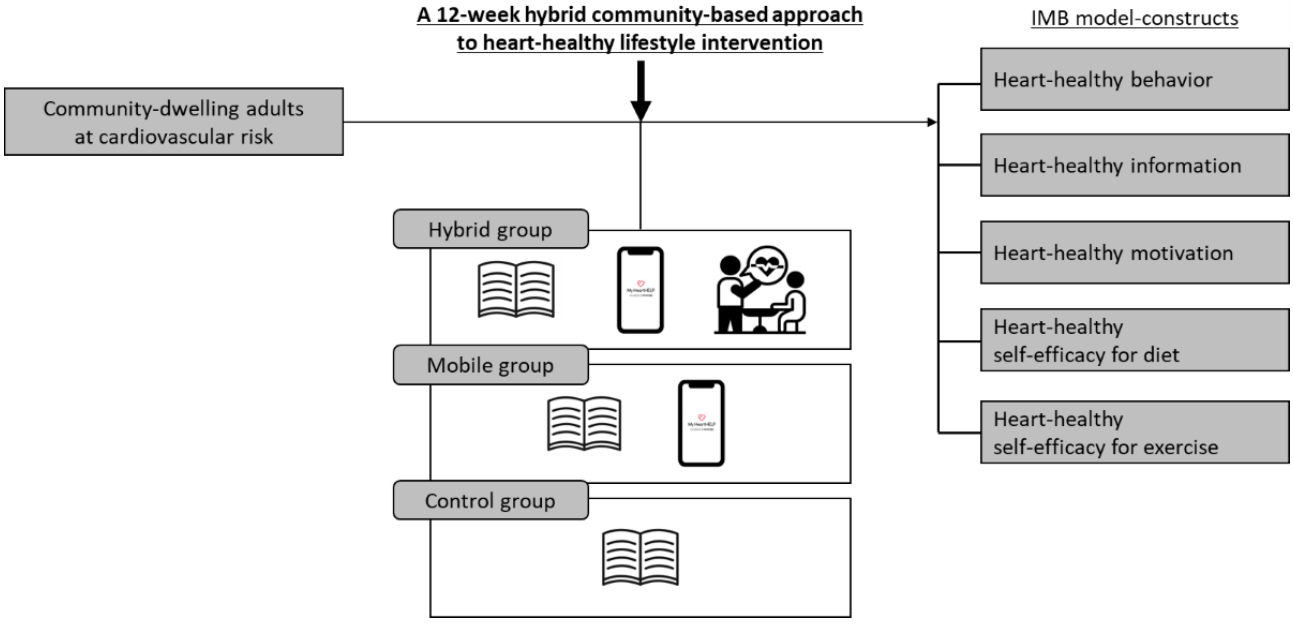
To date, mobile health (mHealth) interventions using websites, smartphones, or videoconferencing (online) have been used to improve heart health outcomes, such as cardiovascular risk parameters [6]. mHealth may help offset limited professional human resources and the time and effort required for expert-centered cardiovascular health care in the community [7]. However, evidence on the effectiveness of mHealth interventions in changing behaviors remains limited [8]. When studied, they have primarily focused on a single approach, such as physical activity [9] or weight loss [10], rather than a comprehensive strategy targeting multiple lifestyle behaviors.

Furthermore, mHealth interventions may face challenges in maximizing educational effects due to a lack of empathic support from the absence of active human interaction [11]. The primary limitation of mHealth interventions may be characterized as the lack of a robust therapeutic alliance, as highlighted by Müssener [12]. To overcome these limitations, mHealth interventions may incorporate tailored interactions using real-time feedback messages as an innovative strategy to strengthen therapeutic alliance and promote heart-healthy behavioral changes [9]. For this purpose, mHealth interventions require technologies that integrate theory-based cognitive behavioral strategies, such as goal-setting, self-monitoring, and reinforcement or feedback [13]. Based on this background, we developed a mobile app called “My HeartHELP,” incorporating 3 behavioral strategies to promote comprehensive heart-healthy behaviors: providing information, encouraging self-monitoring, and delivering real-time automatized feedback messages [14]. The behavioral strategies of “My HeartHELP” may be innovative in the ability to address multiple heart-healthy behaviors simultaneously while tailoring real-time feedback to individual behavioral outcomes. Hence, evidence on the effectiveness of the “My HeartHELP” app on heart-healthy behavioral outcomes is needed.

Nurse-led face-to-face behavioral lifestyle interventions are still required, as they elicit small-to-moderate effects on behavioral changes [15]. However, their effectiveness in modifying lifestyle behaviors remains unclear in community settings without a system that educates and supports community-dwelling individuals in self-management. Among the several behavioral intervention modes proposed, motivational interviewing has been recognized as a potential approach to facilitate behavioral changes through person-centered care, fostering active interaction between the client and provider within the client’s psychosocial context [13]. This method involves counseling techniques such as reflections, affirmations, open questions, and summarizations, which are well-received by clients because they address internal conflicts and guide goal-setting [16]. By focusing on connecting behaviors to desired outcomes and evoking an individual’s intrinsic motivation, motivational interviewing encourages people to take an active role in their own change processes [17]. In the context of behavioral interventions, motivational interviewing has proven effective in managing substance use, smoking cessation, and physical activity [18]. Therefore, motivational interviewing may complement mHealth by addressing its shortcomings and could be integrated into mHealth interventions in community settings.

A hybrid approach integrating mHealth with face-to-face motivational interviewing counseling presents a promising alternative for addressing the limitations of mHealth. This approach offers 2 key advantages. First, it combines the technological convenience of mHealth with the person-centered care of face-to-face interventions, thereby complementing the constraints of online interventions in terms of therapeutic alliance [19]. Second, in-person interactions can enhance engagement in and adherence to lifestyle behaviors recommended by health care expert providers [20]. In this regard, the American Heart Association has posited that a combined approach involving multiple modalities of behavioral interventions targeting cardiovascular risk factor reduction may be more effective than a single-modality approach [13]. Furthermore, the addition of clinical expert counseling to mobile-based cardiovascular health programs has not only been recommended [21] but has also been associated with greater reductions in systolic blood pressure when nurse-led case management was integrated with mHealth interventions, compared to mHealth alone [22]. However, empirical research on whether hybrid interventions that combine online mHealth

XSL•FO
RenderX



and offline face-to-face interventions are more effective than mHealth alone remains limited.

To address the current gap in the literature, we developed and implemented a hybrid community-based approach to a heart-healthy behavioral lifestyle intervention that combines the use of the "My HeartHELP" mobile app with face-to-face motivational interviewing to maximize behavioral outcomes in cardiovascular prevention and promotion. However, little information exists on whether such a hybrid approach is effective and, furthermore, whether it is superior to mobile app use alone in achieving heart-healthy behavioral outcomes within a community setting.

Meanwhile, the Information-Motivation-Behavioral Skills (IMB) model (Multimedia Appendix 1) served as the basis for developing the behavioral strategies of the hybrid community-based approach to a heart-healthy behavioral lifestyle intervention and determining the outcome variables to evaluate its effectiveness. The IMB model explains behavioral changes using constructs such as information, motivation, and behavioral skills [23]. Theoretically, motivation in the IMB model is directly associated with behavioral skills (ie, self-efficacy) and indirectly associated with behavior via self-efficacy [23]. Motivation enhancement may effectively change heart-healthy behaviors when used as part of lifestyle interventions [24]. In particular, the hybrid community-based approach was designed to enhance personal motivation by delivering information and behavioral skills for change through mobile text messaging and individually tailored counseling, while fostering self-monitoring to promote greater self-awareness and adoption of heart-healthy behaviors. Furthermore, its group sessions—grounded in motivational interviewing—were intended to facilitate the exchange of behavioral strategies and experiences through group dynamics, thereby strengthening social support and shared norms and, in turn, enhancing social motivation.

Therefore, the hybrid intervention based on the IMB model has a theoretical foundation aimed at informing individuals about cardiovascular health through frequent text messaging (heart-healthy information) and encouraging them through mHealth and motivational interviewing to promote intrinsic motivation (heart-healthy motivation). This, in turn, enhances behavioral skills (heart-healthy self-efficacy for diet and exercise) through cognitive-behavioral strategies and facilitates behavioral changes (heart-healthy behavior; Figure 1).

Figure 1. A theoretical framework of this study. The hybrid group received a 12-week hybrid intervention combining a mobile app (ie, "My HeartHELP") and face-to-face motivational interviewing; the mobile group used the mobile app (My HeartHELP), and the control group received a brochure on general heart-health. IMB: Information-Motivation-Behavior Skills.

We aimed to examine the effectiveness of a 12-week hybrid community-based heart-healthy lifestyle intervention among community-dwelling adults without a history of cardiovascular disease (Figure 1). We tested 2 hypotheses: first, a mobile group would be more likely to improve heart-healthy information, motivation, behavioral skills, and behavior (ie, IMB model-constructs) and cardiovascular parameters than a control group. Second, a hybrid group would be more likely to improve these outcomes than the mobile or control groups.

Methods

Study Design

This study (clinical trial number ISRCTN83643383) was a randomized controlled trial with 3 arms, parallel groups, and a 12-week follow-up period: a hybrid group, a mobile app group, and a control group. The pretest (T1) was conducted before the 12-week intervention, while the posttest (T2) was conducted after the intervention. This study was conducted in 2 cohort rounds to facilitate the effective implementation of the intervention by optimizing resources within a small research team. The rationale for the separate rounds was based on the

XSL•FO
RenderX

study by Burke et al [25]. The first round was conducted between November 2022 and February 2023, and the second round between February and May 2023 in a community-based setting in Seoul, South Korea.

As this study adopted a prospective, randomized, open-label, blinded end point design [26], double blinding was not feasible due to the nature of the interventions, which involved mobile app use and counseling. Specifically, neither study participants nor interviewers were blinded to this study's groups, but outcome assessors were blinded. We report our trial using the CONSORT (Consolidated Standards of Reporting Trials) guidelines (checklist provided in Multimedia Appendix 2) [27].

Participants

This study's participants comprised 75 community-dwelling adults, and the inclusion criteria were as follows: (1) aged between 20 and 64 years, and (2) having at least one metabolic syndrome according to the National Cholesterol Education Program Expert Panel [28]. The exclusion criteria were as follows: (1) medically diagnosed with diabetes mellitus and taking hypoglycemics or insulin, (2) medically diagnosed with either cardiovascular or psychiatric disease (ie, major depression or anxiety disorder), (3) physical activity limitations, (4) cognitive problems, and (5) inability to use mobile apps.

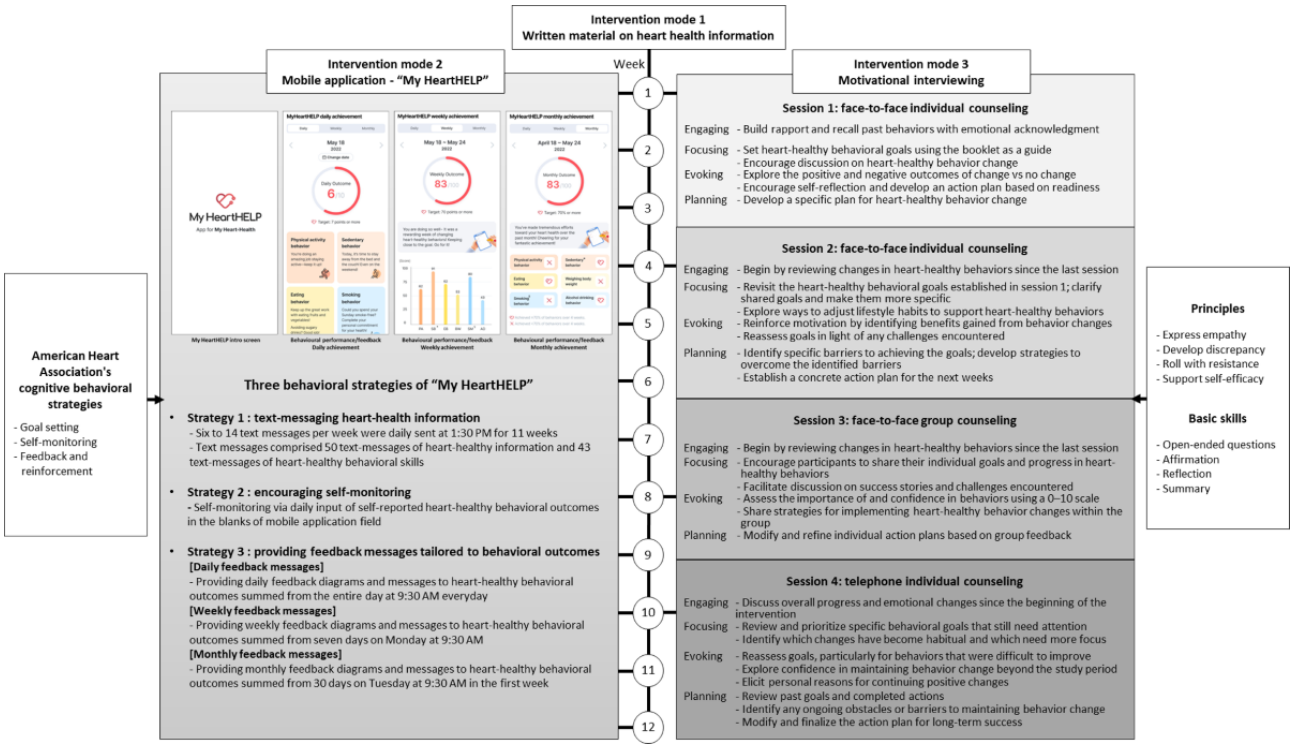
Participants were recruited using a notice on the internal bulletin board of the university with which the researchers were affiliated, as well as on the external bulletin boards of mobile communication platforms. The first round of recruitment was conducted from October 17 to November 11, 2022, and the second round from January 11 to February 3, 2023. When interested candidates contacted the researchers by phone to participate in this study, the researchers determined whether they were eligible and informed them that they could be randomly assigned to 3 groups. After agreeing to participate, participants were asked to attend a preliminary investigation session in person, where the purpose, methods, and procedures of this study were explained in detail based on this study's protocol, and written informed consent was obtained.

Sample Size

The minimum sample size per group was calculated based on the effect size of the composite heart-healthy behavior—the primary outcome variable in this study—between the mobile and control groups. According to Park [29], the mean difference (MD; Δ=change in mean composite heart-healthy behavior score from pretest to posttest) was 0.66 and –0.15 in intervention and control groups, respectively. However, we conservatively assumed that there would be no difference in the composite heart-healthy behavior between the pre- and posttests (ie, 0.0) in the control group. Thus, the effect size assumed in this study was 0.66.

The SD of the mean score changes for each group was estimated as follows, based on the results from the dissertation by Park [29]: pretest score SDs were assumed to be 0.47 and 0.56, and the posttest score SDs were 0.41 and 0.50 for the intervention and control groups, respectively. By conservatively assuming a correlation coefficient of 0.5 between pre- and posttests, and using the method proposed by Abrams et al [30], we projected the SD of the mean score changes from pre- to posttests to be 0.443 and 0.533 for the intervention and control groups, respectively. With these SDs of mean score changes and, under a 2-sided significance level (α) of 2.5%, a minimum of 20 subjects per group was needed to ensure a statistical power (1-β) of 95% to detect the effect size of 0.66. Assuming a 20% dropout rate during this study's period, we planned to enroll 25 participants in each group. Statistical software PASS 2020 (version. 20.0.8; NCSS LLC) was used to calculate the sample size.

Random Allocation



Random allocation in this study was conducted by the principal investigator using an age- and gender-stratified block randomization method with an allocation ratio of 1:1:1 across the 3 study arms. A randomization list was generated for each of the 10 age- and gender-stratified groups (ie, 20-29, 30-39, 40-49, 50-59, and 60-65 years, by gender) using R software (version 3.6.0; R Foundation for Statistical Computing). Study participants were listed in the order in which they were recruited, and each participant was assigned to an appropriately stratified group based on age and sex. Finally, a total of 75 participants were allocated to the hybrid (n=25), mobile (n=25), or control (n=25) groups.

Study Intervention

An outline and details of the hybrid intervention are presented in Figure 2, which contains three intervention modes: (1) intervention mode 1: written materials on general heart-health information, (2) intervention mode 2: the "My HeartHELP" mobile app [14], and (3) intervention mode 3: motivational interviewing counseling. General heart health information was delivered via a brochure, including information on cardiovascular diseases, cardiovascular risk factors, and general heart-healthy lifestyle changes. The duration of intervention modes 2 and 3 was 12 weeks. Specifically, the mobile app was designed for daily use throughout the intervention period, while motivational interviewing was delivered in 4 sessions, each lasting 2 hours, conducted at weeks 1, 4, 8, and 10.

XSL•FO
RenderX

Figure 2. An outline for the 12-week hybrid community-based heart-healthy lifestyle intervention. The 12-week hybrid intervention consisted of the three intervention modes: (1) intervention mode 1: written materials on general heart-health information, (2) intervention mode 2: the "My HeartHELP" mobile app, and (3) intervention mode 3: motivational interviewing counseling. General heart health information was delivered via a brochure, including information on cardiovascular diseases, cardiovascular risk factors, and general heart-healthy lifestyle changes. Please see Multimedia Appendix 3 for a larger version of this figure.

The hybrid group participated in all 3 intervention modes. The mobile group received 2 intervention modes of written materials and the "My HeartHELP" app. The control group received only the written materials.

Participants in both the hybrid and mobile groups attended separate 1-hour preintervention education sessions, which provided an overview of the 12-week intervention schedule and instructions on using the "My HeartHELP" app. A printed booklet containing a QR code for app download was distributed, and participants were informed that the app was freely available for research use. Each session also included a hands-on practice session, during which the research team assisted participants with app registration and guided them in entering sample data into the app.

The "My HeartHELP" app was implemented as an online mode, consisting of 3 strategies: strategy 1—text messaging with heart-health information, strategy 2—encouraging the self-monitoring of 6 lifestyle behaviors (physical activity, nonsedentary behavior, healthy dietary behaviors, nonsmoking, nonalcohol binge drinking, and daily weighing of body weight) [14], and strategy 3—providing automated or tailored feedback messages tailored to individual behavioral outcomes from self-monitoring (Figure 2). The text messaging intervention was delivered daily at 1:30 PM over a period of 1 to 11 weeks and comprised 50 messages with heart-health information and 43 messages focused on heart-healthy behavioral skills. Encouraging self-monitoring was also a daily practice, requiring participants to record behavioral outcomes for the 6 behaviors by entering data into the designated input fields of the app. Automated or tailored feedback messaging, including diagrams and texts, was daily, weekly, and monthly based. As a preparatory step toward developing automated and tailored feedback messaging, the research team established behavioral target goals and their ranges for daily, weekly, and monthly outcomes based on 6 heart-healthy behaviors. According to the ranges, a pool of feedback text messages was developed and embedded into the app's algorithm. For daily outcomes, scores obtained from self-monitoring of the 6 heart-healthy behaviors during the previous day were categorized as either >7 or <7, with the daily goal set at >7 out of a possible 10 points. The daily feedback messages were presented as a diagram and texts at 9:30 AM every day. For weekly outcomes, the average scores over the previous 7 consecutive days were converted to a 100-point scale and classified into 3 categories: ≥70, 50-69, and <50. The weekly goal was set at ≥70. The weekly feedback messages were delivered on Monday at 9:30 AM. For monthly outcomes, the mean scores across the preceding 4 weeks were dichotomized into ≥70 and <70. The monthly feedback messages were delivered as diagrams and text messages on Tuesday at 9:30 AM in the first week. The app automatically delivered tailored feedback messages through an embedded algorithm that operated according to predefined behavioral target goals and their corresponding ranges. Further details are available in the feasibility and acceptability study of the "My HeartHELP" mobile app [14].

Motivational interviewing counseling was an offline face-to-face intervention conducted in 4 sessions: sessions 1 (week 1) and 2 (week 4) for individualized counseling, session 3 (week 8) for group counseling, and session 4 (week 10) for telephone counseling (Figure 2). Each session followed the core processes

XSL•FO
RenderX

of engaging, focusing, evoking, and planning, as outlined in Figure 2 [17]. Engaging focused on building trust, understanding participants' unique perspectives, reviewing past behaviors, and evaluating emotional and behavioral changes [17]. Focusing aimed to clarify shared goals, making them more specific and actionable, while evoking strengthened participants' motivations for change by imagining potential outcomes and assessing their importance and confidence. Planning facilitated the development of practical strategies by identifying barriers to behavior change and determining ways to overcome them. The intervention was tailored to individual lifestyle contexts and used the principles of facilitating empathy, discrepancy, resistance, and self-efficacy along with open-ended questions, affirmations, reflections, and summaries techniques. Additional details are presented in Figure 2.

Fidelity of Intervention

To ensure the fidelity of the "My HeartHELP" app implementation, 2 measures used in previous studies [14,31] were applied: access and self-monitoring rates. Participants in both the hybrid and mobile groups were instructed to access the app daily and self-monitor their behavioral outcomes (ie, fill in the blanks of the behavioral components) daily for 12 weeks. Among those enrolled in the hybrid and mobile groups, 36/47 (76.6%) accessed the app at least once daily, while 45.7/47 (97.3%) engaged daily in self-monitoring of heart-healthy behaviors throughout the 12 weeks.

To ensure the fidelity of motivational interviewing, all authors completed training and certification through motivational interviewing courses, including 10 hours of fundamental information and 8 hours focused on health care [32]. One author implemented the motivational interviewing sessions over 12 weeks as an interventionist, with assistance from another author. To maintain counseling quality, an activity sheet template was developed and used for each session. Regarding attendance adherence, participants in the hybrid group attended 23/23 (100%) of the sessions.

Measures

Heart-Healthy Behavioral Outcomes Variables

The primary outcome was the composite score of heart-healthy behaviors. Secondary outcomes included scores for heart-healthy knowledge, heart-healthy self-efficacy, heart-healthy motivation, and cardiovascular parameters. All outcomes were measured at baseline (T1) and after 12 weeks (T2) using self-reported questionnaires, anthropometric measurements, and blood sampling.

Composite heart-healthy behavior refers to the extent to which participants practiced heart-healthy behaviors for cardiovascular health. This was measured using the Management Behaviors of Metabolic Syndrome Evaluation Tool developed by Kang [33] for individuals with metabolic syndrome. This tool consists of 36 questions: 8 on "physical activity and weight control," 16 on "dietary habits," 3 on "drinking and smoking," 3 on "stress," 2 on "sleep and rest," and 4 on "health check-up and management." The average score was calculated by summing the scores for each item (rated from "never" to "always" on a 4-point Likert scale) and dividing it by the number of items. Higher scores indicated greater heart-healthy behavior. Cronbach α was 0.92 in the study by Kang [33] and 0.91 in this current study.

Heart-healthy information refers to the level of knowledge regarding cardiovascular disease prevention. This was measured using the Heart-Healthy Information Questionnaire developed by Choo et al [34]. This tool consists of 50 questions, each answered as "true," "false," or "don't know." Participants who answered correctly received 1 point. If participants answered incorrectly or did not know, they received 0 points. The total score ranged from 0 to 50 points. The Kuder-Richardson formula 20 was 0.85 in the study by Choo et al [34] and 0.81 in this current study.

Motivation refers to intrinsic motivation levels for practicing heart-healthy behaviors. It was measured using the Intrinsic Motivation Inventory developed by McAuley et al [35], which we modified for the present study. Based on the inventory guidance indicating that subscales may be selectively used according to the study's focus [36], we used 5 of the 7 subscales, excluding 2 subscales. The pressure or tension subscale was excluded because it is more relevant to stressful activities such as competitive sports [37,38] than to heart-healthy behaviors. The relatedness subscale was also excluded because its items capture relational closeness—such as perceived distance, trust, and friendship with specific individuals—which are less relevant to the autonomous, self-directed process of adopting heart-healthy lifestyle habits. Consequently, 5 of the original 7 subscales were used—interest or enjoyment (7 items), perceived competence (6 items), effort or importance (5 items), perceived choice (7 items), and value or usefulness (7 items)—yielding a total of 32 items. The English version of the modified Intrinsic Motivation Inventory was minimally adjusted to fit heart-healthy behaviors, then translated into Korean separately by 3 Korean nursing scholars and consolidated into a single Korean version. A native English speaker back-translated this version, and the final English version was reviewed and confirmed by the original translators. Participants rated items using a 7-point Likert scale ranging from "completely disagree" to "strongly agree," with responses summed and averaged for each participant. Cronbach α was 0.85 in the study by McAuley et al [35] and 0.88 in this current study.

Heart-healthy self-efficacy refers to participants' confidence in their ability to engage in heart-healthy eating and exercise. It was measured using 2 instruments: the Self-Efficacy for Diet and Self-Efficacy for Exercise tools developed by Sallis et al [39]. The Self-Efficacy for Diet instrument comprises 20 items, while the Self-Efficacy for Exercise instrument has 12 items. Scores for eating and exercise habits were calculated by summing the responses on a 5-point Likert scale, ranging from "I cannot do this at all" to "I can definitely do this." Higher scores indicate higher self-efficacy levels. Cronbach α for eating was 0.84 in the study by Shin and Lach [40] and 0.91 in this current study. Cronbach α for exercise was 0.90 in the study by Sallis et al [39] and 0.93 in this current study.

Cardiovascular Parameters

Cardiovascular parameters comprised BMI, waist circumference, blood pressure, fasting glucose, total cholesterol,

XSL•FO
RenderX

low-density lipoprotein cholesterol, and high-density lipoprotein cholesterol. Body weight was measured after an overnight fast using the InBody270 scale (InBody Co, Ltd). Before weighing, participants wore a study-provided gown and removed their shoes. Height was measured using a wall-mounted stadiometer. BMI was calculated as weight (kg) divided by height (m^2). Waist circumference (cm) was measured twice using a Gullick II measuring tape at the midpoint between the lowest rib and the iliac crest, with the average of the 2 measurements used. Blood samples were drawn from the antecubital vein in the morning after a 10-hour overnight fast, without participants taking any current medications, including antihypertensive or lipid-lowering drugs. The samples were analyzed as described in a previous study [41].

Statistical Analysis

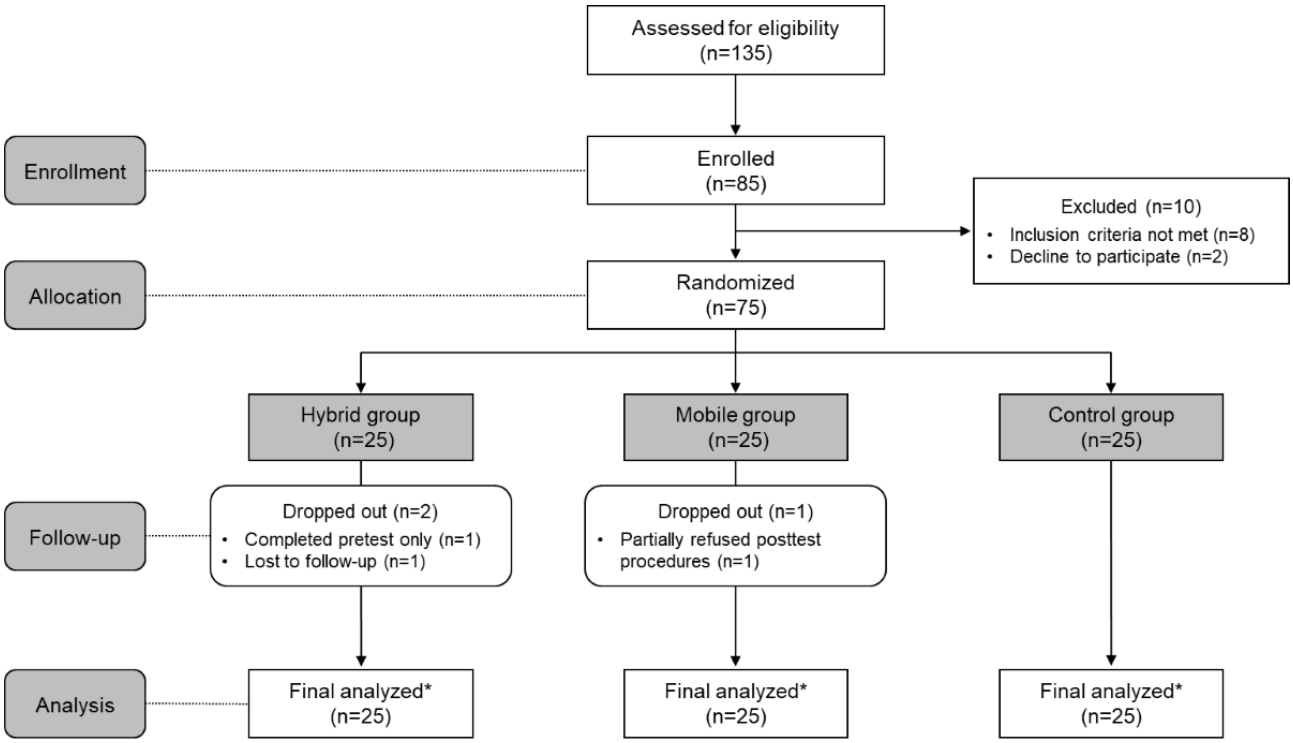
Participants' demographic and baseline characteristics were summarized using descriptive statistics, including frequency, percentage, mean, and SD. To test the homogeneity of the 3 groups' baseline measures, chi-square tests were used for categorical variables, while a 1-way ANOVA was performed for continuous variables (ie, age and study variables).

Both intention-to-treat and per-protocol approaches were used. The intention-to-treat analysis included all randomized participants regardless of adherence to the intervention, whereas the per-protocol population consisted of those who strictly adhered to the intervention protocol [42]. Missing values, which occurred due to nonresponse to the measurements, were not imputed but analyzed as observed. Analysis of covariance was used to compare outcome variables among the hybrid, mobile, and control groups at T2. In this analysis, T2 scores served as the dependent variable, study groups as the main exposure variables, and baseline scores for each respective outcome variable as confounders to adjust for individual differences at the start of the intervention. As a post hoc analysis, the Tukey least significant difference multiple comparison test was performed to identify significant differences between study groups in outcome variable changes. The analyses further examined significant group differences in the subscales of composite heart-healthy behavior and motivation. All statistical analyses were conducted using SPSS/WIN (version 28.0; SPSS Inc), with a 2-sided $P<.05$ considered statistically significant.

Ethical Considerations

This study was approved by the Institutional Review Board of Korea University (KUIRB-2022-0287-01). All participants provided written informed consent. All procedures were performed in accordance with the ethical standards of the Institutional Research Committee and the 2013 Declaration of Helsinki [43].

Safety and security procedures related to the use of the mobile app were carefully implemented. To ensure data privacy, access to the secure data server was restricted to a single designated member of the research team. Data were downloaded and processed offline to enhance data protection and confidentiality. Preintervention education sessions were conducted to inform participants about relevant safety and privacy measures. In addition, real-time user support was offered via KakaoTalk (Kakao Corp), a widely used mobile messaging platform in South Korea, enabling participants to directly communicate with the research team throughout the intervention period. Participants in the control group, mobile group, and hybrid group who completed only the pretest received a KR ₩30,000 (US $21) gift voucher. Participants who successfully completed all stages of the study received monetary compensation according to group assignment: KR ₩150,000 (US $104) for the control group, KR ₩250,000 (US $172) for the mobile group, and KR ₩300,000 (US $207) for the hybrid group. All details related to compensation were fully disclosed to participants during the informed consent process before their enrollment in this study.



Results

Participants' General Characteristics

Three participants dropped out of this study for the following reasons: one participant from the hybrid group due to time constraints (n=1), another from the hybrid group due to loss to follow-up (n=1), and one from the mobile group who declined to participate in the posttest (n=1; Figure 3). Since the findings from both the intention-to-treat and per-protocol analyses yielded identical statistical significance, the results are presented based on the intention-to-treat analysis.

XSL•FO
RenderX

Figure 3. Participant flow in this study. The hybrid group received a 12-week hybrid intervention combining a mobile app (ie, "My HeartHELP") and face-to-face motivational interviewing; the mobile group used the mobile app, and the control group received written material on general heart-health information. *All participants were included in an intention-to-treat analysis.

The participants had a mean age of 43.6 (SD 11.3) years (Table 1). Of all participants, 46 out of 75 (61.3%) were women, and 64 out of 75 (85.3%) were college-educated. Additionally, 32 out of 75 (42.7%) had a median income level greater than or equal to that of the general South Korean population [44]. Among the participants, 52 out of 75 (69.3%) were used, and 16 out of 75 (21.3%) were taking antihypertensive or lipid-lowering medications. No significant differences in general characteristics were observed between the groups (Table 1).

[a]Monthly household income was classified using a cutoff of 5,000,000 won (US $3450; IQR 1767-5300), which represents the median income of the general population in South Korea [44].

[b]Taking either antihypertensives or lowering lipids medications.

Heart-Healthy Behavioral Outcome Variables

Table 2 summarizes the results of the differential effects of the 3 groups on the primary and secondary outcome variables over a 12-week intervention period. Significant differences were observed among the 3 groups in the scores for composite heart-healthy behavior ($F_{2,69}$=7.25, *P*=.001), motivation ($F_{2,69}$=8.54, *P*<.001), self-efficacy for diet ($F_{2,69}$=4.87, *P*=.01), and self-efficacy for exercise ($F_{2,69}$=5.48, *P*=.006). Compared to the control group, the hybrid and mobile groups demonstrated significantly greater increases in the scores for composite heart-healthy behavior (hybrid vs control: MD 0.37, SD 0.10, *P*<.001; mobile vs control: MD 0.26, SD 0.10; *P*=.01), motivation (hybrid vs control: MD 0.74, SD 0.18; *P*<.001; mobile vs control: MD 0.42, SD 0.18; *P*=.02), self-efficacy for diet (hybrid vs control: MD 8.44, SD 2.83; *P*=.004; mobile vs control: MD 6.29, SD 2.77; *P*=.03), and self-efficacy for exercise (hybrid vs control: MD 5.01, SD 2.27; *P*=.03>; mobile vs control: MD 7.23, SD 2.24; *P*=.002). There were no significant differences in the heart-healthy information scores among the 3 groups.

[a]Different superscripts indicate a statistically significant difference by Tukey least significant difference multiple comparison.

[b]Different superscripts indicate a statistically significant difference by Tukey least significant difference multiple comparison.

[c]Different superscripts indicate a statistically significant difference by Tukey least significant difference multiple comparison.

Regarding the subscales of heart-healthy behavior, significant group differences were observed in physical activity and weight control ($F_{2,69}$=4.02, *P*=.02), dietary habits ($F_{2,69}$=5.04, *P*=.009), and health management ($F_{2,69}$=8.67, *P*<.001; Table 2). Specifically, both the hybrid and mobile groups showed significantly greater increases in physical activity and weight control (hybrid vs control: MD 0.38, SD 0.17; *P*=.03; mobile vs control: MD 0.45, SD 0.17; *P*=.01), as well as health management (hybrid vs control: MD 0.62, SD 0.16; *P*<.001; mobile vs control: MD 0.49, SD 0.16; *P*=.002), compared with the control group. Moreover, the hybrid group (MD 0.42, SD 0.13; *P*=.002), but not the mobile group, demonstrated significantly greater improvements in dietary habit scores compared with the control group.

Regarding the subscales of heart-healthy motivation, significant group differences were observed in effort or importance ($F_{2,69}$=9.45, *P*<.001), interest or enjoyment ($F_{2,69}$=10.48, *P*<.001), and perceived competence ($F_{2,69}$=3.28, *P*=.04; Table 2). The hybrid group demonstrated significantly greater increases in interest or enjoyment than both the mobile (MD 0.54, SD 0.27; *P*=.045) and control groups (MD 1.21, SD 0.27; *P*<.001), while the mobile group also showed a significantly greater increase than the control group (MD 0.67, SD 0.26; *P*=.01). Both the hybrid (MD 1.00, SD 0.25; *P*<.001) and mobile (MD 0.79, SD 0.24; *P*=.002) groups showed significantly greater increases in effort or importance compared to the control group; however, there were no significant differences between the hybrid and mobile groups. Finally, the hybrid group (MD 0.70, SD 0.28; *P*=.01), but not the mobile group, demonstrated a significantly greater increase in perceived competence compared to the control group.

Cardiovascular Parameters

Table 3 summarizes the differential effects of the 3 groups on cardiovascular parameters over 12 weeks. Significant differences were observed between the 3 groups in fasting glucose levels ($F_{2,69}$=3.90, *P*=.03), with significant differences between the hybrid and control groups (*P*=.02) and the mobile and control groups (*P*=.02). However, there were no significant differences in the other parameters among the 3 groups.

Discussion

Principal Results

We found that, compared to the control group, both the hybrid and mobile intervention groups demonstrated significantly greater improvements in heart-healthy behavioral outcomes, including composite heart-healthy behavior, its theoretical predictors (heart-healthy motivation and self-efficacy), and fasting glucose levels following the 12-week hybrid intervention for individuals at cardiovascular risk. In particular, the hybrid group—unlike the mobile group—showed significantly greater improvement in dietary behavior, a subscale of composite heart-healthy behavior, compared with the control group, and also demonstrated significantly greater improvements in interest or enjoyment, a core subscale of intrinsic motivation, than the mobile and control groups [45]. These findings suggest that the hybrid community-based heart-healthy lifestyle intervention—integrating the mobile app and motivational interviewing—demonstrated overall effectiveness comparable to the mobile app alone, while yielding greater improvements in dietary behavior and core intrinsic motivation.

The hybrid and mobile groups were more likely to increase the composite score of heart-healthy behaviors than the control group after the 12-week intervention, with no significant difference observed between the 2 groups. However, the hybrid group—unlike the mobile group—showed significantly greater improvement in dietary behavior, a subscale of composite heart-healthy behavior, compared with the control group. The finding regarding composite heart-healthy behavior suggests that motivational interviewing may not have demonstrated superiority over the use of a mobile app alone, indicating that the “My HeartHELP” mobile app itself may effectively facilitate overall improvements in heart-healthy behaviors. The “My HeartHELP” app uniquely incorporates 6 key heart-healthy

XSL•FO
RenderX

behaviors simultaneously, which may significantly affect the composite score of heart-healthy behaviors. Empirically, this positive finding may be explained by the fact that the "My HeartHELP" app incorporates evidence-based behavioral change strategies [10,13,14,23], including text messaging for enhancing information, encouraging self-monitoring, and providing feedback or reinforcement in line with individuals' behavioral goal setting.

To date, few mHealth studies on cardiovascular health have primarily relied on theory-based smartphone apps targeting multiple heart-healthy behaviors, as in our study. Most studies, by contrast, have used a variety of mHealth modalities, such as commercial apps, telephone, web-based, email, and SMS text messaging, each corresponding to a single specific behavior, such as physical activity, weight loss, or smoking [20]. Furthermore, most previous studies have predominantly emphasized health outcomes as direct indicators of effectiveness [6], without accounting for the internal validity of mHealth interventions through behavioral change mechanisms. In this regard, our study may be unique in its integration of a mobile app with evidence-based behavioral change strategies specifically designed to promote multiple heart-healthy behaviors and in its comprehensive evaluation of both behavioral changes and health outcomes, including cardiovascular parameters [14].

Meanwhile, the hybrid group, but not the mobile group, showed a significantly greater improvement in the subscale for dietary behavior after 12 weeks, compared to the control group. This finding indicates that motivational interviewing may have had an additional effect on changing dietary habits through the use of the "My HeartHELP" app. Motivational interviewing has traditionally demonstrated significant effectiveness in promoting behavioral changes in substance use, especially in diverse psychological contexts [17]. Dietary behavior involves adherence to diverse dietary guidelines and the consumption of various food groups [46], making effective intervention challenging without considering the psychological and social contexts of individuals [47]. In this regard, motivational interviewing was incorporated in the present study to mitigate the limitations of mobile apps in facilitating close expert interaction. This approach may be effective in facilitating a person-centered understanding of the psychosocial context of complex eating behavior and allows for personalized adjustments to eating behaviors, thus enhancing the intervention's effectiveness. This highlights motivational interviewing's particular efficacy for complex behavioral domains that require nuanced, individualized support beyond what a mobile app alone can provide.

Our findings demonstrated that both the hybrid and mobile groups exhibited greater increases in overall scores of the heart-healthy motivation compared to the control group, with no significant difference between the hybrid and mobile groups. This current study did not fully support the hypothesis that motivational interviewing would be more effective than using a mobile app alone [48,49]. Nevertheless, the hybrid group demonstrated significantly greater increases in a core subscale of intrinsic motivation—interest or enjoyment [50]—than the mobile group. In this context, the above findings may not entirely rule out the possibility that motivational interviewing could serve as an effective intervention component for strengthening intrinsic motivation [24,51], potentially offering advantages beyond the use of a mobile app alone. This finding also aligns with the conceptualization of intrinsic motivation as measured by the 4 items for interest or enjoyment in the Situational Motivation Scale [45].

However, the lack of overall statistical superiority of motivational interviewing may be explained from 2 perspectives. First, the "My HeartHELP" app incorporated substantial motivational elements, including self-monitoring, automated and tailored feedback, and goal attainment encouragement [52]. Second, the limited dosage of the motivational interviewing—4 sessions over 12 weeks—may have been insufficient to produce statistically significant additive effects across all motivational outcomes [53]. In line with this dosage, the quality and intensity of motivational interviewing delivered in this study may have constrained its effectiveness, beyond that of the mobile app alone, in fostering individuals' autonomy to adjust behavioral goal settings, as both the mobile and hybrid groups adhered to the same predefined behavioral goals. Future research should optimize the dosage of motivational interviewing and enhance its quality of autonomy-supportive interventions, thereby more strategically and intensively enabling participants to independently design their activities and personalize goal-setting, as emphasized in self-determination theory [54].

Theoretically grounded in the IMB model [23], the observed increase in heart-healthy motivation in both the hybrid and mobile groups can be interpreted as evidence that enhanced motivation may have served as a foundational mechanism strengthening the mediating variable—heart-healthy self-efficacy—which, in turn, contributed to improvements in heart-healthy behavior (Multimedia Appendix 1). Consistent with this theoretical pathway, our path analytic data (not shown) indicated that increases in overall heart-healthy motivation scores were significantly and positively associated with increases in self-efficacy for diet (β=.32, *P*=.02) and exercise (β=.38, *P*=.005), as well as with improvements in heart-healthy behaviors (β=.27, *P*=.04). These findings may be attributable to the intervention strategies used in this study, which fostered self-directed, health-oriented internalization through self-monitoring and cognitive reappraisal—encompassing the daily input and reflection on 6 core heart-healthy behaviors via the app and motivational interviewing that encouraged participants to recognize progress and use self-management. Subsequently, self-efficacy for diet and exercise may have been enhanced through text messaging and tailored feedback reflecting individual success (eg, mastery experience) delivered via "My HeartHELP" [14], along with professional encouragement and persuasive support provided through motivational interviewing. Collectively, these cognitive and behavioral mechanisms may have contributed to the observed improvements in overall heart-healthy behaviors in either the hybrid or mobile group.

In our findings, the significantly increased self-efficacy for diet and exercise after 12 weeks of using the "My HeartHELP" app may be explained by the efficacy of the behavioral strategies embedded in the app. Goal-setting and self-monitoring can

XSL•FO
RenderX

contribute to mastery experiences [55] by allowing participants to observe their own progress and achieve incremental success, reinforcing their belief in their ability to sustain heart-healthy behaviors [55]. Moreover, the "My HeartHELP" app's personalized feedback messaging delivered daily, weekly, and monthly based on individuals' behavioral outcomes could function as a form of verbal persuasion, as also described by Bandura [55], reinforcing self-efficacy through experts' positive reinforcement and targeted feedback on behavioral progress. Moreover, the "My HeartHELP" app delivered 43 text messages on behavioral skills, informing users on how to apply these skills in daily life. Mobile apps are currently limited in their ability to sensitively recognize and address individuals' emotional states. However, the 4 core principles of motivational interviewing (ie, expressing empathy, developing discrepancies, rolling with resistance, and supporting self-efficacy) are thought to be effective in addressing such emotional states [17]. Previous studies have suggested that motivational interviewing, as a behavioral intervention, can be highly effective in enhancing individuals' self-efficacy [51]. Nevertheless, the lack of differences observed between the hybrid and mobile-only groups may be due to the strong self-efficacy effects of the mobile app overshadowing the effects of motivational interviewing.

We found no significant differences in heart-healthy information levels among the 3 groups following the 12-week intervention. All participants were provided with educational materials on cardiovascular health; the mobile group received cardiovascular information via text messaging, while the hybrid group received both text messages and individualized information. However, an analysis of the item-response rate revealed that participants in all 3 groups continued to provide incorrect responses to certain items on the Heart-Healthy Information Questionnaire at posttest—items that were nearly identical to those answered incorrectly at baseline [34]—despite completing the 12-week intervention. These findings suggest that interventionists should proactively address specific questionnaire items that participants struggled with at the baseline assessment. Integrating targeted educational reinforcement into the intervention design may be necessary to enhance knowledge acquisition and retention.

Strengths and Limitations of This Study

This study underscored the potential of mHealth within a community setting for behavioral lifestyle interventions by optimizing user-interventionist interactions through tailored feedback delivered via in-app text messaging. To the best of our knowledge, this study is the first to reveal the effectiveness of a hybrid approach combining mobile apps and motivational interviewing counseling on heart-healthy behavioral changes, compared to mobile apps alone, within a community setting. Moreover, this indicated that the mHealth intervention using the mobile app effectively facilitated significant changes in heart-healthy behaviors, and the validity of these changes was confirmed through significant improvements in behavioral predictors based on the IMB model. This is particularly meaningful, as it establishes the internal validity of the intervention, demonstrating that the observed behavioral changes were systematically driven by theoretical constructs.

Nevertheless, this study has several limitations. First, dropouts (2 subjects in the hybrid group and 1 in the mobile group) may have led to a bias influencing the validity of the results, even though we performed an intention-to-treat analysis. Second, the absence of participant blinding in this study's design may have introduced bias into this study's findings. Third, because all the participants in this study were Korean, the results cannot be generalized to other ethnic groups. Fourth, because the survey was conducted online, participants with lower digital literacy were likely underrepresented. This is reflected in the socioeconomic profile of our participants, with a high proportion of college-educated individuals (64/75, 85.3%) compared with the national average in South Korea [36]. These characteristics may have facilitated greater engagement with the mHealth intervention and should be considered when generalizing the findings to populations with lower education levels or limited digital access. Fifth, this study lacks a qualitative component, which limits the understanding of why the intervention was effective from the participants' perspective. Qualitative feedback, such as through user interviews, could have provided invaluable insight into which app features were most engaging or how the motivational interviewing sessions were perceived. Sixth, given that this study targeted multiple healthy lifestyle behaviors, appropriate behavioral and self-efficacy measures specifically designed for the comprehensive assessment of heart-healthy behaviors are lacking. Moreover, the measure of heart-healthy motivation used in this study excluded 2 subscales—relatedness and pressure or tension—because their items were deemed inappropriate for the context of adopting heart-healthy behaviors, although these dimensions, particularly relatedness, may play an essential role. The rationale for this exclusion has been described above in the Methods section. The instrument was developed and refined through a rigorous translation and back-translation process; however, the absence of a formal validation process, including factor analysis and psychometric testing, warrants cautious interpretation of the present findings. Therefore, a subsequent validation study should be conducted among the Korean population. In light of these limitations, future research should prioritize the development and validation of robust assessment tools that accurately capture the multidimensional nature of heart-healthy behavioral constructs, thereby ensuring a more precise evaluation of intervention outcomes.

Implications for Policy and Practice

The use of a mobile app alone may be effective in facilitating changes in heart-healthy behaviors when integrated with evidence-based behavioral strategies. Given the limitations of expert-centered cardiovascular care in community settings, a mobile heart-healthy intervention led by nurses or other health professionals may serve as an efficient and accessible alternative. Although motivational interviewing did not demonstrate universal superiority over the mobile app alone, it remains a valuable component for behavioral interventions. More importantly, the hybrid approach used in this study demonstrated the potential of motivational interviewing not only to enhance intervention effects—particularly in improving intricate heart-healthy dietary behaviors—but also to promote sustainability by reinforcing intrinsic motivation, specifically

XSL•FO
RenderX

interest or enjoyment [45]. We therefore strongly recommend integrating motivational interviewing into mHealth interventions, especially when targeting subtle behavioral changes and fostering core intrinsic motivation, as supported by our findings on the motivation subscales. Furthermore, the intervention could be further strengthened by integrating periodic counseling sessions using the motivational interviewing modality alongside the mobile intervention. Therefore, workforce training programs should be implemented to equip health professionals with the skills necessary to deliver mHealth interventions and motivational interviewing as components of cardiovascular health promotion. This approach could enhance the effectiveness and accessibility of heart health interventions in community settings.

Recommendations for Further Research

Future studies should explore the long-term effects of mobile apps and their combinations with motivational interviewing on heart-healthy behavioral outcomes. Additionally, optimizing the frequency and delivery of motivational interviewing sessions should be considered, particularly within the constraints of limited resources in community settings, to enhance the sustainability and effectiveness of behavioral interventions.

Conclusions

The hybrid community-based heart-healthy lifestyle intervention—integrating the mobile app and motivational interviewing—demonstrated comparable overall effectiveness to the mobile app alone, yet achieved greater improvements in intrinsic motivation (interest or enjoyment) and dietary behavior. These findings highlight the potential of mHealth apps as practical, stand-alone tools to promote cardiovascular health, particularly in community settings with limited access to in-person professional support. However, incorporating motivational interviewing may further enhance internalized motivation and sustain complex behavior changes over time. Health professionals can therefore adopt mHealth either independently or in combination with motivational interviewing to optimize heart-healthy behavioral outcomes. Future studies should optimize integration strategies to enhance effectiveness and evaluate the long-term sustainability of such hybrid approaches.

Abstract

Background: Intermittent fasting emerges as a promising dietary approach against obesity, offering a cost-effective strategy for implementation via web-based platforms. We developed a Brief Online Intermittent Fasting Program (OIF), featuring a self-administered, weekly 1-day fasting regimen with replacement meals delivery, online guidance, and app messaging to support adherence.

Objective: This pilot study aimed to assess the preliminary effectiveness, feasibility, and safety of the OIF on weight loss in adults with overweight and obesity in Japan. Secondary objectives were to assess its effects on body composition and metabolic markers.

Methods: This 12-week, 1:1 randomized controlled trial recruited adults with overweight and obesity (BMI from 23 to <35) in 1 university, 1 hospital, and 2 company offices. Participants were randomized into 2 groups stratified by sex and age (<40 or ≥40 years). The intervention group received very low-calorie (407 kcal) meal replacements for weekly intermittent fasting, online guidance via Zoom (Zoom Video Communications, Inc), and app messages encouraging fasting and healthy lifestyles. The control group received app messages promoting healthy lifestyles only. Interventions were administered by a nonblinded researcher. The primary outcome was the change in body weight after 12 weeks, analyzed using intention-to-treat principles and adjusted for sex, age, and baseline weight. Secondary outcomes encompassed body composition, blood pressure, biomarkers (eg, hemoglobin A_{1c}, triglycerides, and cholesterol), quality of life, physical activity, intervention adherence, and adverse events.

Results: A total of 57 individuals were enrolled (28 in the intervention group and 29 in the control group). At 12 weeks, 25 participants in the intervention group and 27 participants in the control group completed follow-up. The baseline median weight was 75.8 (IQR 68.3-80.6) kg for the intervention group and 74.8 (IQR 69.8-81.8) kg for the control group. The mean weight change was –0.9 (SD 1.9) kg in the intervention group and +0.6 (SD 1.4) kg in the control group. The adjusted between-group difference in weight change was statistically significant at –1.6 (95% CI –2.5 to –0.8) kg. Fat mass change was not statistically significant (–0.1, 95% CI –1.3 to 1.4 kg), but muscle mass reduction was implied (–1.3, 95% CI –2.5 to –0.2 kg). Intervention adherence was 79% (22/28) in the intervention group. No serious adverse events were reported, and there were no significant changes in key biomarkers, such as hemoglobin A_{1c} or quality of life.

Conclusions: The OIF demonstrated effectiveness in promoting modest weight loss among adults with overweight and obesity over 12 weeks, with high feasibility and safety indicated by low dropout rates and absence of serious adverse events. However,

XSL•FO
RenderX

the observed reduction in muscle mass indicates a need for program refinement, such as incorporating exercise guidance, to optimize health outcomes.

intermittent fasting; eHealth; mHealth; mobile health; weight loss; diet; overweight; obesity; randomized controlled trial

Introduction

Obesity is a well-known public health challenge, which increases the risk of cardiovascular diseases and mortality [1]. According to the World Health Organization, at least 2.8 million people die each year as a result of being overweight or obese [2], with the obesity epidemic still escalating at an alarming rate [3]. Moreover, the recent COVID-19 pandemic has further deteriorated our lifestyles and made the development of remote obesity interventions, using the internet, apps, and other web-based technologies, an even more urgent issue [4-6]. Although many web-based programs have been developed, with some degree of effectiveness acknowledged [7,8], few have been successfully implemented in society to yield significant results. Also, criticism exists toward the previous clinical trial approaches, which have focused too much on internal validity [9], indicating a demand for the development of highly feasible online weight loss programs that are easily applied and disseminated into society.

Recently, intermittent fasting (IF) has emerged as a popular strategy for combating obesity [10]. IF is a simple dietary restriction regimen that incorporates periodic fasting (energy restriction of less than 600 kcal) into normal eating habits [11,12]. Recent systematic reviews and meta-analyses have demonstrated the effectiveness of IF for weight loss compared to ad libitum eating [13]. The mechanisms behind weight loss with IF are related to energy restriction, increased fat metabolism, and improved glucose metabolism [14], which are common to any dietary restriction. IF may also provide cardiovascular health benefits. For example, studies with women with obesity show that a weekly IF intervention over 2 months significantly reduced resting heart rate, blood glucose, insulin, and homocysteine levels. These effects are likely associated with reductions in adipokines, including leptin, IL-6, tumor necrosis factor-alpha, and insulin-like growth factor-1, suggesting that IF could mitigate cardiovascular disease risk [15,16]. Additional benefits reported in recent studies include decreased hunger, reduced inflammation, improved cellular repair, regulated hormone production, enhanced immune function, adjusted circadian rhythms, and a more diverse gut microbiome [14,17-21]. Therefore, IF holds significant potential as a promising nonpharmacological approach to improving health at the population level [18]. We particularly focused on the simplicity and feasibility of IF, because a truly successful weight loss approach needs to be simple and sustainable, capable of being incorporated into daily life as lifelong dietary customs [18,21]. Since IF does not require detailed examination of food content or energy calculations, it is easy to implement with brief web-based guidance, having a high possibility of being applied as a cost-effective population approach. However, to the best of our knowledge, no studies have implemented IF as a web-based intervention, leaving a potentially significant solution to obesity unexplored.

To assess the effect of web-based IF administration, we have developed the "Brief Online Intermittent Fasting Program (OIF)," which features self-led fasting practice supported with meal delivery, online guidance, and app messages. The purposes of this pilot study were to evaluate the preliminary effectiveness, feasibility, and safety of the 12-week OIF on weight loss in adults with overweight and obesity in Japan. Secondary objectives were to assess its effects on body composition and metabolic markers.

Methods

Study Design

This pilot study is a 1:1 parallel-group randomized controlled trial (RCT) comparing the intervention group following the OIF with the control group receiving minimal care.

Participants and Setting

Eligibility Criteria

In order to benefit from weight reduction and ensure the safe and stable administration of the OIF, the following eligibility criteria were established.

The inclusion criteria are as follows: individuals with overweight or obesity and with a BMI between 23 and under 35, adults aged 20 years to less than 65 years at the time of consent, those capable of communicating in Japanese, owners of a smartphone with iOS or Android, those who were familiar with using apps on a smartphone and using email and Zoom (Zoom Video Communications, Inc) on either a smartphone or a personal computer, those willing to visit one of the research facilities twice, and consenting to provide blood samples through self-puncture at the measurements. We defined overweight as having a BMI of 23 or above, while the global standard for overweight is a BMI of 25 or above. This adjustment aligns with guidelines from the National Institute for Health and Care Excellence, which recommend lowering the overweight threshold to 23 for Asian populations to enhance metabolic disease prevention in populations with lower obesity prevalence [22].

The exclusion criteria include any of the following: individuals with a history of heart disease, kidney disease, psychiatric disorders, or any serious medical conditions, individuals using diabetes medication (to minimize the risk of hypoglycemia), smokers or heavy drinkers (consuming alcohol on average more

XSL•FO
RenderX

than 4 drinks per day or 14 drinks per week), night shift workers, individuals who may face significant environmental changes during the trial period, individuals with eating disorders, food allergies or alcohol dependence who require specific dietary supervision, women who are breastfeeding, pregnant, or planning to become pregnant during the study, lean individuals with a body fat percentage below 10% for men and 20% for women, athletes engaging in more than 12 hours of training or sports practice per week or those belonging to university sports clubs or professional teams aiming for competition, and any other individuals deemed unsuitable for participation by the researchers.

Setting and Recruitment Procedure

Participant recruitment, measurement, and registration were conducted at Kyoto University and 3 collaborating facilities in Japan: Kusaka Hospital, Cold Storage Japan Inc, and Buddy Training Co, Ltd. We recruited participants through our website (Department of Preventive Services at School of Public Health, Kyoto University), our X (formerly Twitter; X Corp), posters and flyers, and the OReC—a web platform dedicated to research recruitment [23]. Further details on the recruitment procedure and materials are presented in Multimedia Appendix 1.

Sample Size

As this is a pilot RCT, a formal power-based sample size calculation for definitive hypothesis testing was not the primary objective. The main goals were to obtain estimates of effect size to inform the design of a future, larger trial. Based on recommendations for pilot study sample sizes [24], a range of 10-30 participants per group is often considered sufficient for these purposes. To ensure our sample size was within a reasonable range, we referred to previous literature [25,26] and pre-estimated the effect size to be approximately Cohen d=0.5. A sample of 10 participants per group would provide a preliminary indication of such an effect. To account for the potentially high dropout rate common in web-based intervention trials, we determined our target sample size to be 20 participants per group, for a total of 40 participants.

Randomization

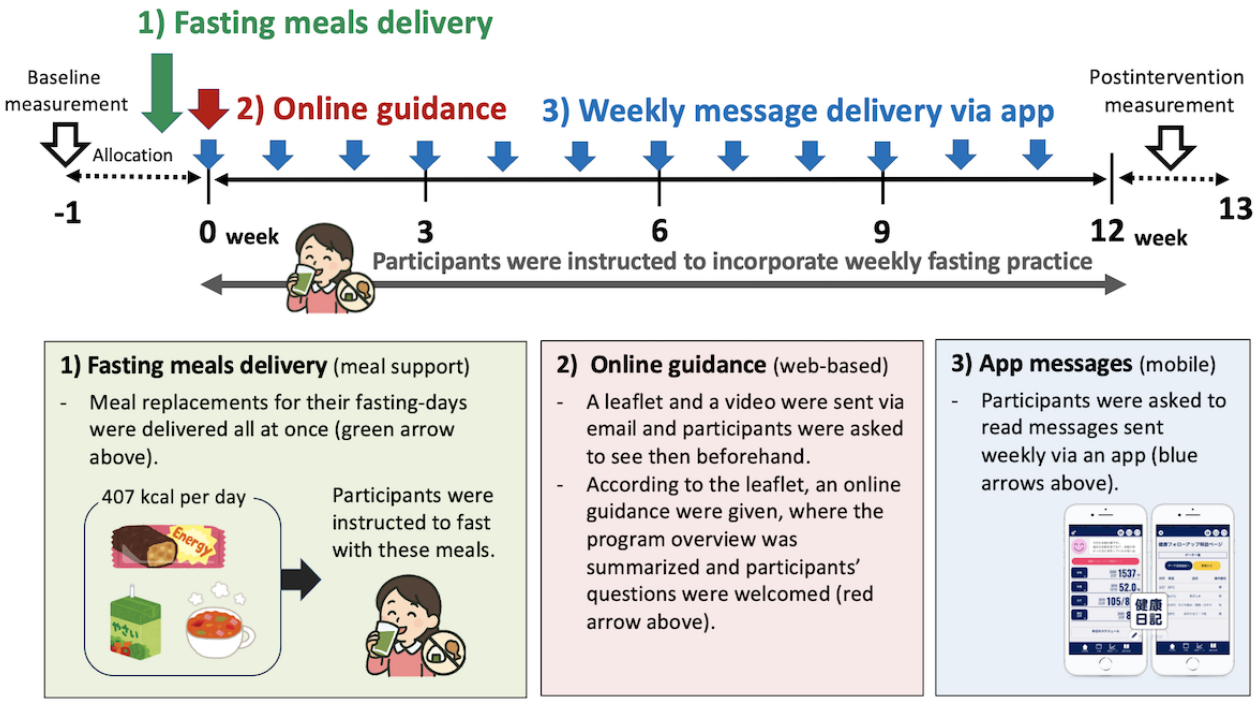
Allocation

The researcher (TN) weekly sent the information (ID, sex, and age) of the registered participants to another researcher (KK) via email. He conducted a 1:1 stratified randomization using computer-generated random sequences, with sex (male or female) and age (<40 or ≥40 years) as stratifying factors. The block sizes were randomly chosen to be either 2 or 4. Allocation concealment was maintained throughout the study.

Blinding

Participants were not blinded due to the nature of the dietary intervention. The implementer of the intervention was also not blinded since it was carried out by the researcher (TN), who knew the allocation results. Although the messages sent via app were also administered by TN and not blinded, the timing of delivery and the number of characters in the messages were standardized across both groups. However, to minimize potential bias, outcome assessors and a statistician analyst were blinded, as suggested by best practices in behavioral studies [27].

Intervention



A nonblinded researcher (TN) administered all the interventions for both groups. Detailed information on interventions was found in Multimedia Appendix 2.

Intervention Group (OIF)

Participants in the intervention group were engaged in the OIF (Figure 1). In this study, fasting was defined as consuming the provided fasting meals by 8 PM without any additional food intake. The OIF comprises three components: (1) meal support (nonweb-based component), (2) a web-based component, and (3) a mobile component. Further details are described in Multimedia Appendix 2.

XSL•FO
RenderX

Figure 1. Overview of the 12-week "Brief Online Intermittent Fasting Program (OIF).".

1. Fasting meals delivery: After the allocation, a 12-day supply of fasting meals was delivered to the intervention group in one batch. Fasting meals consisted of commercially available products that were low in energy, low in saturated fat, and plant-based and were constructed based on previous studies [28,29]. Briefly, it included 1 bottle of tomato juice, 2 bottles of fruit and vegetable juice, 2 servings of instant miso soup, 1 soy bar, and 1 multivitamin-mineral supplement, totaling 407 kcal per day, with 13% protein, 26% fat, and 61% carbohydrates. We developed this 12-week regimen in order to theoretically promote weight loss of 2.4-2.7 kg, which corresponds to a 3% loss of initial weight for a potential participant with a weight of 80 kg and 90 kg, respectively.
2. Online fasting guidance: We sent participants a leaflet detailing OIF (an A4 sheet, double-sided) via email upon allocation. They were directed to watch the prerecorded video (about 9 minutes) before the online guidance and then attended the guidance session via Zoom, which was held on their first day of the trial period and averaged 3.5 (SD 4.1) minutes per participant. They were instructed to replace one day's meals with the provided fasting meals, with a recommendation to fast on a holiday to minimize their burden.
3. Weekly message delivery via app: Participants were instructed to install an app, "Kenko-Nikki (Healthtech Laboratory [HTL], Inc)" [30], detailed in Multimedia Appendix 3. Participants received weekly messages in Japanese (mean 382, SD 126 characters) containing general health advice on diet, exercise, sleep, and encouragement and reminders for their fasting practice through the app.

Control Group—Minimal Care

Similar to the intervention group, participants were directed to read weekly messages containing general health advice on diet, exercise, and sleep. The content of these messages differed partly from those sent to the intervention group, as outlined in Multimedia Appendix 2.

Outcome Definition and Measurement

Data Collection

Overview

Sex, age, medical history, current medical visits, and medication status were collected via a web form at the time of preregistration. This information was reverified at the baseline measurement, along with identity confirmation. The following assessment data were measured at 2 time points—baseline and after 12 weeks, with the exception of adverse events and mild symptoms, adherence, and participants' feedback, which were measured once at 12 weeks, and of self-recorded weight and step counts and fasting status, which were supposed to be measured every day.

Anthropometric Measures

Body weight, fat mass, muscle mass, and basal metabolic rate (BMR) were measured by using the body composition analyzer (MC-780A-N; TANITA Corporation). Height was measured 3 times at the baseline, barefoot, using a portable height measure (Seca 213 l; Seca Japan), and the median value was used. The BMI was calculated based on these data.

Blood Pressure

Measurements of systolic blood pressure (SBP) and diastolic blood pressure (DBP) were taken twice on the upper arm opposite the dominant hand using a blood pressure monitor

XSL•FO
RenderX

(HEM–7511T; OMRON Corporation) while the participant was seated. The average value of these two measurements was used.

Blood Biomarkers

Hemoglobin A_{1c} (HbA_{1c}), triglycerides, total cholesterol, high-density-lipoprotein cholesterol (HDL-C), and low-density-lipoprotein cholesterol (LDL-C) were measured using a point-of-care biochemical analysis device (cobas b 101 plus; Roche Diagnostics KK). Blood sampling involved participants self-puncturing the fingertip of the middle finger on the opposite side of their dominant hand using a spring-loaded lancet (Nipro LS lancet 30G 1.0 mm; Nipro Corporation). Subsequently, research staff aspirated the blood onto the reagent disk for analysis in the device.

Quality of Life

Quality of life (QOL) scores were also evaluated, which were measured using an electronic scoring system for the Short-Form 12-Item Survey-version 2 (SF-12v2) Japanese version [31] (Qualitest). Participants responded to questions on the web system regarding their lives over the past month via their smartphones. These responses were then calculated through the system to obtain physical and mental 2-component summary scores, which are standardized T-scores with a mean of 50 (SD 10), where higher scores indicate better health.

To assess participants' subjective health status, responses to the first question of the SF-12v2 questionnaire, "In general, would you say your health is:," were further analyzed. Response options included "(1) Excellent," (2) Very good," (3) Good," (4) Unsatisfactory," and "(5) Poor."

Physical Activity

Participants' physical activities were self-reported using the short form of the International Physical Activity Questionnaire [32]. The questions were prepared on a Google Form, and participants were asked to respond via smartphone about their physical activity over the past month at the time of final measurement. The amount of total physical activity was calculated as metabolic equivalent of task-minutes per week (METs).

Adverse Events and Mild Symptoms

For the evaluation of the safety, the number of adverse events and the number of individuals experiencing them were investigated. Participants were instructed to consult anytime throughout the study regarding any adverse events or symptoms. In addition, they were asked at the 12-week measurement about the incidence of 20 symptoms prelisted from a prior study [33] (sleep difficulty, hunger, fatigue, headache, diarrhea, sensitivity to cold, dry mouth, back pain, bad breath, muscle pain, abdominal bloating, cravings, vertigo, blurred vision, restless leg, skin rash, nausea, palpitation, dyspepsia, and muscular cramp) via a web form. We primarily evaluated the difference in the number of these 20 events and the number of participants who reportedly experienced them. Other adverse events were also self-reported separately through a free-text web questionnaire at the measurement at 12 weeks.

Adherence

Adherence in the intervention group was defined by the number of actual fasts, based on self-report via a web questionnaire at the 12-week measurement. Adherence in the control group was defined by the read status of messages on the app, with data obtained from the server. The definition of adherence is detailed in the statistical analysis section.

Participants' Feedback

Participants' feedback on each intervention was collected through a web questionnaire at the 12-week measurement.

Self-Recorded Weight and Step Counts

Participants were directed to record their self-measured weight and step counts via the app every day throughout the trial, which was predetermined to be assessed only exploratorily.

Fasting Status

Participants in the intervention group were directed to record the following information on their fasting day: the date, the consumption status of each fasting meal (the extent to which they ate and whether they ate other food or not), and the planned date of the next fasting day. This was also to be exploratorily assessed.

Outcome

The primary outcome was the change in body weight. The changes in BMI, fat mass, muscle mass, BMR, SBP, DBP, HbA_{1c}, triglyceride, HDL-C, and LDL-C were evaluated as secondary outcomes. After formal analysis execution, the number of participants achieving a minimal clinically important change (MIC) was added as an exploratory outcome for post hoc analysis.

Statistical Analysis

Overview

The statistical analysis plan (Multimedia Appendix 4) was fixed before data locking. After finalizing the data, the precoded analysis script (R [R Foundation for Statistical Computing], version 4.3.2) was executed. Statistical estimations were presented with 95% CI. Our predetermined α level was .05. Missing data in outcomes were imputed using the Baseline Observation Carried Forward (BOCF) approach. As this was a pilot study, no formal interim analyses or prespecified stopping guidelines were planned.

Baseline Analysis and Definition of Analysis Population

Baseline characteristics were presented as the number and percentage for sex (male), while continuous variables were presented as median and IQR.

Under the intention-to-treat (ITT) principle, all the allocated participants were regarded as the primary analysis population (ITT).

The per protocol set (PPS) included individuals in the intervention group who adhered to the fasting regimen (reportedly had fasted as instructed at least 10 out of 12 times) and participants in the control group who adhered to the minimal care (had read at least 10 out of the 12 app messages, as

XSL•FO
RenderX

confirmed by server data). Additionally, within the intervention group, participants who reportedly had fasted 10 or more times out of 12 in accordance with our instructions were defined as "adherent," while those who reported fasting 12 times were categorized as "fully adherent."

Safety analyses were conducted on the completers set (CS), defined as participants who were followed up at the 12-week measurement.

In the discussion, we also presented the mean (SD) values of QOL scores for considering generalizability. Additionally, we assessed the subjective health status of participants by analyzing responses to the SF-12v2 questionnaire and comparing them with those from a similar question in a national annual survey conducted in 2022 [34]. We compare the proportions of participants who self-reported positive health status in the SF-12v2 questionnaire's first question, "In general, would you say your health is:" with those from the reference survey, which asked, "How do you rate your current health status?" with similar responses ranging from 1 to 5. In the SF-12v2, the response options were "(1) Excellent, (2) Very good, (3) Good, (4) Unsatisfactory, (5) Poor," while in the reference survey, they were "(1) Good, (2) Satisfactory, (3) Average, (4) Unsatisfactory, (5) Poor." Recognizing the differences in response expression between the 2 surveys, we focused on respondents who considered themselves healthy, combining responses categorized as 1-3. This comparison was predetermined in the protocol.

Analysis of Primary Outcome

The change in body weight was presented as the mean and SD for each group. The primary analysis was to estimate the between-group mean difference under the ITT principle, adjusted for sex, age, and baseline weight using a generalized linear regression model, presented along with a 95% CI and *P* value. The regression coefficients for each covariate were also reported with their 95% CIs. Sensitivity analyses included unadjusted comparisons of crude values (2-tailed Welch *t* test) and per-protocol analysis within the PPS (using the same adjustment as the primary analysis). Additionally, in case of missing weight data, an analysis incorporating the worst-case scenario (imputing the maximum weight gain for the intervention group and the maximum weight loss for the control group from observed data) was predetermined to be added to the sensitivity analysis.

Analysis of Secondary Outcomes

For continuous secondary outcomes, crude (unadjusted) between-group mean differences and 95% CIs were calculated using the Welch *t* test. Total physical activity was also assessed to identify within-group differences, using the Wilcoxon signed-rank test for paired comparisons. In the safety analysis, the number of adverse events and the number of individuals experiencing them were investigated, and the between-group differences in incidence proportions were analyzed by the chi-square test. Additionally, within-group differences of QOL were analyzed by the Wilcoxon signed-rank test. The proportion of follow-up rate, adherence rate, and message-read rate was presented as percentages of the ITT population.

Exploratory Analysis

Self-recorded weight and step counts were predetermined to be assessed for discussion as needed, in cases of high dropout or missing data, for instance. As a post hoc analysis for the primary outcome, the number of participants achieving a MIC was compared between groups, with *P* values reported from the Fisher exact test. In addition, we included an additional sensitivity analysis for CS, which only analyzed the participants who completed the 12-week follow-up.

Methods Alteration After Study Commencement

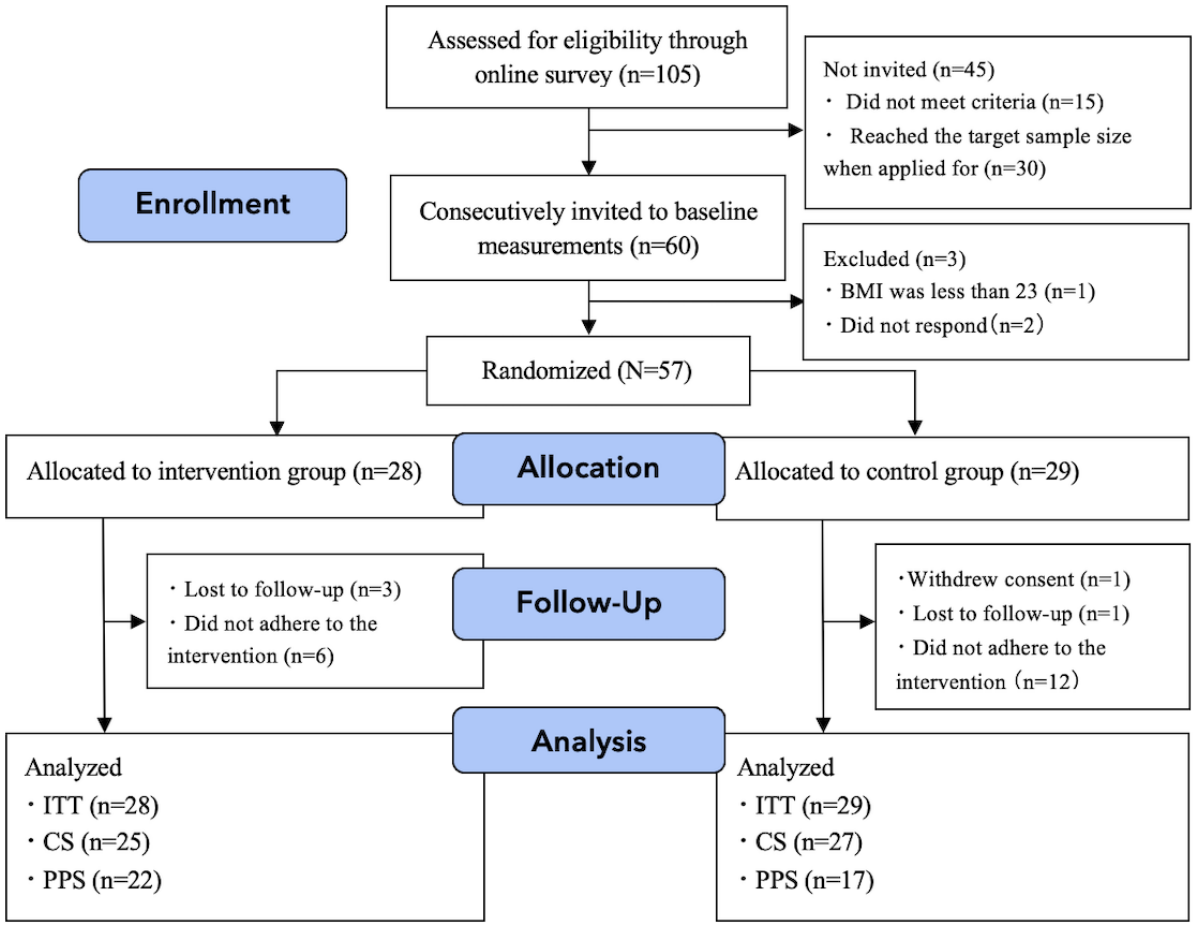
After the recruitment began, 3 collaborative facilities were added, and the initial eligibility criterion of having a BMI between 25 and less than 35 was modified to a BMI between 23 and less than 35. This change required a revision of the protocol and a subsequent review and reapproval by the Ethics Committee. Aspects of the statistical analysis not explicitly outlined in the original protocol were detailed in the statistical analysis plan (Multimedia Appendix 4), with its final version being fixed prior to the data lock.

Ethical Considerations

This study was conducted with the approval of the Kyoto University Graduate School and Faculty of Medicine Ethics Committee and under the authorization of the dean (approval number C1625). The study was registered in the University Hospital Medical Information Network-Clinical Trials Registry (UMIN-CTR), a clinical trial registration service that meets the standards of the International Committee of Medical Journal Editors, on February 27, 2023 (UMIN000050437). Written informed consent was obtained from all participants. To protect privacy, participant data were pseudonymized. The correspondence table linking personal information to the data was stored on a separate USB drive and kept in a locked cabinet within a locked room. This table was deleted after the analysis to prevent reidentification. Participants received a 5000 Japanese yen Amazon gift card as compensation. Other ethical considerations and the consent document were described in Multimedia Appendix 1. This trial was conducted in accordance with the CONSORT (Consolidated Standards of Reporting Trials) 2025 and CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) guidelines (Multimedia Appendix 5). There was no patient or public involvement in the design, conduct, or reporting of the study.

Results

Participants Flow



Participant recruitment took place from July 20, 2023, to October 10, 2023. The follow-up measurement of all the participants ended on January 12, 2024.

Among the 60 individuals invited to the baseline measurement, 57 were eventually registered, with 28 allocated to the intervention group and 29 to the control group (Figure 2). In the intervention group, 3 participants were lost to follow-up (dropped out) due to discontinued contact. In the control group, a participant withdrew consent due to "difficulties in continuing

XSL•FO
RenderX

participation," but agreed to our using his baseline data, allowing us to include him in the ITT population. Another participant was lost to follow-up (dropped out) in the control group. Consequently, of the 57 participants in the ITT population, 89% (25/28) in the intervention group and 93% (27/29) in the control group were followed up (defined together as the CS). The PPS was defined based on adherence, with 22 (vs 17) participants in the intervention (vs control) group. Among the 28 participants in the intervention group, 22 (79%) participants were defined as "adherent" (those who fasted 10 times or more; included in PPS), while 19 (68%) were defined as "fully adherent" (those who fasted 12 times). Among the 29 participants in the control group, 17 (59%) were adherent (who had read 10 app messages or more) and thus were included in PPS. Similarly, 15 (54%) participants in the intervention group had read app messages.

Figure 2. Participants flowchart. CS: completers set; ITT: intention-to-treat; PPS: per protocol set.

Participants Characteristics

Table 1 presents the baseline characteristics of participants in each group. The proportion of men was high in both groups (19/28, 68% in the intervention group vs 19/29, 66% in the control group). The median age was 34 (IQR 29-47) vs 38 (IQR 29-52) years, the median body weight was 75.8 (IQR 68.3-80.6) vs 74.8 (IQR 69.8-81.8) kg, and the median BMI was 27.1 (IQR 24.8-29.8) vs 26.6 (IQR 24.7-28.5) for the intervention (vs control) group. The number of registered participants by facility was as follows: 22 (12 vs 10) participants at Kyoto University, 11 (7 vs 4) participants at Kusaka Hospital, 10 (4 vs 6) participants at Cold Storage Japan Inc, and 14 (5 vs 9) participants at Buddy Training Co, Ltd. Significant imbalances were not observed between the 2 groups across all characteristics.

Table 1. Baseline characteristics of the intervention and control groups (N=57)a.

Characteristic	Intervention (n=28)	Control (n=29)
Sex (male), n (%)	19 (68)	19 (66)
Age (years), median (IQR)	34 (29-47)	38 (29-52)
Weight (kg), median (IQR)	75.8 (68.3-80.6)	74.8 (69.8-81.8)
BMI (kg/cm^2), median (IQR)	27.1 (24.8-29.8)	26.6 (24.7-28.5)
Height (cm), median (IQR)	168 (163-171)	170 (163-175)
Fat mass (kg), median (IQR)	22 (18-28)	22 (18-29)
Muscle mass (kg), median (IQR)	52 (42-56)	52 (41-57)
BMR[b] (kcal), median (IQR)	1529 (1382-1682)	1563 (1369-1703)
SBP[c] (mm Hg), median (IQR)	128 (118-141)	130 (117-142)
DBP[d] (mm Hg), median (IQR)	87 (79-96)	90 (80-99)
HbA_{1c}[e] (%), median (IQR)	5.4 (5.2-5.6)	5.4 (5.2-5.5)
TG[f] (mg/dL), median (IQR)	107 (70-209)	131 (111-208)
Total-C[g] (mg/dL), median (IQR)	187 (165-212)	196 (176-220)
HDL-C[h] (mg/dL), median (IQR)	57 (45-65)	57 (48-66)
LDL-C[i] (mg/dL), median (IQR)	103 (89-122)	112 (80-128)
Total physical activity (METs[j]), median (IQR)	999 (399-1706)	1074 (827-1497)
QOL[k] score[l], median (IQR)		
Physical component summary	50 (47-52)	52 (48-54)
Mental component summary	59 (54-63)	55 (49-58)
Subjective health status[m], n (%)		
Excellent	3 (11)	3 (10)
Very good	9 (32)	5 (17)
Good	15 (54)	15 (52)
Fair	0 (0)	5 (17)
Poor	1 (4)	1 (3)
Registered facility, n (%)		
Kyoto University	12 (43)	10 (35)
Kusaka Hospital	7 (25)	4 (14)
Cold Storage Japan Inc	4 (14)	6 (21)
Buddy Training Co, Ltd.	5 (18)	9 (31)

[a]Data were presented as numbers for sex (male) and registered facilities, and as medians (IQR) for all other variables. The values were rounded for all the variables except for weight, BMI, and hemoglobin A_{1c}.

[b]BMR: basal metabolic rate.

[c]SBP: systolic blood pressure.

[d]DBP: diastolic blood pressure.

[e]HbA_{1c}: hemoglobin $A_{1c.}$

[f]TG: triglyceride.

[g]Total-C: total cholesterol.

[h]HDL-C: high-density-lipoprotein cholesterol.

[i]LDL-C: low-density-lipoprotein cholesterol.

[j]METs: metabolic equivalent of task-minutes per week.

[k]QOL: quality of life.

[l]SF-12v2 (Short-Form 12-Item Survey-version 2) Japanese version was used to obtain each 2-component summary score, which is standardized T-scores with a mean of 50 (SD 10), where higher scores indicate better health.

[m]Calculated from the responses to the first question of the SF-12v2 questionnaire, "In general, would you say your health is:" with options ranging from (1) Excellent, (2) Very good, (3) Good, (4) Unsatisfactory, and (5) Poor.
